Despite recent improvements in techniques for the identification of antisperm antibodies, the clinical utility of these tests should be limited to very select cases until their prognostic value, impact on infertility management, or effectiveness in treatment can be demonstrated in prospective trials. Corticosteroid therapy for men with antisperm antibodies has been studied in a prospective, double-blind, placebo-controlled trial. This trial did demonstrate decreased antisperm IgG in response to corticosteroid therapy; however, no improvement in sperm-bound IgA or pregnancy outcome was observed (285). In fact, there is currently no support for the use of corticosteroid therapy in antisperm antibody-positive patients because IUI alone has been shown to result in higher pregnancy rates than the combination of corticosteroids and timed intercourse (286). In a couple with no identifiable cause for infertility, a positive or negative antisperm antibody test will not alter their proposed therapeutic plan: superovulation and IUI followed by IVF or ICSI (287). A potential role for ASA testing is in the prospective identification of couples predicted to have high nonfertilization rates with conventional IVF who might benefit from a more expeditious move to ICSI. Yet, a cost-effectiveness analysis using the immunobead ASA assay to screen all patients undergoing IVF revealed a test sensitivity of 11.4% in the prediction of low or absent fertilization as well as a low incidence of test positivity (288). As a result, the cost analysis revealed that screening all patients is collectively more expensive than performing ICSI for couples experiencing an IVF cycle with failed fertilization. Thus, the clinical relevance of ASA testing is currently uncertain.

Uterine Factors

Uterine pathologies are the cause of infertility in as many as 15% of couples seeking treatment (289) and are diagnosed in as many as 50% of infertile patients (290,291,292). For patients undergoing *in vitro* fertilization, lower pregnancy rates are observed in the presence of uterine cavity anomalies (293,294). The correction of these anomalies has been associated with improved pregnancy rates (292). Therefore, the evaluation of the couple with infertility should include an assessment of the endometrial cavity. Most endometrial pathologies implicated in infertility result in both structural and functional impairment. Endometrial molecular mechanisms of implantation and gestation are exquisitely controlled and remarkably complex. Consequently, even subtle defects in endometrial progression from the peri-implantation, luteal phase to the mature decidua supporting a placenta and fetus can result in infertility or early pregnancy loss.

Diagnostic Imaging for Uterine Pathology

Uterine abnormalities that have been implicated in infertility include endometrial polyps, submucous fibroids, intrauterine adhesions, mullerian anomalies, prior exposure to *diethylstilbestrol (DES)*, and possibly luteal phase defect. The diagnosis and treatment of these entities may prove crucial to the successful management of the infertile couple. Insofar as it allows assessment of both tubal and uterine pathology, HSG is a reasonable initial imaging technique to use in the basic infertility evaluation. Although HSG has 85% to 100% sensitivity for detecting tubal pathology (228,229), it is only 44% and 75% sensitive in documenting uterine malformations and intrauterine adhesions, respectively (295).

Sonohysterography appears to be superior to HSG in the detection of uterine malformations, correctly identifying 90% of abnormalities in infertile patients (296). These

P.1223

data are consistent with those observed in patients with abnormal uterine bleeding in the general gynecologic setting, where sonohysterography has sensitivities of 87% and 93% in the detection of intrauterine pathology and endometrial polyps, respectively (297,298). Compared with conventional transvaginal ultrasound, sonohysterography has both higher sensitivity (93% versus 65%) and specificity (94% versus 76%) for the detection of endometrial polyps in the patient with abnormal bleeding (298). The use of contrast medium (i. e., Echovist) at the conclusion of saline sonohysterography was initially developed to afford a sonographic assessment of tubal status. When sonographic contrast medium is employed, the study is referred to as hysterosalpingo-contrast sonography, or HyCoSy. A prospective

study investigating the use of HyCoSy as an initial screening study in the infertility evaluation of 103 women demonstrated a 90% concordance between this technique and HSG for the detection of endometrial pathology, but only a 72% concordance in the detection of tubal blockage (299).

Office hysteroscopy has been proven to have superior sensitivity (100%) and specificity (95%) in the evaluation of the endometrial cavity (300). In many practices, diagnostic hysteroscopy is the preferred procedure for the diagnosis of uterine pathology in infertility patients. To optimize visualization of the endometrial cavity during hysteroscopy, the procedure should be performed during the early- to midfollicular phase of the cycle. This also minimizes the possibility of pregnancy. Although excellent acceptance of diagnostic hysteroscopy using a 5-mm scope without analgesia has been reported (301), patient tolerance of office hysteroscopy has been optimized by advancements in pain-control medication regimens. The most important benefit to office hysteroscopy is the ability to immediately treat most pathology that is encountered. Significantly, these operative procedures can be performed using electrolyte distention media. Studies have shown success rates of 98% to 100% with office hysteroscopic procedures (302,303).

Congenital Anomalies of the Uterus

Congenital uterine anomalies may be associated with infertility, spontaneous pregnancy loss in the first or second trimester, or late-trimester pregnancy complications. In women with didelphic, unicornuate, and septate uteri, the rates of spontaneous abortion and preterm delivery are highly increased at 25% to 38% and 25% to 47%, respectively (304). Endometrial dysfunction during the luteal phase may result in infertility, whereas dysfunction occurring after implantation may result in pregnancy loss. Pregnancy outcome in the presence of a uterine anomaly may depend on the location of blastocyst implantation in a particular cycle. This may explain why a woman with a septate uterus might encounter recurrent pregnancy loss after having delivered a term infant. With the exception of a septate uterus, infertility associated with most congenital uterine anomalies is not readily amenable to surgical treatment (305,306). **Laparoscopic-guided hysteroscopic septoplasty can decrease significantly the risk of spontaneous abortion in women with septate uteri, and surgical therapy is indicated in patients with known uterine septi who have recurrent spontaneous abortion** (307). Indications for surgical correction of congenital uterine anomalies when the presenting symptom is infertility are less obvious. Among seven series of hysteroscopic metroplasties performed for infertility, the overall pregnancy rate after treatment was 48% (307). It is still reasonable to consider surgical management in some infertile patients with uterine septi because septoplasty may

maximize the chance of having a live birth by decreasing the associated risks for spontaneous abortion and preterm labor.

In Utero Exposure to Diethylstilbestrol

Exposure to *DES in utero* increases a woman's risk for congenital reproductive tract malformations and obstetric complications, including preterm labor and cervical incompetence (308). In one study, almost 70% of women exposed to *DES in utero* were noted to have uterine malformations on HSG. **The most common malformation was the T-shaped uterus** (309). Whether *DES*-exposed women also have higher rates of infertility remains unclear (310). One investigator reported that decreased fertility in these women was

P.1224

particularly prevalent when constriction of the upper segment of the reproductive tract was present (311). This question is difficult to study, however, because there is great variation in the degree of congenital uterine, tubal, and cervical anomalies associated with exposure. Furthermore, some abnormalities may promote other infertility factors. For instance, cervical anomalies may promote production of suboptimal cervical mucus, or cervical stenosis may promote retrograde menstruation and the subsequent development of endometriosis. In fact, a recent large prospective cohort study of patients with laparoscopically confirmed disease identified a significantly elevated risk (RR 1.8, CI, 1.2–2.8) of endometriosis among women exposed to *DES* (312). Overall, when a *DES*-exposed woman has uterine anomalies on HSG and greater than 1 to 2 years of primary infertility, her prognosis for future pregnancy is extremely poor (313). Metroplasty for correction of T-shaped and hypoplastic *DES*-exposed uteri has unproven value and is not recommended. Results of IVF treatment are generally poor in infertile, *DES*-exposed women. **Although ovarian response rates to COH are comparable in *DES*-exposed women and nonexposed women with unexplained infertility, *DES* exposure is associated with significantly lower implantation rates in IVF** (314).

Acquired Abnormalities of the Uterus

Leiomyomas

Among women with infertility and uterine leiomyomas, many variables may affect pregnancy rates, including leiomyoma size, location, and number (solitary versus multiple) as well as

the presence of symptoms associated with these tumors. **Leiomyomas have not been shown to be a direct cause of infertility.** It has been suggested, however, that uterine leiomyomas might alter uterine contractility and thereby disrupt normal sperm migration. Alternatively, the presence of leiomyomas might adversely affect vascular and molecular profiles of sites of implantation (315). **No prospective, randomized trial comparing expectant management with myomectomy in infertile patients with uterine leiomyomas has yet been conducted.** However, one recent case-control study compared pregnancy outcomes among 106 women who had laparoscopic myomectomy for fibroids, 106 women with uterine fibroids who did not have surgery, and 106 women who had unexplained infertility but no fibroids. Reported live birth rates were significantly different among the study populations: 42% for the laparoscopic surgery group, 11% for the group with myomas but no surgery, and 25% for the unexplained infertility group (316). A meta-analysis of 12 prospective series involving a total of 138 women who underwent abdominal myomectomy for infertility showed that cumulative postprocedure pregnancy rates at 1 year were 57% to 67%. Not surprisingly, pregnancy rates for those women who had no other factor contributing to their infertility were higher than for women with additional causes of infertility (61% versus 38%). Women who were treated for submucous fibroids had a postoperative pregnancy rate of 70% at 1 year (317). One study reported 24-month cumulative conception rates of 87%, 66%, and 47% in patients younger than 30 years of age, 30 to 35 years of age, and older than 35 years, respectively, after abdominal myomectomy in 138 infertile women (318). The presence of other causes of infertility and duration of infertility were factors associated with worst prognosis, whereas the size, number, or site of fibroids did not affect pregnancy outcomes. Others have reported success rates after abdominal myomectomy that are comparable to the 65% pregnancy rate and 50% live delivery rate reported for laparoscopic myomectomy (319). The success of laparoscopic myomectomy, however, is contingent on a number of factors, including stringent criteria for patient selection and the surgeon's experience with the procedure. In addition, appropriate closure of the created uterine defect is essential to minimize the complication of uterine rupture during subsequent pregnancy (320,321). **In short, both myomectomy and superovulation/IUI are reasonable treatment options for women with uterine fibroids and otherwise unexplained infertility, particularly if the leiomyomas are large, submucous, solitary, or distorting the uterine cavity.**

Endometrial Polyps

Even in the absence of abnormal uterine bleeding, endometrial polyps may be discovered in women with infertility. The incidence of asymptomatic endometrial polyps in women with infertility has been reported to range from 10% to 32% (303,322). Because of the influence of circulating estrogen on the development of endometrial polyps, the higher incidence seen in the infertility population may be related to the hyperestrogenemia associated with prior cycles of COH. A recent prospective study of 224 infertile women who underwent hysteroscopy suggested a 50% pregnancy rate achieved with polypectomy (323). Timing hysteroscopic evaluation and treatment immediately before COH has proven benefit (292). In contrast, of 83 patients who were diagnosed with an endometrial polyp during COH for IVF and who underwent hysteroscopy immediately after oocyte retrieval, only 58% had histopathologic confirmation of the diagnosis (324). Although pregnancy rates in these women were similar to those of other IVF patients, spontaneous abortion rates appeared higher in those patients with polyps (324). The threshold of parameters, such as size and number of polyps, at which infertility or miscarriage risk is elevated have not been well described. Nonetheless, **the evidence to date indicates that the targeted removal of endometrial polyps to optimize fertility outcomes is prudent..**

Intrauterine Synechiae or Asherman Syndrome

About 13% of 78 infertile women scheduled for IVF treatment were found to have intrauterine adhesions when evaluated with diagnostic hysteroscopy (323). Causes of intrauterine adhesions are often iatrogenic, with patient histories typically involving intraoperative or postoperative complications of uterine evacuations for menorrhagia, pregnancy termination, or postpartum hemorrhage. Other causes of intrauterine synechiae include intrauterine infection with pathogens such as schistosoma and mycobacteria. In some Third World countries, tuberculous endometritis may be an important cause of uterine factor infertility (325). Tuberculous endometritis differs from most other types of endometrial infection, and uterine scarring and infertility are significant sequelae even after treatment (326). Because intrauterine adhesions may interfere with embryo implantation, severe forms of Asherman syndrome have been associated with amenorrhea, menstrual irregularities, spontaneous abortion, and recurrent pregnancy loss.

Hysteroscopic resection is the method of choice for the management of intrauterine synechiae. Postoperative prevention of reformation of adhesive disease may involve estrogen therapy alone or in combination with intraoperative placement of an intrauterine device such as a pediatric Foley catheter for 1 week. It is thought that estrogens will rapidly rebuild the endometrial lining after surgery and thereby prevent the development of

scar tissue. A typical regimen consists of *conjugated estrogen* at a dosage of 2.5 mg to 5 mg per day for 1 to 2 months. **The surgical management of intrauterine adhesions is reported to be very effective, with pregnancy rates higher than 80% among patients treated for mild to moderate disease (327).**

Disorders of Endometrial Function and Luteal-phase Defect

There are few areas of greater controversy in the field of infertility than those surrounding the existence, diagnosis, and treatment of inadequate luteal phase or **luteal-phase defect (LPD)**. The controversy has been fueled by disagreements about both the definition of this entity and the efficacy of its treatment. **Although variously defined, most agree that luteal-phase defect is present when two endometrial biopsies show a delay of more than 2 days beyond the actual cycle day in the histologic development of the endometrium (328).** The actual cycle day has conventionally been calculated by assigning the onset of the menses following biopsy as day 28 and counting backward to the day of biopsy.

Compromising the reliability of endometrial histology in the diagnosis of LPD are the significant inter- and intraobserver variability in the results of histologic dating (329), the intercycle variation of biopsy results, and debate concerning the proper timing of the

P.1226

biopsy. In a collection of serial luteal-phase endometrial biopsy specimens from normally fertile women, investigators documented isolated out-of-phase specimens in 31.4% of participants with normal cycles and sequential out-of-phase specimens in 6.6%, suggesting that **out-of-phase endometria are common in women with regular cycles (330).** Others have reported that **the frequency of out-of-phase endometrial specimens among infertile patients is no greater than the rate that would occur by chance alone (331,332).**

In light of the discomfort and inconvenience associated with the multiple endometrial biopsies needed to confirm the diagnosis of luteal-phase defect, investigators have attempted to identify alternative markers for the diagnosis of LPD. In addition to delayed endometrial maturation, LPD can also be characterized by histologic asynchrony between endometrial epithelial and stromal compartments. A variety of factors could be responsible for such histologic alterations, including inadequate follicular development, inadequate FSH or LH secretion, hyperprolactinemia, and inadequate progesterone production by the corpus luteum (333).

Although some studies have advocated the use of a threshold luteal-phase serum progesterone level, data that convincingly associate either single or summed midluteal-phase serum progesterone levels with proposed luteal-phase abnormalities are lacking because of the characteristic pulsatile secretion of progesterone (334). Given the concerns over the accuracy of diagnosing LPD, attempts to diagnose this disorder should be confined to infertile patients who lack other identifiable diagnoses and to those in whom treatment specifically directed at luteal-phase defect is being contemplated.

In recent years, a temporal and functional "implantation window" of maximal uterine receptivity has been proposed to occur during the midluteal phase of the human menstrual cycle. **Studies of IVF and embryo transfer indicate that the implantation window lasts from day 5.5 to day 9.5 postovulation** (335). Using a ratio of urinary estrogen metabolites to progesterone metabolites to time ovulation, the percentage of pregnancy losses associated with implantation on postovulation days 9, 10, 11, and beyond day 11 were 13%, 26%, 52%, and 82%, respectively (336).

Luteal-phase defect has been proposed as a cause of a nonreceptive endometrial environment. Specifically, LPD may result in an aberrant molecular profile within the endometrium, which in turn can adversely affect endometrial receptivity to blastocyst implantation. Given the aforementioned concerns regarding histologic dating, recent studies have been directed toward defining more objective molecular markers of endometrial receptivity. To this end, both the presence of pinopodes and molecular markers, such as the expression of integrins, have been proposed as indicators of uterine receptivity (337,338). Although $\alpha\beta3$ integrin expression and pinopode formation appear to be more reliable markers of the implantation window than histologic dating (339), the clinical utility of testing for their presence is questionable because of the significant intercycle variability and poor reproducibility in their expression (340). The value of $\alpha\beta3$ integrin expression as a predictor of pregnancy outcome has been recently refuted in a cohort of 100 consecutive infertile patients who underwent mid- and late luteal, endometrial biopsy-based histologic dating and immunohistochemistry for $\alpha\beta3$ expression (341).

Current treatments for presumed LPD in infertile patients are empiric and reflect the hypothesis that progesterone insufficiency is causal. Treatment, therefore, involves the administration of vaginal micronized (400–600 mg/day) or intramuscular *progesterone* (50–100 mg/day) beginning 3 days after documentation of an LH surge. After ART with protocols involving a GnRH agonist, supplementation via vaginal administration may be preferred (342).

Progesterone supplementation is typically continued until the first day of the next menstrual cycle

value. If a patient becomes pregnant while on therapy, progesterone is continued until 8 to 10 weeks of gestation. Studies supporting progesterone supplementation for LPD have reported improved pregnancy rates after intervention (343). However, these studies have been small and poorly controlled with varied diagnostic criteria. Therefore, a prospective, randomized trial studying the impact of progesterone supplementation on pregnancy rates and outcomes in infertility patients accurately diagnosed with luteal-phase defect is warranted. Until such a study documents unequivocal clinical relevance, the existence of LPD as an entity will remain controversial.

Infectious Factors

The relationship between subclinical infection and fertility has received considerable attention. Particular interest has focused on two potential pathogens: *Chlamydia trachomatis* and *Mycoplasma* species. The association of chlamydia with PID is well established. Chlamydia is the predominant pathogen detected in about 20% of cases of acute salpingitis in the United States. **Chlamydia may produce asymptomatic infection in the female genital tract, and it is likely that some women experience silent tubal infection.** Despite few if any symptoms, these infections may result in significant tubal damage. A possible link between infection and infertility is suggested by evidence that the prevalence of positive chlamydial cultures may be higher among infertile patients than among controls (344). In a study of 286 women undergoing 344 oocyte retrieval procedures, seropositivity for chlamydia and the presence of bacterial vaginosis were highly associated with tubal disease. Reproductive outcomes of IVF, however, were no different than those of controls (345).

In a study of 771 patients undergoing egg retrieval as part of IVF treatment, the incidence of bacterial vaginosis was 25%. **Although their pregnancy rates were not affected, patients with bacterial vaginosis had a significantly higher risk for spontaneous abortion than matched controls, even after adjusting for smoking history, maternal age, the presence of polycystic ovaries, history of recurrent miscarriage, and history of previous live birth** (346). It remains to be determined which factors directly caused this increased rate of spontaneous pregnancy loss. Likewise, **it is not known whether treatment of bacterial vaginosis before or during IVF treatment would alter the rate of spontaneous abortion.**

Mycoplasma species are pleuropneumonia-like organisms. Both *Mycoplasma hominis* and *Ureaplasma urealyticum* have been recovered from the cervical mucus and semen of infertile couples. There also appear to be higher rates of mycoplasma infection among infertile couples than among fertile couples. The effect of these organisms on fertility is unclear. For example, mycoplasma organisms have been isolated from the cervix of the female partner in 47% of previously infertile couples who conceived and 53% of couples who remained infertile (347). The role of treating these infections in an infertile population also is controversial. In one study, 60% of infertile men who tested positive for ureaplasma and whose infection was subsequently treated by antibiotic treatment impregnated their partners; the rate was only 5% among men whose infection was not treated (348). In contrast, a double-blind study of *doxycycline* treatment for mycoplasma infection failed to show an effect on conception rates (347). **Until a clear association has been established between mycoplasma infection or its treatment and fertility outcomes, routine testing for this organism during an infertility evaluation is not warranted.**

Systemic Illness

In general, any severe systemic illness, such as renal failure, liver failure, or metastatic cancer, can lead to disruption of the hypothalamic-pituitary-ovarian axis and cause infertility.

However, because sporadic ovulation is always possible, even after a period of

P.1228

anovulation, use of contraception should be advised if pregnancy is not desired. If a patient with severe systemic illness wishes to conceive, careful preconceptional assessment and counseling is advisable because the risks of fertility treatment and pregnancy can be substantial.

The association of antiphospholipid antibodies, particularly anticardiolipin antibodies and the lupus anticoagulant, with recurrent pregnancy loss led to the investigation of a role for these antibodies in infertility. These antibodies are more prevalent in the infertility population (349). However, the presence of antiphospholipid antibodies has not been found to adversely affect IVF outcomes in a prospective study or in a meta-analysis of seven studies (350,351). **These findings do not support a role for the routine testing of antiphospholipid antibodies in the infertility evaluation.**

Unexplained Infertility

The laboratory assessment of an infertile couple is relatively simple and should

be performed rapidly to establish a diagnosis and initiate appropriate therapy (see Figs. 30.1–30.3). **Evaluation of the man by semen analysis in an accredited laboratory skilled in andrology testing is essential. Ovulation should be documented in women using over-the-counter ovulation detection kits.** If uncertainty surrounding the interpretation of such tests exists, the midluteal serum progesterone level can be assessed to confirm ovulation. Unless laparoscopic surgery is already planned for some other indication, tubal obstruction should be excluded using HSG. If laparoscopy is indicated, laparoscopic chromopertubation can be performed at the time of surgery. Any previous infertility investigations should be reviewed and repeated if the results are in doubt. If the basic evaluation reveals normal semen parameters, evidence of ovulation, patent fallopian tubes, and no other obvious cause of infertility, the couple is diagnosed with unexplained infertility. This diagnosis accounts for up to 30% of couples with infertility (352). **In six randomized studies of couples with unexplained infertility, the cycle fecundity in untreated controls was 3.8%, significantly lower than the 25% fecundity rate observed in normal fertile couples** (353).

Role of Diagnostic Laparoscopy

A controversial issue in the management of unexplained infertility concerns the potential role for laparoscopy in the evaluation of this condition. Previously unsuspected conditions that may be detected during laparoscopy include uterine leiomyomas, peritubal adhesions, and endometriosis. These entities can result in infertility via the distortion of normal tubo-ovarian relationships. Prospective studies have demonstrated HSG to be highly sensitive in the evaluation of tubal patency; thus, laparoscopy is not felt to be necessary to evaluate tubal status when HSG findings are normal. However, **retrospective studies of laparoscopy in infertile patients reveal abnormal findings in 21% to 68% of cases after HSG with normal results** (354). Although the prevalence of pathology exposed by laparoscopy is impressive, the value of the procedure depends on whether it influences treatment decisions or fertility outcomes. In a retrospective review of the laparoscopic surgical reports of 495 couples planned for IUI treatment, laparoscopy revealed abnormalities that changed the treatment decision in 25% of cases (355). The most common disorders encountered in descriptive series include endometriosis (43%) and peritubal adhesive disease (34%) (354).

Whether laparoscopic management of these disorders enhances fertility outcomes remains largely uncertain. In the case of peritubal adhesions, a single nonrandomized study comparing open adhesiolysis versus no treatment showed a

significant increase in the cumulative pregnancy rate at 12 months follow-up (32% versus 11%) (356). Although laparoscopic adhesiolysis has not been studied, it is expected to similarly restore normal tubo-ovarian relationships and optimize fertility outcomes. Validation by a prospective randomized study is warranted.

Endometriosis

The main reason for performing diagnostic laparoscopy in women with unexplained infertility and normal HSG findings is the possibility of identifying and treating endometriosis. The value of diagnosing endometriosis in the absence of tubal obstruction and of its treatment in women with unexplained infertility is an area of considerable debate. It is generally thought that there is a higher prevalence of endometriosis in women with infertility (357). **Clinical evidence linking the presence of endometriosis to infertility exists, but the mechanisms remain unclear. In severe stages of endometriosis, distorted anatomy may explain the association. In cases of minimal or mild disease with normal tubo-ovarian relationships, endometriosis is purported to have a deleterious effect on fertility via associated elevations in a variety of cytokines, including tumor necrosis factor.** These soluble mediators of inflammation may alter the peritoneal, intratubal, or intrauterine environment and adversely affect fertilization, early embryo development, or implantation (358,359,360). Data on the effect of endometriosis on ART pregnancy rates indicate either no significant changes or lower pregnancy rates (361,362,363). The fact that pregnancy rates do not appear to correlate with disease stage (according to the Revised American Society for Reproductive Medicine's classification of endometriosis) further clouds arguments about the importance of endometriosis diagnosis and treatment among infertile couples (364).

Medical therapies for endometriosis that involve hormonal suppression (e.g., combination oral contraceptive pills, GnRH agonists, or danazol) are generally reserved for the treatment of pelvic pain because these treatments preclude pregnancy. Subfertility associated with endometriosis requires alternative, nonsuppressive approaches. In a prospective cohort trial involving 168 infertile women with minimal or mild endometriosis on diagnostic laparoscopy and 263 women with unexplained infertility, the Canadian Collaborative Group on Endometriosis found that fecundity rates were similar in both populations (18.2% versus 23.7%) during 36 weeks of expectant postoperative follow-up (365). The same group performed a randomized

trial comparing 172 women who had ablation or resection of minimal or mild endometriosis with 169 women who were not laparoscopically treated for similar operative diagnoses at diagnostic laparoscopy. Cumulative pregnancy rates were significantly different between treated and control groups at 30.7% and 17.7%, respectively. By 36 weeks of follow-up, fecundity rates were 4.7 and 2.4 per 100 person-months, respectively. The rates of spontaneous abortion (20.6% and 21.6%, respectively) were nearly identical (366). In contrast, the Gruppo Italiano per lo Studio dell'Endometriosi reported that, after 1 year of follow-up, 54 women with otherwise unexplained infertility who underwent resection or ablation of minimal to mild endometriosis had pregnancy rates similar to 47 women whose endometriosis was not treated (24% versus 29%, respectively) (367).

It is possible that any improvement in pregnancy rates resulting from ablation or resection of endometriosis has been so small that a very large trial would be required to document posttreatment differences. It is important to interpret these data in a clinically relevant context. Based on the Canadian prospective randomized trial, it is calculated that one pregnancy would result from the laparoscopic treatment of every 7.7 patients with minimal to mild endometriosis (368). Assuming that 30% of couples with unexplained infertility and otherwise negative findings have mild to minimal endometriosis, 25.4 patients would need to undergo laparoscopy to yield one pregnancy that can be attributed to the treatment of endometriosis (368). In summary, although surgery appears effective for the treatment of endometriosis-associated infertility, the inclusion of a laparoscopic examination in the routine diagnostic evaluation of every infertile patient is subject to debate.

In view of the available evidence, it is reasonable to initiate fertility treatment empirically in women with unexplained infertility and normal HSG findings without assessment of the pelvis by diagnostic laparoscopy. This conclusion is based on a number of issues, including the debated value of diagnostic laparoscopy, known surgical

P.1230

risks of laparoscopy, and proven efficacy of empiric treatment. The optimal timing of laparoscopy is undetermined, and diagnostic laparoscopy can be performed if initial treatments are unsuccessful. If laparoscopy is performed, visible endometriotic lesions should either be ablated or resected. A retrospective study has reported electrocoagulation and resection of endometriosis to have an indistinguishable effect on postprocedure pregnancy outcome (369). **The best overall approach to patients with unexplained infertility involves a discussion of the options of empiric therapy or diagnostic laparoscopy and allowing the patient to actively participate in decisions regarding the course of treatment..**

Treatment of Unexplained Infertility

As requirements for both diagnostic laparoscopy and prior exclusion of endometriosis become less stringent in the diagnosis of unexplained infertility, the potential impact of this broader definition on treatment efficacy must be considered. In a retrospective analysis, 131 women with more than 2 years of unexplained infertility were managed expectantly while waiting for IVF. Their pregnancy rate was only 0.9% per exposure cycle, whereas a similar group of 119 women receiving IVF treatment had a 17% pregnancy rate per cycle (370). **The low spontaneous pregnancy rate in these patients warrants the abandonment of expectant management and the rapid initiation of empiric therapies.** These therapies are aimed at increasing the chances of conception by increasing the available numbers and proximity of healthy gametes.

Treatment typically involves superovulation (increasing female gametes); collecting, washing, and concentrating the semen (increasing motile sperm); and bypassing a potential cervical factor using IUI. Superovulation with *clomiphene citrate* and IUI is usually the initial treatment regimen employed. This therapy is fairly efficacious in many couples with unexplained infertility and is less invasive, less expensive, and associated with fewer complications than other forms of treatment. However, if *clomiphene citrate* with IUI is unsuccessful after 3 months of treatment, then COH using gonadotropin therapy should be undertaken in conjunction with IUI (COH/IUI). If both these approaches fail to result in pregnancy, IVF or ICSI can be performed.

Clomiphene Citrate and Intrauterine Insemination

The rationale for using *clomiphene citrate* to increase the fecundity rate in ovulatory women with unexplained infertility is that of superovulation. Use of IUI has become a standard part of the *clomiphene citrate* regimen in treating these women. The degree of superovulation using *clomiphene citrate* is mild and most commonly results in the release of two eggs in ovulatory women. This low degree of superovulation limits complications such as multiple gestation, but it also limits efficacy. In fact, multiple pregnancy occurs in only 10% of patients treated with *clomiphene citrate*, and most of these are twin pregnancies. **A meta-analysis of six randomized controlled trials has shown the use of *clomiphene citrate* in women with unexplained infertility to be superior to placebo in increasing the clinical pregnancy rates per patient (OR 2.37, CI, 1.22–4.62) and per treatment cycle (OR 2.5, CI, 1.35–4.62) (371)..**

In couples with unexplained infertility, IUI significantly improves fertility outcome when performed in *clomiphene citrate*-treated cycles. A literature review of eight studies involving 932 cycles revealed cycle fecundity rates of 5.6% with *clomiphene citrate* alone compared with 8.3% with combined *clomiphene citrate* and IUI (353). Presumably, IUI bypasses the cervical mucus, which may be suboptimal because of the antiestrogenic effects of *clomiphene citrate*. However, *clomiphene citrate* may result in a thin endometrium, for which estradiol administered orally or vaginally improves outcome. In a randomized, double-blind study involving 64 patients with unexplained infertility undergoing superovulation with *clomiphene citrate*, the addition of *ethinyl estradiol* (0.05 mg daily for 5 days starting on day 8) resulted in a thicker endometrium and a higher ongoing pregnancy rate (37.5% versus 6.25%) (372).

P.1231

An alternative to *clomiphene citrate* is the aromatase inhibitor, *letrozole*. A prospective randomized trial involving 238 superovulation/IUI cycles in couples with unexplained infertility found that the pregnancy rates are similar for *clomiphene citrate* and *letrozole* (8.9% and 11.5%, respectively) (373). However, the rate of spontaneous miscarriage appeared lower in the *letrozole* group (373). Letrozole is reported to result in a luteal phase endometrium that is in phase and has normal thickness with pinopodes (374). Further, the incidence of a thin endometrial echo on ultrasound (≤ 5 mm) is suggested to be rare in *letrozole* cycles when compared with *clomiphene citrate* cycles (194).

Controlled Ovarian Hyperstimulation and Intrauterine Insemination

IUI is considered a standard adjunct to any superovulation treatment in unexplained infertility. A meta-analysis of prospective, randomized trials comparing IUI and timed intercourse in women with unexplained infertility undergoing treatment with gonadotropins determined that the pregnancy rate is higher with IUI (20% versus 11.4%; OR, 1.84; 95% CI, 1.30–2.62) (375). Given the relative imprecision in the prediction of ovulation, the number and timing of intrauterine inseminations has received considerable study. Traditionally, IUI is timed at 3.6 hours after hCG injection, which is close to the time of ovulation; statistically similar pregnancy rates are achieved when the IUI is timed from 32 to 40 hours after hCG (376). When ovulation detection kits are used, the IUI is performed 24 hours after a spontaneous LH surge. **A meta-analysis of six**

prospective, randomized trials comparing one versus two intrauterine inseminations showed no statistically significant improvement in pregnancy rates with two inseminations (377). However, a subanalysis by mode of ovarian stimulation revealed that when *clomiphene citrate* is used, two IUIs were superior to one (15.2% versus 10.3%; $P = 0.03$) in the optimization of pregnancy rates. In the case of gonadotropin-based ovarian stimulation, two IUIs did not demonstrate statistically significant improvement over a single, well-timed IUI.

In a multicenter, prospective, randomized trial involving 932 couples with unexplained infertility, the combination of COH with gonadotropins and IUI proved superior to IUI alone, intracervical insemination (IC) alone, or COH/IC (49). The National Cooperative Reproductive Medicine Network reported that the pregnancy rate was significantly higher in couples who were treated with COH/IUI (33%) than those treated with IUI alone (18%), COH/IC (19%), or IC alone (10%) (49). However, the multiple pregnancy rates also were increased.

Pregnancy rates using IVF have been reported to be higher than those using COH/IUI in the treatment of unexplained infertility (353,378). **However, the risks and costs associated with IVF treatment are appreciably higher, making it standard practice to treat these couples with COH/IUI before attempting IVF** (353). The question of how many COH/IUI cycles should be attempted before conversion to IVF can be a challenging one, especially because this decision is affected by financial as well as medical factors. The relatively low degree of invasiveness and low costs of COH/IUI must be balanced against the potential decrease in ovarian reserve that can compromise IVF success if treatment is delayed. This is a particularly important consideration for the older, infertile couple. **Therefore, it is good practice to recommend, a priori, a maximum number of COH/IUI cycles that will be attempted.** This definition of treatment expectations may help to temper reactions to unsuccessful therapeutic interventions and foster a sense of control among patients.

It has been recommended that patients with unexplained infertility experience no more than three to six COH/IUI cycles before therapy is discontinued or changed (379,380,381). One study recommended a maximum of three trials of COH/IUI, based on the cycle fecundity and cumulative pregnancy rates observed in historical controls involving 594 patients with unexplained infertility. In this study, the investigators reported a mean fecundity rate per cycle of 16.4% and a cumulative pregnancy rate of 39.2% during the first three COH/IUI cycles. Cycles 4 to 6 yielded a mean fecundity rate per cycle of 5.6%

and a cumulative pregnancy rate of 48.5%, a value only 9.3% higher than the rate achieved with three cycles. Alternatively, a historical control group consisting of 131 patients who failed three cycles of COH/IUI had a cycle fecundity rate of 36.6% in their first attempt of IVF/ICSI treatment (382). **Thus, the benefit of continuing COH/IUI treatment beyond three cycles appears to be minimal for patients with unexplained infertility, unless a move to IVF/ICSI treatment is not feasible for the couple..**

The low rates of pregnancy in patients with unexplained infertility using COH/IUI beyond three cycles might be an indication that two (or more) subsets of populations of patients with unexplained infertility exist. **The fact that a significant proportion of these patients with unexplained infertility will exhibit complete failure of *in vitro* fertilization of oocytes suggests that some of these couples may have major defects in fertilization** (383). The rates of complete failure of fertilization with conventional IVF have been reported to be 11.4% and 17.6% in two studies of couples with unexplained infertility (383,384). The overall pregnancy rate, however, was not increased with the use of ICSI, compared with IVF, in patients with unexplained infertility in a prospective, randomized trial (384). Nonetheless, in this context, IVF might be considered diagnostic in identifying those patients with fertilization defects. Because of their high risk for nonfertilization with conventional IVF protocols, it appears reasonable to offer a split of IVF and ICSI on sibling oocytes within a single cycle for couples with unexplained infertility. This approach would prevent the disappointment and loss of potential pregnancy faced by couples with complete fertilization failure discovered during the first IVF cycle (384).

Treatment Options

Gonadotropin Therapy

Medical preparations of gonadotropins (LH, FSH) can be used to stimulate ovarian follicular development or induce ovulation in the treatment of several conditions: .

- **Ovulation induction in anovulatory PCOS that is resistant to ovulation induction by *metformin* and *clomiphene citrate*.**
- **2. Ovulation induction in hypogonadotropic hypogonadism or pituitary dysfunction.**

Superovulation or COH combined with IUI in the treatment of unexplained infertility.**COH in IVF/ICSI.**

Exogenous gonadotropins supplement or replace the woman's own gonadotropins.

Functional ovarian tissue is required for successful treatment because the major actions of gonadotropins are directed at the ovary itself. Recapitulating spontaneous ovulatory cycles, FSH and LH are presumed to act in concert to stimulate folliculogenesis; FSH acts primarily on the granulosa cells, and LH acts on the thecal lutein cells. When the follicles grow to a certain size, treatment with hCG typically is given to promote oocyte maturation, induce ovulation, and allow appropriate corpus luteum formation and function.

Table 30.8 Different Types of Gonadotropin Preparations					
<i>Trade Name</i>	<i>Name of Compound</i>	<i>Source</i>	<i>Amount of FSH per Ampule</i>	<i>Amount of LH per Ampule</i>	<i>Route of Administration</i>
Repronex (Ferring Pharmaceuticals, Inc.)	Menotropin hMG	Extracted urinary	75 IU	75 IU	IM or SC
Menopur (Ferring Pharmaceuticals, Inc.)	Menotropin urinary hMG	Highly purified	75 IU	75 IU	SC
Bravelle (Ferring Pharmaceuticals, Inc.)	Urofollitropin urinary FSH	Highly purified	75 IU	None	IM or SC
Follistim (Organon Inc.)	Follitropin	Recombinant FSH beta	75 IU ^a	None	SC
Gonal-F (Serono Laboratories, Inc.)	Follitropin	Recombinant FSH alpha	75 IU ^a	None	SC
Luveris (Serono Laboratories, Inc.)	Luteinizing hormone	Recombinant LH	N/A	75 IU	SC

FSH, follicle-stimulating hormone; LH, luteinizing hormone; hMG, human menopausal gonadotropin; IM, intramuscularly; SC, subcutaneously; N/A, not applicable.
^aAlso available in pen formulation.

The key differences in the various preparations lie in the methods of extraction or synthesis of FSH and LH, the proportion of each hormone in the preparation, and the route of administration (Table 30.8). Two prospective, randomized controlled trials that compared hMG and recombinant FSH for ovulation induction in PCOS patients and COH/IUI in patients

with unexplained infertility, respectively, found that the type of gonadotropin used did not affect pregnancy rates. However, the cost was significantly higher when recombinant FSH was used (385,386).

The response to gonadotropins varies from person to person. Even the same individual may respond differently to the same gonadotropin regimen in different cycles. Therefore, one of the advantages of using recombinant FSH is an improved batch-to-batch consistency, allowing a more predictable response to the same gonadotropin dosage. However, since the recombinant forms may not elicit optimal response in patients with particular FSH receptor variants, a trial of hMG or highly purified urinary FSH should be considered in patients who have suboptimal response to recombinant FSH. Finally, patients should undergo a full evaluation to ensure that there are no contraindications to gonadotropin therapy (Table 30.9).

Regardless of the indication, regimens involving gonadotropin therapy for ovulation induction or COH follow fairly similar protocols. All include close monitoring of folliculogenesis using transvaginal ultrasonography and assessment of serum estradiol levels. Such monitoring allows informed adjustment of gonadotropin dosages, timed hCG injection and IUI, and most importantly, limitation of complications such as OHSS and multiple gestation. Patient age, ovarian reserve, and infertility diagnosis should be considered in determining the initial gonadotropin dose, the maximum allowable number of follicles, and the speed of ovarian stimulation (or cycle length). Many protocols have been proposed and have in common the key issues involved in gonadotropin stimulation in non-IVF/ICSI cycles.

Baseline Transvaginal Ultrasound Scan

Patients begin therapy on cycle day 2 or 3 after the onset of a spontaneous or induced menses (cycle day 1 is defined as the first day of menses). A baseline transvaginal ultrasound is performed before gonadotropin injections are begun to identify uterine abnormalities such as endometrial polyps, submucosal fibroids, or congenital defects. Hormonally responsive disorders, including endometrial polyps and submucosal fibroids, may not be apparent at this point in the menstrual cycle, when tissues are in a hypoestrogenic state. Therefore, a systematic survey should be repeated in subsequent ultrasound examinations throughout the course of the stimulation protocol (387). The two-hand transvaginal ultrasound technique often allows better visualization over the one-hand technique. This technique combines current technology with the traditional bimanual pelvic examination. The nondominant hand of the ultrasonographer can be used to apply

pressure to improve the definition of pelvic structures (387). The findings of a thin endometrium (<4 mm) and quiescent ovaries on the baseline scan reflect the hypoestrogenic state of the early follicular phase, which is the optimal state with which to commence treatment. Conversely, a thick endometrium represents endogenous hormonal stimulation above normal basal levels, and further testing should be considered to exclude pregnancy and endometrial hyperplasia.

Table 30.9 Contraindications of Gonadotropins for the Treatment of Infertility in Women

1. Primary ovarian failure with elevated follicle-stimulating hormone levels
2. Uncontrolled thyroid and adrenal dysfunction
3. An organic intracranial lesion such as a pituitary tumor
4. Undiagnosed abnormal uterine bleeding
5. Ovarian cysts or enlargement not caused by polycystic ovary syndrome
6. Prior hypersensitivity to the particular gonadotropin
7. Sex hormone-dependent tumors of the reproductive tract and accessory organs
8. Pregnancy

From **Physicians desk reference**. Micromedex (R) Healthcare Series Vol. 107. Thompson PRD and Micromedex Inc., 1974–2004, with permission.

Unilocular, clear cysts may represent functional cysts or unruptured luteinized cysts. Complex ovarian cysts detected at baseline usually reflect old hemorrhagic corpus luteae and are often seen when the patient has been treated with gonadotropins in the previous cycle. Nevertheless, the differential diagnoses, including endometrioma, benign ovarian tumor, or malignancy, must be considered. The management of ovarian cysts present at baseline is controversial. In 174 prospective, non-IVF, COH cycles, a significantly lower cycle fecundity rate was observed with a baseline ovarian cyst larger than 10 mm (388). Confusion may arise secondary to the findings of several IVF studies that reported no adverse effect on pregnancy outcomes associated with the presence of a baseline ovarian cyst (389,390,391). However, extrapolation of results from IVF studies to non-IVF, COH cycles is not necessarily valid. Regardless, the issue continues to be debated even among IVF studies (392). **Ovarian cysts seen at the baseline scan tend to resolve spontaneously within 1 to 2 months. Low-dose oral contraceptive pills (OCPs) have a lower efficacy**

than older, high-dose OCPs in preventing the formation of new cysts (393,394). Because OCPs do not affect the speed of resolution of old cysts, they are not indicated in this setting..

Starting Dose of Gonadotropin

Gonadotropin dosages can be administered every evening, allowing morning measurements of serum estradiol to reflect the steady state. If the patient has had previous gonadotropin treatment, the starting dose should be based on review of ovarian response in previous cycles. The following guidelines can be used for determining the starting dose of gonadotropins in the first COH or ovulation induction cycle: .

- **With unexplained infertility, the patient's age may affect ovarian response, though it may be difficult to predict.** Other markers of ovarian responsiveness (ie, FSH level, antral follicle count) can assist in tailoring the dose. Though no strict guidelines exist, one should always start at lower doses and increase the dose on days 6 and 7, if necessary. For example, a maximum of 75 to 100 IU of gonadotropin per day should be used for women younger than 30 years of age with a normal FSH level, whereas women older than 40 years of age can be started at a maximum of 150 to 300 IU per day.

P.1235

- **Anovulatory PCOS patients should start at 75 IU of gonadotropin per day.** A smaller dose of 50 IU per day sometimes is necessary to minimize the risk for OHSS.
- **Patients with hypogonadotropic hypogonadism usually begin with 75 IU per day.**

Monitoring and Adjustment of Dosage

The dose of gonadotropins is maintained until day 6 or 7, when the serum estradiol level is first measured to document ovarian response. Transvaginal ultrasound also is performed at this time to determine follicular response.

- **If these measurements detect no response, the gonadotropin dosage is increased by 50 to 100 IU per day every 2 to 4 days until a response is evident by rising estradiol levels (or until the maximal dosage is reached).** The maximal dosage is usually 450 IU per day because higher dosages usually do not increase ovarian response (395).

- **Once an ovarian response is obtained, treatment typically is continued without further increase in dose.**

Cycle Progression and Monitoring

Transvaginal ultrasound and serum estradiol measurements are performed every 1 to 2 days to evaluate follicular size, number, and quality. Follicles can be predicted to grow 1 to 2 mm per day after they reach 10 mm, and follicular development is believed to be adequate when maximal follicular diameter exceeds 18 to 19 mm. When hMG is used, the serum estradiol level roughly corresponds to 150 to 250 pg/mL per mature follicle. However, serum estradiol levels may not correlate as closely with the number of mature follicles when recombinant FSH is used. In general, the serum estradiol level can be expected to double every 24 hours if the same dosage of gonadotropins is maintained. Therefore, **the main reasons for monitoring the estradiol levels are as follows:**.

- **To detect missed spontaneous ovulation or premature luteinization, which may be reflected by a drop in serum estradiol levels.**

- **To identify patients at risk for OHSS:**

- **Estradiol levels approaching 800 to 1,000 pg/mL indicate increased risk for OHSS.**

A decrease in gonadotropin dosage should be considered, and 24-hour monitoring is mandated. Withholding gonadotropin in this situation is referred to as "coasting" and is usually followed by a more than 25% decrease in serum estradiol levels while the follicle numbers and diameters increase. If follicle numbers increase to an excessive level, the cycle

should be cancelled (396,397,398).

- **Estradiol levels in the range of 1,500 to 2,000 pg/mL indicate that treatment should absolutely be stopped because of the high risk of OHSS.** All medications should be discontinued, and hCG should not be administered. The patient should be asked to abstain from intercourse until menses occurs because she may spontaneously ovulate. Under these conditions, ovulation and intercourse increase the risk of multiple gestation.

Human Chorionic Gonadotropin Administration

When the largest measured follicle reaches a maximum diameter of 18 to 19 mm or more, 10,000 IU of hCG (*Profasi*) **is administered intramuscularly**. Alternatively, recombinant hCG (*Ovidrel*) can be given at 250 µg subcutaneously (399). Optimal pregnancy rates are achieved with IUI performed at 33 to 39 hours after the hCG injection (376).

Pregnancy Test or Plans for Next Cycle

If menses does not ensue after a treatment cycle, testing for pregnancy should be performed about 15 to 16 days after hCG administration. Testing for serum or urinary levels of β -hCG should not be affected by prior administration of exogenous hCG at this

P.1236

point, and β -hCG should be detectable by either method. If pregnancy does not occur, the cycle should be reviewed. If appropriate follicle size, number, and estradiol levels have been reached, there is no need to change the gonadotropin dosage. The dosage should be changed if COH was inadequate or excessive. If the length of the stimulated cycle was too short (ie, the follicular stimulation was too fast), endometrial maturation could have been suboptimal, and the gonadotropin dosage should be decreased in a subsequent cycle.

Special Issues of COH/IUI in PCOS

PCOS patients represent one of the most challenging subpopulations to treat safely and successfully using COH/IUI. The multiple small ovarian antral follicles characteristic of these patients may be very resistant to stimulation, but they are equally likely to respond and grow with minimal increases in gonadotropin dosage. The incidence of multiple pregnancy and

OHSS is increased in these patients (400). Up to 30% or more of COH cycles may be canceled as a result of excessive follicular development. Several approaches that have been proposed to avoid complications of COH and cycle cancellation include downregulation with GnRH agonists, dual suppression with oral contraceptives and GnRH agonists, pretreatment with *metformin*, and surgical ovarian diathermy (206,401,402,403).

Hypogonadotropic Hypogonadism

Therapy with hMG is most successful in patients with hypogonadotropic hypogonadism, yielding cumulative pregnancy rates of 91.2% after six treatment cycles using hMG alone (404). In this particular group of patients, hMG is recommended over purified FSH for ovulation induction because purified FSH has been associated with a significantly higher total dosage requirement, lower estradiol levels, and decreased number of lead follicles (405). Before ovulation induction in these patients, a baseline transvaginal ultrasound should be performed to determine whether the ovaries appear PCO-like, with multiple small antral follicles, thick stroma, or enlarged ovarian volume. A subset of patients with isolated hypogonadotropic hypogonadism have PCO-like ovaries and respond to gonadotropins much like PCOS patients, exhibiting higher serum estradiol levels and a greater number of follicles (406). Based on this finding, in conjunction with the fact that patients with hypogonadotropic hypogonadism typically are younger and have better ovarian reserve than patients with unexplained infertility, it is prudent to start with small doses of hMG in this population to avoid complications of OHSS and multiple gestation.

Hypothalamic Failure

In most patients with acquired hypogonadotropic hypogonadism secondary to cranial surgery or radiotherapy for various cranial tumors, hypothalamic failure is the source of their dysfunctional hypothalamic-pituitary axis (407). In these patients, GnRH stimulation testing and the assessment of endogenous pulsatile LH secretion often can confirm whether the hypothalamic-pituitary axis is intact. Patients with hypothalamic failure and subsequent ovulatory factor infertility represent the best candidates for ovulation induction with GnRH agonists. To mimic physiologic hypothalamic-pituitary interactions, GnRH agonists must be administered in a pulsatile fashion, thereby avoiding the downregulation of the GnRH receptors that accompanies continuous GnRH agonist stimulation. Coexistent growth hormone deficiency or prolactin abnormalities do not affect the efficacy of pulsatile GnRH agonist therapy (407). Because GnRH agonists are degraded rapidly by gastric enzymes (and

either intravenously or subcutaneously with a minipump delivery system. Adverse effects of pulsatile GnRH agonist therapy are mainly related to pump function and route of delivery (i. e., phlebitis at the needle site). The intravenous route is superior (408), but it is recommended that women with a history of bacterial endocarditis be offered only subcutaneous therapy.

In hypothalamic hypogonadotropic hypogonadism, normal negative and positive feedback mechanisms of the pituitary are functional upon treatment with pulsatile GnRH agonists. In this situation, pulsatile GnRH agonist therapy simulates normal physiology and offers some advantages over hMG as a treatment for ovulatory infertility. More

P.1237

than two dominant follicles are seen in only 18.9% of patients with hypogonadotropic infertility who are treated with pulsatile GnRH agonist, and more than three follicles are seen in only 5.4% of patients (409). Because OHSS is a rare occurrence, less intensive monitoring is required during GnRH agonist treatment cycles. Moreover, the risk for multiple gestation approximates that associated with *clomiphene citrate* therapy—only 8% (409). These are important advantages when compared with gonadotropin therapies. Cumulative pregnancy rates among women with hypothalamic hypogonadism approach 80% after 6 treatment cycles and 93% after 12 GnRH agonist treatment cycles (410), with no documented increase in the rates of spontaneous abortion (411).

The optimal dosing interval for pulsatile GnRH agonist therapy is 60 to 90 minutes, and the usual recommended dosage is 75 to 100 ng/kg/pulse (405,406). Increased dosage of up to 250 ng/kg/pulse has been reported to be required in the successful treatment of a patient with known GnRH receptor mutation (412). With typical regimens of pulsatile GnRH, ovulation occurs on day 14 and can be documented by standard LH testing. Patients treated with pulsatile GnRH usually benefit from luteal-phase support through continuation of the GnRH pump, administration of hCG, or progesterone supplementation.

Assisted Reproductive Technologies

All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined in the United States. In 2000, 73,406 cycles of IVF were performed compared with only 549 cycles of GIFT and 763 cycles of ZIFT

(413). Consequently, the following discussion will focus primarily on IVF and ICSI. **The typical ART cycle (IVF or ICSI) has the following main components:.**

- **COH using gonadotropins, follicular development monitoring with transvaginal ultrasound, and assessment of serum estradiol levels.**
- **Prevention of premature LH surge and ovulation.**
- **Oocyte maturation using hCG.**
- **Oocyte retrieval.**
- **Fertilization by IVF or ICSI.**
- ***In vitro* embryo culture.**
- **Luteal support or endometrial preparation using progesterone supplementation.**
- **Transfer of fresh embryos with possible cryopreservation of excess embryos.**
- **First-trimester pregnancy monitoring.**

Folliculogenesis in the Spontaneous Cycle

In unassisted ovulation, the cohort of follicles destined to begin folliculogenesis in any particular menstrual cycle are recruited in the previous cycle's luteal phase. By about the middle of the next follicular phase, one of these follicles will become dominant, and further development of this dominant follicle suppresses maturation of other follicles within the selected cohort of that particular cycle. Follicular-phase growth of a single dominant follicle in unstimulated cycles induces a series of hormonally

regulated feedback loops, resulting in the midcycle LH surge, which is critical for maturation of the oocyte and ovulation. Progesterone production commences just before ovulation and becomes significantly increased after ovulation. Estradiol production during the follicular phase causes proliferation of the endometrial epithelium. Subsequently, progesterone is critical in the final

maturation of the endometrial glands and stroma required for implantation of the blastocyst. **In the presence of successful implantation, the hCG-stimulated corpus luteum serves as the primary source of progesterone until the placenta independently produces sufficient amounts of progesterone by 8 to 10 weeks of gestation..**

Controlled Ovarian Hyperstimulation

Typical use of gonadotropins for COH in ART is similar to the superovulation protocol used in COH/IUI for unexplained infertility. There are several key differences:.

- **When the GnRH agonist luteal downregulation protocol is used, ovarian suppression should be confirmed by a baseline transvaginal ultrasound examination** showing no ovarian cysts larger than 5 cm (389), a thin endometrium, serum estradiol level of less than 50 pg/mL, and serum progesterone level of less than 1.0 ng/mL. Ovarian suppression usually is achieved after about 10 days of GnRH agonist therapy. Once ovarian suppression is confirmed, COH using gonadotropins can be initiated.
- **In ART, the aim of COH is to recruit more follicles than in COH/IUI.** Unlike COH/IUI, the risk for multiple gestation under ART regimens is strictly dependent on the number of embryos that are transferred and not on the number of follicles recruited.
- **The prevention of a premature LH surge and ovulation is critical to the success of ART.** Spontaneous ovulation is prevented by the routine use of a GnRH agonist, or more recently, a GnRH antagonist. Because these regimens help prevent a premature surge, slightly greater flexibility can be exercised on the day of hCG administration without affecting the pregnancy outcomes (414).
-

The removal of granulosa cells during aspiration of each developing follicle with ART is believed to decrease the risk of subsequent OHSS (415). Thus, higher serum estradiol levels and larger follicular sizes are allowed before hCG administration in ART protocols. The risk of OHSS does, however, remain a major concern (416).

Choice of Gonadotropins

In recent years, improved pregnancy rates have resulted from progress in all facets of ART. Concurrent with improvements in embryo culture and embryo transfer techniques has been the introduction of several generations of gonadotropin formulations. The main focus of these improvements has been directed to increasing the purity of the FSH component in new preparations. As a result, current recombinant FSH preparations contain absolutely no LH and no other protein contaminants. A meta-analysis reported that recombinant FSH improved pregnancy rates when compared with use of purified FSH or highly purified FSH (OR 1.20, 95% CI, 1.02–1.42) (417). The effect of recombinant FSH on the incidence of complications in women undergoing ART has been studied. Several randomized, controlled trials have reported a trend toward an elevated incidence of OHSS with the use of recombinant FSH, although this effect has not reached statistical significance (418,419,420). Collectively, these results suggest an important role for recombinant FSH in ART regimens. This conclusion is based on its characteristic batch-to-batch consistency and subcutaneous route of administration, its possible superiority in outcomes over other gonadotropin preparations used in typical COH, its documented benefits over hMG in PCOS patients, and the small increase in ART pregnancy rates as determined by meta-analysis.

Role of Low-Dose Aspirin in ART

By decreasing platelet aggregation and inhibiting vasoconstriction, low-dose *aspirin* is suggested to increase uterine and ovarian perfusion, thereby enhancing outcomes of IVF and ICSI treatments. **A prospective, randomized trial demonstrated that the use of *aspirin* at a dose of 100 mg/day, initiated at the time of GnRH agonist luteal downregulation and continued throughout COH, resulted in**

an improvement in ovarian response, implantation, and pregnancy rates in IVF (421). Consequently, low-dose aspirin has become a standard part of ART protocols in many clinics. However, subsequent prospective randomized studies have

yielded conflicting results regarding the impact of low-dose *aspirin* on pregnancy outcomes in patients undergoing IVF (422,423). Significant complications have not been reported with the use of low-dose *aspirin* in ART..

Recombinant Human Luteinizing Hormone

According to the two-cell theory of ovarian hormone production, stimulation of the theca lutein cells by LH is critical to the overall development of the ovarian follicle. Highly purified FSH contains minimal amounts of LH (less than 0.1%), and GnRH agonist suppresses endogenous pituitary LH and FSH production. Therefore, it has been suggested that supplemental LH might improve folliculogenesis and pregnancy rates when highly purified or recombinant FSH is used for COH in ART. **A prospective, randomized trial comparing highly purified FSH and highly purified FSH combined with supplemental recombinant human LH has reported a trend toward lower implantation and pregnancy rates when recombinant human LH was added to GnRH agonist-downregulated ovulation induction cycles (424).** Although it is possible that some subset of infertility patients might benefit from recombinant human LH supplementation, the generalized use of this hormone in ART currently appears to be limited.

Prevention of Premature Luteinizing Hormone Surge/Ovulation

GnRH-Agonist Downregulation Regimen

The use of GnRH agonist has become standard in ART protocols. It prevents spontaneous ovulation, decreases treatment complications, and allows the control of ovulation to rest exclusively on administration of exogenous medications. Commercial preparations of GnRH agonist consist of decapeptides that differ from the endogenous GnRH agonist at 2 amino acid residues. These modifications increase both the half-life and the receptor binding affinities of GnRH agonist. When used in a nonpulsatile fashion, GnRH agonist causes an initial agonist effect that is accompanied by upregulation of GnRH receptors within the pituitary gland. This initial activity may be manifested as increased gonadotropin effects, which are referred to as the *flare response*. However, continued administration of GnRH agonist downregulates GnRH receptors, resulting in minimal basal production of LH and FSH and no stimulation of the ovarian follicles. Therefore,

GnRH agonists induces a quiescent hypothalamic–pituitary–ovarian axis and a menopauselike state characterized by low estradiol levels. Consequently, in addition to rash or skin irritation at the subcutaneous injection site, it is not uncommon for patients using GnRH agonist to experience side effects such as hot flashes and moodiness.

The most commonly used regimen for superovulation in ART is called the *long, or luteal, downregulation protocol.* In this protocol, GnRH agonist is started in the luteal phase (day 21) of the previous cycle, which minimizes its flare effect and prevents the follicular recruitment that is thought to begin in the luteal phase. The couple undergoing treatment is advised to abstain from intercourse during the cycle before the start of COH; however, concomitant use of GnRH agonist in the presence of an unsuspected pregnancy has not been reported to be associated with increased spontaneous abortion, congenital abnormalities, or pregnancy complications.

Before the adoption of GnRH agonists as a standard part of ART cycles, premature luteinization and spontaneous ovulation presented significant challenges to the success of ART. Prospective, randomized trials indicate that use of GnRH agonist under the long protocol offers many benefits when compared with either no GnRH agonist use or use

P.1240

commencing in the follicular phase of the ART cycle (called the *short, or flare, protocol*). Use of GnRH agonist in the long protocol significantly lowered the incidence of premature luteinization and spontaneous ovulation, resulting in a lower rate of canceled cycles (425,426,427). Significantly more oocytes and embryos were yielded using the long protocol, whereas the rate of OHSS decreased (425,427). For logistical reasons, patients preferred the convenience of the long protocol because it requires less frequent monitoring (428). Most importantly, clinical pregnancy rates (425) and live birth rates per retrieval (429) were significantly higher using the long protocol. **The benefits of using the long protocol for administration of GnRH agonists greatly outweigh its disadvantages**, which include daily administration (for most preparations, e.g., leuprolide acetate), increased requirement for gonadotropins, and an overall increase in the cost of medication. In a meta-analysis reviewing the efficacy of various GnRH agonist regimens, the authors concluded that the addition of GnRH agonist downregulation to ovulation induction regimens for ART was advantageous (430). They noted an improvement in pregnancy rates and a decrease in cancellation rates with no associated increase in spontaneous abortion rates.

The debate concerning the choice of long or short GnRH agonist protocols was mostly settled by a large, prospective, observational, multicenter study involving 1,244 couples receiving their first

IVF or GIFT treatment. Although serum estradiol levels were higher in patients using short protocols, these patients had 11% fewer oocytes retrieved. Further, the clinical pregnancy rate was 35% lower using the short protocol when compared with the long protocol, even after adjusting for factors such as age, infertility diagnosis, IVF or GIFT therapy, and year of treatment (431). **Currently, the long GnRH agonist protocol is generally recommended for most patients, and use of the short protocol in ART patients with poor ovarian response has not been proved beneficial** (431).

Many other regimens have been suggested for the administration of GnRH agonists in gonadotropin-stimulated cycles. Some of the more commonly used protocols and gonadotropins are summarized in Fig. 30.6. and Table 30.8.

GnRH–Antagonist Regimen

New GnRH antagonists (*Cetrorelix* and *Ganirelix*) have been developed and approved for use in ART protocols. These agents compete with natural GnRH for binding to membrane receptors on pituitary cells and thus control the release of LH and FSH in a dose-dependent manner. The onset of LH suppression is approximately 1 to 2 hours post-administration depending on the dosage used. This suppression is maintained by continuous treatment, and there is a more pronounced effect on LH than on FSH. An initial release of endogenous gonadotropins has not been detected with the use of GnRH antagonists. Because they avoid the flare effect associated with the use of GnRH agonists, they can be started concurrently with gonadotropins and do not require additional time for downregulation. Typically, the antagonist is administered by daily subcutaneous injection, beginning on cycle day 7 or, more commonly, when the lead follicle reaches 14 mm in diameter (432). Alternatively, the medication may be administered as a single bolus dose on approximately cycle day 8. **A Cochrane review of five randomized controlled trials comparing GnRH agonist (long protocol) versus antagonist use in ART cycles showed equivalent efficacy of the two protocols in the prevention of premature ovulation** (433). However, there were significantly fewer pregnancies with the GnRH antagonist protocol (OR 0.79, 95% CI, 0.63–0.99). A significant reduction in the incidence of severe OHSS was observed in the antagonist regimen compared with the long GnRH-agonist protocol (RR 0.36, 95% CI, 0.16–0.80).

hCG Injection

The injection of hCG induces oocyte maturation before retrieval. The dosage of hCG typically is 10,000 IU given intramuscularly or subcutaneously, or 250 µg recombinant hCG

given subcutaneously. Different criteria for hCG injection during COH for ART have been described, but all usually include the presence of one or

two leading follicles with mean diameters larger than 16 to 18 mm, at least two other follicles with mean diameters larger than 14 mm, and serum estradiol levels above defined threshold levels of 300 to 500 pg/mL. Each IVF center sets site-specific criteria based on its own experience and pregnancy outcomes. The overall goal, however, is to time the hCG injection in such a way that the probability of pregnancy is maximized while the probability of premature ovulation is minimized.

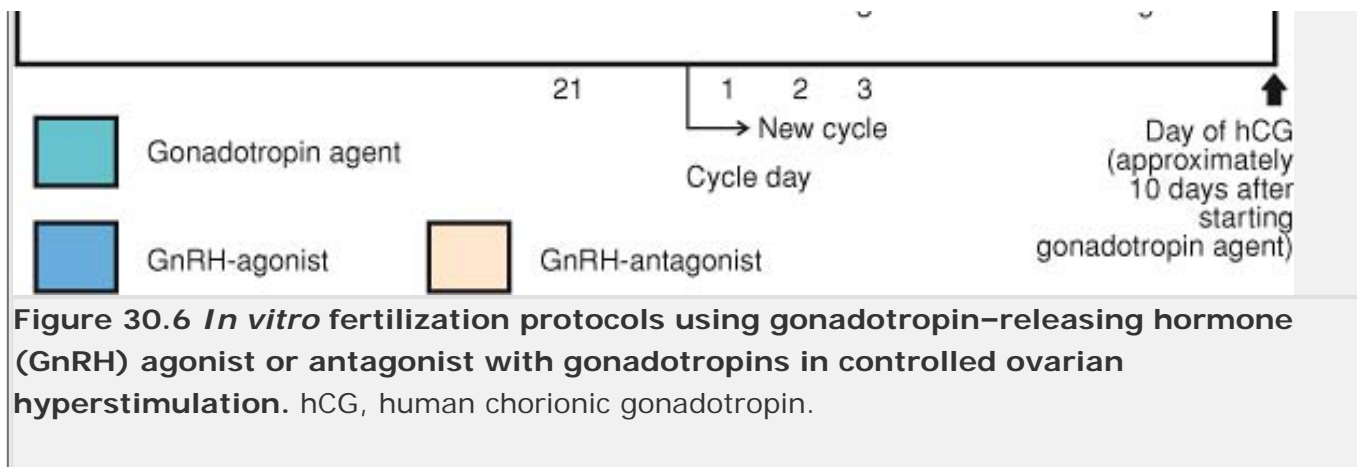

Figure 30.6 *In vitro* fertilization protocols using gonadotropin–releasing hormone (GnRH) agonist or antagonist with gonadotropins in controlled ovarian hyperstimulation. hCG, human chorionic gonadotropin.

Oocyte Retrieval

Oocyte retrieval typically is performed 35 hours after the hCG injection.

Although historically performed by laparoscopy, laparoscopic oocyte retrieval has now been replaced by the transvaginal ultrasound–guided approach.

Transvaginal ultrasound–guided retrieval is markedly less invasive than its laparoscopic counterpart, and the use of ultrasound permits the surgeon to visualize the location of the needle within each ovarian follicle. Intravenous sedation is commonly used for transvaginal ultrasound–guided oocyte retrieval (434,435).

Because the vaginal canal and wall are traversed while using transvaginal ultrasound–guided oocyte aspiration, the possibility of iatrogenically infecting the patient or her oocytes deserves particular consideration. Sterile normal saline usually is used for surgical preparation during

P.1242

(oocyte retrieval. In one prospective, randomized trial comparing sterile normal saline to 1% *povidone–iodine* for this application, the former had higher associated pregnancy rates while maintaining low infection rates (436). Although the exact mechanism for this finding is unclear, it is hypothesized that contact with *povidone–iodine* could potentially harm oocytes. Therefore, **if *povidone–iodine* is used, it is recommended that the vagina be lavaged with normal saline after preparation. In addition, routine antibiotic prophylaxis is recommended for transvaginal ultrasound procedures. Such prophylaxis reduces the incidence of postprocedure positive microbiology cultures of embryo catheter tips in 78% of patients undergoing embryo transfer. The importance**

of this effect is suggested by the fact that lower implantation and pregnancy rates are associated with positive microbial catheter–tip cultures (437)..

Performance of the retrieval uses a long, 16– or 17–gauge needle, secured by a guide onto the transvaginal ultrasound probe. The needle is used to traverse the upper vaginal wall and enter into a follicle under direct, real–time transvaginal ultrasound guidance. Follicular fluid is then aspirated into sterile, prewarmed culture tubes. This process is repeated until all the follicles are aspirated. At the end of the procedure, a speculum is inserted into the vagina, and the cervix and vaginal walls are inspected for bleeding. **Although transvaginal ultrasound–guided oocyte retrieval is both rapid and minimally invasive, all potential risks, albeit rare, should be clearly explained to the patient before IVF treatment begins. These risks include the following:**

- **Excessive bleeding, possibly requiring blood transfusion.**
- **Potential needle–induced injury to structures in proximity to the ovaries, including bowel, bladder, and major blood vessels, which may require repair by emergency laparotomy, resulting in an abdominal surgical scar.**
- **Late infectious complications, such as abscesses in the peritoneum, bowel, ovary, or uterus, which may require hospitalization for intravenous administration of antibiotics or surgical interventions. (In the specific case of iatrogenic tubo–ovarian abscess, failure of medical treatment may necessitate surgical removal of the tubes and ovaries.)**
- **Risks associated with intravenous sedation or general anesthesia.**
- **A remote risk that no oocytes will be obtained or fertilized.**

IVF and ICSI

Fertilization of the human oocyte by human sperm *in vivo* requires the interaction

of capacitated spermatozoa with ovulated oocytes, most often within the ampullary portion of the fallopian tube. Capacitation of sperm takes place in the female reproductive tract and involves both changes in sperm motility and changes in the sperm cell membrane that allow the acrosome reaction. Acrosome-reacted sperm are able to penetrate the oocyte's cumulus oophorus and zona pellucida, binding to the oocyte cell membrane and promoting fertilization. The interaction of spermatozoa and oocyte is not a chance occurrence; complex oocyte-sperm intercommunications appear to play an important role in this process (438).

The mandate of the ART team is to attempt to recreate precisely those processes known to occur in unassisted conception. In all ART procedures, male gametes are initially collected directly by ejaculation into a sterile cup. They are then processed, concentrated, and incubated in protein-supplemented media for 3 to 4 hours before being used for fertilization. This final incubation allows for sperm capacitation. Before fertilization, retrieved oocytes also are cultured in protein-supplemented media for about 6 to 8 hours. For IVF purposes, 50,000 to 100,000 capacitated sperm are placed in culture with a single oocyte; 16 to 20 hours later, fertilization is documented by the presence of two pronuclei within the developing embryo.

Indications for ICSI are discussed under the section of "Male Factor Infertility." The procedure itself begins by stripping all granulosa cells from the aspirated cumulus complex

P.1243

(oocyte and surrounding cells). This is followed by micromanipulation of egg and sperm under magnification. A holding pipette is used to stabilize the egg while an injection pipette is used to insert a viable sperm into the ooplasm of the egg.

Luteal Support

The act of retrieving oocytes and associated granulosa cells may adversely affect subsequent corpus luteal function, resulting in subsequent progesterone insufficiency. Therefore, the requirement for luteal support represents yet another way in which ART cycles differ from COH/IUI protocols. **Luteal support is usually initiated on the day after oocyte retrieval for ART. Commonly used regimens include the following:**

- ***Progesterone in oil 50 mg, once a day, intramuscularly.***

- **Vaginal progesterone suppositories, 200 mg twice to three times a day.**

- **Oral micronized progesterone, 200 mg twice a day.**

Despite similar levels of circulating progesterone, the oral regimen is associated with decreased per-embryo implantation rates when compared with use of intramuscular progesterone (439).

Embryo Transfer

In unassisted conception, the fertilized oocyte traverses through the fallopian tube for 2 to 3 days before entry into the uterus for implantation. This transport is largely dependent on directional ciliary movement within the fallopian tube, although tubal muscular contractions may be involved (440). The embryo is normally at the morular or early blastocyst stage of development when it reaches the uterine cavity. By this time, and under the influence of luteal-phase levels of progesterone, the endometrium has undergone the decidual changes that prepare it for implantation. **The embryo resides in the intrauterine cavity for 2 to 3 days before implantation. During this period, the zona pellucida detaches, allowing implantation to occur 5 to 7 days after fertilization..**

ART protocols for *in vitro* embryo culture and development attempt to recapitulate the timing and conditions of these events, albeit in an incredibly simplified fashion. The development of sequential media has allowed embryos to be grown *in vitro* up to 5 to 6 days after oocyte retrieval. After *in vitro* development, an embryo or multiple embryos are transferred into the cavity of the uterus. Criteria for embryo morphology—including cell number, symmetry, fragmentation, and granularity—are used in most centers to judge the quality of a particular embryo. However, these methods of assessment do not necessarily correlate well with genetic or embryonic developmental potential (441).

In an effort to better assess and select for transfer those embryos that will result in successful pregnancy, investigators have evaluated the advantages of extending the *in vitro* embryo culture period before transfer. *In vitro* culture to day 5 postretrieval allows the evaluation and selection of embryos at the blastocyst stage. It is likely that this extended culture does, in fact, increase the ability to judge appropriately the quality of an embryo. For instance, grading of the blastocyst according to the morphology of the inner cell mass

and trophectoderm has been correlated with implantation and pregnancy rates (442). Because of its increased implantation rate, extended embryo culture offers the advantage of limiting the number of transferred embryos while maintaining pregnancy rates. The true value of blastocyst transfer may therefore lie in its potential to decrease the rates of high-order multiple gestation resulting from ART. There appears to be an increased risk for monozygotic twinning of embryos cultured to the blastocyst stage (443), although this finding is currently being debated.

Pregnancy rates resulting from blastocyst transfer range between 44% for low-scoring blastocysts and 87% for top-scoring ones. Another predictor of the success rate of day 5 transfer is the number of eight-cell embryos on day 3 (443). Extended culture to

P.1244

the blastocyst stage (day 5) has been advocated by some to be beneficial for all IVF patients, with overall pregnancy rates of up to 43.8% (442,444). Others recommend it only if there are three or more eight-cell embryos on day 3 of *in vitro* culture (444). The application of extended embryo culture and blastocyst transfer requires laboratory specialization; therefore, the practice is institution specific.

Technical Aspects of Embryo Transfer

Despite its theoretic simplicity, transcervical embryo transfer into the intrauterine cavity is a procedure that requires significant skill. Correct performance of the procedure is thought to exert a significant impact on clinical outcome. Apart from the skill and experience of the operator, variables such as aspiration of cervical mucus (445), visualization by ultrasound guidance (446), duration of supine position immediately after embryo transfer (447), and type of bacteria cultured from the transfer catheter-tip postprocedure (448) have all been suggested to affect pregnancy outcomes. Microbial contamination of the embryo transfer is especially relevant because it may be prevented by antibiotic prophylaxis at the time of oocyte retrieval and careful handling of the catheter. Pregnancy rates are reduced by half in women with positive catheter-tip cultures (449).

Many different types of catheters have been used to perform embryo transfers, including hard catheters (*Erlangen, Tefcat, Tom Cat, Norfolk*) and soft catheters (*Frydman, Wallace*). The Frydman and Wallace catheters are thought to be less traumatic to the endometrium. However, no catheter has been shown to be definitively superior (450,451).

In women with a history of tubal disease, the difficulty of embryo transfer has

been associated with an increased risk of ectopic pregnancy (452). The number of transfer attempts, the time required for embryo transfer procedures, and the presence of blood inside the transfer catheter after the procedure do not affect clinical outcomes (453). In a series of more than 800 consecutive embryo transfer procedures, 85.9% were easy, 8.4% were difficult, 3.2% needed to be repeated, and 2.5% required cervical dilation. Technical difficulties, repeated embryo transfers because of retained embryos, and cervical dilation for stenosis did not affect the pregnancy rates in this study (454). The timing of the correction of cervical hindrances to embryo transfers may be important. Specifically, although it markedly facilitated the embryo transfers itself, cervical dilation at the time of oocyte retrieval in patients with a history of very difficult embryo transfer was associated with poor pregnancy outcome (1 in 41 cycles) (455). In contrast, surgical treatment of anticipated problems before commencement of IVF/embryo transfer yields good pregnancy rates. For example, hysteroscopic examination of the cervical canal may reveal a ridge, which can be resected (456). Alternatively, transcervical placement of a Malecot catheter at the time of hysteroscopy has been successful in allowing facile entry into the uterine cavity during subsequent embryo transfer or IUI. The Malecot catheter can be left in place for several weeks after hysteroscopy while the patient is maintained on *doxycycline* 100 mg twice daily. It is easily removed using gentle traction in the office as the day of embryo transfer approaches (457). Good clinical pregnancy outcomes have been reported for both techniques.

Cryopreservation of Embryos

The success of modern ovulation induction and fertilization regimens often results in embryos in excess of the number appropriate for transfer in a single treatment cycle. Cryopreservation of these embryos permits embryo transfer to the same patient in unstimulated cycles in the future. Some patients receive cryopreserved embryos during "natural" cycles, whereas other patients undergo endometrial preparation with sequential administration of exogenous estrogen and progesterone. Either regimen is significantly less expensive than a gonadotropin-stimulated cycle. More importantly, the risks of surgical complications and OHSS are nonexistent in cycles using cryopreserved embryos. Therefore, **pregnancies resulting from transfer of cryopreserved embryos effectively reduce the costs of pregnancy per ovulation stimulation. Conversely, in cryopreserved cycles, not all embryos survive**

thawing, and the pregnancy rates are lower than those using fresh embryos. In transfers of cryopreserved embryos using nondonor eggs (eggs from the intended recipient), 90% of

thawing procedures resulted in viable embryos for transfer. The rates of pregnancy and delivery were 22.2% and 20.4%, respectively, for cryopreserved embryo transfer procedures (413).

Pregnancy Testing and Follow-up of Early Pregnancy

The uncertainties surrounding ART treatment and its outcomes can be highly stressful, and treated couples are understandably anxious to obtain a pregnancy test as early as possible (458). **Serial quantitative hCG levels may be obtained starting on day 16 after oocyte retrieval. Serum hCG levels taken earlier than this day may give false-negative or false-positive results.** The latter may reflect the use of intramuscular hCG to trigger ovulation because this exogenous hCG can be detected for up to 14 days after injection (459). Day 16 serum quantitative hCG levels lower than 50 IU/L are associated with a 35% chance of an ongoing intrauterine pregnancy; levels greater than 500 IU/L are predictive of successful outcome in more than 95% of cases (460). **A single serum progesterone level on day 16 does not provide further prognostic value and is therefore not recommended..**

Patients usually undergo serial serum hCG level assessment early in pregnancy, followed by transvaginal ultrasound at 5 to 6 weeks of gestation to document intrauterine location of the pregnancy and the number of gestational sacs. This is especially important for patients with risk factors for ectopic pregnancy, those who are experiencing vaginal bleeding, and those at high risk for higher-order multiple gestation. In addition, such close follow-up in early pregnancy is both indicated and necessary among ART patients because an ongoing pregnancy requires patients to continue daily self-administration of supplemental progesterone (until the luteal-placental shift at about 9 to 10 weeks of gestation). **Transvaginal ultrasound at 7 to 8 weeks for identification of fetal cardiac activity can provide further reassurance..**

Success Rates

Success rates of IVF vary from program to program. Within a program, the rates of success vary with the patient's diagnosis and age. **The most comprehensive assessment of the efficacy of ART programs in North America comes from the database of the Society for Assisted Reproductive Technology (SART)** (413). The society's data collection began in 1985, and its annual summary is published in an effort to improve the quality of statistical reporting on ART. The database attempts to eliminate the effects of interprogram variation. The most recently published report of the society summarizes the results of ART in the United States and Canada for the year 2000, which are depicted in Table 30.10

(413). **Information on SART and registered ART clinics are accessible by the public at <http://www.sart.org>.** Significant improvements in overall ART outcomes have been made when compared with previously published results. In 2000, a 29.9% (28.4% in 1997 and 16.8% in 1992) rate of delivered pregnancies was reported per oocyte retrieval for standard IVF, with a cancellation rate of 14.3% (21.7% in 1997 and 15.4% in 1992), a pregnancy loss rate of 16.7% (18.1% in 1997 and 20% in 1992), and an ectopic pregnancy rate of 2.1% (0.9% in 1997 and 1.2% in 1992) per transfer. The delivered–pregnancy rate for cryopreserved embryo transfer was 20.4% in 2000 (18.8% in 1997 and 11.6% in 1992). Although the rates of birth defects did not appear to differ from those of the general population, the SART reporting system was not designed to specifically address this issue.

The age of the woman proved a significant determinant of success in ART (413)

(Table 30.11). Women aged 41 years and older had a delivery rate per retrieval of only 10.5%. The increase in cancellation rates with age—most likely the result of poor ovarian response—was consistent with significantly decreased ovarian reserve in older women. With the high efficacy of ICSI as a treatment for male factor infertility, the delivery rates per retrieval among couples with male factor infertility were comparable to those achieved in couples without male factor for a given female age group.

Treatment with Donor Oocytes

Women with premature ovarian failure have very few reproductive options. The use of donor oocytes may represent the only proven method by which most of these patients can become pregnant. Other patients to be considered for donor oocyte technology may include those with poor oocyte quality (including some patients with failed fertilization), those with poor ovarian response to stimulation, and those with a history of multiple failed ART cycles. Using embryos fertilized from donor eggs in 418 fresh embryo transfers involving 276 recipients, pregnancy and delivery rates were 36.2% and 29.3%, respectively. The cumulative pregnancy rate after four cycles reached 87.9% (461).

P.1247

Treatment with donor oocytes is available in many ART programs. **The method of donor selection is an important consideration.** Some patients may wish to find their own donor in a sister or friend. Others may choose to use an agency to identify a donor, who can remain anonymous. Although some ART programs may choose to be excluded from the matching process, most will assume the responsibility of screening the donor for medical, reproductive, and psychological fitness. **Like semen donors, potential oocyte donors must be stringently assessed, including screening for transmittable infectious or genetic diseases. Unlike semen, however, oocytes cannot presently be cryopreserved and quarantined.** Hence, the risk for transmission of infectious agents cannot be completely averted. Moreover, because oocyte donation involves COH, a donor is exposed to the same intensive monitoring and significant potential complications inherent to this intervention. Potential donors must be provided with detailed educational information, and meticulous informed consent is mandatory. In addition to undergoing medical screening, oocyte donors are subjected to a comprehensive psychosocial evaluation before being accepted as program participants. Even with such extensive screening and preparation, there is a significant dropout rate for both anonymous and directed oocyte donors (462). Because many potentially litigious issues arise in the administration of such a program, legal counsel is important in the management of an ovum donation center.

Considerable coordination is required to ensure that the recipient's endometrium

is appropriately prepared when embryos freshly fertilized from the donor oocytes are ready to be transferred (463). Regimens for ovulation induction and oocyte retrieval for the oocyte donor follow those of standard IVF protocols (Fig. 30.7.). Although the oocyte donor is exposed to many of the adverse effects of COH protocols (OHSS, postoperative pelvic discomfort, surgical and anesthesia risks, and medication side effects), her risk for multiple gestation and ectopic pregnancy can be virtually eliminated if she abstains from intercourse during her stimulation cycle.

To ensure adequate endometrial preparation, many recipients of donor oocytes are taken through a "mock" cycle before their actual treatment cycle. During the mock cycle, all hormonal agents are administered, and endometrial adequacy is documented by timed endometrial biopsies. The impact that the completion of a mock cycle might have on the pregnancy rates of subsequent ART cycles with donor eggs has not been studied in a randomized trial. However, such a cycle allows assessment of important factors such as patient compliance, histologic evidence of endometrial response to exogenous hormones, and the ease of embryo transfer (464). Many regimens for endometrial preparation have been described, although successful pregnancies have also been reported after embryo transfer in natural cycles. **Following is a typical regimen for endometrial preparation in recipients of donor oocytes:.**

- **If the recipient has no baseline ovarian function, no downregulation or baseline testing is required. However, if the recipient has endogenous ovarian function, GnRH agonist is started on day 21 in the luteal phase of the previous cycle. At onset of menses, downregulation is confirmed by the presence of serum estradiol levels of less than 50 pg/mL or an ultrasound examination documenting absence the of ovarian cysts. Once downregulation is confirmed, the dose of GnRH agonist is reduced..**

- **Start *estradiol* administration (*Estraderm* patches 0.2 mg every 48 hours, or *Vivelle* patches 0.2 mg every 48 hours, or *Estrace* 1.0 mg orally once per day)..**

- **Monitor serum estradiol levels every 3 to 7 days and adjust dosage to maintain serum estradiol levels of 150 to 300 pg/mL or continue fixed dose..**

- **Continue *estradiol* supplementation for at least 21 days at dosages that maintain**

these estrogen levels..

- **The progesterone start day is scheduled according to the day of embryo transfer (in a therapeutic cycle) or the day of endometrial biopsy (in a mock cycle)..**

P.1248

- **Start progesterone administration, 25 to 50 mg intramuscularly (day 1), then increase to 50 to 100 mg/day intramuscularly the following day..**
- **Discontinue GnRH agonist administration on day 2 of *progesterone* use..**
- **Mock cycle: Perform endometrial biopsy 10 to 12 days after *progesterone* is started. Therapeutic cycle: Perform embryo transfer on day 4 of *progesterone* use..**
- **Measure quantitative hCG 16 days or more after the date of donor oocyte retrieval..**

Figure 30.7 Regimens of ovarian stimulation and hormone replacement used to synchronize the development of ovarian follicles in the oocyte donor and the endometrial cycle in the recipient. Philadelphia, PA: Current Sciences Group, 1998, with permission.*).

P.1249

Many controversial issues and much ethical debate surround oocyte donation. Donors' expectations regarding the process itself, the quality of their medical care, and their level of involvement in decisions can be addressed by a conscientious ART team (465). Other topics, such as methods of donor recruitment and amounts of financial compensation, are much more challenging issues (466,467). Further effort is warranted to help clarify these issues and provide access to this highly efficacious ART treatment.

Complications of Assisted Reproductive Technology

Multiple Gestation

Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications. In recent years, it has been reported that only 20% of higher-order multiple gestations are the result of spontaneous conceptions. The remaining 80% are attributable to reproductive interventions. Of these multiple gestations, one half are attributable to ART and one half to the use of ovulation drugs in non-ART cycles (468). Because the average age of women attempting pregnancy has risen during recent decades and increased maternal age affects the incidence of multiple gestation, rates of higher-order multiple gestation must be adjusted for maternal age when compared over time (469). For decades before 1971, higher-order multiple gestation occurred at a maternal age-adjusted incidence of about 30 per 100,000 live births from spontaneous conceptions (469,470). This incidence rose to 173.6 per 100,000 live births in 1997 (469) (Table 30.12). Because higher-order multiple gestations are predominantly triplets (91.2% were triplets in 1997) (468), this rate represents 6,737 triplets born in the United States in 1997 alone

(Table 30.13).

Significant medical risks accompany higher-order multiple gestation. There is an increased incidence of potentially life-threatening obstetric conditions such as acute fatty liver (471) and severe preeclampsia (472). The rate of fetal death during the third trimester is also unacceptably high at almost 17% (473). Obstetrically, triplets are at increased risk for preterm birth, low birth weight (<2,500 g), and very low birth weight (<1,500 g) compared with singletons or twins (474,475). When adjusted for gestational age at birth,

P.1250

triplets have the same rates of neonatal morbidity and mortality as twins and singletons (476,477), but triplets typically deliver much earlier. One notable exception is that preterm triplets are at significantly greater risk of severe retinopathy of prematurity, even when they are delivered at the same gestational age as a matched singleton or twin (477). Because of the extensive obstetric and neonatal intensive care required in higher-order multiple gestation pregnancies, enormous expenditures are required to provide medical care to these families (478). Finally, although not fully described, the immediate and long-term emotional and psychological impact on the mother, her partner, and the family unit, including other siblings, is likely to be daunting.

^bNumber of triplets per 100,000 live-born infants.

^cBased on number of ART-associated triplets and total number of triplets, 1990 and 1991.

^dPercentage of triplets by spontaneous conception, percentage of triplets using ART, and estimated percentage of triplets using ovulation drugs add up to 100% overall triplet ratio.

From **Centers for Disease Control and Prevention**. Contribution of assisted reproductive technology and ovulation-inducing drugs to triplet and higher-order multiple births—United States, 1980–1997. *MMWR Morb Mortal Wkly Rep* 2000;49:535–538, with permission.

To ameliorate this trend in higher-order multiple gestations, a number of medical and nonmedical causes are being identified. Non-ART COH with gonadotropins is a highly efficacious and commonly used treatment modality for infertile couples. It is significantly less expensive than ART and thereby more accessible to many patients. Unfortunately, it is associated with a 20% incidence of twin gestations and 10% incidence of higher-order multiple gestation (49). Current monitoring protocols for non-ART COH based on assessment of serum estradiol levels and the number of large follicles detected by ultrasound cannot entirely predict the risk for higher-order multiple gestation (479). **The risk for higher-order multiple gestation is significantly increased with younger age, peak serum estradiol levels greater than 1,385 pg/mL, and a total number of follicles of seven or more** (479). It is difficult to discern the significance of this latter measurement, however, because total follicle number depends on which follicles are measured, and it is unclear what should be the smallest reportable size. Further, a high total number of follicles may result from overstimulation of a patient with normal ovaries but unexpectedly high ovarian response or from treatment of a patient with PCO-like ovaries. Because the prevention and management strategies would differ for these two conditions, further stratification of patients and characterization of the COH cycles may clarify relative risks and direct efforts to more effectively prevent OHSS and multiple gestation. Suggestions to

P.1251

reduce higher-order multiple gestation in non-ART COH are being explored. None is without cost. One option would promote lowering the dosage of gonadotropins used in COH to aim at a lesser degree of ovarian response. This approach will almost certainly lower pregnancy rates. An alternative would be fewer interventions with non-ART COH and substitution with ART. In ART, the rate of higher-order multiple gestation is determined by the number of embryos transferred, not the ovarian response, which allows greater control of the higher-order multiple gestation rate. This approach would require a dramatic change in the guidelines for insurance company reimbursement of infertility treatments, however, or would necessitate the financing of such treatment by the couple. Currently, there are no accepted criteria guiding when a non-ART cycle should be canceled in an attempt to reduce the risk for higher-order multiple gestation. Informed recommendations for such standardization would be helpful.

More progress is being made toward reduction of higher-order multiple gestation in ART. One approach, discussed under "Embryo Transfer," would involve broader use of extended embryo culture, in which embryos are allowed to grow to the blastocyst stage *in vitro*. Blastocysts have been shown to have greater developmental potential and higher

implantation rates than day 3 embryos, so that even if fewer (a maximum of one to two) blastocysts are transferred, pregnancy rates remain high (442). Another approach would follow the lead of countries outside the United States that have defined set limits for the maximum number of embryos transferred in a given ART cycle. The American Society of Reproductive Medicine has recently addressed this issue by publishing guidelines for embryo transfer during ART. **Briefly, a maximum of two, three, and four embryos can be transferred to women with above-average prognosis (age <35 years), average prognosis (age between 35 and 37 years), and below-average prognosis (age 38–40 years) respectively** (480). In donor oocyte cycles, the age of the donor (not the recipient) should be used to determine the number of embryos to be transferred. Data on the efficacy of this protocol are expected to be available in a few years. **Others have advocated similarly stringent guidelines, promoting the transfer of a maximum of two embryos in ART cycles to minimize the risk for higher-order multiple gestation** (481). Cryopreservation of excess embryos should be encouraged to promote more cycles involving transfer of cryopreserved embryos. Universal application of such changes will force patients and doctors to emphasize cumulative birth rates rather than pregnancy rate per cycle. By focusing on cumulative birth rates, patients can have more realistic expectations, and the demand to have an excessive number of embryos transferred would decrease (482,483). As discussed for non-ART COH, these changes will involve alterations in the entire financial reimbursement structure for ART services. There is no doubt that this approach will present many challenges.

Other factors contributing to the increased rates of higher-order multiple gestation have been identified. It has been suggested that government-mandated annual reporting of clinic-specific pregnancy rates places undue emphasis on pregnancy rate per cycle. This may encourage the promotion of higher pregnancy rates at the expense of higher multiple pregnancy rates. If the goal of infertility therapy is the delivery of a healthy baby, both pregnancy rates and incidence of multiple gestation must be considered in determining treatment efficacy. Financial reimbursement schedules by insurance companies, lack of federal support for IVF research, and insufficient patient education regarding the true risk for higher-order multiple gestation are all being examined (484,485,486,487).

On the scientific front, new technologies, such as **preimplantation genetic diagnosis, may ultimately eliminate the risk of higher-order multiple gestation. Preimplantation genetic diagnosis is a clinical diagnostic procedure that can be performed on the embryo itself to determine whether a particular genetic abnormality is present before its transfer into the uterus** (488). Preimplantation genetic diagnosis has been developed in an effort to improve the chances of having healthy infants in families at high risk for a particular genetic disease. It is most frequently performed using blastomere (a cell from a

day 3 embryo containing six to eight cells) biopsy, followed by genetic testing on the cell obtained. The technique chosen for diagnostic testing depends on the type of genetic defect being investigated. For example, fluorescence *in situ* hybridization (FISH) can be used to assess aneuploidy, translocation, and other structural chromosomal defects (489). This technique can also be used to exclude transmission of X-linked diseases by identification of X and Y chromosomes, thus allowing transfer of only female embryos (490). Alternatively, familial single gene mutations can be identified by extracting blastomere DNA, followed by polymerase chain reaction, restriction enzyme digest, or sequencing. In a recent study involving 262 ART cycles, the embryos obtained from women with a poor prognosis (characterized by age older than 35 years with previous IVF failures and karyotypic defects) were randomized to preimplantation genetic diagnosis for aneuploidy or a control procedure. Those chromosomes commonly involved in aneuploidies (X, Y, 13, 14, 15, 16, 18, 21, and 22) were assessed using FISH in the study group. Although fewer embryos were transferred in the group undergoing preimplantation genetic diagnosis, higher clinical pregnancy rates (37% versus 27%) and implantation rates (22.5% versus 10.2%) were reported when compared with controls (491). Preimplantation genetic diagnosis may assist in the selection of euploidic embryos, thereby offering tremendous potential in the effort to reduce the risk of higher-order multiple gestation.

As progress is being made to eradicate the complication of higher-order multiple gestation, others have suggested ways to reduce subsequent risks once higher-order multiple gestation has occurred. **One option for preventing some of the maternal and fetal complications of higher-order multiple gestation involves the judicious use of selective pregnancy termination or multifetal reduction.** Although any higher-order multiple gestation is a candidate for this procedure, the reduction of triplet to twin pregnancies is most common and best studied. Overall, about 14% of triplet pregnancies reduce spontaneously to twin pregnancies after fetal heart activity is documented on transvaginal ultrasound at 8 to 9 weeks of gestation (492,493). Although some studies have not found multifetal reduction to result in significant improvement in gestational length or intrauterine growth restriction (493,494), many centers have reported improved outcomes after reductions to twin gestations. Twin gestations after reduction have similar outcomes when compared with spontaneous twin gestations (495,496). Reduction of triplet to twin gestation has been reported to decrease the risk for preterm birth (497), low birth weight (497), preeclampsia (496), and delivery before 36 weeks (496). Specifically, the rates of preterm birth before 28, 32, and 34 weeks of gestation, as well as birth weights of less than 1,000, 1,500, and 2,000 g, were significantly lower in

twins after reduction from triplet pregnancy compared with triplets who did not undergo reduction (498). However, any benefits achieved for newborn health often incur tremendous emotional, psychological, and physical costs. **The major complications of fetal reduction include a 13% risk for premature rupture of the membranes for triplet to twin reduction** (499). There is a 5% to 10% risk of losing the entire pregnancy (500) after reduction has occurred. Further, major depression occurs in 80% of women who lose the pregnancy as a complication of fetal reduction and in one third of women who have live twins after fetal reduction (501).

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome is a medical complication that is both completely iatrogenic and unique to the treatment of infertility. Although the pathophysiology of OHSS is not well understood, the signs and symptoms of this disease can be attributed to local and systemic increase in capillary permeability. These changes, in turn, result in the depletion of intravascular volume at the expense of third-space fluid accumulation.

Ovarian hyperstimulation syndrome has been directly associated with increasing numbers of stimulated follicles and retrieved oocytes (502,503), the presence of PCOS (504,505,506), and high serum estradiol levels (502,507,508). Despite these associations,

P.1253

however, hyperestrogenemia is not currently thought to be the main cause of OHSS (509,510,511,512). Rather, the increased production of vasoactive substances—such as prorenin, renin, angiotensin-converting enzyme, angiotensin I, angiotensin II, and angiotensinogen—by the hyperstimulated ovaries has been implicated (513,514,515,516,517,518,519,520,521). Still, it remains possible that hyperestrogenemia, especially in the presence of hemoconcentration, has important effects on the thromboembolic risks demonstrated with OHSS.

Inflammatory responses are certainly present in OHSS patients, with possible roles for cytokines, histamine, and prostaglandins in the disease pathogenesis (522,523,524). In particular, the link between vascular endothelial growth factor (VEGF) and OHSS has been extensively studied. Vascular endothelial growth factor has been shown to exhibit a dose-related expression in human granulosa cells upon stimulation by hCG (525). Further, serum VEGF levels correlate with OHSS severity (526,527) demonstrating a sensitivity and specificity of 100% and 60%, respectively (527). The central role of an inflammatory response is supported by a number of other findings. For instance, mast cells are abundant

in ovulatory follicles (528), and histamine blockade has been reported to ameliorate and, in some cases, even prevent OHSS in animal models (523,529). Furthermore, it is clinically well recognized that allergy or hypersensitivity act as risk factors for the development of OHSS (502). To date, however, scientific evidence for these factors is still considered preliminary, and further investigation is warranted to clarify their true role in OHSS (512).

Recently, **a distinction between early- and late-onset OHSS has been described** (530). **Early OHSS, with onset arbitrarily set within 9 days of oocyte retrieval, is associated with higher serum estradiol levels and follicle numbers during COH. In contrast, late OHSS has onset more than 9 days after oocyte retrieval. Late-onset OHSS has been associated not with measures of follicular response, but with multiple gestation.** Early and late OHSS may even reflect somewhat distinct pathophysiologic mechanisms. It has been proposed that early OHSS may result from ovarian stimulation by the exogenous hCG given to trigger ovulation, whereas late OHSS may be more closely linked to the endogenous hCG produced when pregnancy ensues (530).

Ovarian hyperstimulation syndrome has a varied spectrum of clinical presentation.

An attempt to better understand this heterogeneity led to the development of a staging system for OHSS that would reflect symptom severity. **This classification categorizes patients according to mild, moderate, and severe disease** (531). In mild OHSS, patients often report mild abdominal distention and soreness, nausea, and vomiting. Ovarian enlargement can be 5 to 12 cm. Moderate disease is marked by the presence of abdominal ascites on ultrasound examination. Severe disease is diagnosed when there are clinical signs of tense ascites, hydrothorax, shortness of breath, hemoconcentration, hypercoagulability, or any complications of OHSS such as renal failure, thromboembolism, or acute respiratory distress syndrome (ARDS).

This classification may serve as a useful guide; however, its application may sometimes be misleading. For example, ovarian enlargement is common after COH and, by itself, is not informative. Furthermore, many patients experience mild pelvic soreness and abdominal bloating after COH, and their ovaries may be enlarged when viewed on transvaginal ultrasound. Whether these patients reflect an abnormal response to COH or merely represent a subset of normal responders is debatable. The fact that reported incidence of OHSS after COH has ranged from 7.3% (mild or moderate disease) and 4.2% (severe disease) to 33% overall may suggest that the staging system is itself open to interpretation (502,531).

Management of OHSS

Patients undergoing COH with or without ART should be educated about the signs and symptoms of OHSS. They should be instructed to contact their health care provider if they experience abdominal bloating, abdominal discomfort or pain, early satiety, nausea, vomiting, decreased urine output, or weight gain of more than 2 lb per day. Patients with these initial symptoms should be fully assessed to establish their

baseline condition for future comparisons, if that should become necessary. Pertinent points in the assessment of patients with OHSS are as follows: .

History:.

- **Age, history of OHSS in previous infertility treatment, history of PCOS.**
- **Characteristics of COH (dose of gonadotropins, number of follicles, number of eggs for an ART cycle, peak serum estradiol level, date of hCG administration, date of oocyte retrieval, date of embryo transfer, number of embryos transferred at embryo transfer).**
- **Onset of symptoms, their progression (stable versus rapidly worsening), and their severity.**

Specific questions should address the presence of the following symptoms: .

- **Abdominal discomfort, pain, bloating; increased abdominal girth; early satiety.**
- **Shortness of breath, chest pain.**
- **Nausea, vomiting.**
- **Weight gain (total amount gained since start of COH and pounds gained per day).**

- **Decreased urine output.**

A complete physical examination should be performed, with specific attention to the following areas:

- **Signs of hypotension, hemodynamic instability, and dehydration.**

- **Chest: evidence of pleural edema or effusion, congestive heart failure, limited chest expansion because of ascites.**

- **Abdomen: ascites (mild, moderate, tense), peritoneal signs.**

- **Peripheral exam: pitting edema.**

- **Pelvic exam is contraindicated because enlarged ovaries can be fragile and prone to torsion.**

The following investigations should be performed:

- **Complete blood count, prothrombin time, partial thromboplastin time, serum electrolytes, liver function tests, creatinine, blood urea nitrogen.**

- **Chest x-ray if there is significant shortness of breath or abnormalities on chest exam (shielding the pelvis can protect potential pregnancy from irradiation).**

- **Transvaginal ultrasound to document the baseline amount of ascites and size of ovaries.**

- **Documentation of oxygen saturation is indicated if there is evidence of**

respiratory compromise.

- **Serum hCG on day 16 after oocyte retrieval if embryo transfer has occurred.**

This initial assessment should enable the clinician to decide whether the patient with OHSS needs to be admitted to the hospital for observation and supportive care. Accepted indications for hospitalization include inability to tolerate oral hydration,

P.1255

hemodynamic instability, respiratory compromise, tense ascites, hemoconcentration, leukocytosis, hyponatremia, hyperkalemia, abnormal renal or liver function, and decreased oxygen saturation. If the diagnosis and its severity remain in doubt after initial assessment, it is reasonable to observe patients overnight while further assessing fluid balance and the presence of oliguria. The need for more prolonged hospitalization often becomes rapidly evident. The presence of peritoneal signs, such as abdominal rebound tenderness or guarding, in a patient with possible OHSS may indicate ovarian torsion, hemorrhage, or rupture of enlarged ovarian cysts. These signs may also represent those rare cases of postovocyte retrieval tubo-ovarian abscess. **Admission to the hospital is mandatory, and admission to an intensive care setting should be seriously considered, if the patient has complications of OHSS such as renal failure, ARDS, thromboembolic disease, or severe hydrothorax.**

The onset of OHSS soon after hCG administration or oocyte retrieval is associated with an increased risk for progression to severe disease. Pregnancy is also known to cause worsening of OHSS, most likely as a result of ovarian stimulation by endogenous hCG. Therefore, in cases of very early-onset OHSS, the benefits of withholding embryo transfer, cryopreserving these embryos, and performing embryo transfer in a future unstimulated cycle should be considered and discussed.

Outpatient Management

If outpatient management is appropriate, the patient should be instructed to limit her activity, to weigh herself daily, and to monitor her fluid intake (at least 1 L/day of mostly electrolyte-balanced fluid) and output. Daily follow-up by telephone or visit is important because the severity of OHSS may change at any time. The patient should contact her health care provider if she notes worsening of the symptoms or if her weight gain increases to more than 2 lb per day. Reassessment is indicated in these situations.

Inpatient Management

Inpatient management of patients with OHSS involves meticulous monitoring of vital signs and fluid balances as well as supportive care. This care includes use of intravenous hydration and prevention of complications such as thromboembolic prophylaxis, although more invasive interventions, such as paracentesis, may become necessary. Following is a typical inpatient protocol used for management of patients with moderate to severe OHSS: .

The initial assessment should be performed as outlined previously, accompanied by the following assessments: .

- **Vital signs (including oxygen saturation monitoring if respiratory compromise is present) every 4 hours initially.**
- **Fluid intake and output measurements.**
- **Daily weights and abdominal girth.**
- **Daily hematocrit, leukocyte count, serum electrolytes, renal function tests.**
- **Liver function tests, prothrombin time, partial thromboplastin time obtained on admission and repeated as necessary.**

Supportive Care: .

- **If hypotension or oliguria is present, a bolus of 1 L of normal saline should be given over 1 hour then maintained with D5 normal saline (or D5_{1/2} normal saline) at 150 mL/h.**
If hypotension or oliguria is not present, but the hematocrit is greater than 45%, maintenance with D5 normal saline at 150 mL/h should be initiated.

The maintenance rate for intravenous fluids can be lowered if the hematocrit is normal. Although administration of intravenous fluids will certainly lead to

P.1256

an increase in third spacing, it is important to maintain adequate intravascular volume and urine output. The hematocrit may need to be monitored twice a day initially; the intravenous fluid maintenance can be titrated downward as the hematocrit normalizes. This should help to minimize third-spacing side effects. Lactated Ringer's solution should not be used for intravenous hydration in patients with OHSS..

- **If oliguria persists, a small bolus of 250 to 500 mL of normal saline can be given to increase urine output.** The efficacy of *albumin* (or other plasma expanders) in the treatment or resolution of OHSS has not been studied in a prospective, randomized fashion. However, it is reasonable to attempt gentle diuresis in a patient who has normal blood pressure and hematocrit but in whom oliguria or weight gain persists. Diuresis may be accomplished using sequential administration of 50 mL of 25% *albumin* followed by *furosemide*, 10 mg given intravenously. This combination can be repeated 3 to 4 times per 24 hours as necessary. Serum sodium, potassium, and creatinine must be monitored closely when employing *albumin* or *furosemide* diuresis.

- **Small amounts of fluid can be taken orally.** As the OHSS improves, the amount of intake can be increased as the intravenous fluid maintenance decreases. During the resolution of OHSS, a maximum total input of 1 L/day has been recommended to prevent increases in third spacing (512).

- **Paracentesis is indicated if the patient has severe abdominal discomfort and respiratory compromise caused by large volumes of ascites.** Hydrothoraces have also been reported to resolve after paracentesis. The presence of massive ascites, combined with persistent oliguria or hypotension despite medical therapy, is also an indication for paracentesis because diuresis often results after the severe abdominal pressure is relieved. Both abdominal paracentesis under ultrasound guidance and transvaginal ultrasound-guided paracentesis are acceptable practices (532,533).

- **If embryo transfer has already been performed or is scheduled,**

progesterone supplementation should be given as indicated by the ART

protocol. Administration of progesterone is not thought to affect OHSS adversely.

However, pregnancy may cause worsening of OHSS as a result of the stimulation of the ovaries by increasing levels of endogenous hCG.

- **Antiemetics and analgesics (i.e., acetaminophen) can be given to relieve symptoms..**

- **Complications of OHSS, such as ARDS, thromboembolism, and renal failure, should be treated in an intensive care setting when indicated..**

Preventative Measures:

- **Hemoconcentration and severe leukocytosis are considered risk factors for thromboembolic disease in patients with OHSS (512). Therefore, heparin, (unfractionated or low molecular weight) should be considered for all patients with OHSS to prevent thromboembolism.** In addition, vascular support stockings should be used in ambulatory patients. Intermittent compression stockings should be used for patients who are not ambulating.

Prevention of OHSS

Because OHSS can potentially cause severe and sometimes life-

threatening complications, prevention is an essential consideration. When high estradiol levels (>3,000 pg/mL) are noted before hCG administration, prevention of OHSS can be attempted by coasting. Coasting involves withholding gonadotropin and delaying hCG until serum estradiol levels decrease or follicular diameter of greater than or equal to 18 mm is seen on transvaginal ultrasound (396,397,398). Coasting does not completely prevent severe OHSS or cycle cancellation, but it does minimize the risk for severe OHSS

while maintaining high pregnancy rates. An alternative strategy to minimize OHSS risk involves cryopreservation of embryos at the pronucleate stage and transfer of thawed embryos in a subsequent cycle using endometrial preparation without COH. The strategy of

cryopreservation results in excellent pregnancy and live birth rates comparable to similar cycles with fresh embryo transfer. The incidence of severe OHSS appears to be reduced, but more importantly, the duration of severe OHSS may be shortened when cryopreservation strategies are used (534,535,536).

Unfortunately, even with close monitoring and use of the lowest possible doses of gonadotropins during COH, it still may prove difficult to prevent OHSS. A novel strategy that may remedy these difficulties involves the *in vitro* maturation (IVM) of oocytes. Using IVM, immature follicles are aspirated and the retrieved oocytes are grown *in vitro* until mature. This is potentially advantageous because IVM completely obviates the need to stimulate the ovaries with gonadotropins. Once ICSI is performed on IVM oocytes, embryos are transferred to the uterus, which has been hormonally prepared. *In vitro* maturation is particularly applicable to women with PCOS, who have a known increased risk for OHSS and whose ovaries are characterized by multiple small follicles that can be aspirated in the absence of stimulation. *In vitro* maturation has been reported to yield pregnancy rates of 27.1% to 38% in women with PCOS (537,538,539). However, data on long term effects on fetal and postnatal development are not yet available.

Ectopic and Heterotopic Pregnancy

The incidence of ectopic pregnancy is 2% in the general population (540). However, its incidence is increased after ART and can be as high as 4% (541). The timing of embryo transfer (cleavage stage versus blastocyst stage) does not appear to influence the incidence (542). The main risk factors for ectopic pregnancy in IVF treatment are tubal factor infertility and, possibly, previous myomectomy (541). **The incidence of heterotopic pregnancy, which is normally rare, is particularly high (1%) after IVF treatment.** Multiple gestation and high hormonal levels during COH and early pregnancy have been suggested as possible causes. **It is important to have a high index of suspicion for the occurrence of heterotopic pregnancies because only 40% to 84% of cases can be diagnosed with transvaginal ultrasound at the initial presentation (543,544).** After treatment of the heterotopic gestation with laparoscopy, laparotomy, or ultrasound-guided injection of potassium chloride into the extrauterine pregnancy, the overall delivery rate for the intrauterine pregnancy is 66% (543).

Risk of Cancer after Fertility Therapy

The possibility that ovulation-inducing medications might promote the development of cancers

of the reproductive tract, specifically with regard to ovarian cancer, was introduced in the early 1990s (545). One theory behind this proposed risk is that ovarian cancer may arise, in some cases, as the result of damage to the ovarian epithelium during ovulation. Lactation, oral contraceptives, late onset of menarche, early menopause, and multiparity are known to protect against ovarian cancer. Moreover, each is associated with a reduction in the total lifetime number of ovulatory cycles. The lower risk of ovarian cancer in women with increased length of anovulation raised the question of whether dramatic increase in the number of eggs ovulated during superovulation therapy would, in turn, increase the risk of ovarian cancer. Alternatively, some believe that because gonadotropins (FSH and LH) increase cellular proliferation and division within ovarian follicles, their use might create a predisposition to cancer. Both of the most common hormonal therapies used for induction of ovulation — *clomiphene citrate* and *exogenous gonadotropins*—result in increased gonadotropin stimulation of the ovary. These therapies might, therefore, increase the incidence of ovarian cancer in treated infertility patients. Concern about this potential risk for cancer after fertility therapy has also been extended to other organs, including the uterus and breast.

Currently, several factors prevent an accurate calculation of the true risk for developing cancer of the breast, uterus, or ovary after treatment with ovulation-inducing agents. First, contemporary fertility treatments and their dosages remain relatively new and are usually

P.1258

used in women younger than 40 to 45 years of age. Because ovarian, uterine, and some breast cancers typically occur in older women, the number of patients who were treated with fertility drugs and are now in their middle to late 60s may still be too small to detect elevations in cancer risk. Second, it is hard to differentiate the effect of fertility treatment from the effect that being infertile itself might have on future development of malignancies of the breast, uterus, or ovary. Finally, most of the studies addressing these risks are clouded by small numbers, intake of a variety of medications, and recall bias. All these factors make the interpretation of data difficult (546).

Two of the more recent studies failed to attribute an increased risk for breast, uterine, or ovarian cancer to medications used for superovulation in the treatment of infertility (547,548). One study evaluated more than 20,000 women with exposure to fertility drugs used for IVF and compared them with nearly 10,000 infertile controls. The authors reported no overall increased incidence of uterine, breast, or ovarian cancers in women exposed to medications used for IVF (548). Two other interesting findings represent some of the limitations to these types of studies. **The authors reported that the risk of ovarian and uterine cancer was higher in women with unexplained infertility, regardless of**

whether they had received ovulation induction medications. This may suggest risks associated with the unexplained infertility itself, or the possibility of undiagnosed cancers causing infertility. In addition, the authors reported an increase in the risk of breast and uterine cancer only within the first year after receiving infertility medications for IVF. Patients undergoing IVF are followed closely and may, therefore, be more likely to report early signs or symptoms of these cancers to their physicians. Alternatively, rather than causing these cancers, fertility medications may only stimulate the growth and subsequent diagnosis of pre-existing tumors.

Psychological Support

Stress, as manifested by anxiety or depression, is thought to be increased in women experiencing infertility. The relationship between stress and infertility is complex and may represent a vicious cycle in which infertility results in stress, which results in further difficulty in conceiving (549,550,551). Results from a recent prospective, randomized trial support the value of group cognitive-behavioral therapy among infertile couples (552). This therapy uses a variety of approaches, including relaxation training such as yoga, cognitive restructuring, methods for emotional expression, and information on nutrition and exercise with respect to infertility. Although the mechanism by which relaxation therapies aid fertility is unknown and issues such as high dropout rates need to be addressed by further research, **the option of psychological support and counseling, on an individual or group basis, should be offered to patients experiencing infertility** (553).

Other Considerations

One of the most important aspects of the treatment of patients with subfertility or infertility is the process of deciding when no further treatment will be pursued. This crucial topic must be addressed early in infertility therapy. Patients must be accurately informed of estimated success rates and reasonable expectations for all therapeutic interventions. It is equally important to identify an end point to medical intervention at the outset of treatment. This end point offers patients a mental time frame in which they can make both medical and personal decisions. One viable alternative for many couples is adoption, although the process of adoption has become increasingly complex. **Many patients may want to simultaneously explore infertility therapy and adoption. The choice of which course to pursue is a very difficult decision that may be facilitated by both physician input and strong psychosocial counseling and support..**

Preservation of Fertility in Cancer Patients

Aside from helping subfertile couples build families, technologic advances in tissue and gamete cryopreservation, in combination with ART, have made future fertility possible for some men and women who are faced with surgery, radiotherapy, or chemotherapy for

P.1259

cancer treatment. **Sperm cryopreservation has become a widely available option to allow fertility preservation in young men whose cancer treatment may render them infertile.** The wide range of neoplastic disorders for which sperm cryopreservation have been successful include leukemia, lymphoma, Hodgkin's lymphoma, non-Hodgkin's lymphoma, and testicular cancer (554). Although most patients with these disorders are systemically ill and therefore exhibit decreased total motile sperm counts when compared with patients who do not have cancer, fewer than 20% have azoospermia, and cryopreservation is possible in most patients (554). Further, cryopreserved sperm from cancer patients tolerate thawing as well as samples obtained from patients without cancer (555).

Unfortunately, the efficacy of oocyte cryopreservation lags behind that of sperm preservation. Married women who are scheduled to undergo sterility-inducing cancer treatments may take the option of completing an IVF cycle so that oocytes can be fertilized and the resulting embryos can be cryopreserved for transfer later in life. However, an IVF cycle may require 2 weeks to complete, rendering this option unrealistic for patients in whom a delay in cancer treatment would compromise their prognosis. Even patients who are able to undergo IVF treatment usually do not have the time necessary for use of a downregulation protocol. Consequently, these women are usually prescribed the shorter, flare protocol, which may give suboptimal response (431). Use of GnRH antagonists may offer a special advantage in this situation. These agents can induce hypothalamic-pituitary downregulation after being started on day 6 of gonadotropin treatment, which obviates the need for the more time-consuming use of GnRH agonists (556).

Patients who are single or who have medical contraindications to IVF treatment may be candidates for ovarian tissue cryopreservation. Ovarian cortical biopsy specimens containing numerous primordial follicles have been successfully retrieved by a laparoscopic approach in healthy volunteers and in cancer patients (557,558,559). **It remains to be determined whether this promising technology creates a risk for reintroduction of malignant cells after autotransplantation of ovarian tissue and whether thawed immature oocytes should be used in *in vitro* maturation protocols..**

Recurrent Pregnancy Loss

Laura Fox-Lee

Daniel J. Schust

- **Isolated spontaneous pregnancy loss is remarkably common. Recurrent pregnancy loss (RPL) affects between 1 in 300 and 1 in 100 couples.**
- **After several pregnancy losses, the chance of having a viable birth is greater than that of having another loss, even without treatment. Prognosis can improve dramatically with treatment of a known underlying cause of RPL.**
- **Parental chromosomal abnormalities and antiphospholipid antibody syndrome (APAS) are the only undisputed causes of RPL. Other well-described causes include anatomic, endocrine, thrombotic, and possibly other immunologic factors.**
- **The state of coagulability is a fine balance between pro- and antithrombotic pathways. The hypercoagulability of pregnancy can be largely attributed to increases in prothrombotic factors and decreases in those that inhibit coagulation.**
-

The immunologic interactions at the maternal–fetal interface reflect the presence of unique cellular constituents combined with the actions of steroid hormones, protein hormones, and metabolic factors.

- **Evaluation of patients with RPL should include a detailed patient and family history, an examination focusing on endocrine and anatomic abnormalities, and laboratory studies limited to evaluating treatable etiologies.**

- **Early pregnancies in patients with RPL should be monitored with ultrasound examinations, assessment of β -human chorionic gonadotrophin (hCG) levels if indicated, and frequent visits with psychological support. In the event of pregnancy loss, tissues should be obtained for karyotype analysis.**

- **In treating RPL, there is evidence to support repairing anatomic abnormalities, correcting pre-existing endocrine disorders, and treating APAS and other thrombophilic disorders.**

P.1278

Advances in the ability to document and diagnose early pregnancy have revealed that spontaneous pregnancy loss is a common event. Spontaneous pregnancy loss is, in fact, the most common complication of pregnancy. Approximately 70% of human conceptions fail to achieve viability, and an estimated 50% are lost before the first missed menstrual period (1). Most of these pregnancy losses are unrecognized. Studies using sensitive assays for human chorionic gonadotropin (hCG) indicate that the actual rate of pregnancy loss after implantation is 31% (2). Of pregnancies that are clinically recognized, loss occurs in 15% before 20 weeks of gestation (from last menstrual period) (3,4).

Traditionally, recurrent abortion has been defined as the occurrence of three or more clinically recognized pregnancy losses before 20 weeks from the last menstrual period. Using this definition, recurrent pregnancy loss (RPL) occurs in approximately 1 in 300 pregnancies (2). Clinical investigation of pregnancy loss, however, may be initiated after two consecutive spontaneous abortions, especially when fetal heart activity is identified before any of the pregnancy losses, when the woman is older than 35 years of age, or when the couple has had difficulty conceiving. If clinical intervention is undertaken in the form of investigation after two spontaneous abortions, approximately 1% of pregnant women will require evaluation (3). Even with a history of RPL, a patient is more likely to carry her next pregnancy successfully to term than to miscarry. **For patients with a history of RPL, the risk of subsequent pregnancy loss is estimated to be 24% after two clinically recognized losses, 30% after three losses, and 40% to 50% after four losses (5).** These data make clinical study of RPL and its treatment difficult because very large groups of patients must be studied to demonstrate the effects of any proposed therapeutic intervention.

Etiology

Parental chromosomal abnormalities and thrombotic complications of the antiphospholipid antibody syndrome (APAS) are the only undisputed causes of recurrent abortion. However, collectively these abnormalities account for less than 10% to 15% of RPLs. Although the exact proportion of patients diagnosed with a

particular abnormality may vary among the populations studied, other associations have been made with anatomic abnormalities (12%–16%), endocrine problems (17%–20%), infections (0.5%–5%), and immunologic factors, including those associated with the APAS (20%–50%). Other miscellaneous factors have been implicated and account for approximately 10% of cases. Even after a thorough evaluation, however, the potential cause remains unexplained in about one third to one half of cases (3,6) (Table 31.1).

Genetic Factors

The most common inborn parental chromosomal abnormalities contributing to recurrent abortion are balanced translocations (7,8,9). In balanced translocations, one parent carries an overall normal gene content but has a piece of one chromosome inappropriately attached to another. Depending on the nature of the translocation (reciprocal or Robertsonian), the gametes produced by the translocation carrier will be normal (reciprocal only), balanced, or unbalanced for the translocated DNA. If fertilized by a chromosomally normal gamete, the resulting embryo may be chromosomally normal (reciprocal only) or may be a balanced or unbalanced carrier of the translocation. Most gametes and embryos with abnormal chromosomal status will not survive. Of those that do survive, live offspring will either be carriers of a balanced translocation or, for Robertsonian translocations, be monosomic or trisomic for the translocated chromosomal DNA.

P.1279

P.1280

Among the possible chromosomal monosomies, only that of the X chromosome typically permits viable offspring. On careful examination, however, many of these offspring may exhibit mosaicism. Embryonic chromosomal monosomy may be particularly prevalent among patients with histories of RPL who are undergoing *in vitro* fertilization (10). Compared with monosomies, chromosomal trisomies (e.g., trisomy 13, 18, and 21) appear to be more readily tolerated, although mosaicism may be implicated with these abnormalities as well.

Table 31.1 Proposed Etiologies for Recurrent Spontaneous Abortion

<i>Etiology</i>	<i>Proposed Incidence</i>
Genetic factors	3.5%–5%
1. Chromosomal	
2. Single gene defects	
3 Multifactorial	
Anatomic factors	12%–16%
1. Congenital	
a. Incomplete mullerian fusion or septum resorption	
b. DES exposure	
c. Uterine artery anomalies	
d. Cervical incompetence	
2. Acquired	
a. Cervical incompetence	
b. Synechiae	
c. Leiomyomas	
d. Adenomyosis	
Endocrine factors	17%–20%

1. Luteal phase insufficiency	
2. Polycystic ovarian syndrome, including insulin resistance and hyperandrogenism	
3. Other androgen disorders	
4. Diabetes mellitus	
5. Thyroid disorders	
6. Prolactin disorders	
<i>Infectious factors</i>	0.5%–5%
1. Bacteria	
2. Viruses	
3. Parasites	
4. Zoonotic	
5. Fungal	
<i>Immunologic factors</i>	20%–50%
1. Cellular mechanisms	
a. Suppressor cell or factor deficiency	
b. Alterations in major histocompatibility antigen expression	
c. Alterations in cellular immune regulation	
1. Th1 immune responses to reproductive antigens (embryo or trophoblast)	
2. Th2 cytokine or growth factor deficiency	
3. Hormonal-progesterone, estrogen, prolactin, androgen alterations	
4. Tryptophan metabolism	
2. Humoral mechanisms	
a. Antiphospholipid antibodies	
b. Antithyroid antibodies	
c. Antisperm antibodies	
d. Antitrophoblast antibodies	
e. Blocking antibody deficiency	
<i>Thrombotic factors</i>	? incidence
1. Heritable thrombophilias	
a. Single gene defects factor V Leiden (fVL), MTHFR, factor deficiencies	
b. Antibody-mediated thromboses (APAS, anti-beta2G1)	Most are included among other categories (e.g., immune, genetic)
<i>Other factors</i>	10%
1. Altered uterine receptivity (integrins, adhesion molecules)	
2. Environmental	
a. Toxins	
b. Illicit drugs	
c. Cigarettes and caffeine	

3. Placental abnormalities (circumvallate, marginate)**4. Medical illnesses (cardiac, renal hematologic)****5. Male factors****6. Exercise****7. Dyssynchronous fertilization**

DES, diethylstilbestrol; MTHFR, methylene tetrahydrofolate reductase; APAS, antiphospholipid antibody syndrome.

Neither family history nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses (9), the chance of detecting a parental chromosomal abnormality also is increased among couples that have never experienced a live birth. Abnormalities may also be detected by parental karyotype analysis of couples with a history of spontaneous abortions interspersed with stillbirths and live births (with or without congenital anomalies).

P.1281

Unfortunately, the use of parental karyotyping in the evaluation of structural chromosomal causes of RPL may ultimately become insufficient. Evidence now suggests that paternal chromosomal abnormalities may be isolated within particular fertilizing spermatozoa (11), and aneuploid spermatozoa may be particularly motile (12).

Other structural chromosome anomalies, such as inversions and insertions, as well as chromosomal mosaicism and single gene defects, may also contribute to recurrent abortion. X-linked disorders can be linked to recurrent abortion in female offspring but uncommonly result in recurrent abortion of male offspring (13). Single gene defects and their resulting disorders (e.g., the delta f 508 mutation and cystic fibrosis) may be recognized through analysis of detailed family histories or the identification of some pattern of anomalies characteristic of a known heritable syndrome.

Thrombophilias

The role of inherited thrombophilias in RPL has generated a great deal of interest (14,15,16). This heterogeneous group of disorders results in increased venous or arterial thrombosis. Their associations with pregnancy loss rest on both proved (17) and hypothetical alterations in placental growth and development, particularly placental vascular development. Abnormal placental vascularization and inappropriate placental thrombosis would link these thrombophilic states to pregnancy loss. Although some thrombophilic states may be acquired, most are heritable. **Those heritable thrombophilias most often linked with reference to RPL include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V, deficiencies in proteins C and S, mutations in the prothrombin gene promotor, mutations in prothrombin, and mutations in antithrombin III.**

As with spontaneous pregnancy loss, inherited and combined inherited-acquired thrombophilias also are surprisingly common. More than 15% of Caucasians carry an inherited thrombophilic mutation (15). **The most common of these are factor V Leiden mutations, mutations in the promoter region of the prothrombin gene, and mutations in the gene encoding methylene tetrahydrofolate reductase (MTHFR).** These disorders have been estimated to be present in their heterozygous state in approximately 5%, 2% to 3%, and 11% to 15% of healthy Caucasian populations, based on various studies (16,17,18,19,20). These common mutations are associated with mild

thrombotic risks. It remains unclear whether homozygous *MTHFR* mutations even is associated with vascular disease (21). **In contrast, more severe thrombophilic deficiencies, such as those of antithrombin and protein S, are much less common in the general population.** These epidemiologic data support the hypothesis that a selective genetic advantage may accompany carriage of common heritable thrombophilias. To illustrate this point, women with activated protein C resistance caused by the factor V Leiden mutation have reduced blood loss at delivery (22), and factor V Leiden carriage has been shown to improve pregnancy rates in intracytoplasmic sperm injection/ *in vitro* fertilization, suggesting a positive role in implantation (23). It is important to note that the epidemiology of factor V Leiden mutations is specific to Caucasian populations. Factor V Leiden and prothombin gene mutations are rare in African and Asian populations, despite similar incidences of venous thromboembolism (VTE) in these groups (24,25,26,27). Protein C, protein S, and antithrombin mutations are the most important risk factors for VTE among many Chinese populations (28). These ethnic and geographic differences are important considerations when faced with decisions concerning diagnostic testing in patients with a history of recurrent fetal loss.

Inherited thrombophilic mutations have been estimated to be causative in 50% of VTE during pregnancy (15). Approximately 40% of episodes of venous or arterial thromboembolic phenomena occur in patients carrying a heritable mutation (29). Associations between thrombophilias and adverse fetal outcomes cover a range of early gestational and obstetric disorders. These disorders include isolated and recurrent, early and late spontaneous pregnancy losses, intrauterine growth restriction (IUGR), intrauterine fetal demise

P.1282

(IUFD), placental abruption, and pregnancy-induced hypertension (PIH). This discussion will focus on pathophysiologic mechanisms, diagnostic testing, and treatment strategies for patients with RPL who may have an inherited or acquired predisposition to thrombosis (excluding the antiphospholipid syndrome).

The basis for the association between adverse fetal outcomes and heritable thrombophilias has focused on the mechanisms of impaired placental development and function secondary to venous or arterial thrombosis at the maternal–fetal interface. These findings have been noted in the placentas of women with adverse fetal outcomes and known inherited thrombophilias, but have occurred likewise in patients with similar outcomes who lack inherited thrombophilic risk (30,31,32,33,34). Discussions of the role of placental thrombosis in early pregnancy losses (≤ 10 weeks of gestation) have been particularly contentious, citing a series of experiments showing that maternal blood does not flow into the intervillous spaces of the human placenta until approximately 10 weeks of gestation (35,36,37,38). Before establishment of intervillous circulation, however, nutrient transfer from maternal blood to fetal tissues appears to depend on transudation that, in turn, relies on flow through the uterine vasculature. This finding suggests that maternal or fetal thrombotic episodes in the developing placental vasculature could equally be devastating before or after the establishment of intervillous circulation near 10 weeks of gestation. Timing of fetal demise among patients with pregnancy loss, however, does provide diagnostic clues, and its documentation is important in investigations into the causes and treatment of RPL.

Most preclinical and early clinical pregnancy losses are the result of *de novo* fetal aneuploidy (39). This is also thought to be true of anembryonic pregnancy losses. The presence of pregnancy losses resulting from *de novo* fetal aneuploidy, whether early and undocumented or documented through evaluation of chromosomal content in fetal tissues, complicates the results of many published studies. **The presence or absence of fetal aneuploidy must be documented in all investigations of RPL, and their potential as**

a confounding factor should be discussed in any assessment of outcome. The timing of fetal demise and the need for chromosomal analysis of any collected fetal tissue should be carefully weighed when diagnostic and therapeutic investigations into thrombophilia-related causes of RPL are being considered. **Very early pregnancy losses (biochemical, anembryonic) and known aneuploid fetal losses may be less likely to be altered by the presence of an underlying thrombophilic state and can reasonably be dismissed as indications for thrombophilia testing among patients with otherwise unexplained RPL.**

The coagulation system relies on a complex cascade of prothrombotic enzymatic activations (often via serine proteases) in delicate balance with antithrombotic pathways. Although pregnancy is most simply described as prothrombotic, the alterations in the coagulation system associated with pregnancy represent a state of compensated disseminated intravascular coagulation (DIC) (40). Human hemochorial placentation is unique and inherently unstable. Placental development involves invasion into the maternal decidua and its vasculature and requires precise control of hemostasis and fibrinolysis. Delicate control mechanisms exist locally within the placenta (41) and globally within the pregnant woman. Hormonal and related physiologic changes characteristic of pregnancy affect important components of the clotting cascade, the fibrinolytic cascade, and platelet physiology.

Clot formation can be initiated through two pathways, called the extrinsic and intrinsic clotting cascades (Fig. 31.1). Both respond to blood vessel damage and the release of tissue factor (TF). Tissue factor is a glycoprotein expressed on the surface of cells surrounding blood vessels. It is not expressed on the endothelium of the blood vessel itself, so exposure of blood to TF is a sensitive indicator of vascular damage. The extrinsic clotting cascade begins with the interaction of newly released TF with factor VII of

P.1283

the clotting cascade. The complex formed by TF and factor VII can either directly activate factor X or activate factor X via the intrinsic pathway. In the intrinsic pathway, the TF/factor VII complex activates factor IX to factor IXa (activated factor IX). Factor IXa then complexes with factor VIIIa. In combination, factors IXa and VIIIa activate factor X. Activation of factor XII after binding to negatively charged surfaces also can initiate the intrinsic pathway. Via this route, activated factor XII cleaves factor XI, generating factor XIa. Factor XIa can act as an alternate activator of factor IX. Extrinsic and intrinsic clotting cascades converge in the activation of factor X to factor Xa. Activated factor X (Xa) catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). The presence of activated factor V, factor Va, is required for this conversion. Thrombin, in turn, converts fibrinogen to fibrin, an essential building block for stable clot formation. Thrombin also activates factor XIII, which in turn cross-links fibrin monomers and thereby stabilizes the fibrin clot.

Figure 31.1 The clotting cascade. Physiologic clotting is initiated by endothelial cell damage or abnormal exposure of negatively charged phospholipids to serum and blood components. Procoagulant pathways in black are part of the clotting cascade and are prothrombotic. Both lead to activation of cascades of proteolytic enzymes and cleavage of clotting factors. The extrinsic and intrinsic pathways are initiated by distinct mechanisms. They merge at the activation of factor X to form the common pathway. For all coagulation factors, the subscript *a* denotes the activated form of the factor.

To avoid uncontrolled thrombosis in response to tissue damage or alternate activation of the coagulation cascade, a number of antithrombotic control mechanisms are activated in conjunction with clot formation (Fig. 31.2). Important to this discussion are those mechanisms involving antithrombin (formerly antithrombin III), protein C, and protein S. Proteins C and S are vitamin K-dependent factors that are activated on clot formation. Activation is initiated by complexes of thrombomodulin and thrombin at sites of endothelial damage. Complexes of activated protein C and S inactivate factors Va and VIIIa, thereby inhibiting their associated procoagulant activities. Antithrombin is a serine

P.1284

protease inhibitor that binds irreversibly to serine proteases. Proteases that bind antithrombin include factors IXa, Xa, XIa, and XIIa. Antithrombin also accelerates dissociation of factor VIIa tissue factor complexes, thereby inhibiting intrinsic and extrinsic clotting pathways at their points of initiation. Finally, as its name suggests, antithrombin binds to and inhibits thrombin (factor IIa). Fibrinolysis also acts to delimit uncontrolled coagulation (see Fig. 31.2). Mechanisms for fibrinolysis include cleavage of the fibrin clot by plasmin and the formation of fibrin degradation products (FDPs or FSPs). Plasmin activity is, in turn, controlled by plasminogen activator inhibitors (e.g., PAI-1).

Figure 31.2 Physiologic mechanisms that counteract the clotting cascade. The procoagulant cascade is inhibited by several physiologic mechanisms. The balance between pro- and antithrombotic pathways determines the state of coagulability. Antithrombotic mechanisms include the action of antithrombin (AT) and of proteins C and S. The sites of inhibition by these substances are depicted by an X. Plasminogen activator inhibitors 1 and 2 (PAI-1 and PAI-2) indirectly inactivate plasmin. Plasmin plays an important role in the dissolution of coagulated blood. For all coagulation factors, the subscript *a* denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

Prothrombotic changes associated with pregnancy include increases in the amounts or the activities of factors in the clotting cascade and decreases in those counteracting clotting. The former includes pregnancy-associated elevations in factors VII, VIII, X, XII, von Willebrand's factor, and fibrinogen levels (40,42,43). All of these factors increase throughout gestation. Factor II, factor V, and factor XIII levels also increase early in pregnancy but return to normal levels after the first trimester (40,44). Normal pregnancy has been associated with the development of activated protein C resistance (acquired APCR)

P.1285

via mechanisms that remain unclear (45). Changes in balancing antithrombotic control mechanisms during pregnancy also favor clot formation. Whereas the activities of protein C and antithrombin remain fairly constant during the course of pregnancy, those of protein S decrease significantly. Protein S activity decreases in conjunction with pregnancy-induced increases in the production of C4b-binding protein, a complement factor-binding protein that forms a complex with protein S, making it unavailable for interaction with activated protein C (46). This increased binding, however, does not fully explain the level of decrease in protein S activity during pregnancy (46).

Fibrinolysis is impaired during pregnancy, with decreases in fibrinolytic activity beginning at approximately 11 to 15 weeks of gestation (40). A significant factor in this impairment is a marked decrease in plasmin activity resulting from placental production of the plasmin-inhibitor, PAI-2 (47,48). In conjunction with these changes, however, FDP levels rise in pregnancy, beginning at approximately 20 weeks of gestation and continuing their rise throughout pregnancy (40,48). In normal pregnancy, platelet function and turnover is unchanged (Fig. 31.3). In the third trimester, platelet number typically decreases, the result of increased platelet consumption. This benign gestational thrombocytopenia can reach levels less than $80 \times 10^9/L$ (49). Collectively, pregnancy-associated alterations in the amounts and activities of prothrombotic clotting factors, anticoagulant control mechanisms, and fibrinolysis support the determination of human pregnancy as a state of

P.1286

compensated DIC. Although these changes reverse during the 4 to 6 weeks following delivery (40,49), **the vascular damage associated with delivery is an additional significant risk factor for thrombosis, making the immediate postpartum period an important continuation of the prothrombotic state associated with pregnancy.**

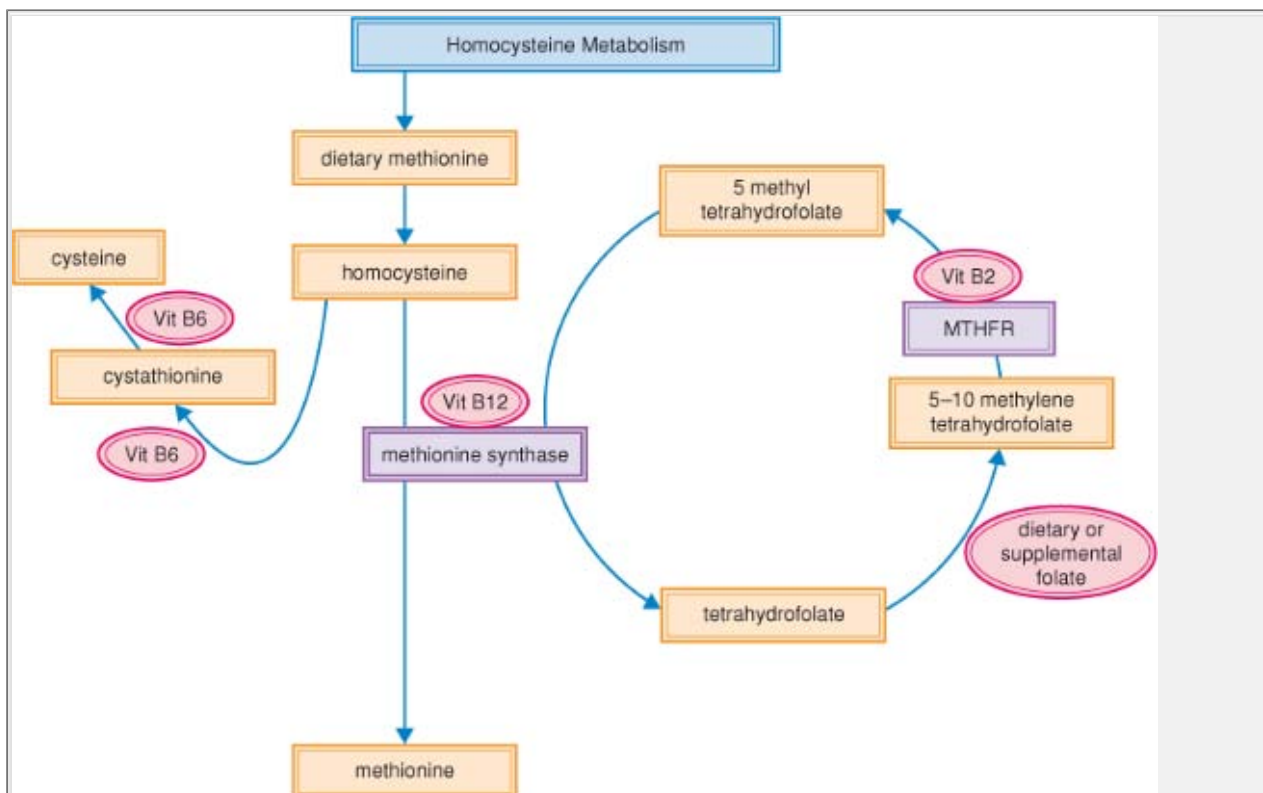

Figure 31.4 Homocysteine metabolism. Dietary methionine is metabolized either to cysteine or back into methionine. Homocysteine, a prothrombotic metabolite, is an intermediate in this process. Conversion of homocysteine to methionine requires transfer of a methyl group from 5 methyl tetrahydrofolate. The conversion of folate to 5 methyl tetrahydrofolate is a multistep process requiring vitamin B₂ as a cofactor for the enzyme, methylene tetrahydrofolate reductase (MTHFR). Vitamin (Vit) B₁₂ is a required cofactor for the enzyme methionine synthase. Vitamin B₆ is also required for metabolism of sulfur-containing amino acids, such as methionine.

Circulating homocysteine is derived from dietary methionine. Homocysteine, in turn, is metabolized either into cystathionine or back into methionine (Fig. 31.4). The latter process involves the enzyme methionine synthase. Methionine synthase requires donation of a methyl group from 5 methyl tetrahydrofolate to produce methionine, and the enzyme *methylene tetrahydrofolate reductase (MTHFR)* is involved in the production of 5 methyl tetrahydrofolate from dietary folate sources (14). The nutritional supplements folic acid, vitamins B₂, B₆, and B₁₂ are all required for proper metabolism of homocysteine; therefore, their deficiency is associated with acquired elevations in circulating homocysteine levels (15,18,50). Although heritable deficiencies in the enzymes required for metabolism of homocysteine have been described for the pathways leading to cystathionine formation and those involved in reconversion to methionine (14,50,51,52). Point mutations in *MTHFR* are surprisingly common (16,19), and can be associated with hyperhomocysteinemia and thrombosis (50,51,52).

Those heritable thrombophilias most often linked to RPL include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V, deficiencies

in proteins C and S, and mutations in the prothrombin promoter and antithrombin. These inherited disorders are mainly autosomal dominant and display a wide variation in prevalence and in the severity of morbidity associated with gene carriage. The latter

two characteristics have direct reciprocal correlations in the Caucasian population. **Consistent with general thrombotic risk, carriage of combinations of two or more inherited thrombophilic defects has particularly strong association with adverse pregnancy outcomes** (16,19,53). Acquired thrombophilias associated with RPL include hyperhomocysteinemia and activated protein C resistance. Most of the data linking thrombophilic states to recurrent fetal loss consist of small- to moderate-sized prevalence studies (53,54,55,56,57,58,59,60,61). Recent attempts to pool these data into meta-analyses have allowed more informed recommendations on the testing of patients presenting with RPL (62,63,64). Collectively, these studies suggest that testing for the factor V Leiden mutation, protein S levels, prothrombin promoter mutations, homocysteine levels, and global activated protein C resistance is of use in Caucasian patients with a history of repetitive first- or second-trimester losses. These recommendations do not necessarily apply to non-Caucasian patients. Individual studies directly linking hyperhomocysteinemia, folic acid, vitamin B₁₂, and *MTHFR* mutations to RPL have been contradictory (30,31,51,52,53,54,55,56). Recent studies that have evaluated pooled data from previous investigations (one via meta-analysis) show these conditions to be linked to risk of RPL (62).

With the recent completion of the human genome project and the rapid development of novel and improved molecular cytogenetic techniques (65), many advances and additional insights into the contribution of parental genetic abnormalities to RPL can be anticipated.

Anatomic Abnormalities

Anatomic abnormalities of the both the uterine cervix and the uterine body have been associated with RPL. These anatomic causes may be either congenital or acquired. During development, the uterus forms via the apposition of a portion of bilateral hollow tubes called the müllerian ducts. The dissolution of the walls of these ducts along their site of apposition allows formation of the intrauterine cavity, the intracervical canal, and the upper vagina. Congenital uterine anomalies may, therefore, include incomplete müllerian duct fusion, incomplete septum resorption, and uterine cervical anomalies. Although the causes underlying many of the congenital anomalies of the female reproductive tract are unclear, it has been well documented that prenatal exposure to maternally ingested diethylstilbestrol (DES) results in complex congenital uterine, cervical, and vaginal changes.

Historically, all congenital reproductive tract abnormalities have been linked to both isolated spontaneous pregnancy loss and to RPL (66), although the presence of an intrauterine septum and prenatal exposure to DES demonstrate the strongest associations (67,68). In fact, women with an intrauterine septum may have as high as a 60% risk for spontaneous abortion (69). Uterine septum-related losses most frequently occur during the second trimester. However, if an embryo implants into the poorly developed endometrium overlying the uterine septum, abnormal placentation and resultant first-trimester losses may occur as well (70). The most common uterine congenital anomaly associated with *in utero* DES exposure is hypoplasia, which may contribute to first- or second-trimester spontaneous abortions, incompetent cervix, and premature labor (71,72). Congenital anomalies of the uterine arteries also may contribute to pregnancy loss via adverse alterations in blood flow to the implanted blastocyst and developing placenta (73).

Acquired anatomic anomalies have likewise been linked to both isolated and RPL. These abnormalities include such disparate conditions as intrauterine adhesions, uterine fibroids, and endometriosis. Endometrium that develops over an intrauterine synechiae or over a fibroid that impinges in the intrauterine cavity (submucous) may be inadequately vascularized (74). This may promote abnormal placentation for any embryo

attempting to implant over such lesions. Although data supporting these concepts are a bit tenuous, this abnormal placentation may lead to spontaneous pregnancy loss. Less clear is the association between intramural fibroids and RPL, but it is suggested that large (greater than 5 cm) intramural fibroids are associated with pregnancy loss and that removal improves outcomes (67,75).

Endocrine Abnormalities

The endocrinology of normal pregnancy is complex. **Because spontaneous pregnancy is critically dependent on appropriately timed endocrinologic changes of the menstrual cycle, it is not surprising that those endocrine abnormalities that ultimately alter pregnancy maintenance may mediate their effects during the follicular phase of the cycle in which conception occurs, or even earlier.** Modifications in follicular development and ovulation, in turn, may be reflected in abnormalities of blastocyst transport and development, alterations in uterine receptivity to the implanting blastocyst, and improper functioning of the corpus luteum. **Beginning with ovulation and lasting until approximately 7 to 9 weeks of gestation, maintenance of early pregnancy depends on the production of progesterone by the corpus luteum. Normal pregnancies are characterized by a luteal-placental shift at about 7 to 9 weeks of gestation, during which the developing placental trophoblast cells take over progesterone production and pregnancy maintenance (76). Spontaneous pregnancy losses occurring before 10 weeks of gestation may result from a number of alterations in normal progesterone production or utilization. These include failure of the corpus luteum to produce sufficient quantities of progesterone, impaired delivery of progesterone to the uterus, or inappropriate utilization of progesterone by the uterine decidua.** Pregnancy failures may also occur near the time of the expected luteal-placental shift if the trophoblast is unable to produce biologically active progesterone following demise of the corpus luteum.

Endocrinologic factors associated with recurrent abortion include luteal phase insufficiency, diabetes mellitus, hypersecretion of luteinizing hormone (LH), thyroid disease, and potentially insulin resistance and the polycystic ovarian syndrome (PCOS), hyperprolactinemia, and decreased ovarian reserve. Luteal phase insufficiency or luteal phase defects (LPD) are characterized by inadequate luteal milestones. They most likely relate to adverse pregnancy outcome via inadequate or improperly timed endometrial development at potential implantation sites. Luteal phase defect has many causes, some of which are associated with hypersecretion of LH. Although the mechanism underlying the association of elevated LH levels with RPL remains incompletely understood, abnormal LH secretion may have direct effects on the developing oocyte (premature aging), on the endometrium (dyssynchronous maturation), or both. Many patients with elevated LH levels also display physical, endocrinologic, and metabolic characteristics of PCOS. In fact, **some studies report ovarian radiologic evidence of PCOS in as many as 40% to 80% of patients experiencing RPL (77,78).** In addition to inappropriately elevated LH levels, PCOS patients are frequently obese and often have elevated circulating androgen levels. Although not undisputed (78), both changes have been linked to RPL (77,79), and elevated androgen levels have been shown to adversely affect markers of uterine receptivity in women with a history of RPL (80).

Many women with PCOS have metabolic alterations in glycemic control characterized by insulin resistance (see Chapter 29). This too may be directly or indirectly related to adverse pregnancy outcome, and it may be linked to the mechanisms for spontaneous pregnancy loss among women with type 2 diabetes mellitus (81). Women with overt type 2

diabetes mellitus appear to exhibit a threshold of pregestational glycemic control above which spontaneous pregnancy loss is increased (82,83). In fact, hyperglycemia has now been linked directly to embryonic damage (84). In cases of advanced type 2 diabetes with accompanying vascular complications, subsequent pregnancy loss may result from compromised blood flow to the uterus.

Patients with thyroid disease often have concomitant reproductive abnormalities, including ovulatory dysfunction and LPD. In addition, the metabolic demands of early pregnancy mandate increased levels of thyroid hormones. It is, therefore, not surprising that hypothyroidism has been associated with spontaneous pregnancy loss and with RPL (85). Whether clinically euthyroid patients with antithyroid antibodies have higher rates of RPL continues to be debated (86,87,88,89). The mechanism for an association remains unclear; however, these antibodies may be markers of more generalized autoimmunity or may predict an impaired ability of the thyroid gland to respond to the demands of pregnancy.

Two additional endocrinologic abnormalities have been linked with RPL, although data to support these associations are lacking. **Animal models suggest that elevated prolactin levels may adversely affect the function of the corpus luteum; however, this concept is not well supported in humans (90,91).** Some have suggested that elevated prolactin levels may promote pregnancy wastage via direct effects on the endometrium or indirect immunomodulatory mechanisms (92). Most recently, attempts have been made to correlate markers of ovarian reserve (day 3 follicle-stimulating hormone and day 3 estradiol response to the *clomiphene* challenge test) with RPL (78,93,94). At present, no consensus exists concerning this potential association.

Maternal Infection

Infection of the reproductive tract with bacterial, viral, parasitic, zoonotic, and fungal organisms has been linked theoretically to pregnancy loss. The most extensively studied pathogens are mycoplasma, ureaplasma, *Chlamydia trachomatis*, and β -streptococcus (95,96), and recent data have focused on the roles of some of these proposed organisms in RPL. One prospective comparison trial involving 70 patients with RPL reported no elevations in any markers for present or past infection with *C. trachomatis* when compared with controls (97). In contrast, a very large, prospective trial has demonstrated a link between the detection of bacterial vaginosis and history of second-trimester pregnancy loss among 500 patients with RPL (98). In this study, the likelihood of detecting bacterial vaginosis positively correlated with cigarette smoking.

The mechanism linking specific organisms to either isolated or RPL remains unclear and must certainly differ among infectious organisms. Certain viral organisms, such as herpes simplex virus (HSV) (99) and human cytomegalovirus (CMV) (100) can directly infect the placenta and fetus. The resulting villitis and related tissue destruction may disrupt pregnancy. Another theoretic possibility is that infection-associated early pregnancy loss may result from immunologic activation that occurs in response to pathologic organisms. A large body of evidence supports the role of this mechanism in adverse events that occur later in gestation, such as intrauterine growth restriction (101), premature rupture of membranes, and preterm birth (102). Alternatively, mechanisms that protect the fetus from autoimmune rejection also may protect virally infected placental cells from recognition and clearance. This could potentially promote periods of unfettered infectious growth for some of the pathogenic organisms gaining entry to the reproductive tract (103).

Immunologic Phenomena

Although there has been extensive information published on the immunologic aspects of RPL, there is a lack of consensus as to the mechanisms and the impact of therapeutic intervention. The detection of a therapeutic effect is difficult, and studies are complicated by the fact that many patients with RPL seek care after the pregnancy is lost but before the fetus or embryo is expelled. In these cases, the physiologic immune reaction to the presence of nonviable tissue may mask any alternative, underlying immune causes for the demise itself. Finally, it is very likely that there is a wide variety of immune

P.1290

alterations that may cause isolated or RPL. At least ten well-supported immune mechanisms, each potentially important in pregnancy maintenance, have been identified (104).

Before launching into the most commonly accepted causes of immune-mediated pregnancy loss, a brief review of some of the important concepts in basic immunology is warranted for reference. These descriptions are presented in general terms here and further defined in Chapter 6.

Immune responses classically are divided into *innate* and *acquired* responses. *Innate responses* represent the body's first line of defense against pathogenic invasion. They are rapid and are not antigen specific. Cell types and mechanisms typically considered vital to innate immunity include complement activation, phagocytosis by macrophage, and lysis by natural killer (NK) and natural killer T (NKT) cells and possibly by TCR $\gamma\delta$ ⁺ T cells. *Acquired immune responses*, in contrast, are antigen specific and are largely mediated by T cells and B cells. Acquired responses can be further classified as *primary* (response associated with initial antigen contact) and *secondary* (rapid and powerful anamnestic responses associated with subsequent contact to the same antigen).

Antigen specificity is generally regulated by two sets of genes in the major histocompatibility complex (MHC), located on chromosome 6 in humans. MHC class I molecules (HLA-A, -B, and -C) are present on the surface of nearly every cell in the human body and are important in defense against oncogenic transformation and intracellular pathogens, such as viral infection. Class I MHC molecules act as important ligands for both the T-cell receptor on CD8⁺ cytotoxic/suppressor T cells and for a variety of receptors on NK cells (105). Class II MHC molecules (HLA-DR, HLA-DP, and HLA-DQ), in contrast, are present on the surface of a limited number of antigen-presenting cells, including dendritic cells, macrophage and monocytes, B cells, and tissue-specific cells such as the Langerhans cells in the skin. These molecules are important in defense against extracellular pathogens, such as bacterial invaders. The major ligand for MHC class II is the T-cell receptor on CD4⁺ T helper cells.

One very important concept in immunology that has particular application to pregnancy is that of immune tolerance. It has been well described that bone marrow-derived T cells pass through the fetal thymus during early development. During this developmental interval, the T cells encounter a process termed *thymic education*. During thymic education, T cells are chosen that express either the CD4 or the CD8 co-receptor, and autoreactive cells are effectively eliminated. In short, this education promotes T-cell tolerance, allowing selection and survival only of those T cells that can recognize nonself but will not react against self.

Recently, a subpopulation of CD4⁺ T cells has been described that strongly express CD25 on their cell surface. These CD4, CD25⁺ cells are called regulatory T lymphocytes (T reg cells) (106). T reg cells, when activated by autoantigens, can suppress activated inflammatory cells. They may have particular importance in avoidance of tissue destruction associated with inflammation, possibly with applications to tolerance.

These immunologic characteristics have been most thoroughly described and investigated for the immune effector cells populating the peripheral immune system. The peripheral immune system consists of the spleen and peripheral blood, and it is generally responsible for protection against blood-borne pathogens. Pathogens that enter the host via the extensive surface areas of the lacrimal ducts, respiratory system, gastrointestinal tract, mammary ducts, and genitourinary tract encounter a very distinct and important immune environment—that of the mucosal immune system. Although the mucosal immune system may be responsible primarily for the initial protection against most exogenous pathogens, knowledge of its immune characteristics lags far behind that of the peripheral immune

P.1291

system. Insight into the specific characteristics of immunity within the reproductive tract is even further limited.

Cellular Immune Mechanisms

Many of the immune theories surrounding the causes of isolated and recurrent spontaneous pregnancy losses have stemmed from attempts to define immunologic rules as they apply specifically to the mucosal reproductive tract. Four main questions summarize much of the theoretical thinking surrounding pregnancy maintenance and reproductive immunology:

- Which immune cells populate the reproductive tract, particularly at implantation sites?
- How do these cells arrive at this mucosal immune site, and are they educated in the same way as those populating the periphery?
- How do the characteristics of antigen presentation differ at the maternal–fetal interface?
- What regulatory mechanisms specifically affect reproductive tract immune cells?

Resident Cells

Immune cells populating the reproductive tract exhibit many characteristics that distinguish them from their peripheral counterparts. In particular, the human endometrium is populated by T cells, macrophage, and NK-like cells, but very few B cells (107,108). The relative proportions of these resident cells vary with the menstrual cycle and change dramatically during early pregnancy. In fact, **around the time of implantation, one particular cell type comprises between 70% and 80% of the total endometrial lymphocyte populations** (107,108). This cell type is called a variety of names, including *decidual granular lymphocytes (DGL)*, *large granular lymphocytes (LGL)*, and *decidual NK cells*. This heterogeneity of names reflects the fact that this particular cell type differs from similar cells isolated from the periphery, although most believe it to be an NK cell variant. If these cells are considered NK, the implantation site represents the largest accumulation of NK cells in any state of human health or disease. The true function of these cells remains unclear, but their remarkable abundance at the maternal–fetal interface is compelling (109,110). Other immune cells that have been described in the periphery have characteristics of both NK cells and of T cells. These NKT cells have recently been shown to play a role in pregnancy loss in animal models (111). They are present in the decidua in

humans and may play an important immunoregulatory role at this site (112).

In the peripheral immune compartment, most T cells express a T-cell receptor made up of an $\alpha\beta$ heterodimer (TCR $\alpha\beta^+$). In addition to TCR $\alpha\beta^+$ T cells, the human reproductive tract also is populated by a subset of T cells with a distinctive T cell receptor composed of the $\gamma\delta$ heterodimer (TCR $\gamma\delta^+$), and the numbers of these cells increases in early pregnancy (113,114,115). TCR $\gamma\delta^+$ T cells appear to fulfill functions quite distinct from their $\alpha\beta^+$ counterparts; these functions may include direct, non-MHC-restricted recognition of antigens within tissues (116). In fact, TCR $\gamma\delta^+$ T cells may fill a protective niche missed or poorly covered by B cells and TCR $\alpha\beta^+$ T cells. The role and importance of TCR $\gamma\delta^+$ cells in the reproductive tract and, more particularly, in pregnancy maintenance deserves further attention.

Finally, it has been suggested that **a subset of macrophage, termed "suppressor" macrophage, may be implicated in pregnancy maintenance**. These specific cells differ from typical macrophage in their promotion of anti-inflammatory effects, and they have been detected in normal murine placenta (117). Their presence in human decidual specimens requires further investigation. T reg cells are also of the "suppressor" functional phenotype. In pregnant mice and women, these specialized CD4⁺ cells are systemically

P.1292

expanded in an alloantigen independent fashion (118) and can suppress adverse maternal responses to self (119) and to the fetus (120).

The human decidua is populated by characteristic immune effector cells. Investigations into whether alterations in these cells (including T cells, decidual NK cells, and NKT cells) determine pregnancy outcome have been hampered by insufficient patient numbers to allow meaningful conclusions. These immune cell populations have been reported to be altered in patients with RPL (121,122,123) but not in patients experiencing isolated spontaneous pregnancy losses (115).

Immune Cell Education and Homing to the Reproductive Tract

The implanting fetus represents the most common model of allograft acceptance. The ability of the maternal immune system to avoid rejection of the implanting fetus in an uncomplicated pregnancy is a manifestation of immune tolerance. This observation raises questions about how the resident decidual immune effector cells are selected and educated, how they are recruited to reproductive sites, and how they are maintained once they reach this destination. Animal studies have suggested that the rules for selection and maintenance of these cells, in terms of their requirement for MHC and their education within the thymus, may be distinct from those governing either peripheral immune cells or cells within other mucosal sites, including the intestine (124). The immunophenotypes of immune cells populating the human reproductive tract are distinct from both the periphery and from other mucosal sites (125,126). The education of TCR $\gamma\delta^+$ cells populating epithelial sites may occur outside the thymus and might involve mechanisms that substitute for or modify interaction with MHC (115,127). The development of MHC specificity among NK cells is undergoing careful dissection in animal models (128,129) with the hope that these investigations will shed light on similar processes in humans and, specifically, on the selection and maintenance characteristics of decidual NK cells.

It is now becoming increasingly evident that the cells populating mucosal immune tissues select these sites through interactions between cell surface molecules on the immune cell (*integrins*) and cell surface molecules on the endothelial cells of blood vessels within the mucosal tissues (e.g., *selectins*, *VCAM*, *MECA*). This

cellular recruitment process, called homing, has been most thoroughly described for the intestine (130,131). However, both murine (130,132) and human (133) reproductive tract tissues express these integrin/vascular ligand pairs, and the extension of these findings to pregnancy maintenance will surely prove fruitful. Understanding the mechanisms of selection, education, and maintenance of reproductive tract immune effector cells in the normal state is of paramount importance to determining the effects of alterations on disorders and their treatment.

Antigen Presentation at the Maternal-Fetal Interface

Historically, it was proposed that one method by which the implanting trophoblastic allograft could potentially avoid immune detection by the maternal host would be by making itself antigenically invisible. It could downregulate its expression of the MHC-encoded transplantation antigens (some of which would be of paternal origin) and thereby avoid recognition as nonself. Although current knowledge of immunology now makes this theory somewhat obsolete (134), the implanting fetus does, in fact, use this strategy to some extent. It is certainly true that placental trophoblast cells do not express MHC class II molecules (135,136).

Unlike nearly every other cell in the human body, trophoblast cells do not express the classical MHC class I transplantation antigens HLA-A and -B. Rather, a subpopulation of placental cells, specifically the extravillous cytotrophoblast cells, express the classical MHC class I HLA-C products and the nonclassical HLA-E and -G products (103,137,138,139,140,141). These extravillous cytotrophoblast cells are of particular interest because they are characterized by remarkable invasive potential (142,143). These cells move from the tips of the anchoring villae of the human placenta and invade deeply into the maternal

P.1293

decidua. They can even replace cells within the walls of decidual arterial vessels (142,143,144). Although the invasive characteristics of extravillous cytotrophoblast may reflect non-MHC-related mechanisms, including well-described integrin switching (145), the intimate contact of these fetal-derived cells with maternal immune effector cells exposes the fetus to recognition as nonself.

It is not known why all placental cells downregulate expression of HLA-A and -B, whereas invasive extravillous cytotrophoblast express HLA-C, -E, and -G. Because NK cells of the innate immune system recognize and kill cells that express no MHC (134), the complete downregulation of MHC would cause trophoblast cells to act as targets for those NK cells that are pervasive at sites of implantation. In addition to possible protection from direct NK cell-mediated killing, the expression of HLA-C, -E, and -G by trophoblast cells may serve a variety of alternative roles. Natural killer cell receptor-mediated interactions with extravillous cytotrophoblast MHC could modulate cytokine expression profiles at the maternal-fetal interface (109,110). **Major histocompatibility complex expression may aid in decidual and vascular invasion by the trophoblast, an activity essential for proper placental development** (146). Whereas definitive correlations between placental MHC class I expression patterns and RPL have yet to be reported, trophoblast expression of HLA-G has been linked to other disorders of placental invasion, such as preeclampsia (146,147). Genetic mutations at the HLA-G locus have also been linked to RPL in some but not all studies (148,149,150,151). Finally, soluble or secreted trophoblast MHC products may aid in the development of maternal immune tolerance to the placenta (152).

Aberrant expression of class II MHC determinants, or enhanced expression of MHC class I on syncytiotrophoblast occurring in response to IFN- γ (153), could mediate abortion by enhancing cytotoxic T-cell attack (154). This theory appears unlikely, however, because

the expression of classical MHC antigens does not seem to be induced on aborted tissues from women experiencing one or more pregnancy losses (155). Finally, MHC class II genotypes appear to affect susceptibility to a variety of diseases, including diabetes and other autoimmune diseases. **A similar link between MHC class II typing and adverse pregnancy outcome has been reported for RPL (156).**

Regulation of Decidual Immune Cells

The characteristics of the interactions between decidual immune effector cells and the implanting fetus may be determined by factors other than those already mentioned. Local regulation of the cells that populate the human decidua will further modify the effects of selection, maintenance, and homing, as well as the distinctive characteristics of antigen presentation at the maternal–fetal interface. These regulatory effects are often targets of investigative efforts because they may offer more direct insight into potential therapies for immune-mediated disorders of pregnancy maintenance. **Three such regulatory mechanisms include (i) alterations in T-helper cell phenotypes, (ii) reproductive hormones and immunosuppression, and (iii) tryptophan metabolism.**

Antigen-stimulated immune responses involving CD4⁺ T cells can be divided into two major classes: T helper 1 (TH1) responses and T helper 2 (TH2) responses.

This subclassification may be overly simple, but it has been useful in broadly defining types of immune responses based on the characteristics of the CD4⁺ cells present, as well as their associated cytokines. The production of these responses rests on the environment in which relatively undifferentiated CD4⁺ TH0 cells become differentiated. Thus, TH0 cells exposed to IFN- γ become TH1-type cells, and those exposed to interleukin IL-1,-4 become TH2-type cells (157). Responses from TH1 cells are associated with inflammation and primarily involve interferon (IFN)- γ and IL-2, and tumor necrosis factor (TNF)- β . Responses from TH2 cells are associated with antibody production and the cytokines IL-10, IL-4, IL-5, and IL-6 (157,158,159). Although TNF- α can be secreted by both TH1 and TH2 cells, it is most often characteristic of a TH1 response (160,161). **A reciprocal regulating relationship exists between TH1 and TH2 cells and cytokines**

P.1294

(162,163,164), with one response supporting its own persistence while averting conversion to the other.

Extending these immune regulatory phenomena to pregnancy, the type of CD4⁺ cellular response to the implanting fetus is controlled not only by the types of cells (e.g., T helper cells) in the decidua, but also by the cytokine environment at the maternal–fetal interface. As mentioned previously, the human endometrium and decidua are replete with immune and inflammatory cells capable of cytokine secretion (165,166,167). Cytokines may affect reproductive events either directly or indirectly, depending on the specific cytokines secreted, their concentrations, and the differentiation stage of potential reproductive target tissues. It is now well documented that TH1-type cytokines can be harmful to an implanting embryo (168,169). **Furthermore, most agree that some patients with RPL exhibit a dysregulation of their T helper cellular immune response to antigens at the site of implantation, with typical shifts toward TH1 inflammatory responses (170,171).** Depending on the individual series, 60% to 80% of nonpregnant women with a history of otherwise unexplained recurrent spontaneous abortion have been found to have evidence of abnormal *in vitro* TH1 **cellular immune responses**. Fewer than 3% of women with normal reproductive histories demonstrate these responses (171,172). Rather, most women with normal pregnancies have a TH2 immune response to trophoblast antigens (171).

Methods for the documentation of cytokine dysregulation among patients with RPL also vary

among investigators; some groups have confirmed this abnormality within the endometrium (173,174,175) or among immune cells isolated from the decidua (176) of these patients. Others use peripheral blood lymphocytes (PBL) from women with a history of RPL and stimulate them *in vitro* with trophoblast antigens (171,177). One study documented aberrant cytokine secretion when PBL from patients with RPL were stimulated *in vitro* by HLA-G bearing cells (178), whereas another study demonstrated that decidual and peripheral immune cells exhibit a shift toward the TH2 phenotype when exposed to HLA-G (179). Whether peripheral cytokine levels reflect T-helper cell dysregulation at the maternal-fetal interface or whether this dysregulation affects peripheral as well as local immune response during pregnancy remains controversial (180,181). Finally, as with all immune theories, there seems to be significant redundancy in the need for particular cytokines and soluble immunoregulatory factors at the site of implantation. To date, animal models with directed gene deletions have shown few of these factors (e.g., leukemia inhibitory factor) to be absolutely essential to pregnancy maintenance (182,183).

Although many mechanisms are aimed at avoiding maternal immune recognition of the implanting fetus, research in both humans and animals indicates that immune responses to fetal antigens can be detected (184,185,186). Thus, the regulation of this response at the maternal-fetal interface may be critical. The concept that successful pregnancy requires some form of generalized suppression of maternal immune response is supported by reports that failure to downregulate maternal responses to recall antigens, such as tetanus toxoid and influenza, is associated with poor pregnancy outcome among patients with RPL (187). Regulatory T cells as well as reproductive hormones appear important in this respect. Reproductive hormones have dramatic effects on peripheral cell-mediated immunity, as demonstrated by well-documented and notable sex differences in immune responsiveness (188). The levels of these potentially immunosuppressive hormones are elevated in pregnant women. The fact that the levels of these hormones at the maternal-fetal interface may be far above those in the maternal circulation during pregnancy (189) may explain an apparent inconsistency: overall immune responsiveness during pregnancy appears to change little, whereas local suppression at the maternal-fetal interface may be vital.

It has been suggested that the immunosuppressive effects of progesterone within the reproductive tract are at least partially responsible for the maintenance of the

P.1295

semiallogeneic implanting fetus (190). *In vitro* studies have shown that progesterone mediates its suppression of T cell effector function by alterations in membrane-resident potassium channels and cell membrane depolarization. This action, in turn, affects intracellular calcium signaling cascades and gene expression (191), and it may be mediated by nonclassical steroid receptors (192) or may not involve a receptor at all (192,193). Progesterone-mediated changes in T cell gene expression have been associated with the development of TH2-type T helper cell responses and with increased leukemia inhibitory factor expression (176,194). Because a shift in the intrauterine immune environment from TH2 to TH1 has been linked with early spontaneous pregnancy loss (171,176), the elevated intrauterine concentrations of progesterone characteristic of early pregnancy may promote an immune environment favoring pregnancy maintenance. *In vitro* evidence indicates that progesterone can inhibit mitogen-induced proliferation of and cytokine secretion by CD8⁺ T cells (195) and can alter the expression of a transcription factor that drives the development of TH1 cells (196).

Levels of estrogen increase dramatically during pregnancy, and attention has focused on the role of estrogen in immune modulation. A group of animal studies has shown that estrogens improve immune responses in males after significant trauma and hemorrhage (197), suppress cell-mediated immunity after thermal injury (198), and protect against chronic renal allograft rejection (199). *In vitro*, estrogens appear to downregulate delayed-type

hypersensitivity (DTH) reactions and promote the development of TH2-type immune responses, particularly at the elevated estrogen concentrations typical of pregnancy (200,201).

One additional regulatory mechanism proposed for the induction of maternal tolerance to the fetal allograft involves the amino acid tryptophan and its catabolizing enzyme indoleamine 2,3 dioxygenase (IDO). The IDO hypothesis of tolerance in pregnancy rests on data that T cells need tryptophan for activation and proliferation (202), and that local alterations in tryptophan metabolism at the maternal–fetal interface could either activate or fail to suppress maternal antifetal immunoreactivity (203). Recent studies in mice have shown that the inhibition of IDO leads to loss of allogeneic, but not syngeneic fetuses, and that this effect is mediated by lymphocytes (204). Further support lies in studies demonstrating that hamsters fed diets high in tryptophan have increased rates of fetal wastage (205). Extending this theory to humans requires further investigation. The expression of IDO in human uterine decidua (206) and the alterations in serum tryptophan levels with increasing gestational age during human pregnancy (207) suggest a potential local immunoregulatory mechanism.

Although associations between the development of endometriosis and immunologic abnormalities are now being defined (208), the link between endometriosis and RPL is unclear. **The occurrence of RPL in the presence of endometriosis may involve cellular or humoral dysfunction** (209,210).

Humoral Immune Mechanisms

Pregnancy-specific antigens can elicit humoral responses, and patients with RPL can display altered humoral responses to endometrial and trophoblast antigens (Table 31.2) (171,211). Nevertheless, most literature surrounding humoral immune responses and RPL focus on organ-nonspecific autoantibodies associated with APAS. Historically, these IgG and IgM antibodies were thought to be directed against negatively charged phospholipids. Those phospholipids most often implicated in RPL are cardiolipin and phosphatidylserine. Most recently, however, it has been shown that antiphospholipid antibodies often are directed against a protein cofactor, called β 2 glycoprotein 1, that assists antibody association with the phospholipid (212,213). Antiphospholipid antibodies were originally characterized by prolongation of phospholipid-dependent coagulation tests *in vitro* (activated partial thromboplastin time [aPTT], Russell Viper Venum Time) and by thrombosis *in vivo*. The association of these antiphospholipid antibodies with thrombotic complications has been

P.1296

P.1297

termed the *antiphospholipid syndrome*, and although many of these complications are systemic, some are pregnancy specific—spontaneous abortion, stillbirth, intrauterine growth retardation, and preeclampsia (214). A reassessment of the criteria used to diagnose APAS resulted in the development of the Sapporo criteria, which include adverse pregnancy outcomes. These criteria, which have been validated clinically (215,216), are as follows:

Table 31.2 Concepts in Reproductive Immunology

Cellular immunity**1. Resident endometrial/decidual cells**

- a. Few B cells
- b. TCR α ; β ⁺ and TCR γ δ ⁺ cells are present, TCR γ δ ⁺ cells increase in early pregnancy
- c. NK-like, large granular lymphocytes (decidual NK cells) accumulate at sites of implantation
- d. NKT cells and "suppressor" macrophage
- e. T reg cells

2. Immune cell education and homing

- a. Thymic versus extrathymic education
- b. Possible in situ education and maintenance
- c. Integrins/vascular ligand pairs and mucosal homing

3. Antigen presentation

- a. MHC class II molecules are not expressed in the placenta
- b. Classical MHC class I molecules HLA-A and HLA-B are not expressed in the placenta
- c. Extravillous cytotrophoblast cells express HLA-C, HLA-E, and HLA-G

4. In situ immunoregulation

- a. Th1/Th2 cytokine microenvironments and dysregulation
- b. Hormonal immunomodulation
 1. Progesterone
 2. Estrogen
 3. Human chorionic gonadotropin (hCG)
 4. Prolactin
 5. Androgens
 6. Others
- c. Tryptophan metabolism and indoleamine 2,3 dioxygenase (IDO)
- d. Leukemia inhibiting factor (LIF)

Humoral immunity**1. Fetal antigens are recognized by the maternal immune system and humoral responses are mounted****2. Organ nonspecific autoantibodies**

- a. Anticardiolipin antibodies
- b. Lupus anticoagulant
- c. Anti- β glycoprotein 1 (anti- β G) antibodies
- d. Antiphosphatidylserine antibodies

3. Organ-specific autoantibodies

- a. Antithyroid antibodies
- b. Antisperm antibodies
- c. Antitrophoblast antibodies
 1. Blocking antibodies
 2. HLA sharing
 3. Trophoblast/lymphocyte cross-reactive antibodies (TLX)

NK, natural killer; NKT, natural killer T; MHC, major histocompatibility complex.

Laboratory Assessment

For a patient to be diagnosed with APAS, one or more clinical and one or more laboratory criteria must be present:

Clinical

- **One or more confirmed episode of vascular thrombosis of any type**
 - **Venous**
 - **Arterial**
 - **Small vessel**
- **Pregnancy complications**
 - **Three or more consecutive spontaneous pregnancy losses at less than 10 weeks of gestation**
 - **One or more fetal deaths at greater than 10 weeks of gestation**
 - **One or more preterm births at less than 34 weeks of gestation secondary to severe preeclampsia or placental insufficiency**

Laboratory

(Testing must be positive on two or more occasions, 6 weeks or more apart.)

- **Positive plasma levels of anticardiolipin antibodies of the IgG or IgM isotype at medium to high levels**
- **Positive plasma levels of lupus anticoagulant**

The presence of antiphospholipid antibodies (anticardiolipin or lupus anticoagulant) during pregnancy is a major risk factor for an adverse pregnancy outcome (217). In large series of couples with recurrent abortion, the incidence of the APAS was between 3% and 5% (95). The presence of anticardiolipin antibodies among patients with known systemic lupus erythematosus portends less favorable pregnancy outcome (218).

A number of mechanisms whereby antiphospholipid antibodies might mediate pregnancy loss have been proposed. Antibodies against phospholipids could increase thromboxane and decrease prostacyclin synthesis within placental vessels. The resultant prothrombotic environment could promote vascular constriction, platelet adhesion, and placental infarction (219,220,221). Alternatively, *in vitro* evidence from trophoblast cell lines indicates that IgM action against phosphatidylserine inhibits formation of syncytial trophoblast (222), which is required for proper placental function. One study demonstrated that

both extravillous cytotrophoblast and syncytiotrophoblast cells synthesize $\beta 2$ glycoprotein 1, the essential cofactor for antiphospholipid antibody binding (223). Although it gives insight into pathophysiology, the prognostic value of serum levels of specific antibodies against $\beta 2$ glycoprotein 1 with respect to pregnancy outcome among RPL patients is poorer than that of standard anticardiolipin antibodies (224,225). Some have proposed that sera from antibody-positive patients with RPL are particularly adept at inhibiting trophoblast adhesion to endothelial cells *in vitro* (226). Others have noted rapid development

P.1298

of atherosclerosis in the decidual spiral arteries of patients who test positive for antiphospholipid antibodies (227). Finally, still others have suggested that levels of the placental antithrombotic molecule—annexin V—are reduced within the placental villi from those women with RPL who test positive for antiphospholipid antibody (228). However, placental pathologic evidence supporting causal involvement of APAS in pregnancy loss often is equivocal. The lesions characteristic of this syndrome (placental infarction, abruption, and hemorrhage) often are missing in women with antiphospholipid antibodies (229), and these same lesions can be found in placentae from women with recurrent abortion who do not have biochemical evidence of antiphospholipid antibodies (230).

One additional group of autoantibodies that have been linked to RPL is the antithyroid antibodies (ATA). Although the overall significance of these antibodies is unclear (231,232), one large retrospective study showed an increased prevalence of these antibodies among women with a history of RPL, even in the absence of thyroid endocrinologic abnormalities (89). However, another study reported that the presence of serum ATA had no effect on pregnancy outcome in euthyroid pregnant patients with a history of RPL (87).

Other antibody-mediated mechanisms for recurrent abortion have been proposed, including antisperm and antitrophoblast antibodies, as well as blocking antibody deficiency. Although each hypothesis has been shown to have minimal relevance to RPL (95,154), their discussion is warranted because therapies aimed at these disorders persist. Historically, the blocking antibody deficiency hypothesis has received the most attention. This hypothesis is based on a supposition that blocking factors (presumably antibodies) were required to prevent a maternal, cell-mediated, antifetal immune response that was believed to occur in all pregnancies. It was therefore proposed that in the absence of these blocking antibodies, abortion occurred (233). This supposition has never been substantiated (234,235). For example, maternal hyporesponsiveness in mixed lymphocyte culture with paternal stimulator cells was originally proposed to identify women with deficient blocking activity (233). Investigations based on this type of testing were continued by others (236,237), who proposed that parental HLA sharing resulted in a predisposition to blocking antibody deficiency. These reports were limited by small sample size, retrospective nature, and lack of population-based controls. One prospective, population-based control study conclusively demonstrated that HLA heterogeneity was not essential for successful pregnancy (238). However, follow-up studies have now shown that, in the exceedingly rare case of complete sharing of the entire HLA region, spontaneous pregnancy losses do increase (239). This particular 10-year prospective trial concluded, however, that HLA typing is of no use in outbred populations because only isolated and significantly inbred populations have such HLA homogeneity. Further evidence refuting the blocking antibody hypothesis for recurrent abortion comes from reports of successful pregnancies both among women who do not produce serum factors capable of mixed lymphocyte culture inhibition (233) and among women who do not produce antipaternal cytotoxic antibodies (234). Those mixed lymphocyte culture results that demonstrate hyporesponsiveness in some patients with RPL are now believed to represent the effect of the pregnancy loss rather than the cause of recurrent abortion (186,233,234,235).

One final theory that arose out of the blocking antibody investigations involved a novel HLA-linked alloantigen system. The finding that polyclonal rabbit antisera could recognize both lymphocytes and trophoblast cells suggested the existence of trophoblast-lymphocyte crossreactive alloantigens (called TLX) (240). These TLX were, in turn, linked to maternal blocking antibody deficiency and RPL. The TLX hypothesis is now of historical relevance only. The theory was invalidated when TLX was found to be identical to CD46, a complement receptor that is thought to protect the placenta from complement-mediated attack (241). CD46 was not a novel alloantigen. It can be found on a wide variety of cells, thus explaining the cross-reactive nature of the original rabbit antisera.

P.1299

It is important to conclude this in-depth discussion of the immune-mediated mechanisms of isolated and recurrent pregnancy loss by suggesting that pregnancy may not require an intact maternal immune system at all. Supporting this concept are data showing that agammaglobulinemic animals and women can successfully reproduce (242). Furthermore, viable births also occur in women with severe immune deficiencies, and in murine models that lack T and B cells (severe combined immunodeficiency [SCID] mice), and in those that display a congenital absence of a thymus (nude mice). Immune factors may play important roles in a significant proportion of patients with recurrent pregnancy loss, however, and their presence is the subject of immense research to better define this role.

Other Factors

The implantation of the blastocyst within the uterine decidua represents an exquisitely scripted crosstalk between embryo and mother. Alterations in this dialogue often result in improper implantation and placental development. For instance, RPL has been linked to a dysregulation in the expression patterns of vascular endothelial growth factors (VEGF) on the developing placenta and their requisite receptors within the maternal decidua (243). Cellular and extracellular matrix adhesion properties may also be involved in this dialogue. The concept of uterine receptivity has been emboldened by the description of endometrial integrins and the timing of integrin switching during implantation (244). Others have reported decreased levels of endometrial mucin secretion (245) and reductions in the endometrial release of soluble intercellular adhesion molecule I (246) among women with histories of RPL. Programmed cell death (apoptosis) may also play an essential role in normal placental development. Alterations in two important apoptotic pathways—Fas-Fas ligand and bcl2—have been linked to RPL and poor pregnancy outcome (104,247).

A variety of environmental factors have been linked to sporadic and recurrent early spontaneous pregnancy loss. These are difficult studies to perform because, in humans, they must all be retrospective, and they are all confounded by alternative or additional environmental exposures. Nevertheless, the following factors have been linked to pregnancy loss: exposure to medications (e.g., antiprogestogens, antineoplastic agents, and inhalation anesthetics), exposure to ionizing radiation, prolonged exposure to organic solvents, and exposure to environmental toxins, especially heavy metals (248,249,250,251). Exposure to heavy metals has recently been shown to have both endocrine and immune effects that could lead to poor placentation and subsequent pregnancy loss (252). Associations between spontaneous pregnancy loss and exposures to video display terminals, microwave ovens, high-energy electric power lines, and high altitudes (e.g., flight attendants) have not been substantiated (253,254). There is no compelling evidence that moderate exercise during pregnancy is associated with spontaneous abortion. In the absence of cervical anatomic abnormalities or incompetent cervix, coitus does not appear to increase the risk of spontaneous pregnancy loss (255,256). **Exposure to three particular substances—alcohol, cigarettes, and caffeine—deserves specific attention.** Although some

conflicting data exist (257,258), one very large epidemiologic study has shown that **alcohol consumption during the first trimester of pregnancy, at levels as low as 3 drinks per week, is associated with an increased incidence of spontaneous pregnancy loss (259). Cigarette smoking has also been linked to early spontaneous pregnancy loss (260,261); however, this is also not without controversy (262). Alcohol and tobacco intake in the male partner correlates with the incidence of domestic violence, which in turn is associated with early pregnancy loss (263). Finally, a growing body of literature suggests that consumption of coffee and other caffeinated beverages during early pregnancy is related to adverse pregnancy outcome (261,264).** One highly publicized report casts doubt on the definition of a lower limit for safe use of caffeine in the first trimester of pregnancy (261). Obesity (265), stress (266), and use of nonsteroidal

P.1300

anti-inflammatory agents during early pregnancy (267,268) have all been linked to an increased rate of isolated spontaneous pregnancy loss.

Preconception Evaluation

Evaluation of recurrent spontaneous abortion should include obtaining a thorough history from both partners, performing a physical assessment of the woman (with attention to the pelvic examination), and a limited amount of laboratory testing (Table 31.3).

History

A description of all prior pregnancies and their sequence, as well as whether histologic assessment and karyotype determinations were performed on previously aborted tissues, is an important aspect of the history. **Approximately 60% of abortuses lost before 8 weeks of gestation have been reported to be chromosomally abnormal (269); most of these pregnancies are affected by some type of trisomy, particularly trisomy 16 (270). The most common single chromosomal abnormality is monosomy X (45X), especially among anembryonic conceptuses (271).** Aneuploidy may be detected less often in miscarriage specimens when the couple experiencing recurrent abortions is euploidic. Alternatively, some investigators have suggested that because aneuploidy is common among miscarriage specimens from patients experiencing both isolated and recurrent spontaneous pregnancy losses, the documentation of aneuploidy in tissues from patients with RPL does not affect their prognosis for future pregnancy maintenance (9).

Most women with RPL tend to experience spontaneous abortion at approximately the same gestational age in sequential pregnancies. Unfortunately, the gestational age when pregnancy loss occurs, as determined by last menstrual period, may not be informative because there is often a 2- to 3-week delay between fetal demise and signs of pregnancy expulsion (272). The designation of couples into primary or secondary categories also is not helpful for either the diagnosis or management in most cases. Approximately 10% to 15% of couples cannot be classified into either primary or secondary categories, because although their first pregnancy resulted in a loss, it was followed by a term delivery before subsequent losses.

It is important to elicit any history of subfertility or infertility among couples with RPL. This condition is defined by the inability to conceive after 12 months of unprotected intercourse. By definition, 15% of all couples will meet this criteria; this number increases to 33% among couples with RPL. Because many pregnancies are lost before or near the time of missed menses, subfertility among patients with RPL may, in some cases, reflect recurrent preclinical losses. Menstrual cycle history may provide

information about the possibility of oligo-ovulation or other relevant endocrine abnormalities in patients with RPL. An assessment of the timing of intercourse relative to ovulation should be reviewed with couples in an effort to detect dyssynchronous fertilization that could contribute to pregnancy loss (273). A personal and family history of thrombotic events or renal abnormalities may provide vital information. A family history of pregnancy losses and obstetric complications should be discussed specifically. Detailed information about drug and environmental exposure should also be obtained.

Physical Examination

A general physical examination should be performed to detect signs of metabolic illness, including PCOS, diabetes, hyperandrogenism, and thyroid or prolactin disorders. During the pelvic examination, signs of infection, DES exposure, and previous

P.1301

P.1302

trauma should be ascertained. Estrogenization of mucosal tissues, cervical and vaginal anatomy, and the size and shape of the uterus should also be determined.

Table 31.3 Investigative Measures Useful in the Evaluation of Recurrent Early Pregnancy Loss

History
1. Pattern, trimester, and characteristics of prior pregnancy losses
2. History of subfertility or infertility
3. Menstrual history
4. Prior or current gynecologic or obstetric infections
5. Signs or symptoms of thyroid, prolactin, glucose tolerance and hyperandrogenic disorders (including PCOS)
6. Personal or familial thrombotic history
7. Features associated with the antiphospholipid syndrome (thrombosis, false positive test for syphilis)
8. Other autoimmune disorders
9. Medications
10. Environmental exposures, illicit and common drug use (particularly caffeine, alcohol, cigarettes, and in utero DES exposure)
11. Genetic relationship between reproductive partners
12. Family history of recurrent spontaneous abortion, obstetric complications, or any syndrome associated with embryonic or fetal losses
13. Previous diagnostic tests and treatments
Physical Examination
General physical examination with particular attention to:
1. Obesity
2. Hirsutism/acanthosis
3. Thyroid examination
4. Breast examination/galactorrhea
5. Pelvic examination

a. Anatomy
b. Infection
c. Trauma
d. Estrogenization
e. Masculinization
Laboratory
1. Parental peripheral blood karyotype
2. Hysterosalpingography or office hysteroscopy, followed by hysteroscopy/laparoscopy, if indicated
3. Thyroid-stimulating hormone level, serum prolactin level if indicated
4. Anticardiolipin antibody level
5. Lupus anticoagulant (activated partial thromboplastin time or Russell Viper Venom)
6. Complete blood count with platelets
7. Factor V Leiden, G20210A prothrombin gene mutation, protein S activity, homocysteine level, activated protein C resistance
8. Protein C activity, antithrombin level if personal or family history of VTE
PCOS, polycystic ovarian syndrome; DES, diethylstilbestrol; VTE, venous thromboembolism.

Laboratory Assessment

Valuable Tests

Laboratory assessment of couples with RPL should include the following tests:

- **Parental peripheral blood karyotyping with banding techniques**
- **Assessment of the intrauterine cavity with either office hysteroscopy, sonohysterography or hysterosalpingography, followed by operative hysteroscopy if a potentially correctable anomaly is found**
- **Thyroid function testing, including serum thyroid-stimulating hormone levels**
- **Anticardiolipin antibody and lupus anticoagulant testing (aPTT or Russell Viper Venom testing)**
- **Thrombophilia testing:**
- **Factor V Leiden, G20210A prothrombin gene mutation, protein S activity**
- **Serum homocysteine levels**
- **In the presence of a family or personal history of VTE, protein C and antithrombin activity**

- **Possible alterations based on ethnic background: Factor V Leiden and prothrombin are rare in African and Asian populations; Protein C and S are the most common inherited thrombophilias in Chinese populations**
- **Platelet levels**

Tests with Unproven Utility

A number of laboratory assessments are being evaluated for use in patients with a history of RPL. At present, results are either too preliminary to warrant recommendation or the results of studies have been too contradictory to allow final determination of their value. **Tests with unproven or unknown utility include:**

- **Evaluation of ovarian reserve using day 3 serum follicle-stimulating hormone levels or the clomiphene challenge test is of limited value because decreased ovarian reserve may portend poor outcome in all patients, including those with RPL (274,275).**
- **Testing for serologic evidence of PCOS using luteinizing hormone or androgen values may be useful (77,78,79,80,276).**
- **Testing for peripheral evidence of TH1/TH2 cytokine dysregulation may be of value.** Although large studies have failed to demonstrate an association between peripheral cytokine alterations and pregnancy outcome among patients with RPL (180), smaller studies have reported peripheral shifts toward TH1 profiles only in those patients with RPL who subsequently lose their pregnancy (181). One study documented a shift toward TH1 profiles at the time of fetal demise in these patients; however, it is difficult to determine a cause-and-effect relationship (277).

- **Preconceptional testing for the prevalence and activity of peripheral NK cells has been reported in small studies to help determine the prognosis and to assist with patient counseling (278,279).** Still, peripheral NK cells may not adequately represent those at the site of implantation, and this testing remains unproven.
- **Testing for antithyroid antibodies, even among women with RPL who are euthyroid, remains controversial.** Although some have shown no association between the presence of antithyroid antibodies and recurrent loss (231), others have demonstrated an increased prevalence among patients with a history of RPL (89,232). However, even if the prevalence of antithyroid antibodies is increased among these patients, the significance of their presence is questionable (87).
- **Testing for the presence of a variety of autoantibodies (other than lupus anticoagulant and anticardiolipin antibody) has been hotly debated without consensus (280,281).** Testing for some antiphospholipid antibodies, such as antiphosphatidylserine and anti- β 2 glycoprotein 1 (anti- β 2g), is compelling because their

presence has been connected to placental pathology (222,223,224,225). One recent, large series has shown anti- β 2g to be associated with risk for RPL (282). In patients with known autoimmune diseases and RPL, additional antiphospholipid testing may be warranted (283).

- **Cervical cultures for mycoplasma, ureaplasma, and chlamydia may be considered.**

- **The Noyes criteria has low interobserver reproducibility and accuracy and thus cannot reliably be used to diagnose a luteal phase defect on timed endometrial biopsy (284).** This tool lacks precision and does not alter clinical management (285).

The following investigations have no place in the care of patients with recurrent spontaneous pregnancy loss:

- Evaluations that involve extensive testing for serum or site-specific auto- or alloantibodies (including antinuclear antibodies and antipaternal cytotoxic antibodies) are both expensive and unproven. Their use often serves only to verify the statistical tenet that if the number of tests performed reaches a critical limit, the results of at least one will be positive in every patient.

- Testing for parental HLA profiles is never indicated in outbred populations. The association of HLA sharing with poor pregnancy outcomes is applicable only to those populations that have very high and sustained levels of marriage within a limited community (239).

- Use of mixed lymphocyte cultures has not proven useful. Use of other immunologic tests also is unnecessary unless these studies are performed, with informed consent, under a specific study protocol in which the costs of these experimental tests are not borne by the couple or their third-party payers.

- Suppressor cell factor determinations; cytokine, oncogene, and growth factor measurements; and embryotoxic factor assessment are not clinically justified.

Postconception Evaluation

Following conception, patients with histories of RPL should be monitored closely to provide psychological support and to confirm intrauterine pregnancy and its viability.

P.1304

The incidence of ectopic pregnancy (286,287) and complete molar gestation (287,288) is increased in women with a history of recurrent spontaneous pregnancy loss.

Although somewhat controversial (289), some data suggest that the risk of pregnancy complications other than spontaneous abortion are not significantly different between women with and those without a history of recurrent losses (89,290). Two exceptions to this observation are women who have antiphospholipid antibodies and those who have an intrauterine infection.

Determining serum levels of β -human chorionic gonadotropin (hCG) may be helpful in monitoring early pregnancy until an ultrasonographic examination can be performed; however, inadequate β -hCG levels do not always occur in pregnancies that ultimately abort (291). Other hormonal determinations are rarely of benefit because levels are often normal until fetal death or abortion occurs (292). The best method for monitoring

in early pregnancy is ultrasonography.

Serial ultrasonography and a variety of hormonal and biochemical measurements during early pregnancy have prognostic value in women with histories of recurrent losses (293). If used, **serum β -hCG levels should be monitored serially from the time of a missed menstrual period until the level is approximately 1,200 to 1,500 mIU/mL, at which time an ultrasonographic scan is performed and blood sampling is discontinued.** Ultrasonographic assessment may then be performed every 2 weeks until the gestational age at which previous pregnancies were aborted. If pregnancy has been confirmed but fetal cardiac activity cannot be documented by approximately 6 to 7 weeks of gestation (by sure menstrual or ultrasonographic dating), intervention is recommended to expedite pregnancy termination and to obtain tissue for karyotype analysis. Nuchal lucency measurement (11–12 weeks) and/or maternal serum analysis (with nuchal lucency and/or at 15–18 weeks) may be used for prenatal assessment. Amniocentesis may be recommended to assess the fetal karyotype after the pregnancy has progressed past the time of prior losses.

The importance of obtaining karyotypic analysis from tissues obtained after pregnancy demise in a woman experiencing recurrent losses cannot be overemphasized. Results may suggest karyotypic anomalies in the parents. The documentation of aneuploidy may have important prognostic implications and may direct future interventions. Karyotypic analysis is financially prudent among patients with histories of RPL (294). Obtaining karyotypic data from aborted specimens is complicated by difficulties in culturing cells from tissues that may have significant inflammation or necrosis and contamination of specimens with maternal cells. Efforts to develop methods that avoid such difficulties include the application of comparative genomic hybridization technology to RPL (295). This technology has even been used successfully with archived and paraffin-embedded pregnancy tissues (296). In the future, fetal karyotype assessment may also be performed using DNA isolated from nucleated fetal erythrocytes in maternal blood (297).

Therapy

Advances in the treatment of patients with RPL have been regrettably slow. Although there has been a rapid expansion in knowledge of the molecular and subcellular mechanisms involved in implantation and early pregnancy maintenance, extension of these concepts to prevention of RPL has lagged. In addition to these limitations, progress toward treatment of most causes of RPL has been hampered by a variety of factors. The condition itself has not been defined consistently. **The results of clinical trials involving patients with RPL patients are, therefore, often nearly impossible to compare and evaluate.** Trial design is frequently substandard, with lack of rationale, lack of appropriate controls, and poor statistical analysis limiting the ability to draw rational conclusions from reported results. Finally, epidemiologic data indicate that most patients with a history of RPL will,

P.1305

in fact, have a successful pregnancy the next time they conceive (5). For these reasons, with few exceptions, most therapies for RPL must be considered experimental. Until further study is completed, treatment protocols involving these therapies should be undertaken only with informed consent and in the setting of a well-designed, double-blinded, placebo-controlled clinical trial.

Common therapeutic options that currently exist for patients with RPL include the use of donor oocytes or sperm, the use of preimplantation genetic diagnosis, the use of antithrombotic interventions, the repair of anatomic anomalies, the correction of any endocrine abnormalities, the treatment of infections, and a variety of

immunologic interventions and drug treatments. Psychological counseling and support is recommended for all patients.

Genetic Abnormalities

No therapies are presently available to treat those parental chromosomal anomalies that potentially contribute to recurrent abortion. Three alternative approaches exist when genetic factors are linked to RPL. Some approaches, **such as antithrombotic therapy** for patients with inherited thrombophilias, are directed to the effects of the genetic abnormality. Other techniques, such as **preimplantation genetic diagnosis**, attempt to identify those particular embryos that are affected by chromosomal disorders and select against them. **Recent evidence suggests that in women with a history of three or more spontaneous pregnancy losses, a subsequent pregnancy loss has a 58% risk of chromosomal abnormality (298). If the incidence of chromosomal abnormalities among the conceptuses of patients with RPL is this high, it could be argued that the use of assisted reproductive technologies, including preimplantation genetic diagnosis, might be indicated for all patients with unexplained RPL.**

Preimplantation genetic diagnosis involves the removal of a single cell from an *in vitro*-matured embryo. Genetic testing can be performed on this cell to rule out gross chromosomal abnormalities or the presence of specific genetic diseases (e.g., cystic fibrosis). Embryos that are diagnosed with genetic abnormalities are not replaced into the uterine cavity. Those demonstrated to be genetically normal would be considered appropriate for transfer into the uterus. Use of preimplantation genetic diagnosis, therefore, has the potential to dramatically reduce the incidence of pregnancy loss arising from a genetic cause. Use of preimplantation genetic diagnosis in patients with known heritable genetic disorders (e.g., cystic fibrosis, X-linked disorders) is presently in widespread use. Women with a history of RPL have a higher incidence of aneuploid embryos than those without a history of losses (298,299). For this reason, RPL has recently been considered as a reasonable indication for the use of *in vitro* fertilization with preimplantation genetic diagnosis. The efficacy of this technique in the treatment of patients with RPL continues to be investigated (300,301).

The third approach to patients with genetic factors and RPL is particularly relevant to those with Robertsonian translocations involving homologous chromosomes. In these patients, their genetic anomaly always results in embryonic aneuploidy. Therefore, **use of either donor oocyte or donor sperm, depending on the affected partner, is recommended.** Use of donor gametes among patients with a history of RPL has been shown to be as effective as its use in matched patients without such a history (302). Synchronization of intercourse with ovulation may benefit some patients with genetic factor RPL (273). In all cases, genetic counseling is warranted.

Anatomic Anomalies

Hysteroscopic resection represents state-of-the-art therapy for submucous leiomyomas, intrauterine adhesions, and intrauterine septa. This approach appears to limit

postoperative sequelae while maintaining efficacy in terms of reproductive outcome (67,69). Use may even be safely extended to patients with DES exposure, hypoplastic uteri, and complicating septal anomalies (67,69,303). Attempts to improve on standard hysteroscopic metroplasty, which typically is performed in the operating room using general anesthesia, often with laparoscopic guidance, are presently under investigation. Ultrasonographically guided transcervical metroplasty has been reported to be safe and effective (304). Ambulatory, office-based procedures (305), including septum

resection under fluoroscopic guidance (306), also are options.

For patients with a history of loss secondary to cervical incompetence, placement of a cervical cerclage is indicated. This procedure usually is performed early in the second trimester after documentation of fetal viability. Cervical cerclage should be considered as a primary intervention for women with DES-associated uterine anomalies. If endometriosis is encountered during a diagnostic evaluation, it should be resected laparoscopically.

Endocrine Abnormalities

Some investigators have proposed the use of ovulation induction for the treatment of RPL based on the hypothesis that ovulation induction is associated with healthier oocytes (307,308). Healthier oocytes, in turn, may decrease the incidence of luteal phase insufficiency, which should result in improved pregnancy maintenance. This approach grossly oversimplifies the mechanisms involved in implantation and early pregnancy maintenance. Empiric use of empiric ovulation induction for treatment of unexplained RPL should be viewed with caution because recent evidence from small studies indicates such use is not effective (308). In some subsets of patients with RPL, use of ovulation induction could be of benefit. For instance, stimulating folliculogenesis with ovulation induction or luteal phase support with progesterone should be considered for women with luteal phase insufficiency. The efficacy of these therapies, however, has never been substantiated (309). Ovulation induction might also be beneficial for women with hyperandrogen and LH hypersecretion disorders, especially following pituitary desensitization with gonadotropin-releasing hormone agonist therapy (95). This treatment also remains controversial; according to findings from the only large, prospective, randomized controlled trial to date, neither prepregnancy pituitary suppression nor luteal phase progesterone supplementation has therapeutic efficacy (310).

Based on the association between PCOS, hyperandrogenism, hyperinsulinemia, and RPL (77,78,79,80), there has been increasing support for the use of insulin-sensitizing agents in the treatment of RPL that occurs in the presence of PCOS (311,312). Prepregnancy glycemic control may be particularly important for women with overt diabetes mellitus (81,82). Thyroid hormone replacement with *Synthroid* may be helpful in cases of hypothyroidism. There is no place in the medical management of recurrent abortion for either thyroid medication or *bromocriptine* for women who do not have a thyroid or prolactin disorder.

Infections

Empiric antibiotic treatment has been used for couples with recurrent abortion, despite its unproven efficacy. **Elaborate testing for infectious factors and use of therapeutic interventions is not justified unless a patient is immunocompromised or a specific infection has been documented** (96). For cases in which an infectious organism has been identified, appropriate antibiotics should be administered to both partners, followed by posttreatment cultures to verify eradication of the infectious agent before attempting conception.

P.1307

Immunologic Factors

Immune-mediated RPL has received more attention than any other single etiologic classification. Nevertheless, techniques for diagnosis and treatment of most cases remains unclear (154,313,314,315). **Most therapies for proposed immune-related RPL must be considered experimental.** As stated earlier, it is known that the developing conceptus

contains paternally inherited gene products and tissue-specific differentiation antigens and that maternal recognition of these antigens occurs (184,185,186). Historically, it has been speculated that both inappropriately weak immune responses to these antigens and unusually strong responses could result in early pregnancy loss. As a consequence, both immunostimulating and immunosuppressive therapies have been proposed.

Immunostimulating Therapies: Leukocyte Immunization

Stimulation of the maternal immune system using alloantigens on either paternal or pooled donor leukocytes has been promoted for patients with immune RPL, and a number of reports support possible mechanisms for potential therapeutic value (316,317,318,319). Both individual clinical trials and meta-analyses, however, report conflicting results concerning the efficacy of leukocyte alloimmunization in patients with RPL (320,321,322,323,324,325). This lack of consensus most certainly reflects the remarkable heterogeneity in study design, patient selection, and therapeutic protocols, as well as the typically small numbers of enrolled subjects in these investigations. One published analysis reports that approximately 11 women with unexplained recurrent abortion would need to be immunized with alloantigenic lymphocytes before one additional live birth was achieved (322). Approximately 92% of successful pregnancy outcomes in this study were not attributable to leukocyte immunization. Whether the 8% successful pregnancy rate achieved in leukocyte-immunized women is clinically relevant remains uncertain. **One of the largest trials evaluating the efficacy of leukocyte immunization in patients with unexplained RPL is a part of the *Recurrent Miscarriage (REMIS)* study (324). This large (more than 90 patients per treatment arm), prospective, placebo-controlled, randomized, double-blinded investigation showed no efficacy for paternal leukocyte immunization in couples with unexplained RPL. A Cochrane review of 19 well-designed trials of immunotherapy for RPL found no evidence that paternal or allogeneic leukocyte immunization altered pregnancy outcome in women with otherwise unexplained RPL (326). Leukocyte immunization also poses significant risk to both the mother and her fetus (296,297). Several cases of graft-versus-host disease, severe intrauterine growth retardation, and autoimmune and isoimmune complications have been reported (321,322,327,328,329,330). In addition, alloimmunization to platelets contained in the paternal leukocyte preparation has been associated with cases of potentially fatal fetal thrombocytopenia. **The routine use of this therapy for recurrent abortion (that, at best, will only be efficacious in one of 11 women treated) cannot be clinically justified at present. The procedure should be performed only as part of an appropriately controlled trial using informed consent.** Other immunostimulating therapies have been proposed and abandoned. Intravenous preparations consisting of syncytiotrophoblast microvillus plasma membrane vesicles have been used to mimic the fetal cell contact with maternal blood that normally occurs in pregnancy (331). The efficacy of this therapy has not been established (326,331). The use of third-party seminal plasma suppositories has also been attempted (332), based on the misconception that TLX was part of an idio-anti-idiotypic control system (333). Third-party seminal plasma suppositories for recurrent abortion have no scientifically credible rationale and should not be used.**

Immunosuppressive Therapies

Immunosuppressive and other immunoregulating therapies have been advocated for cases in which abortion was believed to be due to antiphospholipid antibodies or to inappropriate cellular immunity toward the implanting fetus. Again, study design problems, including small numbers of recruited patients, lack of prestratification by maternal age and number of prior losses before randomization, and other methodologic and statistical inaccuracies,

preclude definitive statements regarding therapeutic efficacy for most of the proposed immunosuppressive approaches.

Intravenous Immunoglobulin

Intravenous immunoglobulins (IVIg) are composed of pooled samples of immunoglobulins harvested from a large number of blood donors. Studies on the use of IVIg therapy in the treatment of RPL are based on the theory that some patients have an overzealous immune reactivity to their implanting fetus. Although IVIGs do have immunosuppressive effects, the mechanisms underlying this immune modulation are only partially understood. These mechanisms may include decreased autoantibody production and increased autoantibody clearance, T cell and Fc receptor regulation (334), complement inactivation (335), enhanced T cell suppressor function, decreased T-cell adhesion to the extracellular matrix (336), and downregulation of TH1 cytokine synthesis (337). **Based on a large number of relatively small studies using a variety of treatment protocols, there remains no conclusive evidence to suggest that use of IVIg in the treatment of patients with unexplained (and presumed immunologic) RPL has any benefit** (338,339,340,341,342). **The Cochrane review of immune therapy for RPL also addressed IVIg therapy and reported that its use did not alter pregnancy outcomes in patients with otherwise unexplained RPL** (326). Improved posttreatment pregnancy rates may be seen when IVIg is used in those specific patients with autoimmune-mediated pregnancy loss associated with APAS (343,344). Therapy with IVIGs for RPL is expensive, invasive, and time-consuming, requiring multiple intravenous infusions over the course of pregnancy. Side effects of IVIg therapy include nausea, headache, myalgias, and hypotension. More serious adverse effects include anaphylaxis (particularly in patients with IgA deficiency) (345).

Progesterone

As mentioned earlier, progesterone also has known immunosuppressive effects (188,189,190,191,195,196). **A number of studies using *in vitro* cellular systems relevant to the maternal-fetal interface have now shown that progesterone either inhibits TH1 immunity or causes a shift from TH1 to TH2-type responses** (176,194,195,196,346,347). Progesterone has been administered both intramuscularly and intravaginally for the treatment of RPL. It is thought that vaginal administration may increase local, intrauterine concentrations of progesterone better than systemic administration. Vaginal formulations may, therefore, provide a better method of attaining local immunosuppressive levels of progesterone while averting any adverse systemic side effects. **Although both vaginal and intramuscular progesterone therapy are associated with few minor side effects, their efficacy in the treatment of either unexplained RPL or RPL associated with TH cell dysregulation has never been investigated appropriately.**

Other immunoregulating therapies theoretically useful in treating RPL include the use of cyclosporine, pentoxifylline, and nifedipine, although maternal and fetal risks with these agents preclude their clinical use. Plasmapheresis has also been used to treat women with recurrent abortion and antiphospholipid antibodies (348). Generalized immunosuppression with corticosteroids, such as prednisone, has been advocated during pregnancy for women with recurrent losses and chronic intervillitis (349) and APAS. Although corticosteroids have shown some promise in these patients (349,350), maternal and fetal side effects and the availability of alternative therapies have limited their use. **The efficacy and side effects**

of prednisone plus low-dose *aspirin* was examined in a recent, large, randomized, placebo-controlled trial treating patients with autoantibodies and RPLs. Pregnancy outcomes for treated and control patients were similar; however, the incidence of maternal diabetes and hypertension and the risk of premature delivery were all increased among those treated with prednisone and *aspirin* (351).

Antithrombotic Therapy

Therapy for patients with RPLs associated with either APAS or other thrombophilic disorders has focused on the use of antithrombotic medications.

Unlike immunosuppressive treatments, this approach mainly treats the effect (hypercoagulability) but not the underlying cause (e.g., genetic, APAS) of RPL. However, there are reports that *heparin*, a typical anticoagulant, may exert direct immunomodulatory effects by binding to antiphospholipid antibodies (352) and may decrease movement of inflammatory cells

P.1309

to sites of alloantigen exposure (353). **The combined use of low-dose *aspirin* (75–80 mg/day) and subcutaneous unfractionated *heparin* (5,000–10,000 units twice daily) during pregnancy has been best studied among women with APAS and appears to be efficacious** (354,355,356). A typical regimen for women with antiphospholipid antibody syndrome would include use of *aspirin* (80 mg every day) beginning with any attempts to conceive. After pregnancy has been confirmed, 10,000 IU unfractionated *sodium heparin* is administered subcutaneously twice daily, throughout gestation. An aPTT should be obtained weekly, and dosages of *heparin* should be adjusted until anticoagulation is achieved. Patients using this therapy should be treated in conjunction with a perinatologist because of their increased risks of preterm labor, premature rupture of the membranes, intrauterine growth restriction, intrauterine fetal demise, and preeclampsia. Other potential risks include gastric bleeding, osteopenia, and abruptio placenta.

The effectiveness of antithrombotic therapy in the treatment of patients with APAS and RPL has led to efforts to expand treatment in new directions. These directions include the use of *low-molecular weight heparin (LMWH)*, the use of antithrombotic therapy in patients with thrombophilia and RPL who do not have APAS, and even the use of such therapy among patients with RPL who do not have thrombophilia (unexplained recurrent losses).

Low-molecular weight heparin is superior to unfractionated heparin in the treatment of many clotting disorders (357,358). *Low-molecular weight heparin* has the advantage of an increased antithrombotic ratio when compared with unfractionated *heparin*. This characteristic results in improved treatment of inappropriate clotting but fewer bleeding side effects. In addition, LMWH has been associated with a decreased incidence of thrombocytopenia and osteoporosis when compared with its unfractionated counterpart. Finally, LMWH has a long half-life and requires less frequent dosing and monitoring, thereby improving patient compliance. **Although its safe use in pregnancy is still being evaluated, LMWH has shown promise when combined with low-dose *aspirin* in the treatment of RPL associated with APAS** (355). One study comparing the use of unfractionated *heparin* and *aspirin* to LMWH and *aspirin* in the treatment of women with APAS and adverse pregnancy outcomes showed the therapies had similar effects (359). Efficacy has also been suggested for similar treatment of RPL associated with other thrombophilias, including activated protein C resistance associated with factor V Leiden, mutations in the promoter region of the prothrombin gene, and decreases in protein C and protein S activities (359,360,361,362,363). The use of LMWH for this indication appears to have an excellent safety profile for mother and fetus (364,365).

The prophylactic use of daily low-dose *aspirin* has become common practice based on its

perceived cardiovascular effects combined with its low incidence of side effects. Its sole use in the treatment of RPL has likewise gained momentum, and many patients with histories of recurrent loss will either self-prescribe this therapy or will inquire about its usefulness. At present, there are no good data supporting its use either in patients with heritable thrombophilias or in the general RPL population. In fact, although studies are small, **the use of low-dose aspirin alone has not been shown to be effective in the treatment of RPL associated with APAS** (366,367). In these patients, it should be used in combination with unfractionated or low-molecular-weight *heparin*. One large study evaluating the therapeutic efficacy of empiric use of low-dose *aspirin* among 805 patients with unexplained RPL concluded that such therapy cannot be justified in patients with early losses but may benefit patients with second trimester losses (367).

Reports of an increased incidence of isolated spontaneous pregnancy loss with the use of aspirin in early pregnancy have raised questions about this practice (368,369). These reports are poorly designed and do not adequately address the level of exposure (81 mg versus 325 mg). At this time, **aside from use in combination with heparin for patients with RPL and APAS, and in patients with late losses, aspirin should be avoided during early pregnancy.**

P.1310

More directed antithrombotic therapies have also been described for the treatment of RPL among patients with thrombophilias. For instance, the use of protein C concentrates has been associated with favorable pregnancy outcome in a patient with a history of thrombosis, recurrent fetal losses, and protein C deficiency (370).

As mentioned previously, vitamins B₆, B₁₂, and folate are important in homocysteine metabolism (15,18), and hyperhomocysteinemia is linked to RPL (17,25,62). Women with RPL and isolated fasting hyperhomocysteinemia should be offered supplemental folic acid (0.4–1.0 mg/day), vitamin B₆ (6 mg/day), and possibly vitamin B₁₂ (0.025 mg/day) (371,372,373,374). Fasting homocysteine levels should be retested after treatment. If levels are normalized or remain only marginally elevated, no further therapy is necessary. Homocysteine levels will predictably decrease during pregnancy.

Treatment of women with RPL and an identified inherited or acquired thrombophilia should be based on their history:

- **If venous thromboembolism occurs during the index pregnancy, posthospitalization management requires therapeutic anticoagulation:**
 - Unfractionated heparin: 10,000 to 15,000 U subcutaneously every 8 to 12 hours (monitor to keep aPTT 1.5–2.5 times normal), or
 - LMWH: *enoxaparin* 40 to 80 mg subcutaneously twice daily or *dalteparin* 5,000 to 10,000 U subcutaneously twice daily. Consider monitoring trough factor Xa levels in the third trimester.
- **If there is a personal history of venous thromboembolism (particularly in previous pregnancy or with hormonal contraceptive use) or a strong thrombophilic family history, treat with therapeutic anticoagulation.**
- **If combined thrombophilic defects are detected, treat with therapeutic anticoagulation.**
-

If an isolated thrombophilic defect is detected and there is no personal or strong family history of thrombotic complications, consider prophylactic anticoagulation:

- **—Unfractionated *heparin*: 5,000 U subcutaneously twice daily (first trimester), 7,500 U subcutaneously twice daily (second trimester), and 10,000 U subcutaneously (third trimester)**
- **—LMWH: *enoxaparin* 40 mg subcutaneously daily or *dalteparin* 5,000 U subcutaneously daily**
- **Consider prophylactic anticoagulation in women with RPL and hyperhomocysteinemia refractory to dietary intervention. Therapy should be initiated with documentation of pregnancy. There are no data suggesting initiation preconceptionally improves outcomes.**

Thrombotic risk is greatest during the postpartum period. Anticoagulation should be reinitiated after delivery in doses reflecting predelivery treatment regimens. Postpartum anticoagulation should be continued for 6 to 12 weeks postpartum. Women may continue injectable therapy or transition to oral anticoagulants (e.g., *coumarin*). Use of *heparin* or of *coumarin* derivatives does not prohibit breastfeeding.

Psychological Support

Experiencing isolated or recurrent losses can be emotionally devastating. The risk of major depression is increased greater than twofold among women with spontaneous pregnancy loss; in most women it arises in the first weeks following delivery (375). A caring and empathetic attitude is prerequisite to all healing. The acknowledgment of the pain and suffering couples have experienced as a result of recurrent abortion can be

P.1311

a cathartic catalyst enabling them to incorporate their experience of loss into their lives rather than their lives into their experience of loss (95). **Referrals to support groups and counselors should be offered.** Self-help measures, such as meditation, yoga, exercise, and biofeedback may also be useful.

Prognosis

The prognosis for successful pregnancy depends both on the potential underlying cause of pregnancy loss and (epidemiologically) on the number of prior losses (Table 31.4). As previously discussed, epidemiologic surveys indicate that the chance of a viable birth even after four prior losses may be as high as 60%. Depending on the study, **the prognosis for successful pregnancy in couples with a cytogenetic basis for reproductive loss varies from 20% to 80%** (376,377,378). **Women with corrected anatomical anomalies may expect a successful pregnancy in 60% to 90% of cases** (376,377,379,380). **A success rate higher than 90% has been reported for women with corrected endocrinologic abnormalities** (376). **Between 70% and 90% of pregnancies reported among women receiving therapy for antiphospholipid antibodies have been viable** (381,382).

Many forms of pre- or postconceptional tests have been proposed to help

predict pregnancy outcome (172,187,279,383,384); none has been fully substantiated in large, prospective trials. The documentation of fetal cardiac activity with ultrasonography may offer prognostic value; however, it appears that predictions may be greatly affected by any underlying diagnosis. In one study, the live birth rate following documentation of fetal cardiac activity between 5 and 6 weeks from the last menstrual period was approximately 77% in women with two or more unexplained spontaneous abortions

P.1312

(385). It may be important to note that most of the patients in this study had evidence of inappropriate antitrophoblast cellular immunity. Others have shown that 86% of patients with antiphospholipid antibodies and RLP had fetal cardiac activity detected before subsequent demise (386). Most recently, however, **a prospective, longitudinal, observational study of 325 patients with unexplained RLP showed that only 3% of 55 miscarriages occurred following the detection of fetal cardiac activity using transvaginal ultrasonography (387).**

Table 31.4 Prognosis for a Viable Birth

Following:	
One spontaneous loss	76%
Two spontaneous losses	70%
Three spontaneous losses	65%
Four spontaneous losses	60%
With:	
Genetic factors	20%–80%
Anatomic factors	60%–90%
Endocrine factors	>90%
Infectious factors	70%–90%
Antiphospholipid antibodies	70%–90%
Th1 cellular immunity	70%–87%
Unknown factors	40%–90%
Following detection of fetal cardiac activity:	
Unexplained RPL	77%–97%
APAS and RPL	Much lower

RPL, recurrent pregnancy loss; APAS, antiphospholipid antibody syndrome.

Menopause

Jan L. Shifren

Isaac Schiff

- **Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women but may continue for 10 years or longer in some others.**
- **Topical vaginal application of low doses of estrogen is an effective and safe treatment of vaginal dryness, dyspareunia, and some urinary symptoms.**
- **Counseling women to alter modifiable risk factors is important for both the prevention and treatment of osteoporosis. Many women have diets deficient in calcium and vitamin D and will benefit from dietary changes and supplementation. Women should receive 1,000 to 1,500 mg of calcium**

and 400 to 800 IU of vitamin D daily.

Contraindications to hormone therapy use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, active thromboembolic disorders, and active liver or gallbladder disease. Relative contraindications include heart disease; migraine headaches; and previous liver or gallbladder disease, or endometrial cancer, or thromboembolic events.

Menopause, the permanent cessation of menstruation, occurs at a mean age of 51 years. Despite a great increase in the life expectancy of women, the age at menopause has remained remarkably constant. **A woman in the United States today will live approximately 30 years, or greater than a third of her life, beyond the menopause.** After menopause, the ovaries cease to produce significant amounts of estrogen; therefore, symptoms and diseases associated with estrogen deficiency are of increasing importance to women's health.

The age at menopause appears to be genetically determined and is unaffected by race, socioeconomic status, age at menarche, or number of prior ovulations. Factors that are toxic to the ovary often result in an earlier age of menopause; women who smoke experience an earlier menopause (1), as do many women exposed to chemotherapy or

P.1324

pelvic radiation. Women who have had surgery on their ovaries, or have had a hysterectomy, despite retention of their ovaries, also may experience early menopause (2). **Premature ovarian failure, defined as menopause before the age of 40 years, occurs in approximately 1% of women.** It may be idiopathic or associated with a toxic exposure, chromosomal abnormality, or autoimmune disorder.

Although menopause is associated with changes in the hypothalamic and pituitary hormones that regulate the menstrual cycle, menopause is not a central event, but rather primary ovarian failure. At the level of the ovary, there is a depletion of ovarian follicles, most likely secondary to apoptosis or programmed cell death. The ovary, therefore, is no longer able to respond to the pituitary hormones, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), and ovarian estrogen and progesterone production cease.

Androgen production from the ovary continues beyond the menopausal transition because of sparing of the stromal compartment. Androgen concentrations are lower in menopausal women than in women of reproductive age. This finding appears to be associated more with aging and decreased functioning of the ovary and adrenal glands over time rather than with menopause per se. Menopausal women continue to have low levels of circulating estrogens, principally from peripheral aromatization of ovarian and adrenal androgens. Adipose tissue is a major site of aromatization, so obesity affects many of the sequelae of menopause. **The ovarian-hypothalamic-pituitary axis remains intact during the menopausal transition; thus, FSH levels rise in response to ovarian failure and the absence of negative feedback from the ovary.** Atresia of the follicular apparatus, in particular the granulosa cells, results in reduced production of estrogen and inhibin, resulting in reduced inhibin levels and elevated FSH levels, a cardinal sign of menopause.

Several staging systems have been developed to describe the many changes that encompass the transition from reproductive life to postmenopause. The late reproductive years are characterized by regular menses associated with elevated FSH levels. **The menopausal transition is characterized by elevated FSH levels associated with variable cycle lengths and missed menses, whereas the postmenopausal period is marked by amenorrhea. The menopausal transition begins with variability in menstrual cycle length accompanied by rising FSH levels and ends with the final menstrual period. Menopause is defined retrospectively as the time of the final menstrual period followed by 12 months of amenorrhea. Postmenopause describes the period following the final menses (3).**

The pathophysiologic consequences of menopause may be best understood by considering that the ovary is a woman's only source of oocytes, her primary source of estrogen and progesterone, and a major source of androgens. Menopause results in infertility secondary to oocyte depletion. Ovarian cessation of progesterone production appears to have no clinical consequences except for the increased risk of endometrial proliferation, hyperplasia, and cancer associated with continued endogenous estrogen production or administration of unopposed estrogen therapy in menopausal women. The possible effects of declining androgen concentrations that occur with aging are an area of both controversy and active investigation.

The major consequences of menopause are related primarily to estrogen deficiency. It is very difficult to distinguish the consequences of estrogen deficiency from those of aging, as aging and menopause are inextricably linked. Studying the effects of estrogen deficiency and replacement in young women with ovarian failure or of drugs that suppress estrogen synthesis (such as gonadotropin-releasing hormone antagonists) helps to distinguish between the effects of aging and estrogen deficiency. These models are imperfect, though, and differ from natural menopause in many ways.

P.1325

Principal health concerns of menopausal women include vasomotor symptoms, urogenital atrophy, osteoporosis, cardiovascular disease, cancer, cognitive decline, and sexual problems. Options for caring for menopausal women have increased greatly since hormone therapy (HT) was first introduced in the 1960s. With respect to hormone use, there are many choices of hormone type, dose, and method of administration. Not only have new forms of estrogens and progestins been introduced, but novel ways of combining the two hormones are available. In addition to hormones, selective estrogen receptor modulators (SERMs) and bisphosphonates are available for treatment. Women are requesting more information on complementary and alternative therapies, which are being studied more carefully. The many options now available make caring for postmenopausal women more rewarding as well as more challenging.

Health Concerns After Menopause

Vasomotor Symptoms

Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women, but may continue for up to 10 years or

longer in others. Hot flashes are the primary reason women seek care at menopause and request HT. Hot flashes not only disturb women at work and interrupt daily activities but also disrupt sleep (4). Many women report difficulty concentrating and emotional lability during the menopausal transition. Treatment of vasomotor symptoms should improve these cognitive and mood symptoms if they are secondary to sleep disruption and resulting daytime fatigue. The incidence of thyroid disease increases as women age; therefore, thyroid function tests should be performed if vasomotor symptoms are atypical or resistant to therapy.

The physiologic mechanisms underlying hot flashes are incompletely understood. A central event, probably initiated in the hypothalamus, drives an increased core body temperature, metabolic rate, and skin temperature; this reaction results in peripheral vasodilation and sweating in some women. The central event may be triggered by noradrenergic, serotonergic, or dopaminergic activation. Although an LH surge often occurs at the time of a hot flash, it is not causative, because vasomotor symptoms occur in women who have had their pituitary glands removed. Exactly what role estrogen plays in modulating these events is unknown. Vasomotor symptoms are a consequence of estrogen withdrawal, not simply estrogen deficiency. For example, a young woman with primary ovarian failure resulting from Turner syndrome will have a very high FSH level and low estrogen levels, but she will not experience hot flashes until she is treated with estrogens and then therapy is withdrawn.

Systemic estrogen therapy is the most effective treatment available for vasomotor symptoms and associated sleep disturbance. Although standard doses are usually effective, younger women and those with recent oophorectomy may need higher doses. Healthy women in the perimenopausal transition who are experiencing bothersome hot flashes but still menstruating may benefit from oral contraceptives. The high doses of estrogens and progestins in oral contraceptives not only effectively treat vasomotor symptoms but also provide cycle control. Very-low-dose estrogen therapy also effectively treats hot flashes for many women. Low-dose oral esterified and conjugated estrogens (0.3 mg daily) (5,6) or transdermal estradiol (0.025 mg weekly) (7) often is effective and is associated with minimal side effects and endometrial stimulation. Progestin therapy must be given concurrently if a woman has not had a hysterectomy, although with low-dose estrogen therapy, intermittent progestin treatment may be an option.

Given the known risks, described in detail later in this chapter, HT should be used at the lowest effective dose for the shortest amount of time that meets treatment goals. The majority of women with very bothersome hot flashes at the time of the menopausal

P.1326

transition will benefit from short-term therapy and be able to wean off hormones after several years of use. A major risk of HT, breast cancer, does not appear to increase until after 4 to 5 years of use.

Because vasomotor symptoms appear to be the result of estrogen withdrawal, rather than simply low estrogen levels, if cessation of estrogen therapy is desired, the dose should be reduced slowly over several months. Abruptly stopping treatment may result in a return of disruptive vasomotor symptoms. This recommendation is based on clinical experience, as no controlled trials have been performed to examine the optimal way to cease HT use.

One possible approach to stopping therapy is to reduce the dose and dosing interval slowly, and to let the patient's symptoms guide the pace at which she discontinues

therapy. For example, initially, the patient would be prescribed a reduced dose of HT every day for 2 to 3 months. She would then take the reduced dose every other day for 2 to 3 months, then every third day for 2 to 3 months, and then stop if she is doing well.

When a woman chooses not to take estrogen or when it is contraindicated, other options are available (Table 32.1) (8). Progestin therapy alone is an option for some women.

Medroxyprogesterone acetate (MPA) (Provera) (20 mg/day) and *megestrol acetate (Megace)* (20 mg 2 times daily) effectively treat vasomotor symptoms (9). Several drugs that alter central neurotransmitter pathways also are effective. Agents that decrease central noradrenergic tone, such as *clonidine (Catapres)*, relieve hot flashes, whereas *yohimbine*, an agent that increases noradrenergic tone, exacerbates symptoms (10). *Clonidine* has been shown in randomized, placebo-controlled trials to significantly reduce vasomotor symptoms (11). It may be used orally (0.1–0.2 mg/day) or as a weekly transdermal patch (0.1 mg/day). Potential side effects include orthostatic hypotension and drowsiness.

Table 32.1 Options for the Treatment of Vasomotor Symptoms
<i>Hormone therapy</i>
•Estrogen therapy
•Combination estrogen/progestin therapy
•Progestin therapy
<i>Nonhormonal prescription medications</i>
•Clonidine
•Selective serotonin and norepinephrine reuptake inhibitors
•Gabapentin
<i>Nonprescription medications</i>
•Isoflavone supplements
•Soy products
•Black cohosh
•Vitamin E
<i>Lifestyle changes</i>
•Reducing body temperature
•Maintaining a healthy weight
•Smoking cessation
•Paced respiration

P.1327

Selective serotonin reuptake inhibitors (SSRIs) also are effective in relieving hot flashes. In a double-blind, randomized, placebo-controlled trial of *paroxetine CR (Paxil)* (12.5 and 25 mg/day), menopausal women with hot flashes experienced a significant reduction in both the frequency and severity of episodes (12). Hot flash composite scores decreased 62% in the *paroxetine* group versus 38% in the placebo group. Actual hot flash frequency decreased by 3.3 hot flashes per day with *paroxetine* versus 1.8 on placebo. The improvement in vasomotor symptoms was independent of any significant change in mood or

anxiety symptoms. Both doses were effective, but the lower dose was better tolerated. The most common side effects were headache, nausea, and insomnia. A modest improvement in symptoms also occurred in a randomized, double-blind, placebo-controlled, crossover trial of *fluoxetine* (*Prozac*) (20 mg/day) (13). Not all studies show an improvement in vasomotor symptoms with SSRIs. In a 9-month, double-blind, parallel-group trial, there was no significant improvement in hot flashes with either *fluoxetine* or *citalopram* (*Celexa*) (10–30 mg/day) compared with placebo (14).

Modulation of other central neurotransmitters with different antidepressants also may be effective, but have greater potential for adverse effects. *Venlafaxine* (*Effexor*) (75 mg/day), a serotonin and norepinephrine reuptake inhibitor, significantly reduced hot flashes in a controlled trial (15). Hot flash scores decreased 61% in the *venlafaxine* group compared with 27% in the placebo group. The active treatment group experienced significantly more side effects, including dry mouth, nausea, and anorexia. A dopamine antagonist, *verapride* (*Agreal*) (100 mg/day), significantly reduced hot flashes in a controlled trial, but side effects of this class of agent include somnolence, hyperprolactinemia, galactorrhea, and tardive dyskinesia.

Gabapentin (*Neurontin*), a gamma-aminobutyric acid analogue approved for the treatment of seizures, also reduced hot flash frequency and severity significantly more than placebo in a double-blind, randomized trial (16). Hot flash scores decreased 54% in the women treated with *gabapentin* (900 mg/day) compared with a 31% reduction in placebo-treated women. The most common adverse events were somnolence, dizziness, and rash.

Bellergal, a combination of *ergotamine*, *phenobarbital*, and *belladonna alkaloids* approved for the treatment of migraines, also reduces hot flashes (17). Its use, though, is limited by anticholinergic side effects, including dry mouth, constipation, and drowsiness.

Many menopausal women are interested in trying nutritional and vitamin supplements for relief of hot flashes. Many of these therapies are claimed to relieve hot flashes but rarely are studied in controlled trials (18). Vasomotor symptoms are particularly sensitive to placebo treatments. Several controlled studies demonstrate a reduction in vasomotor symptoms with soy supplementation, whereas others do not. In one randomized study, soy protein (60 g/day) reduced hot flashes by 45%, a significantly greater reduction than the 30% seen in placebo-treated women (19). In another controlled trial, use of *isoflavones* (100 mg/day) significantly decreased vasomotor symptoms when compared with placebo, while also reducing total and low-density lipoprotein cholesterol (20). A large controlled trial of soy protein, with and without isoflavones, demonstrated no effect of isoflavones on vasomotor symptoms (21). Soy-related compounds may act as SERMs, with their effects modulated through interactions with the estrogen receptor.

Although often recommended, *vitamin E* (800 IU/day) only minimally reduced hot flashes in a placebo-controlled, randomized, crossover trial (22). Uncontrolled studies of acupuncture (23), exercise, and paced respiration show an improvement in vasomotor symptoms with the use of these techniques. Women may choose to use alternative and complementary therapies for relief of symptoms, but they should be aware that their safety and efficacy are unproved. Being in a cool environment is associated with fewer subjective

and objective hot flashes (24), so women experiencing symptoms should be encouraged to keep

the room temperature low and wear light, layered clothing. Overweight women and those who smoke have more severe vasomotor symptoms than women of normal weight and nonsmokers. These findings provide additional reasons to encourage women to lose weight and stop smoking (25,26).

Urogenital Atrophy

Urogenital atrophy results in vaginal dryness and pruritus, dyspareunia, dysuria, and urinary urgency. These common problems in menopausal women respond well to therapy.

Systemic estrogen therapy is effective for the relief of vaginal dryness, dyspareunia, and urinary symptoms. For women who should not or choose not to use estrogen therapy, another option is topical application. Because systemic absorption is low, endometrial stimulation is minimal; thus vaginal estrogen therapy may be appropriate even for symptomatic women with breast cancer. Low doses of *estrogen cream (Premarin, Estrace)* (0.5 g) are effective when used only 1 to 3 times weekly (27). An *estradiol vaginal tablet (Vagifem)* (25 µg) inserted twice weekly, which may be less messy and easier to use than estrogen cream, is available. An *estrogen containing vaginal ring (Estring)* (7.5 µg/day), which is placed in the vagina every 3 months and slowly releases a low dose of estradiol, also is available (28).

Studies of the vaginal tablets and ring have confirmed endometrial safety at 1 year, but studies are not available on the long-term effects of low-dose vaginal estrogen therapy on the endometrium. Women using vaginal estrogen therapy should be asked to report any vaginal bleeding, and this bleeding should be evaluated thoroughly. Typically, systemic progestin therapy is not prescribed to women using low-dose vaginal estrogen. In the absence of supportive evidence, it is not unreasonable to recommend the use of progestin for 12 to 14 days, every 6 to 12 months, in women who are long-term users of vaginal estrogens, especially overweight women or those otherwise at increased risk for endometrial hyperplasia. Lubricants (e.g., *Replens, KY Jelly*) are a nonhormonal alternative for reducing discomfort with intercourse in the presence of urogenital atrophy.

Vaginal estrogen therapy appears to reduce urinary symptoms, such as frequency and urgency, and has been shown to reduce the likelihood of recurrent urinary tract infections in postmenopausal women (29). The effect of estrogen therapy on urinary incontinence is unclear. Whereas the results of some studies suggest improvement in incontinence with estrogen therapy, others show a worsening of symptoms (30).

Osteoporosis

Osteoporosis, or low bone mass, affects an estimated 30 million women in the United States, or approximately 55% of women older than age 50 years (31). **Annual expenditures for medical care of osteoporotic fractures in the United States total \$15 billion.** Because therapy is most likely to benefit those at highest risk, it is important to review a woman's risk factors for osteoporosis when making treatment decisions and to consider bone mineral density screening for high-risk women (Table 32.2). Nonmodifiable risk factors include age, Asian or Caucasian race, family history, small body frame, history of a prior fracture, early menopause, and prior oophorectomy. Modifiable risk factors include decreased intake of calcium and vitamin D, smoking, and a sedentary lifestyle. Medical conditions associated with an increased

risk of osteoporosis include anovulation during the reproductive years (eg, secondary to excess exercise or an eating disorder), hyperthyroidism, hyperparathyroidism, chronic renal disease, and diseases requiring systemic corticosteroid use.

Table 32.2 Risk Factors for Osteoporosis
<i>Nonmodifiable</i>
•Age
•Race (Caucasian, Asian)
•Small body frame
•Early menopause
•Prior fracture
•Family history of osteoporosis
<i>Modifiable</i>
•Inadequate intake of calcium and vitamin D
•Smoking
•Low body weight
•Excess alcohol use
•Sedentary lifestyle
<i>Associated Medical Conditions</i>
•Hyperthyroidism
•Hyperparathyroidism
•Chronic renal disease
•Conditions requiring systemic corticosteroid use

Bone mineral density (BMD) measurements may be used to diagnose osteoporosis, determine fracture risk, and identify women who would benefit from therapeutic interventions. **Dual x-ray absorptiometry (DXA) of the hip and spine is the primary technique for BMD assessment. BMD is expressed as a T-score, which is the number of standard deviations from the mean for a young, healthy woman. A T-score above -1 is considered normal, a value between -1 and -2.5 denotes osteopenia, and a score below -2.5 indicates osteoporosis.** Although there is a strong association between BMD and fracture risk, a woman's age, overall health status, and risk for falls also influence her fracture risk.

Evaluation of BMD by DXA is recommended for all women aged 65 and older, regardless of risk factors, and for younger postmenopausal women with 1 or more risk factors, other than being white and menopausal (32). Osteoporosis may be assumed in any menopausal woman with a low-impact trauma fracture.

Counseling women to alter modifiable risk factors is important for both the prevention and treatment of osteoporosis. Many women have diets deficient in calcium and vitamin D and will benefit from dietary changes and supplementation. Women should receive 1,000 to 1,500 mg of calcium and 400 to 800 IU of vitamin D daily. This may be achieved through diet or vitamin and mineral supplementation. Reducing the risk of osteoporosis is another

of the many health benefits of smoking cessation and regular exercise. Treatment is indicated for all women with osteoporosis as well as for those with osteopenia and additional risk factors. Drug therapies for the prevention and treatment of osteoporosis are principally antiresorptive drugs that reduce bone loss and anabolic agents that stimulate new bone formation (Table 32.3).

Hormone therapy is effective in preventing and treating osteoporosis. In observational studies, estrogen therapy has been shown to reduce osteoporosis-related fractures by

P.1330

approximately 50% when started soon after menopause and continued long term. It also significantly decreases fracture rates in women with established disease (33). **The Women's Health Initiative (WHI) randomized controlled trial confirmed a significant (34%) reduction in hip fractures in healthy women receiving HT (conjugated equine estrogen 0.625 mg with MPA 5 mg; PremPro) after a mean follow-up of 5 years (34) (Table 32.4).** Recent studies demonstrate that even very-low-dose estrogen therapy (*estradiol* 0.25 mg/day; *conjugated equine estrogen* 0.3 mg/day with *MPA* 1.5 mg/day, [*PremPro*]; *transdermal estradiol* 0.025 mg/day [*Climara, Vivelle, Alora*]; and 0.014 mg/day [*Menostar*]), combined with calcium and vitamin D, produce significant increases in bone mineral density compared with placebo (35,36,37).

Table 32.3 Options for Osteoporosis Prevention and Treatment

Bisphosphonates

Fosamax (Alendronate) (35–70 mg/week)

Actonel (Risedronate) (35 mg/week)

Boniva (Ibandronate) (150 mg/month)

- Additional potential benefits: none
- Potential risks: esophageal ulcers
- Side effects: gastrointestinal distress, arthralgias/myalgias

Hormone Therapy

Estrogen or Estrogen/Progestin Therapy

- Additional potential benefits: treatment of vasomotor symptoms and urogenital atrophy
- Potential risks: breast cancer, gallbladder disease, venous thromboembolic events, cardiovascular disease, stroke
- Side effects: vaginal bleeding, breast tenderness

Selective Estrogen Receptor Modulators (SERMS)

Evista (Raloxifene) (60 mg/day)

- Additional potential benefits: reduced risk of breast cancer
- Potential risks: venous thromboembolic events
- Side effects: vasomotor symptoms, leg cramps

Other

Calcitonin (Miacalcin) (200 IU /day intranasally or 100 IU/day subcutaneously or intramuscularly)

- Additional potential benefits: none

- Potential risks: none

- Side effects: rhinitis, back pain

Forteo (Teriparatide) (20 µg/day subcutaneously)

- Additional potential benefits: none

- Potential risks: osteosarcoma after long-term use in rodents, hypercalcemia

- Side effects: leg cramps

Bisphosphonates, including *alendronate* (Fosamax, 35–70 mg weekly), *risedronate* (Actonel, 35 mg weekly), and *ibandronate* (Boniva, 150 mg monthly) specifically inhibit bone resorption and are very effective for both osteoporosis prevention and

P.1331

treatment (38,39). Patients should be instructed to take these drugs on an empty stomach with a large glass of water and then to remain upright for at least 30 to 60 minutes. The major side effect is gastrointestinal distress; esophageal ulceration is a rare occurrence. Once-weekly administration of high-dose *alendronate* or *risedronate* is therapeutically equivalent to daily dosing and more convenient for patients. Monthly dosing with *ibandronate* is very convenient and may result in improved long-term continuance with bisphosphonate therapy.

Table 32.4 Summary of Women's Health Initiative Study Results	
Risks per 10,000 Person-Years Attributable to Estrogen Plus Progestin^a	
	Per 10,000 Person-Years
Excess Risk	Additional Cases
Coronary heart disease	7
Stroke	8
Pulmonary embolism	8
Invasive breast cancer	8
Dementia (WHIMS) (<i>subset older than age 65</i>)	23
Reduced Risk	Fewer Cases
Hip fracture	5
Colorectal cancer	6
Risks per 10,000 Person-Years Attributable to Estrogen Alone (Hysterectomized Women)^b	
	Per 10,000 Person-Years
Excess Risk	Additional Cases
Stroke	12
Deep venous thrombosis	6
Reduced Risk	Fewer Cases
Hip fracture	6
No Difference	
Coronary heart disease	
Invasive breast cancer	

Colorectal cancer

WHIMS, Women's Health Initiative Memory Study.

^a From **Writing Group for the Women's Health Initiative Investigators**. Risks and benefits of estrogen plus progestin in healthy postmenopausal women: principal results from the Women's Health Initiative randomized controlled trial. *JAMA* 2002; 288: 321–333; and **Shumaker S, Legault C, Rapp S, et al**. Estrogen plus progestin and the incidence of dementia and mild cognitive impairment in postmenopausal women. *JAMA* 2003; 289: 2651–2662.

^b From **Women's Health Initiative Steering Committee**. Effects of conjugated equine estrogen in postmenopausal women with hysterectomy. *JAMA* 2004; 291: 1701–1712.

Selective estrogen receptor modulators are compounds that act as both estrogen agonists and antagonists, depending on the tissue. Raloxifene (Evista, 60 mg) is a SERM that has been approved for both the prevention and treatment of osteoporosis (40).

Raloxifene exercises estrogenlike actions on bone and lipids without stimulating the breast or endometrium (41). *Calcitonin* nasal spray (*Miacalcin*, 200 IU) is another approved treatment for established osteoporosis. Parathyroid hormone (human recombinant PTH 1-34) (*teriparatide*, *Forteo*, 20 µg subcutaneously) is a novel therapy for osteoporosis. Unlike most

P.1332

treatments for osteoporosis that inhibit bone resorption, parathyroid hormone stimulates new bone formation. Treatment of postmenopausal osteoporotic women with parathyroid hormone by daily subcutaneous injection results in dramatic increases in vertebral, femoral, and total body bone mineral density, and significant reductions in vertebral and nonvertebral fractures (42). Parathyroid hormone is indicated for postmenopausal women with osteoporosis who are at very high risk for fracture.

Cardiovascular Disease

Cardiovascular disease is the leading cause of death for women, accounting for approximately 45% of mortality. Nonmodifiable risk factors include age and family history. Modifiable risk factors include smoking, obesity, and a sedentary lifestyle. Medical conditions associated with an increased risk of heart disease include diabetes, hypertension, and hypercholesterolemia.

Advising women to alter modifiable risk factors and adequately treating diabetes, hypertension, and hypercholesterolemia are important measures in reducing the risk of heart disease. In the past, prevention of heart disease was thought to be a potential benefit of HT. Epidemiologic studies report an approximately 50% decrease in heart disease in woman who use HT (43,44). This observed reduction in coronary heart disease was thought secondary to beneficial effects of HT on lipid levels (45) and direct actions on the vascular wall. Observational studies are prone to bias, though, and woman who choose to use hormones are generally at lower risk for heart disease than those who do not (46).

The WHI randomized controlled trial of combination HT versus placebo showed that not only does HT not prevent heart disease in healthy women, it actually increases the risk of cardiovascular events (34). The WHI is a 15-year study sponsored by the National Institutes

of Health that examines ways to prevent heart disease, osteoporosis, and breast and colorectal cancer in women. There are several different studies in WHI involving more than 160,000 healthy postmenopausal women. The WHI randomized controlled trial enrolled approximately 16,000 women nationwide between the ages of 50 and 79 years. The average age of women in the study was 63 years. The major goal of the WHI clinical trial was to determine whether combined estrogen and progestin HT prevented heart disease and fractures, and whether there were risks associated with HT use. **After an average of 5 years of follow-up, heart disease and stroke were significantly increased in HT users by 29% and 41%, respectively.**

Approximately 11,000 women without a uterus participated in a separate WHI study and were randomized either to estrogen alone or placebo. After an average follow-up of 7 years, there was no increased risk of heart disease in estrogen users (47). Estrogen use did have adverse vascular effects, however, increasing the risk of stroke by 39% and venous thromboembolism by 33%.

There appears to be no role for HT in the prevention of cardiovascular disease, not only in healthy women, but also in women with established heart disease. The Heart and Estrogen/Progestin Replacement Study (HERS), a randomized, placebo-controlled trial of combination estrogen–progestin therapy for secondary prevention of heart disease, also did not demonstrate any reduction in cardiovascular events (48). Overall, there were no significant differences in cardiovascular outcomes between HT and placebo-treated women. There was a significant time factor, however, with more cardiovascular events occurring in women using HT in year 1, and fewer in years 4 and 5.

The WHI trials and the HERS study examined only treatment with *conjugated equine estrogens* and *medroxyprogesterone acetate*. The effects of other oral estrogen agents, transdermal estradiol, cyclic HT, or therapy with other progestins may be different. In

P.1333

addition, the average age of women participating in these trials was more than 15 years beyond the age at which women typically initiate HT for the treatment of vasomotor symptoms. It is possible that early initiation of HT may result in a more favorable risk-benefit profile. In the absence of data from randomized controlled trials, the conservative approach is to assume that the risks of various HT regimens are similar.

Selective estrogen receptor modulators, such as *raloxifene*, also improve the lipid profile, decreasing total and low-density lipoprotein cholesterol similarly to oral HT, but without increasing high-density lipoprotein cholesterol or triglycerides (49). Whether the beneficial effects of *raloxifene* on lipid levels will translate into a reduced incidence of heart disease currently is being studied in the Raloxifene Use for the Heart (RUTH) trial, a large randomized, placebo-controlled study examining the effects of *raloxifene* on cardiovascular disease. In a secondary analysis of **results from a randomized, controlled trial of *raloxifene* versus placebo in more than 7,000 women with osteoporosis, there were no significant differences between groups with regard to coronary and cerebrovascular events. Among a subset of approximately 1,000 women with increased cardiovascular risk at baseline, the women who received *raloxifene* experienced a significant 40% reduction in cardiovascular events (50).**

Breast Cancer

Breast cancer is the most common cancer in women, is the second leading cause of cancer death, and is a major health concern for menopausal women (51). For women in the United States, the lifetime risk of developing invasive breast cancer is 12%; therefore, any therapies that reduce or increase this risk will have a major impact on women's health. Risk factors for breast cancer include age, early menarche, late menopause, family history, and prior breast disease, including epithelial atypia and cancer. Oophorectomy and term pregnancy before the age of 30 are associated with reduced risk. Many of these risk factors are consistent with the hypothesis that prolonged estrogen exposure increases the risk of breast cancer.

Long-term use of HT is associated with an increased risk of breast cancer (52).

Observational studies show a relative risk of approximately 1.3 with long-term HT use, generally defined as greater than 5 years. The results of several studies suggest that the risk of breast cancer associated with the use of estrogen alone may be lower, with a higher risk in users of estrogen plus progestin (53,54). The WHI randomized controlled trial demonstrated a significant (26%) increase in the risk of invasive breast cancer after approximately 5 years of use of HT (34). In women with a prior hysterectomy, there was no increased risk of breast cancer after an average of 7 years of estrogen use alone (47).

The SERM *tamoxifen* (Nolvadex) is an estrogen antagonist in the breast that is used in the treatment of estrogen-receptor positive breast cancer. *Tamoxifen* (20 mg) also has been approved for the prevention of breast cancer in high-risk women, resulting in an approximately 50% reduction in the risk of disease (55). *Raloxifene* also may reduce the risk of breast cancer. Postmenopausal women receiving *raloxifene* as part of a large osteoporosis treatment trial experienced a 76% reduction in the risk of invasive breast cancer compared with placebo-treated women (56). The Study of Tamoxifen and Raloxifene (STAR) trial is comparing the effectiveness of *raloxifene* and *tamoxifen* for the prevention of breast cancer in high-risk women. The Continuing Outcomes Relevant to Evista (CORE) trial is evaluating the effect of *raloxifene* on breast cancer risk in women with osteoporosis.

The risk of venous thromboembolism (VTE) is increased approximately threefold with the use of *tamoxifen* and *raloxifene*. This increase is similar to the increased risk that occurs in HT users. Hot flashes are increased with *raloxifene* and *tamoxifen* use, and *raloxifene* is associated with leg cramps. *Tamoxifen* acts as an estrogen agonist in the

P.1334

endometrium, increasing the risk of endometrial polyps, hyperplasia, and cancer, whereas no endometrial stimulation is seen with *raloxifene*.

Performing a screening mammography examination annually for women older than age 50 years reduces breast cancer mortality. Monthly breast self-examination also is recommended. Women at increased risk for breast cancer are advised not to use HT, or to use it only short term. Women at high risk also may elect to take *tamoxifen* therapy.

Alzheimer Disease

Alzheimer disease is the most common form of dementia. Women are at greater risk for developing the disease than men, and the number of affected individuals in the United States is expected to double to more than 8 million by 2010. Several small trials and observational studies have suggested that hormone therapy use may decrease the risk of

Alzheimer disease (57). A randomized, controlled study in women with mild to moderate Alzheimer disease, however, showed that 1 year of estrogen treatment neither slowed disease progression nor improved cognition (58). The effect of HT on cognitive function in women without dementia was studied in the WHI Memory Study (WHIMS), a randomized, double-blind, placebo-controlled trial of women aged 65 years or older enrolled in the WHI trial. In contrast to the findings of observational studies, **women randomized to HT in WHIMS experienced a significant twofold increased risk of dementia, most commonly Alzheimer disease** (59). In addition, HT use was associated with an adverse effect on cognition. Compared with placebo-treated women, women in the HT group scored significantly lower on the Modified Mini-Mental State Examination (60). **Given the increased incidence of stroke identified in HT users in the WHI trial, it is possible that small, undetected cerebrovascular events were more likely to occur in the HT group, increasing the risk of dementia.**

Risks of Hormone Therapy

In addition to an increased risk of heart attack, stroke, breast cancer, and Alzheimer disease, VTEs are increased approximately two- to threefold with HT use. This was confirmed in the WHI clinical trial, in which women assigned to HT experienced twice the incidence of deep venous thrombosis and pulmonary embolism than women randomized to placebo (34). Women taking HT should be advised to stop therapy several days before elective surgery or periods of prolonged immobilization. It is possible that transdermal estrogen therapy may not be associated with an increased risk of VTE. In one case-control study, oral but not transdermal estrogen therapy was associated an increased risk of VTEs (61). There also is a twofold risk of gallbladder disease with HT use. Common side effects include breast tenderness, exacerbation of migraine headaches, and vaginal bleeding.

Contraindications to HT use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, active thromboembolic disorders, and active liver or gallbladder disease. Relative contraindications include heart disease; migraine headaches; and a history of liver or gallbladder disease, endometrial cancer, or thromboembolic events. These situations require a thoughtful assessment of potential risks and benefits and documentation of informed patient consent before treatment.

The use of unopposed estrogen is associated with an increased risk of endometrial hyperplasia and cancer. Therefore, combination *estrogen-progestin* therapy is recommended for all women with a uterus. Treatment may be provided in a sequential manner, with *estrogen* daily and *progestin* for 12 to 14 days of each month, or in a continuous-combined fashion with *estrogen* and a lower dose of *progestin* daily.

P.1335

Sequential regimens result in regular, predictable vaginal bleeding. The benefit of continuous-combined regimens is that approximately 60% to 70% of women will experience amenorrhea by the end of 1 year of therapy; the problem is that the bleeding that does occur is irregular and unpredictable (62). Several new combination therapies have been approved for use that combine *norethindrone acetate* (*NETA*) as the progestin, with either *ethinyl estradiol* (*FemHRT*) or *estradiol* (*Activella*). These products, as well as the low-dose *PremPro* formulations (0.45/1.5, 0.3/1.5 mg/day), have a lower incidence of breakthrough

bleeding than other continuous-combined regimens. In general, older women and women who have been menopausal for several years experience less irregular bleeding with continuous-combined regimens than do younger, recently menopausal women.

For women who note symptoms of depressed mood or bloating with *MPA*, oral natural *micronized progesterone* (*Prometrium*, 100–200 mg/day) is approved for use in HT regimens. It results in a more favorable lipid profile and may have different side effects (45). The major adverse effect of oral progesterone appears to be drowsiness, which may be a benefit for some women if taken at bedtime. *Micronized progesterone* contains peanut oil and should not be used by women with peanut allergies. Other options for women with intolerance to progestin therapy include using cyclic progestins only 3 to 4 times per year, rather than 12 to 14 days of each month. A progestin-containing intrauterine device or vaginal progesterone cream also may be used. When utilizing an unapproved progestin regimen, increased surveillance of the endometrium with serial ultrasound monitoring and/or endometrial biopsy is indicated (63). Various formulations used for HT are shown in Table 32.5.

Sexual Dysfunction

Many women experience sexual dysfunction, although the exact incidence and etiology are unknown. Sexual dysfunction may involve decreased interest or desire to initiate activity, as well as decreased arousal or ability to achieve an orgasm during sexual relations. The etiology of sexual dysfunction often is multifactorial, including psychological problems such as depression or anxiety disorders, conflict within the relationship, issues relating to prior physical or sexual abuse, medication use, or physical problems that make sexual activity uncomfortable, such as endometriosis or atrophic vaginitis. Analyzing data from the National Health and Social Life Survey, a probability sample of sexual behavior conducted in 1992 with a cohort of adults, **the prevalence of sexual dysfunction in the United States was estimated to be as high as 43% in women and 31% in men** (64). Although some studies describe decreased levels of sexual desire and activity in older women, sexual concerns are common and not specifically a problem of menopause.

Female sexual dysfunction after menopause is a complex problem with many etiologies. Careful evaluation of physiological, psychological, lifestyle, and relationship variables is required to optimize therapy. Treatment of anxiety and depression, adjustment of antidepressant medication, and relationship counseling may improve sexual function. Specific exercises and activities, often performed under the guidance of a sex therapist, aid many women and couples with sexual dysfunction. Specific treatment of genitourinary atrophy with systemic or local vaginal estrogen therapy or vaginal lubricants effectively reduces dyspareunia and may improve sexual arousal and response. ***Sildenafil citrate (Viagra)* was ineffective in a large randomized, double-blind, placebo-controlled study of women with sexual dysfunction** (65). A clitoral therapy device (*EROS-CTD™*) approved by the U.S. Food and Drug Administration may increase clitoral blood flow and improve arousal in some women (66).

Androgen therapy may have a role in the treatment of sexual dysfunction in menopausal women who have low androgen levels and no other identifiable cause

P.1336

P.1337

for their sexual problem (67). Although ovarian and adrenal androgen levels decline with age,

there is not an abrupt decrease in the production of these hormones at menopause as that which occurs with ovarian estradiol (68). Surgical menopause is an exception; **testosterone levels decrease by approximately 50% following bilateral oophorectomy.**

In a double-blind, crossover study of surgically menopausal women, the administration of supraphysiologic doses of intramuscular *testosterone* resulted in significantly higher scores of sexual desire, fantasy, and arousal than did treatment with estradiol alone or placebo (69). In a double-blind, randomized study of the effects on libido of oral *methyltestosterone* (1.25 mg/day) combined with *esterified estrogens* (0.625 mg/day, *Estratest HS*), women randomized to treatment with the estrogen-androgen combination reported significantly improved sexual interest and desire compared with women treated with estrogen alone (70). In randomized, double-blind, placebo-controlled studies of estrogen-treated women without ovaries who had sexual dysfunction, physiologic testosterone therapy administered by a transdermal patch resulted in significant increases in sexual activity and pleasure (71,72).

P.1338

A popular, but untested treatment is the use of a small amount of *testosterone ointment* or *cream* (1%), compounded at many pharmacies, applied topically to the vagina, arms, or low abdomen.

Table 32.5 Hormone Therapy Options^a

Table 32.5 Hormone Therapy Options^a			
Oral Estrogen Products			
Composition	Product Name	Dose (mg/day)	
Conjugated equine estrogens	<i>Premarin</i>	0.3, 0.45, 0.625, 0.9, 1.25	
Synthetic conjugated estrogens	<i>Cenestin</i>	0.3, 0.45, 0.625, 0.9, 1.25	
Esterified estrogens	<i>Menest</i>	0.3, 0.625, 1.25, 2.5	
17β-estradiol	<i>Estrace, generics</i>	0.5, 1.0, 2.0	
Estrone (estropipate)	<i>Ortho-Est, Ogen, generics</i>	0.625, 1.25	
Transdermal/Topical Estrogen Products			
Composition	Product Name	Release Rate (mg/day)	Dose
17β-estradiol matrix patch	<i>Alora</i>	0.025, 0.05, 0.075, 0.1	Twice weekly
	<i>Climara</i>	0.025, 0.0375, 0.05, 0.075, 0.1	Once weekly
	<i>Esclim</i>	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
	<i>Menostar</i>	0.014	Once weekly

	<i>Vivelle (Dot)</i>	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
17β-estradiol reservoir patch	<i>Estraderm</i>	0.025, 0.05, 0.1	Twice weekly
17β-estradiol	<i>Estrogel</i>	0.035	Daily application via metered-dose pump
17β-estradiol	<i>Estrasorb</i>	0.05	Daily application of 2 packets
Vaginal Estrogen Products			
Composition	Product Name	Recommended Dose	
Vaginal Creams			
17β-estradiol	<i>Estrace vaginal cream</i>	0.5–1 g, 2–3 times weekly	
Conjugated equine estrogens	<i>Premarin vaginal cream</i>	0.5–1 g, 2–3 times weekly	
Vaginal Rings			
17β-estradiol	<i>Estring</i>	Device releases 7.5 μ g/day for 90 days	
Estradiol acetate	<i>Femring</i>	Device releases 5 or 10 μ g/day for 90 days (systemic estradiol levels achieved)	
Vaginal Tablet			
Estradiol hemihydrate	<i>Vagifem</i>	1 tablet (25 μ g) twice weekly	
Progestogens			
Composition	Product Name	Dose	
Progestin: Oral Tablet			
Medroxyprogesterone acetate	<i>Provera, generics</i>	2.5, 5, 10 mg	
Norethindrone	<i>Micronor, Nor-QD, generics</i>	0.35 mg	
Norethindrone acetate	<i>Aygestin, generics</i>	5 mg	
Megestrol acetate	<i>Megace</i>	20, 40 mg	
Progestin: Intrauterine System			
Levonorgestrel IUS	<i>Mirena</i>	20 μ g/day release rate (5-year use)	
Progesterone: Oral Capsule			
Micronized progesterone USP	<i>Prometrium</i>	100, 200 mg	
Progesterone: Vaginal Gel			

Progesterone	<i>Prochieve 4%</i>	45 mg/applicator
Combination Estrogen-Progestogen Products		
Composition	Product Name	Dose (per day)
Oral Continuous-Cyclic Regimen		
Conjugated equine estrogens (E)	<i>Premphase</i>	0.625 mg E + 5.0 mg P
+medroxyprogesterone acetate (P)		(E alone days 1–14, E +P days 15–28)
Oral Continuous-Combined Regimen		
Conjugated equine estrogens (E)	<i>Prempro</i>	0.625 mg E + 2.5 or 5.0 mg P
+medroxyprogesterone acetate (P)		0.3 or 0.45 mg E + 1.5 mg P
Ethinyl estradiol (E)	<i>Femhrt</i>	5 µg E + 1 mg P
+norethindrone acetate (P)		
17β-estradiol (E)	<i>Activella</i>	1 mg E + 0.5 mg P
+norethindrone acetate (P)		
Oral Intermittent-Combined Regimen		
17β-estradiol (E)	<i>Ortho-Prefest</i>	1 mg E + 0.09 mg P
+norgestimate (P)		(E alone for 3 days, followed by E +P for 3 days)
Transdermal Continuous-Combined Regimen		
17β-estradiol (E)	<i>CombiPatch</i>	0.05 mg E + 0.14 or 0.25 mg P
+norethindrone acetate (P)		Twice weekly
17β-estradiol (E)	<i>Climara Pro</i>	0.045 mg E + 0.0015 mg P
+ levonorgestrel (P)		Once weekly
^a Table modified from North American Menopause Society . <i>Menopause practice: a clinician's guide</i> . Cleveland, OH: North American Menopause Society, 2004. Used with permission.		

Potential risks of androgen therapy include hirsutism, acne, irreversible deepening of the voice, and adverse changes in liver function and lipid levels. As most androgens are aromatized to estrogens, androgen therapy may pose the same risks as estrogen therapy. Women who elect a trial of therapy should be informed of the potential risks, unproven efficacy, and off-label nature of use.

Summary

There are many options available to address the quality of life and health concerns of menopausal

women. Currently, the primary indication for HT is the alleviation of hot flashes and associated symptoms. Further details regarding these recommendations have been published by the American College of Obstetricians and Gynecologists and the North American Menopause Society (73,74). **Women must be informed of the potential benefits and risks of all therapeutic options, and care should be individualized based on a woman's medical history, needs, and preferences.**

Uterine Cancer

John R. Lurain

- **Most risk factors for the development of endometrial carcinoma are related to prolonged, unopposed estrogen stimulation.**
- **Office endometrial aspiration biopsy is the accepted first step in evaluating a woman with abnormal uterine bleeding or suspected endometrial pathology.**
- **Papillary serous and clear cell endometrial carcinomas make up less than 10% of endometrial cancers, yet account for more than one half of all endometrial cancer deaths.**
- **Most patients with endometrial cancer should undergo surgical staging, including abdominal exploration, peritoneal cytology, hysterectomy, bilateral salpingo-oophorectomy, and selective pelvic and para-aortic lymphadenectomies.**
- **The most important adverse prognostic variables in endometrial cancer are advancing patient age, nonendometrioid or grade 3 histology, deep myometrial invasion, lymph-ovascular space invasion, large tumor size, cervix extension, lymph node metastasis, and intraperitoneal spread.**
- **Postoperative adjuvant radiotherapy in selected patients with endometrial cancer decreases the risk of local vaginal/pelvic recurrence and improves disease-free survival.**
- **Overall 5-year survival rate in endometrial cancer is approximately 75%.**
- **Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread, and management.**

Endometrial carcinoma is the most common malignancy of the female genital tract, accounting for almost one half of all gynecologic cancers in the United States.

In 2006, an estimated 41,200 new cases and 7,350 cancer-related deaths are anticipated. Endometrial carcinoma is the fourth most common cancer, ranking behind breast, lung, and bowel cancers, and the eighth leading cause of death from malignancy in women. Overall, about 2% to 3% of women develop endometrial cancer during their lifetime (1).

P.1344

In recent years, certain factors have led to an increasing awareness of and emphasis on diagnosis and treatment of endometrial cancer. These factors include the declining incidence of cervical cancer and related deaths in the United States, prolonged life expectancy, postmenopausal use of hormone therapy, and earlier diagnosis. The availability of easily applied diagnostic tools and a clearer understanding of premalignant lesions of the endometrium have led to an increase in the number of women diagnosed with endometrial cancer. Although endometrial carcinoma usually presents as early-stage disease and can generally be managed without radical surgery or radiotherapy, deaths from endometrial carcinoma now exceed those from cervical carcinoma in the United States. **Endometrial cancer is a disease that occurs primarily in postmenopausal women and is increasingly virulent with advancing age. The role of estrogen in the development of most endometrial cancers has clearly been established. Any factor that increases exposure to unopposed estrogen increases the risk for endometrial cancer.**

During the past several decades, the histopathology, spread patterns, and clinicopathologic factors that affect the prognosis of endometrial cancers have been better defined. Management of endometrial cancer has evolved from a program of preoperative intrauterine or external pelvic irradiation followed by hysterectomy based on clinical staging, to an individualized approach using hysterectomy as primary therapy and employing additional postoperative treatment depending on surgical and pathologic findings. Further analysis and investigation are needed to determine whether this initial operative approach to treatment and staging, followed by targeted postoperative therapy, will translate into improved survival rates and lower morbidity.

Epidemiology and Risk Factors

There appear to be two different pathogenetic types of endometrial cancer (2). **Type I, accounting for about 75% to 85% of cases, occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either endogenous or exogenous.** In these women, tumors begin as hyperplastic endometrium and progress to carcinoma. These "estrogen-dependent" tumors tend to be better differentiated and have a more favorable prognosis than tumors that are not associated with hyperestrogenism. **Type II endometrial carcinoma occurs in women with no source of estrogen stimulation of the endometrium.** These spontaneously occurring cancers are not associated pathologically with endometrial hyperplasia, but may arise in a background of atrophic endometrium. They are less differentiated and associated with a poorer prognosis than estrogen-dependent tumors. These "estrogen-independent" tumors tend to occur in older, postmenopausal, thin women and are present disproportionately in African-American and Asian women. Over the past decade, molecular genetic studies have shown that these two tumor types evolve via distinct pathogenetic pathways (3). **The most frequent early molecular genetic alterations in type I tumors are mutations in the *PTEN* tumor suppressive gene and *K-ras* oncogene and microsatellite instability. Type II tumors are more often associated with *p53* mutations.**

Several risk factors for the development of endometrial cancer have been identified (4,5,6,7,8,9) (Table 33.1). **Most of these risk factors are related to prolonged, unopposed estrogen stimulation of the endometrium.** Nulliparous women have 2 to 3 times the risk of parous women. Infertility and a history of irregular menses as a result of anovulatory cycles (prolonged exposure to estrogen without sufficient progesterone) increase the risk. Natural menopause occurring after age 52 years increases the risk for endometrial cancer 2.4 times compared with women who experienced menopause before 49 years of age, probably as a result of prolonged exposure of the uterus to progesterone-deficient menstrual cycles. **The risk of endometrial cancer is increased 3 times in women who are 21 to 50 pounds overweight and 10 times in those more than 50 pounds overweight** (resulting from

excess estrone as a result of peripheral conversion of adrenally derived androstenedione by aromatization in fat).

Table 33.1 Risk Factors for Endometrial Cancer

<i>Characteristic</i>	<i>Relative Risk</i>
Nulliparity	2-3
Late menopause	2.4
Obesity	
21-50 lb overweight	3
>50 lb overweight	10
Diabetes mellitus	2.8
Unopposed estrogen therapy	4-8
<i>Tamoxifen</i> therapy	2-3
Atypical endometrial hyperplasia	8-29
HNPCC syndrome	20
HNPCC, hereditary nonpolyposis colorectal cancer.	

Other factors leading to long-term estrogen exposure, such as polycystic ovary syndrome and functioning ovarian tumors, also are associated with an increased risk for endometrial cancer. Menopausal estrogen therapy without progestins increases the risk of endometrial cancer 4 to 8 times. This risk increases with higher doses and with more prolonged use and can be reduced to essentially baseline levels by the addition of progestin (8). It has been noted that the use of the antiestrogen *tamoxifen* for treatment of breast cancer is associated with a two- to threefold increased risk for the development of endometrial cancer, although this finding is confounded by the apparent greater risk of endometrial cancer in women who have breast cancer, with or without treatment with tamoxifen (9,10). Diabetes mellitus increases a women's risk for endometrial cancer by 1.3 to 2.8 times. **Women with hereditary nonpolyposis colorectal cancer syndrome (HNPCC), a cancer susceptibility syndrome with germline mutations in mismatch repair genes *MLH1*, *MSH2*, and *MSH6*, have a 40% to 60% lifetime risk for endometrial as well as colon cancer** (11). Other medical conditions, such as hypertension and hypothyroidism, have been associated with endometrial cancer, but a causal relationship has not been confirmed.

Endometrial Hyperplasia

Endometrial hyperplasia represents a spectrum of morphologic and biologic alterations of the endometrial glands and stroma, ranging from an exaggerated physiologic state to carcinoma

in situ. **Clinically significant hyperplasias usually evolve within a background of proliferative endometrium as a result of protracted estrogen stimulation in the absence of progestin influence.** Endometrial hyperplasias are important clinically because they may cause abnormal bleeding, be associated with estrogen-producing ovarian tumors, result from hormonal therapy, and precede or occur simultaneously with endometrial cancer.

The most recent classification scheme endorsed by the International Society of Gynecological Pathologists is based on architectural and cytologic features as well as long-term studies that reflect the natural history of the lesions (12) (Table 33.2).

<i>Type of Hyperplasia</i>	<i>Progression to Cancer (%)</i>
Simple (cystic without atypia)	1
Complex (adenomatous without atypia)	3
Atypical	
Simple (cystic with atypia)	8
Complex (adenomatous with atypia)	29

From **Kurman RJ, Kaminski PF, Norris HJ**. The behavior of endometrial hyperplasia: a long term study of "untreated" hyperplasia in 170 patients. *Cancer* 1985;56:403-412, with permission.

Architecturally, hyperplasias are either simple or complex; the major differing features are complexity and crowding of the glandular elements. **Simple hyperplasia** is characterized by dilated or cystic glands with round to slightly irregular shapes, an increased glandular-to-stromal ratio without glandular crowding, and no cytologic atypia. **Complex hyperplasia** has architecturally complex (budding and infolding), crowded glands with less intervening stroma without atypia. **Atypical hyperplasia refers to cytologic atypia and can be categorized as simple or complex, depending on the corresponding glandular architecture.** Criteria for cytologic atypia include large nuclei of variable size and shape that have lost polarity, increased nuclear-to-cytoplasmic ratios, prominent nucleoli, and irregularly clumped chromatin with parachromatin clearing (see Fig. 33.1).

The risk of endometrial hyperplasia progressing to carcinoma is related to the presence and severity of cytologic atypia. Kurman and colleagues retrospectively studied endometrial curettings from 170 patients with untreated endometrial hyperplasia followed a mean of 13.4 years (13). They found that **progression to carcinoma occurred in 1% of patients with simple hyperplasia, 3% of patients with complex hyperplasia, 8% of patients with atypical simple hyperplasia, and 29% of patients with atypical complex hyperplasia.** Most of the hyperplasias seemed to remain stable (18%) or regress (74%). The premalignant potential of hyperplasia is influenced by age, underlying ovarian disease, endocrinopathy, obesity, and exogenous hormone exposure (14,15).

As many as 25% to 43% of patients with atypical hyperplasia detected in an endometrial biopsy or curettage specimen will have an associated, usually well-differentiated, endometrial carcinoma detected during hysterectomy (16). Marked cytologic atypia, a high mitotic rate, and marked cellular stratification are features of atypical endometrial hyperplasia most often associated with the finding of an undiagnosed carcinoma at hysterectomy.

In a report of 85 menopausal women with endometrial hyperplasia treated with medroxyprogesterone acetate (10–20 mg/day), 84% of 65 who did not have cytologic atypia had complete reversal of the lesions, 6% developed recurrent hyperplasia, but none developed cancer at a mean follow-up interval of 7 years (17). By contrast, of 20 patients with cytologic atypia, only 50% responded to progestin, 25% developed recurrent hyperplasia, and 25% developed adenocarcinoma. In another study, hyperplasia resolved in 94% of 32 patients with atypical endometrial hyperplasia who were treated with megestrol acetate (20–40 mg/day); however, relapse occurred in all 7 patients who discontinued progestin therapy (18).

Conversely, **high-dose progestin therapy (medroxyprogesterone acetate, 200 mg/day, or megestrol acetate, 160 mg/day) has been reported to have successfully reversed atypical hyperplasia and well-differentiated endometrial adenocarcinoma in 16 (94%) of 17 and 9 (75%) of 12 premenopausal women younger than age 40, respectively. The average treatment course required to achieve disease regression was 9 month (range**

3–18 months) (19). Subsequent pregnancies after progestin treatment of endometrial hyperplasia and even well-differentiated cancer have occurred and can apparently be enhanced

by the use of assisted reproductive technologies (20).

Figure 33.1 Atypical hyperplasia (complex hyperplasia with severe nuclear atypia) of endometrium. A: The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. **B:** Higher magnification demonstrates disorderly nuclear arrangement and nuclear enlargement and irregularity. Some contain small nucleoli. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Progestin therapy is very effective in reversing endometrial hyperplasia without atypia but is less effective for endometrial hyperplasia with atypia. For women with endometrial hyperplasia without atypia, ovulation induction, cyclical progestin therapy (e.g., *medroxyprogesterone acetate*, 10-20 mg/day for 14 days per month), or continuous progestin therapy (e.g., *megestrol acetate*, 20-40 mg/day) appear to be effective. Continuous progestin therapy with *megestrol acetate* (40-160 mg/day) is probably the most reliable treatment for reversing complex or atypical hyperplasia. Therapy should be continued for 2 to 3 months, and endometrial biopsy should be performed 3 to 4 weeks after completion of therapy to assess response.

Periodic endometrial biopsy or transvaginal ultrasonography is advisable in patients being monitored after progestin therapy for atypical hyperplasia because of the presence of undiagnosed cancer in 25% of cases, the 29% progression rate to cancer, and the high recurrence rate after treatment with progestins. For women with atypical complex hyperplasia who no longer desire fertility, hysterectomy is recommended.

Endometrial Cancer Screening

Screening for endometrial cancer should currently not be undertaken because of the lack of an appropriate, cost-effective, and acceptable test that reduces mortality (21,22,23).

Routine Papanicolaou's (Pap) testing is inadequate and endometrial cytologic assessment is too insensitive and nonspecific to be useful in screening for endometrial cancer even in a high-risk population.

A progesterone challenge test reveals whether the endometrium has been primed by estrogen, but it does not identify abnormal endometrial pathology. Transvaginal ultrasonographic examination of the uterus and endometrial biopsy are too expensive to be employed as screening tests.

Although many risk factors for endometrial cancer have been identified, screening of high-risk individuals could at best detect only one half of all cases of endometrial cancer.

Furthermore, no controlled trials have been carried out to evaluate the effectiveness of screening for endometrial cancer. Screening for endometrial cancer or its precursors may be justified for certain high-risk women, such as those receiving postmenopausal estrogen therapy without progestins and members of families with hereditary nonpolyposis colorectal cancer (24). Conversely, women taking *tamoxifen* receive no benefit from routine screening with transvaginal ultrasonography or endometrial biopsy (25,26).

Fortunately, most patients who have endometrial cancer present with abnormal perimenopausal or postmenopausal uterine bleeding early in the development of the disease, when the tumor is still confined to the uterus. Application of an appropriate and accurate diagnostic test in this situation usually results in early diagnosis, timely treatment, and a high cure rate.

Endometrial Cancer

Clinical Features

Symptoms

Endometrial carcinoma most often occurs in women in the sixth and seventh decades of life, at an average age of 60 years; 75% of cases occur in women older than 50 years of

P.1348

age. **About 90% of women with endometrial carcinoma have vaginal bleeding or discharge as their only presenting symptom.** Most women recognize the importance of this symptom and seek medical consultation within 3 months. Some women experience pelvic pressure or discomfort indicative of uterine enlargement or extrauterine disease spread. Bleeding may not have occurred because of cervical stenosis, especially in older patients, and may be associated with hematometra or pyometra, causing a purulent vaginal discharge. This finding is often associated with a poor prognosis (27). **Less than 5% of women diagnosed with endometrial cancer are asymptomatic.** In the absence of symptoms, endometrial cancer is usually detected as the result of investigation of abnormal Pap test results, discovery of cancer in a uterus removed for some other reason, or evaluation of an abnormal finding on a pelvic ultrasonography examination or computed tomography (CT) scan obtained for an unrelated reason. Women who are found to have malignant cells on Pap test are more likely to have a more advanced stage of disease (28).

Abnormal perimenopausal and postmenopausal bleeding should always be taken seriously and be properly investigated, no matter how minimal or nonpersistent. Causes may be nongenital, genital extrauterine, or uterine (29). Nongenital tract sites should be considered based on the history or examination, including testing for blood in the urine and stool.

Invasive tumors of the cervix, vagina, and vulva are usually evident on examination, and any tumors discovered should be biopsied. Traumatic bleeding from an atrophic vagina may account for up to 15% of all causes of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.

Possible uterine causes of perimenopausal or postmenopausal bleeding include endometrial atrophy, endometrial polyps, estrogen therapy, hyperplasia, and cancer or sarcoma (30,31,32,33) (Table 33.3). Uterine leiomyomas should never be accepted as a cause of postmenopausal bleeding. **Endometrial atrophy is the most common endometrial finding in women with postmenopausal bleeding, accounting for 60% to 80% of such bleeding.** Women with endometrial atrophy have usually been menopausal for about 10

years. **Endometrial biopsy often yields insufficient tissue or only blood and mucus, and usually bleeding ceases after biopsy.** Endometrial polyps account for 2% to 12% of postmenopausal bleeding. Polyps are often difficult to identify with office endometrial biopsy or curettage. Hysteroscopy, transvaginal ultrasonography, or both may be useful adjuncts in identifying endometrial polyps. Unrecognized and untreated polyps may be a source of continued or recurrent bleeding, leading eventually to unnecessary hysterectomy.

Estrogen therapy is an established risk factor for endometrial hyperplasia and cancer. **The risk for endometrial cancer is 4 to 8 times greater in postmenopausal women receiving unopposed estrogen therapy, and the risk increases with time and higher estrogen doses.** This risk can be decreased by the addition of a progestin to the estrogen, either cyclically or continuously. Endometrial biopsy should be performed as indicated to assess

P.1349

unscheduled bleeding or annually in women not taking a progestin. **Endometrial hyperplasia occurs in 5% to 10% of patients with postmenopausal uterine bleeding.** The source of excess estrogen should be considered, including obesity, exogenous estrogen, or an estrogen-secreting ovarian tumor. **Only about 10% of patients with postmenopausal bleeding have endometrial cancer.**

<i>Cause of Bleeding</i>	<i>Percentage</i>
Endometrial atrophy	60-80
Estrogen replacement therapy	15-25
Endometrial polyps	2-12
Endometrial hyperplasia	5-10
Endometrial cancer	10

Premenopausal women with endometrial cancer invariably have abnormal

uterine bleeding, which is often characterized as menometrorrhagia or oligomenorrhea, or cyclical bleeding that continues past the usual age of menopause. The diagnosis of endometrial cancer must be considered in premenopausal women if abnormal bleeding is persistent or recurrent or if obesity or chronic anovulation is present.

Signs

Physical examination seldom reveals any evidence of endometrial carcinoma, although **obesity and hypertension are commonly associated constitutional factors**. Special attention should be given to the more common sites of metastasis. Peripheral lymph nodes and breasts should be assessed carefully. Abdominal examination is usually unremarkable, except in advanced cases in which ascites or hepatic or omental metastases may be palpable. On gynecologic examination, the vaginal introitus and suburethral area, as well as the entire vagina and cervix, should be carefully inspected and palpated. Bimanual rectovaginal examination should be performed specifically to evaluate the uterus for size and mobility, the adnexa for masses, the parametria for induration, and the cul-de-sac for nodularity.

Diagnosis

Office endometrial aspiration biopsy is the accepted first step in evaluating a patient with abnormal uterine bleeding or suspected endometrial pathology (34). The diagnostic accuracy of office-based endometrial biopsy is 90% to 98% when compared with subsequent findings at dilation and curettage (D & C) or hysterectomy (35,36,37).

The narrow plastic cannulas are relatively inexpensive, can often be used without a tenaculum, cause less uterine cramping (resulting in increased patient acceptance), and are successful in obtaining adequate tissue samples in more than 95% of cases. If cervical stenosis is encountered, a paracervical block can be performed, and the cervix can be dilated. Premedication with an antiprostaglandin agent can reduce uterine cramping. Complications following endometrial biopsy are exceedingly rare; uterine perforation occurs in only 1 to 2 cases per 1,000. Endocervical curettage may also be performed at the time of endometrial biopsy if cervical pathology is suspected. **A Pap test is an unreliable diagnostic test because only 30% to 50% of patients with endometrial cancer have abnormal Pap test results (38).**

Hysteroscopy and D & C should be reserved for situations in which cervical stenosis or patient tolerance does not permit adequate evaluation by aspiration biopsy, bleeding recurs after a negative endometrial biopsy, or the specimen obtained is inadequate to explain the abnormal bleeding. Hysteroscopy is more accurate in identifying polyps and submucous myomas than endometrial biopsy or D & C alone (39,40,41).

Transvaginal ultrasonography may be a useful adjunct to endometrial biopsy for evaluating abnormal uterine bleeding and selecting patients for additional testing (42,43,44,45). Transvaginal ultrasonography, with or without endometrial fluid instillation (sonohysterography), may be helpful in distinguishing between patients with minimal endometrial tissue whose bleeding is related to perimenopausal anovulation or postmenopausal atrophy and patients with significant amounts of endometrial tissue or polyps who are in need of further evaluation. The finding of an endometrial thickness greater than 4 mm, a polypoid endometrial mass, or a

P.1350

collection of fluid within the uterus requires further evaluation. Although most studies agree that an endometrial thickness of 5 mm or less in a postmenopausal woman is consistent with atrophy, more data are needed before ultrasonography findings can be considered to eliminate the need for endometrial biopsy in a patient who has symptoms (46).

Mixed carcinoma

Pathology

The histologic classification of carcinoma arising in the endometrium is shown in Table 33.4 (12,47).

Endometrioid Adenocarcinoma

The endometrioid type of adenocarcinoma accounts for about 80% of endometrial carcinomas. These tumors are composed of glands that resemble normal endometrial glands; they have columnar cells with basally oriented nuclei, little or no intracytoplasmic mucin, and smooth intraluminal surfaces (see Fig. 33.2). As tumors become less differentiated, they contain more solid areas, less glandular formation, and more cytologic atypia. The well-differentiated lesions may be difficult to separate from atypical hyperplasia.

Criteria that indicate the presence of invasion and are used to diagnose carcinoma are desmoplastic stroma, glands back-to-back without intervening stroma, extensive papillary pattern, and squamous epithelial differentiation. These changes, with the exception of the infiltrating pattern with desmoplastic reaction, require an area of involvement equal to or exceeding one half of a low-power microscopic field (LPF) (>.1 LPF; 4.2 mm in diameter) (48,49).

The differentiation of a carcinoma, expressed as its grade, is determined by architectural growth pattern and nuclear features (Table 33.5). **In the International Federation of Gynecology and Obstetrics (FIGO) grading system proposed in 1989, tumors are grouped into three grades: *grade 1*, 5% or less of the tumor shows a solid growth pattern; *grade 2*, 6% to 50% of the tumor shows a solid growth pattern; and *grade 3*, more than 50% of the tumor shows a solid growth pattern. The presence of notable nuclear atypia that is inappropriate for the architectural grade increases the tumor grade by one.**

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component. This FIGO system is applicable to all endometrioid carcinomas, including its variants, and to mucinous carcinomas. In serous and clear cell carcinomas, nuclear grading takes precedence; however, most investigators believe that these two carcinomas should always be considered high-grade lesions, making grading unnecessary.

Figure 33.2 Well-differentiated adenocarcinoma of endometrium. The glands and complex papillae are in direct contact with no intervening endometrial stroma, the so-called back-to-back pattern. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Table 33.5 FIGO Definition for Grading of Endometrial Carcinoma

Histopathologic degree of differentiation:

G1 <5% nonsquamous or nonmorular growth pattern

G2 6%-50% nonsquamous or nonmorular growth pattern

G3 >50% nonsquamous or nonmorular growth pattern

Notes on pathologic grading:

Notable nuclear atypia, inappropriate for the architectural grade, raises a grade 1 (G1) or grade 2 (G2) tumor by one grade.

In serous adenocarcinoma, clear cell adenocarcinoma, and squamous cell carcinoma, nuclear grading takes precedence.

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

FIGO, International Federation of Gynecology and Obstetrics.

Figure 33.3 Adenocarcinoma with squamous differentiation of endometrium. This lesion is also classified as adenoacanthoma. Squamous cells with eosinophilic cytoplasm and distinct cell borders form solid clusters in the lumina of neoplastic glands. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

P.1351

P.1352

P.1353

About 15% to 25% of endometrioid carcinomas have areas of squamous differentiation (see Fig. 33.3). In the past, tumors with benign-appearing squamous areas were called *adenoacanthomas*, and tumors with malignant-looking squamous elements were called *adenosquamous carcinomas*. It is now recommended that the term *endometrial carcinoma with squamous differentiation* be used to replace these two designations because the degree of differentiation of the squamous component parallels that of the glandular component and the behavior of the tumor is largely dependent on the grade of the glandular component (50,51).

Avilloglandular configuration is present in about 2% of endometrioid carcinomas (52,53). In these tumors, the cells are arranged along fibrovascular stalks, giving a papillary appearance but maintaining the characteristics of endometrioid cells. The villoglandular variants of endometrioid carcinomas are always well-differentiated lesions that behave like the regular endometrioid carcinomas, and they should be distinguished from papillary serous carcinomas. **Secretory carcinoma is a rare variant of endometrioid carcinoma that accounts for about 1% of cases** (54,55). It occurs mostly in women in their early postmenopausal years. The tumors are composed of well-differentiated glands with intracytoplasmic vacuoles similar to early secretory endometrium. These tumors

P.1354

behave as regular well-differentiated endometrioid carcinomas and generally have an excellent prognosis. Secretory carcinoma may be an endometrioid carcinoma that exhibits proggestational changes, but a history of proggestational therapy is rarely elicited. Secretory carcinoma must be differentiated from clear cell carcinoma because both tumors have predominately clear cells. These two tumors can be distinguished by their structure:

secretory carcinomas have uniform glandular architecture, uniform cytology, and low nuclear grade, whereas clear cell carcinomas have more than one architectural pattern and a high nuclear grade.

Mucinous Carcinoma

About 5% of endometrial carcinomas have a predominant mucinous pattern in which more than one half of the tumor is composed of cells with intracytoplasmic mucin (56,57). Most of these tumors have a well-differentiated glandular architecture; their behavior is similar to that of common endometrioid carcinomas, and the prognosis is good. It is important to recognize mucinous carcinoma of the endometrium as an entity and to differentiate it from endocervical adenocarcinoma. Features that favor a primary endometrial carcinoma are the merging of the tumor with areas of normal endometrial tissue, presence of foamy endometrial stromal cells, presence of squamous metaplasia, or presence of areas of typical endometrioid carcinoma. Positive perinuclear immunohistochemical staining with vimentin suggests an endometrial origin (58).

Papillary Serous Carcinoma

About 3% to 4% of endometrial carcinomas resemble serous carcinoma of the ovary and fallopian tube (59,60,61,62). Most often, these tumors are composed of fibrovascular stalks lined by highly atypical cells with tufted stratification (see Fig. 33.4). Psammoma bodies frequently are observed.

***Uterine papillary serous carcinomas (UPSC)* are all considered high-grade lesions.** They are commonly admixed with other histologic patterns, but mixed tumors behave as aggressively as pure serous carcinomas. Serous carcinomas are often associated with lymph-vascular space and deep myometrial invasion. Even when these tumors appear to be confined to the endometrium or endometrial polyps without myometrial or vascular invasion, **they behave more aggressively than endometrioid carcinomas and have a propensity to spread intra-abdominally, simulating the behavior of ovarian carcinoma.** Of patients with clinical stage I disease, more than one half are found to have deep myometrial invasion, three fourths manifest lymph-vascular space invasion (LVSI), and about one half have extrauterine disease detected at surgery.

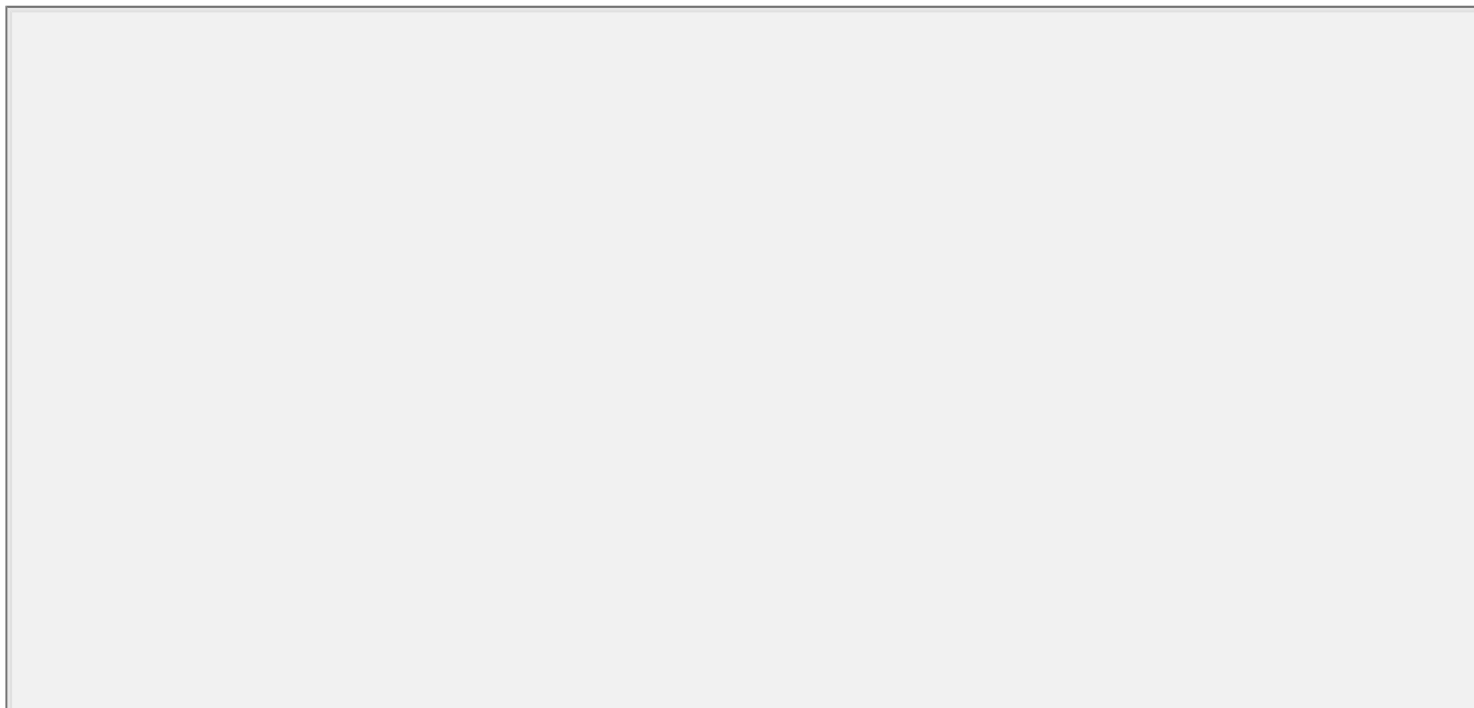

The first description of UPSC, in 1982, noted that this entity usually occurred in

elderly, hypoestrogenic women who presented with advanced-stage disease and accounted for up to one half of deaths from endometrial carcinoma (59). Since then, several reports have documented the aggressive nature and poor prognosis of UPSC. Even when the disease was confined to an endometrioid polyp without other evidence of spread, recurrence developed in more than one half of patients (60,61). More recently, in a report on 50 patients surgically staged with UPSC, extrauterine disease was found in 72%. Presence of lymph node metastases, positive peritoneal cytology, and intraperitoneal tumor did not correlate with increasing myometrial invasion (62).

Clear Cell Carcinoma

Clear cell carcinoma accounts for less than 5% of all endometrial carcinomas (54,63,64). Clear cell carcinoma usually has a mixed histologic pattern, including papillary, tubulocystic, glandular, and solid types.

The cells have highly atypical nuclei and abundant clear or eosinophilic cytoplasm. Often, the cells have a hobnail configuration arranged in papillae with hyalinized stalks (see Fig. 33.5).

Figure 33.4 Papillary serous carcinoma of endometrium. Branching papillae are supported by delicate fibrovascular cores and lined with columnar cells with moderate nuclear atypism, multiple nucleoli, and mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Clear cell carcinoma characteristically occurs in older women and is a very aggressive type of endometrial cancer; the prognosis is similar to or worse than that of papillary serous carcinoma. Overall survival rates of 33% to 64% have been reported. Myometrial invasion and LVSI are important prognostic indicators.

Squamous Carcinoma

Squamous carcinoma of the endometrium is rare. Some tumors are pure, but most have a few glands. To establish primary origin within the endometrium, there must be no connection with or spread from cervical squamous epithelium. Squamous carcinoma often is associated with cervical stenosis, chronic inflammation, and pyometra at the time of diagnosis. This tumor has a poor prognosis, with an estimated 36% survival rate in patients with clinical stage I disease (65).

Simultaneous Tumors of the Endometrium and Ovary

Synchronous endometrial and ovarian cancers are the most frequent simultaneously occurring genital malignancies, with a reported incidence of 1.4% to 3.8% (66,67,68,69,70). Most commonly, both the ovarian and endometrial tumor are well-differentiated endometrioid adenocarcinomas of low stage, resulting in an excellent prognosis. Patients often are premenopausal and present with abnormal uterine bleeding. The ovarian

P.1356

cancer usually is discovered as an incidental finding and is diagnosed at an earlier stage because of the symptomatic endometrial tumor, leading to a more favorable outcome. Up to 29% of patients with endometrioid ovarian adenocarcinomas have associated endometrial cancer. If more poorly differentiated, nonendometrioid histologic subtypes are present or if the uterine and ovarian tumors are histologically dissimilar, the prognosis is less favorable. Immunohistochemical studies, flow cytometry, and assessment of molecular DNA patterns to detect loss of heterozygosity may be helpful in distinguishing between metastatic

and independent tumors, but the differential diagnosis can usually be determined by conventional clinical and pathologic criteria.

Figure 33.5 Clear cell adenocarcinoma of the endometrium. Back-to-back glands lined by polygonal to columnar cells with distinct cell membrane, abundant granular to clear cytoplasm, and variably sized nuclei (including binucleated and multinucleated forms) with prominent nucleoli (magnification $\times 400$). (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Pretreatment Evaluation

After establishing the diagnosis of endometrial carcinoma, the next step is to evaluate the patient thoroughly to determine the best and safest approach to management of the disease. A complete history and physical examination is of utmost importance. Patients with endometrial carcinoma are often elderly and obese and have a variety of medical problems, such as diabetes mellitus and hypertension, that affect surgical management. Any abnormal symptoms, such as bladder or intestinal symptoms, should be evaluated.

P.1357

On physical examination, attention should be directed to enlarged or suspicious-feeling lymph nodes, abdominal masses, and possible areas of cancer spread within the pelvis. Evidence of distant metastasis or locally advanced disease in the pelvis, such as gross cervical involvement or parametrial spread, may alter the treatment approach. Stool should be tested for occult blood.

Chest radiography should be performed to exclude pulmonary metastasis and to evaluate the cardiorespiratory status of the patient. Other routine preoperative studies should include electrocardiography, complete blood and platelet counts, serum chemistries (including renal and liver function tests), blood type and screen, and urinalysis. Other preoperative or staging studies are neither required nor necessary for most patients with endometrial cancer. **Studies such as cystoscopy, colonoscopy, intravenous pyelography, barium enema, and CT scanning of the abdomen and pelvis are not indicated unless dictated by patient symptoms, physical findings, or other laboratory tests** (71). Ultrasonography and magnetic resonance imaging (MRI) can be used to assess myometrial invasion preoperatively with a fairly high degree of accuracy (72). This information may be of use in planning the surgical procedure with regard to whether lymph node sampling should be undertaken.

Serum CA125, an antigenic determinant that is elevated in 80% of patients with advanced epithelial ovarian cancers, also is elevated in most patients with advanced or metastatic endometrial cancer (73). In one study, 23 of 81 patients with apparently localized disease preoperatively had elevated CA125 levels. At surgery, 20 (87%) of these 23 patients with an elevated CA125 were found to have extrauterine disease, whereas only 1 of 58 patients with a normal CA125 had disease spread outside the uterus (74). Another study found that 78% of endometrial cancer patients with lymph node metastases had an elevated preoperative CA125 level (75). Preoperative measurement of serum CA125 may, therefore, help determine the extent of surgical staging and, if elevated, may be useful as a tumor marker in assessing response to subsequent therapy (76,77).

Clinical Staging

Clinical staging, according to the 1971 FIGO system (Table 33.6), **should be performed in patients who are deemed not to be surgical candidates because of their poor medical condition or the spread of their disease** (78). With improvements in preoperative and postoperative care, anesthesia administration, and surgical techniques, almost all patients are medically suitable for operative therapy. One study reported an

P.1358

operability rate of 87% in a series of 595 consecutive patients with clinical early-stage endometrial cancer (79). A small percentage of patients will not be candidates for surgical staging because of gross cervical involvement, parametrial spread, invasion of the bladder or rectum, or distant metastasis.

Table 33.6 FIGO Clinical Staging of Endometrial Carcinoma (1971)

Stage	Characteristic
I	Confined to the corpus
Ia G123	Uterine cavity <8 cm
Ib G123	Uterine cavity >8 cm
II	Involves the corpus and cervix, but has not extended outside the uterus
III	Extends outside the uterus, but not outside the true pelvis
IV	Extends outside the true pelvis or obviously involves the mucosa of the bladder or rectum
IVa	Spread to adjacent organs
IVb	Spread to distant organs

FIGO, International Federation of Gynecology and Obstetrics.

Table 33.7 FIGO Surgical Staging for Endometrial Carcinoma (1988)	
Stage	Finding
Ia G123	No myometrial invasion
Ib G123	< ½ Myometrial invasion
Ic G123	> ½ Myometrial invasion
IIa G123	Extension to endocervical glands
IIb G123	Cervical stromal invasion
IIIa G123	Positive uterine serosa, adnexa, and/or peritoneal cytology
IIIb G123	Vaginal metastasis
IIIc G123	Metastasis to pelvic and/or para-aortic lymph nodes
IVa G123	Tumor invasion of bladder and/or bowel mucosa
IVb	Distant metastasis including intra-abdominal and/or inguinal lymph nodes

FIGO, International Federation of Gynecology and Obstetrics.

Surgical Staging

Most patients with endometrial cancer should undergo surgical staging based on the 1988 FIGO system (80,81,82) (Table 33.7). At a minimum, the surgical procedure

should include sampling of peritoneal fluid for cytologic evaluation, exploration of the abdomen and pelvis with biopsy or excision of any extrauterine lesions suggestive of metastatic cancer, extrafascial hysterectomy, and bilateral salpingo-oophorectomy. The uterine specimen should be opened and tumor size (83), depth of myometrial involvement (84,85,86), and cervical extension assessed. Any suspicious pelvic and para-aortic lymph nodes should be removed for pathologic examination.

Additionally, clinically negative retroperitoneal lymph nodes should be sampled in all patients with one or more of the risk factors noted in Table 33.8. Tumor histology and depth of myometrial invasion appear to be the two most important factors in determining the risk for lymph node metastasis (81,82). The overall incidence of lymph node metastasis in clinical stage I endometrial cancer is about 3% in grade 1, 9% in grade 2, and 18% in grade 3 tumors (Table 33.9). Less than 5% of patients with no myometrial invasion or with superficial (<50%) myometrial invasion have lymph node metastasis, compared with about 20% of patients with deep (>50%) myometrial invasion (Table 33.10). **Pelvic**

P.1359

lymph node metastases are present in less than 5% of grade 1 and 2 tumors with superficial myometrial invasion, in about 15% of grade 1 and 2 tumors with deep myometrial invasion or grade 3 tumors with superficial invasion, and in more than 40% of grade 3 tumors with deep myometrial invasion (see Fig. 33.6). About one half to two thirds of patients with positive pelvic lymph nodes also have para-aortic lymph node metastases, but the aortic nodes are seldom involved in the absence of pelvic nodal disease. Cervical involvement is associated with about a 15% risk of pelvic or para-aortic node metastasis (82). **The incidence of lymph node metastasis also correlates with tumor size (<2 cm, 4%; >2 cm, 15%; entire cavity, 35%)** (83). Extrauterine spread of disease increases the risk of pelvic and para-aortic nodal metastasis. Adnexal metastasis increases the risk for pelvic and para-aortic nodal metastasis to 32% and 20%, respectively. Of patients with positive peritoneal cytology, 25% have positive pelvic nodes, and 19% have positive para-aortic nodes (82).

Table 33.9 Relationship of Grade to Lymph Node Metastasis in Clinical Stage I Endometrial Carcinoma

Grade	No.	Pelvic Nodes		Aortic Nodes	
		No.	%	No.	%
1	180	5	3	3	2
2	288	25	9	14	5
3	153	28	18	17	11

From **Creasman WT, Morrow CP, Bundy BN, et al.** Surgical pathologic spread patterns of endometrial cancer. *Cancer* 1987;60:2035-2041, with permission.

Selective pelvic and high common iliac/para-aortic lymph node dissections should, therefore, be performed in the presence of adnexal or cervical involvement, a large (> 2 cm) tumor, deep ($> 50\%$) myometrial invasion, or a moderate to poorly differentiated endometrioid, papillary serous, or clear cell tumor. Because fewer than 10% of patients with lymphatic metastasis have grossly enlarged nodes, palpation is not an acceptable alternative to biopsy. Conversely, because almost

all patients with lymph node metastases have one or more of the aforementioned risk factors, lymph node biopsies are not required in patients assessed intraoperatively to be at very low risk for lymphatic metastasis (ie, patients with small [<2 cm] grade 1 endometrial cancers with only superficial myometrial invasion). In addition, partial omentectomy should be considered in some high-risk patients, especially those with papillary serous and mixed mullerian tumors, which have a propensity for intra-abdominal spread and upper-abdominal recurrence.

Adjuvant pelvic irradiation is recommended for the high-risk group but not for the low-risk group. (From **DiSaia PJ, Creasman WT.** Management of endometrial adenocarcinoma, stage I with surgical staging followed by tailored adjuvant radiation therapy. *Clin Obstet Gynecol* 1986;13:751, with permission.)

P.1360

Extended surgical staging, including selective pelvic and para-aortic lymphadenectomy, in patients with endometrial cancer does not significantly add to the morbidity from hysterectomy, which is primarily related to other factors, such as patient weight, age, and race; operating time; and surgical technique. The complication rate with this type of surgery is about 20%; about 6% of these complications are serious. The most common complications are wound infection, embolic phenomena, excess blood loss, gastrointestinal injury or obstruction, and lymphocyst formation (87,88,89,90,91).

In addition, **selective pelvic and para-aortic lymphadenectomy may have a therapeutic effect** (92,93). One study noted that patients who underwent pelvic lymph node sampling had a significant survival advantage overall in both low-risk and high-risk groups (92). Likewise, para-aortic lymphadenectomy has been found to be a significant positive predictor for recurrence-free survival in patients with high-risk endometrial cancer. Among 137 high-risk patients, the 5-year progression-free survival rate was 77% for patients undergoing para-aortic lymph node dissection, compared with 62% for patients not having para-aortic lymphadenectomy (93).

Modified from Creasman WT, Morrow CP, Bundy BN, et al. Surgical pathologic spread patterns of endometrial cancer. <i>Cancer</i> 1987;60:2035-2041, with permission.	

Surgical staging is extremely important when one considers the poor correlation of preoperative evaluation and clinical staging with surgical and pathologic findings. In a comparison of preoperative findings with surgical pathology, tumor histology was changed in 27% of patients, tumor grade was changed in 34% of patients, and stage was changed in 51% of patients (94). In the Gynecologic Oncology Group (GOG) series, 22% of 621 patients with clinical stage I endometrial cancer had evidence, discovered at staging laparotomy, of extrauterine spread, including lymph node metastasis, adnexal spread, peritoneal implants, and positive peritoneal cytology (82) (Table 33.11). In two other studies, extrauterine spread was found in clinical stages I (19%) and II (40%), with an overall incidence of 23.4% (95) and in

19 (12.3%) of 154 clinical stage I and II patients (96). In a retrospective comparison of clinical and surgical stage with respect to survival in 156 patients with endometrial cancer, surgery resulted in an increase in the stage in 12.4% and 27.3% of clinical stage I and II patients, respectively (97). Surgical stage was found to be the most important factor affecting prognosis.

All patients with endometrial cancer who are taken to the operating room for primary therapy should, therefore, be prepared to undergo surgical staging. Such staging may include selective pelvic and para-aortic lymph node dissection, in addition to hysterectomy and salpingo-oophorectomy, based on the intraoperative assessment of risk for lymph node metastasis or other extrauterine spread.

Surgical staging identifies most patients with extrauterine disease and has a significant impact on treatment decisions. Surgical staging also identifies patients with uterine risk factors, including deep myometrial invasion, cervical extension, and LVSI. The identification of these factors allows for a more informed approach to the use of postoperative adjuvant radiotherapy, and it is hoped that this approach will improve survival and spare many patients unnecessary exposure to radiation (98,99,100,101,102,103,104,105).

Prognostic Variables

Although stage of disease is the most significant variable affecting survival, a number of other individual prognostic factors for disease recurrence or survival have been identified, including tumor grade, histopathology, depth of myometrial invasion, patient age, and surgical—pathologic evidence of extrauterine disease spread (Table 33.12). Other factors, such as tumor size, peritoneal cytology, hormone receptor status, flow cytometric analysis, and oncogene perturbations, have also been implicated as having prognostic importance.

Age

In general, younger women with endometrial cancer have a better prognosis than older women. Two reports observed no deaths related to disease in patients with endometrial cancer diagnosed before 50 years of age (98,106). Another series demonstrated a 60.9% 5-year survival rate for patients older than 70 years of age, compared with 92.1% survival rate for patients younger than 50 years of age (107). Decreased survival was associated with an increased risk for extrauterine spread (38% versus 21%) and deep myometrial invasion (57% versus 24%) for these two groups. The GOG reported 5-year survival rates of 96.3% for patients 50 years of age or younger, 87.3% for patients 51 to 60 years, 78% for patients 61 to 70 years, 70.7% for patients 71 to 80 years, and 53.6% for patients older than 80 years (108).

Increased risk for recurrence in older patients has also been related to a higher incidence of grade 3 tumors or unfavorable histologic subtypes; however, age appears to be an independent prognostic variable. Increasing patient age has been found to be independently associated with disease recurrence in endometrial cancer. In one study, the mean age at diagnosis of patients who had recurrence or died of disease was 68.6 years, compared with 60.3 years for patients without recurrence. For every 1-year increase in age, the estimated rate of recurrence increased 7%. None of the patients younger than 50 years of age developed recurrent cancer, compared with 12% of patients aged 50 to 75 years and 33% of patients older than 75 years (103).

Histologic Type

Nonendometrioid histologic subtypes account for about 10% of endometrial cancers and carry an increased risk for recurrence and distant spread (109,110). In a retro

P.1363

spective review of 388 patients treated at the Mayo Clinic for endometrial cancer, 52 (13%) had an uncommon histologic subtype, including 20 adenosquamous, 14 papillary serous, 11 clear cell, and 7 undifferentiated carcinomas. In contrast to the 92% survival rate among patients with endometrioid tumors, the overall survival for patients with one of these more aggressive subtypes was only 33%. At the time of surgical staging, 62% of the patients with an unfavorable histologic subtype had extrauterine spread of disease (109).

Histologic Grade

Histologic grade of the endometrial tumor is strongly associated with prognosis (82,88,100,101,102,103,104,105). In one study, recurrences developed in 7.7% of grade 1 tumors, 10.5% of grade 2 tumors, and 36.1% of grade 3 tumors. Patients with grade 3 tumors were more than 5 times more likely to have a recurrence than were patients with grade 1 and 2 tumors. The 5-year disease-free survival rates for patients with grades 1 and 2 tumors were 92% and 86%, respectively, compared with 64% for patients with grade 3 tumors (103). Another study reported similar results, noting recurrences in 9% of patients with grade 1 and 2 tumors compared with 39% of patients with grade 3 lesions (101). Increasing tumor anaplasia is associated with deep myometrial invasion, cervical extension, lymph node metastasis, and both local recurrence and distant metastasis.

Myometrial Invasion

Because access to the lymphatic system increases as cancer invades into the outer one half of the myometrium, increasing depth of invasion has been associated with increasing likelihood of extrauterine spread and recurrence (81,102,105).

The association of depth of myometrial invasion with extrauterine disease and lymph node metastases has been confirmed (81). Of patients without demonstrable myometrial invasion, only 1% had pelvic lymph node metastasis, compared with patients with outer one third myometrial invasion who had 25% pelvic and 17% aortic lymph node metastases. Survival also decreases with increasing depth of myometrial invasion. In general, patients with noninvasive or superficially invasive tumors have an 80% to 90% 5-year survival rate, whereas those with deeply invasive tumors have a 60% survival rate. The most sensitive indicator

of the effect of myometrial invasion on survival is distance from the tumor—myometrial junction to the uterine serosa. Patients with tumors that are less than 5 mm from the serosal surface are at much higher risk for recurrence and death than those with tumors greater than 5 mm from the serosal surface (111,112).

Lymph—Vascular Space Invasion

Lymph-vascular space invasion appears to be an independent risk factor for recurrence and death from all types of endometrial cancer (94,112,113,114). The overall incidence of LVSI in early endometrial cancer is about 15%, although it increases with increasing tumor grade and depth of myometrial invasion. One study reported LVSI in 2% of grade 1 tumors and 5% of superficially invasive tumors, compared with 42% of grade 3 tumors and 70% of deeply invasive tumors (113). Another study reported deaths in 26.7% of patients with clinical stage I disease who had LVSI, compared with 9.1% of those without LVSI (93). Likewise, an 83% 5-year survival rate has been reported for patients without demonstrable LVSI, compared with a 64.5% survival rate for those in whom LVSI was present (114). Using multivariate analysis, only depth of myometrial invasion, DNA ploidy, and vascular invasion—associated changes correlated significantly with survival of patients with stage I endometrial adenocarcinomas in another report (115).

Isthmus and Cervix Extension

The location of the tumor within the uterus is important. Involvement of the uterine isthmus, cervix, or both is associated with an increased risk for extrauterine disease and lymph node metastasis as well as recurrence. One study reported that if the fundus of the uterus alone was involved with tumor, there was a 13% recurrence rate, whereas if the lower uterine segment or cervix was involved with occult tumor, there was a 44%

recurrence rate (100). A subsequent GOG study found that tumor involvement of the isthmus or cervix without evidence of extrauterine disease was associated with a 16% recurrence rate and a relative risk of 1.6 (88). Patients with cervical involvement also tended to have higher-grade, larger, and more deeply invasive tumors, undoubtedly contributing to the increased risk for recurrence.

Adnexal Involvement

Most patients with adnexal spread have other poor prognostic factors that place them at high risk for recurrence. For the 20% of patients with adnexal spread as their only high-risk factor, however, the survival rate has been reported to be as high as 85% (88).

Peritoneal Cytology

The significance of malignant peritoneal cytology in endometrial cancer is a controversial issue (116). Several reports in the literature have noted increased recurrence rates and decreased survival rates and, on this basis, have recommended treatment for positive cytology (117,118,119). In an early report, positive peritoneal cytology was noted in 26 (16%) of 167 patients with clinical stage I adenocarcinoma of the endometrium (117). Recurrent cancer developed in 10 (38%) of these 26 patients, compared with 14 (10%) of 141 patients with negative cytology. Positive peritoneal cytology was found to be associated with deep myometrial invasion, cervical involvement, adnexal spread, and lymph node metastasis, as well as a propensity for intra-abdominal disease recurrence. Several subsequent reports supported the observation that positive peritoneal cytology was associated with an increased risk for cancer recurrence (118,119). Most of the studies included patients with other evidence of extrauterine disease spread and were performed without appropriate multivariate analysis and with patients who were incompletely staged. The GOG study, however, critically analyzed 1,180 clinical stage I and II endometrial cancer patients in whom appropriate surgical and pathologic staging was performed (88). Considering only the 697 patients for whom peritoneal cytology status and adequate follow-up were available, 25 (29%) of 86 patients with positive cytology developed recurrence, compared with 64 (10.5%) of 611 patients with negative cytology. They noted, however, that 17 of the 25 recurrences in the positive cytology group were outside the peritoneal cavity.

In contrast to these reports, **an equal number of studies have found no significant relationship between malignant peritoneal cytology and an increased incidence of disease recurrence in early endometrial cancer** (119,120,121,122). In a prospective evaluation of peritoneal cytology in 157 patients with clinical stage I endometrial cancer who underwent primary surgical therapy (120), no treatment was directed specifically to positive cytology. Positive cytology was not significantly associated with disease recurrence. Recurrence developed in 5 (17%) of 30 patients with positive cytology and in 11 (9%) of 127 patients with negative cytology. Of the 5 patients with positive

peritoneal cytology who had disease recurrence, only one recurrence arose within the peritoneal cavity. Patients with malignant washings often had other poor prognostic factors: 37%, deep myometrial invasion; 37%, grade 3 tumors; 17%, positive lymph nodes. Disease recurred in none of the patients with positive cytology who had no other poor prognostic factors. A subsequent study confirmed by multivariate analysis that positive peritoneal cytology was not an independent prognostic factor for endometrial cancer recurrence. Only 6 (22%) of the 27 patients with positive cytology as their only evidence of extrauterine disease spread suffered a recurrence despite no therapy directed toward this finding (103). **Positive peritoneal cytology seems to have an adverse effect on survival only if the endometrial cancer has spread to the adnexa, peritoneum, or lymph nodes, not if the disease is otherwise confined to the uterus** (121,122,123). More grade 3 tumors (41% versus 19%), vascular invasion (18% versus 6%), adnexal spread (18% versus 4%), lymph node metastasis (29% versus 8%), and intraperitoneal spread (18% versus 2%) occurred in patients with positive peritoneal cytology, which contributed to the overall recurrence rate of 47% in these patients (121). The 5-year survival rate for patients with positive peritoneal cytology with disease otherwise confined to the uterus exceeds 90%.

The following conclusions may be reached regarding the prognostic implications of positive peritoneal cytology:

- **Positive peritoneal cytology is associated with other known poor prognostic factors.**
- **Positive peritoneal cytology in the absence of other evidence of extrauterine disease or poor prognostic factors probably has no significant effect on recurrence and survival.**
- **Positive peritoneal cytology, when associated with other poor prognostic factors or extrauterine disease, increases the likelihood for distant as well as intra-abdominal disease recurrence and has a significant adverse effect on survival.**
- **Use of several different therapeutic modalities has not resulted in any proven benefit to patients with endometrial cancer and positive peritoneal cytology.**

Lymph Node Metastasis

Lymph node metastasis is the most important prognostic factor in clinical early-stage endometrial cancer. Of patients with clinical stage I disease, about 10% will have pelvic and 6% will have para-aortic lymph node metastases. Patients with lymph node metastases have almost a sixfold higher likelihood of developing recurrent cancer than patients without lymph node metastases. One study reported a recurrence rate of 48% with positive lymph nodes, including 45% with positive pelvic nodes and 64% with positive aortic nodes, compared with 8% with negative nodes. **The 5-year disease-free survival rate for patients with lymph node metastases was 54%, compared with 90% for patients without lymph node metastases** (103). The GOG found that the presence or absence of para-aortic lymph node metastases was of paramount importance in determining prognosis. Of 48 para-aortic node—positive patients, 28 (58%) developed progressive or recurrent cancer, and only 36% of these patients were alive at 5 years, compared with 85% of patients without para-aortic node involvement (87).

Intraperitoneal Tumor

Extrauterine metastasis, excluding peritoneal cytology and lymph node metastasis, occurs in about 4% to 6% of patients with clinical stage I endometrial cancer.

Gross intraperitoneal spread has been highly correlated with lymph node metastases; one study noted that 51% of patients with intraperitoneal tumor had positive lymph nodes, whereas only 7% of patients without gross peritoneal spread had positive nodes (82). Extrauterine spread other than lymph node metastasis is also significantly associated with tumor recurrence. Another study found that 50% of patients with extrauterine disease developed recurrence, compared with 11% of patients without extrauterine disease, making recurrence almost 5 times more likely in patients with extrauterine disease spread. **The 5-year disease-free survival rate for patients with nonlymphatic extrauterine disease was 50%, compared with 88% in other patients** (103).

Tumor Size

Tumor size is a significant prognostic factor for lymph node metastasis and survival in patients with endometrial cancer (83,124). One report determined tumor size in 142

patients with clinical stage I endometrial cancer and found lymph node metastasis in 4% of patients with tumors 2 cm or smaller, in 15% of patients with tumors larger than 2 cm, and in 35% of patients with tumors involving the entire uterine cavity (83). Tumor size better defined an intermediate-risk group for lymph nodes metastasis (ie, patients with grade 2 tumors with less than 50% myometrial invasion). Overall, these patients had a 10% risk for lymph node metastasis, but there was no nodal metastasis associated with tumors 2 cm or

smaller, compared with 18% when tumors were larger than 2 cm. Five-year survival rates were 98% for patients with tumors 2 cm or smaller, 84% for patients with tumors larger than 2 cm, and 64% for patients with tumors involving the whole uterine cavity (124).

Hormone Receptor Status

Estrogen receptor and progesterone receptor levels have been shown to be prognostic indicators for endometrial cancer independent of grade in several studies (125,126,127,128,129,130,131). Patients whose tumors are positive for one or both receptors have longer survival times than patients whose carcinomas lack the corresponding receptors. Even patients with metastasis have an improved prognosis with receptor-positive tumors (128). Progesterone receptor levels appear to be stronger predictors of survival than estrogen receptor levels, and the higher the absolute level of the receptors, the better the prognosis.

DNA Ploidy and Proliferative Index

About two thirds of endometrial adenocarcinomas have a diploid DNA content as determined by flow cytometric analysis (115,129,132,133,134,135,136,137,138,139,140). **The proportion of nondiploid tumors increases with stage, lack of tumor differentiation, and depth of myometrial invasion.** In several studies, DNA content has been related to clinical course of the disease, with death rates generally reported to be higher in women whose tumors contained aneuploid populations of cells. The proliferative index also is related to prognosis.

Genetic and Molecular Markers

Mutations in codons 12 or 13 of the **K-ras** oncogene have been reported in 10% to 20% of endometrial adenocarcinomas (141). **The presence of mutations of K-ras appears to be**

an independent unfavorable prognostic factor (142,143). E-cadherin, an oncogene responsible for cell-to-cell adhesion that seems to play a critical role in initiation and progression of endometrial neoplasia, is found in 5% to 50% of endometrial carcinomas. Reduced expression of e-cadherin is related to advanced stage disease (144,145). Overexpression of the HER-2/*neu* oncogene, which encodes for a cell surface glycoprotein that is similar to the human epidermal growth factor receptor, has been identified in 10% to 15% of endometrial adenocarcinomas. It is more frequently found in women with metastatic disease, and overexpression has been related to diminished progression-free survival (146,147,148). **Alteration of the tumor suppressor gene *p53* has been demonstrated in about 20% of endometrial carcinomas and has been associated with papillary serous cell type, advanced stage, and poor prognosis** (139,149,150,151). Expression of *MIB-1* (*Ki-*), a proliferation marker, has been associated with extrauterine disease spread and decreased survival (152). Analysis of homozygous deletions on chromosome 10q23 in human cancer has led to the discovery of the *PTEN* tumor-suppressor gene. Mutations and deletions of the *PTEN* gene occur in 30% to 80% of endometrial cancers, which tend to be endometrioid, well differentiated, and minimally invasive (153,154,155). **Microsatellite instability, present in about 20% of endometrial cancers, appears to be restricted to endometrioid adenocarcinomas and is associated with other molecular features that predict a favorable outcome, including *PTEN* mutation and absence of *p53* overexpression** (156,157).

Treatment

An algorithm for the management of patients with clinical stage I and II endometrial cancer is presented in Figure 33.7.

Surgery

Abdominal Hysterectomy

Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the primary operative procedures for carcinoma of endometrium. The adnexa should be removed because they may be the site of microscopic metastasis, and patients with

endometrial carcinoma are at increased risk for ovarian cancer occurring either simultaneously or developing later. Removal of a segment of vagina below the cervix is not necessary.

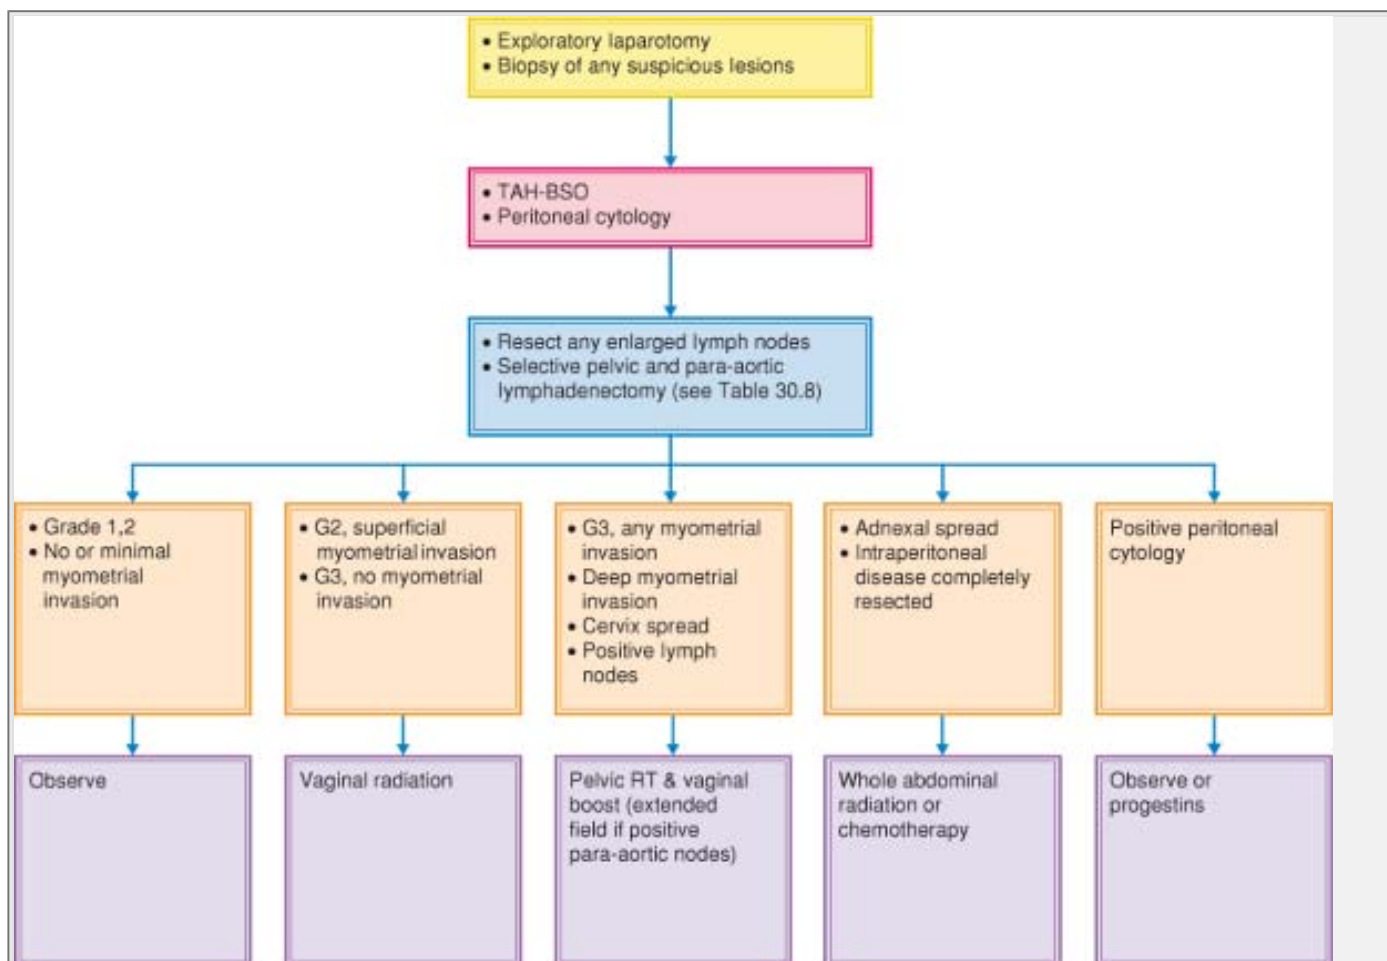

Figure 33.7 Management of patients with clinical Stage I and II endometrial carcinoma. TAH, total abdominal hysterectomy; BSO, bilateral salpingo-oophorectomy; RT, radiotherapy.

Laparotomy is performed through an abdominal incision that is adequate to allow thorough intra-abdominal exploration and retroperitoneal lymph node dissection, if necessary. A lower-abdominal midline vertical incision is most commonly used, although a lower-abdominal transverse, muscle-dividing incision (e.g., Maylard incision) or muscle-detaching incision (e.g., Cherney incision) usually provides adequate exposure. After opening the

abdomen, peritoneal washings are taken from the subdiaphragmatic area, paracolic gutters, and pelvis using 50 mL of saline for each. These washings are sent to the cytology laboratory for examination. Exploration of the abdomen and pelvis is then performed, noting particularly the diaphragm, liver, omentum, and pelvic and aortic lymph nodes. The uterus should be observed for tumor on the serosal surface. Any suspicious-looking lesions or lymph nodes should be excised for biopsy or removed for histologic examination. The uterus is opened in the operating room, and tumor size, depth of myometrial invasion, and cervical extension are assessed. This information, along with the surgical findings and knowledge of the preoperative histology, influences whether pelvic and aortic lymph node dissection is indicated. The uterus is sent to the pathology laboratory, where tissue can be obtained for measurement of steroid hormone receptors and flow cytometry.

P.1368

For patients in whom lymph node sampling is indicated, lower para-aortic lymph node resection can be accomplished by extending the pelvic peritoneal incisions over the common iliac arteries and lower aorta. Samples of lymph nodes along the upper common iliac vessels are removed from either side and the fat pad overlying the vena cava. Pelvic lymph node samples are obtained by removing nodes overlying the midportion of the external iliac artery and vein and within the obturator fossa above and along the obturator nerve. An omental biopsy or partial omentectomy may also be performed.

Vaginal Hysterectomy

Vaginal hysterectomy may be considered for selected patients who are extremely obese and have a poor medical status, or for patients with extensive uterovaginal prolapse. The disadvantages to this approach are that bilateral salpingo-oophorectomy often is technically difficult and abdominal exploration and lymph node sampling cannot be performed. **Vaginal hysterectomy is, therefore, particularly suitable for patients who are at low risk for extrauterine spread of disease (i.e., those with clinical stage I, well-differentiated tumors). In one report, a 94% survival rate was found in 56 patients with clinical stage I endometrial carcinoma treated by vaginal hysterectomy, with or without postoperative radiotherapy (mostly brachytherapy).** Three fourths of these patients had grade 1 lesions (158). Others have reported similar good results (159,160,161). Vaginal hysterectomy clearly is preferable to radiation therapy alone, but generally should

be reserved for specific patients.

Laparoscopic Management

Recent advances in endoscopic surgery have allowed application of a laparoscopic approach to the management of endometrial cancer. Since 1992, **there have been several reports that have documented the feasibility of laparoscopically assisted vaginal hysterectomy with bilateral salpingo-oophorectomy and laparoscopic retroperitoneal lymph node sampling for staging and treatment of patients with endometrial cancer** (162,163,164). In an early study of 59 patients with endometrial cancer managed laparoscopically, 29 had retroperitoneal lymph node sampling (162). In a comparison study of the results of laparoscopic versus traditional laparotomy management of 44 patients with endometrial cancer, 20 patients underwent successful laparoscopic management, 15 had both pelvic and para-aortic lymph node sampling, and 4 had pelvic node sampling only. There was no difference in the number of lymph nodes (19 versus 17) removed in the laparoscopy and laparotomy groups, respectively. Patients undergoing laparoscopic management had shorter hospital stays (2.5 versus 5.0 days) and a lower overall complication rate, although all three patients who had serious complications (one ureteral injury and two small bowel herniations through 12-mm trocar sites) were in the laparoscopy group (163). A subsequent retrospective analysis compared the clinical outcomes and hospital charges for 69 women with early-stage endometrial cancer who underwent laparoscopically assisted vaginal hysterectomy, compared with 251 women who had traditional laparotomy. The patients managed laparoscopically had fewer complications, shorter hospital stays, and lower overall hospital charges than those who underwent laparotomy. Furthermore, there was no difference in recurrence rates between the two groups (164). Several other retrospective studies have evaluated the validity of laparoscopic surgery in endometrial cancer (165,166,167,168,169). In general, these studies demonstrated no differences in number of lymph nodes, estimated blood loss, and disease-free recurrence or survival with laparoscopic versus laparotomy approach to treatment, whereas decreased perioperative morbidity, longer operating times, shorter hospital stays, and earlier return to work were associated with laparoscopy compared with laparotomy. **There has been only one randomized trial published comparing laparoscopically assisted vaginal hysterectomy versus abdominal surgery in patients with endometrial cancer** (170). Seventy patients with FIGO stages I to III were randomized to laparoscopically assisted simple or radical hysterectomy versus simple or

radical abdominal hysterectomy with or without lymph node dissection. **Blood loss and transfusion rates were lower in the laparoscopy group, whereas lymph node yield, duration of surgery, and incidence of postoperative complications were similar for both groups. Overall and recurrence-free survival did not differ significantly between the two operative approaches.**

Although results of laparoscopic management of endometrial cancer are encouraging, long-term survival analysis is lacking and the risks of port-site metastasis (171), vaginal cuff recurrence (172), and higher incidence of positive peritoneal cytology (173) have been noted. The GOG is currently conducting a large, randomized trial comparing laparoscopically assisted hysterectomy and staging with standard laparotomy approach to evaluate the equivalence of these two approaches with respect to complications and outcomes.

Radical Hysterectomy

Radical hysterectomy, with removal of the parametria and upper vagina, as well as bilateral pelvic lymphadenectomy, does not improve survival of patients with clinical stage I disease compared with extrafascial hysterectomy and bilateral salpingo-oophorectomy alone (174,175,176,177). Radical hysterectomy also increases both intraoperative and postoperative morbidity and should not, therefore, be performed for treatment of apparent early endometrial cancer.

Radiation Therapy

Primary surgery followed by individualized radiation therapy has become the most widely accepted treatment for early-stage endometrial cancers. However, about 5% to 15% of endometrial cancer patients have severe medical conditions that render them unsuitable for surgery (79). These patients tend to be elderly and obese with multiple chronic or acute medical illnesses, such as hypertension, cardiac disease, diabetes mellitus, and pulmonary, renal, and neurologic diseases.

Several series have shown that radiotherapy is effective treatment for patients with inoperable endometrial cancer (178,179,180,181,182,183,184,185,186,187) (Table 33.13). One reported on the treatment of 120 patients with clinical stage I and 17

patients with clinical stage II endometrial cancer with radiation alone, 85% of whom received only intracavitary irradiation. Because of the high incidence of death caused by intercurrent illness in this group of patients, the 5- and 10-year overall survival rates were only 55% and 28%, respectively, compared with disease-specific survival rates of 87% and 85%, respectively. There was no difference in disease-specific survival rates between patients with stage I and II disease. Intrauterine cancer recurred in 14% of patients, and extrauterine pelvic disease recurred in 3%. The authors also treated 15 patients with stage III and IV disease, usually with a combination of external-beam and intracavitary radiation therapy, yielding a 5-year disease-specific survival rate of 49%. Five patients (3%) had serious late complications of radiation therapy (187).

Although it is generally agreed that intracavitary irradiation is necessary to achieve adequate local control, the indications for external-beam radiation therapy in the primary treatment of endometrial cancer are less well defined. Patients with cervical involvement and known or suspected extrauterine pelvic spread undoubtedly would benefit from external-beam radiation therapy. Theoretically, external-beam irradiation could also sterilize microscopic nodal disease and possibly increase the radiation dose to deep myometrial or subserosal uterine disease, which may receive an insufficient dose from intracavitary irradiation alone. A correlation between tumor grade and recurrence has been noted in several reports. One found that the 5-year progression-free survival rate for medically inoperable patients with clinical stage I disease treated with radiotherapy alone was 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors (184). Therefore, **patients with grade 3 tumors and a known propensity for deep myometrial invasion and lymph node metastasis also may benefit from external-beam therapy.**

*For all stages combined.

From **Kupelian PA, Eifel PJ, Tornos C, et al.** Treatment of endometrial carcinoma with radiation therapy alone. *Int J Radiat Oncol Biol Phys* 1993;27:817-824, with permission.

The decision to treat a patient who has endometrial cancer with radiation alone must involve a careful analysis of the relative risks and benefits of surgery. Although radiation alone can produce excellent survival and local control, it should be considered for definitive treatment only if the operative risk is estimated to exceed the 10% to 15% risk for uterine recurrence expected with radiation treatment alone.

Postoperative Adjuvant Therapy

Postoperative therapy should be based on prognostic factors determined by surgical

and pathologic staging. Patients can generally be classified into three treatment categories (Table 33.14).:

- **Low Risk Patients who show a low incidence of recurrence and a high rate of cure without any postoperative therapy**
- **Intermediate Risk Patients who have a reduced rate of surgical cure but may or may not benefit from additional therapy**
- **High Risk Patients who have a high rate of recurrence and a low survival rate without postoperative therapy**

Options for postoperative management in these patients include observation, vaginal vault irradiation, external pelvic irradiation, extended-field (pelvic and para-aortic) irradiation, whole-abdomen irradiation, progestins, or systemic chemotherapy (see Fig. 33.7).

Observation

Patients with grade 1 and 2 lesions without myometrial invasion (stage Ia, grades 1 and 2) have an excellent prognosis and require no postoperative therapy. In a GOG

P.1371

study, there were no recurrences and a 100% disease-free 5-year survival rate in the 91 patients in this category, 72 of whom had received no additional treatment after hysterectomy (88). Other investigators have reported equally favorable results with only surgical therapy in similar patients (188,189).

Table 33.14 Postoperative Management of Endometrial Carcinoma Based on Surgical-Pathologic Findings and Stage

<i>Surgical-Pathologic Findings</i>	<i>Stage</i>	<i>Postoperative Treatment</i>
Low risk		
G1, G2, no myoinvasion No cervix/isthmus invasion Negative peritoneal cytology No LVSI No evidence of metastasis	Ia G1, 2	None
Intermediate risk		
G1, G2, <50% myoinvasion G3, no myoinvasion	Ib G1, 2 Ia G3	Vaginal cuff irradiation
G3, <50% myoinvasion G1, G2 isthmus/cervix extension	Ib G3 IIa G1, G2	Pelvic versus vaginal cuff irradiation

Positive peritoneal cytology	IIIa (+1 cytology)	Progestin
High risk		
Adnexal/serosal/parametrial spread Vaginal metastasis	IIIa G1, G2, G3 IIIb G1, G2, G3	Pelvic and vaginal irradiation (Extended-field radiation therapy if positive aortic/ common iliac lymph nodes)
Lymph node metastasis	IIIc G1, G2, G3	
Bladder/rectal invasion Intraperitoneal spread	IVa IVb	Pelvic and vaginal irradiation Whole-abdomen irradiation; systemic chemotherapy
LVSI, lymph-vascular space invasion.		

Vaginal Vault Irradiation

Numerous studies have shown that the incidence of vaginal recurrence in patients with tumors apparently confined to the uterus can be reduced from as high as 15% to 1% or 2% by the administration of vaginal irradiation. This finding is important because vaginal vault recurrence carries a poor prognosis (190,191). Preoperative or

postoperative vaginal vault irradiation use has been found to decrease the incidence of vaginal recurrence from 14% to 1.7% and to improve 5-year survival rates from 75% to over 90% (99,192). In a 10-year follow-up of a randomized trial comparing surgery alone (total abdominal hysterectomy and bilateral salpingo-oophorectomy) with preoperative and postoperative radium treatment in patients with clinical stage I endometrial adenocarcinoma, the incidence of vaginal recurrence was 7.5% with hysterectomy alone, 4.5% with preoperative intracavitary radium followed by hysterectomy, and 0% with hysterectomy followed by postoperative vaginal radium (193). In a subsequent study of 92 patients with surgical stage I disease who had grade 1 or 2 tumors with less than 50% myometrial invasion treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy and postoperative vaginal cesium or radium, there were no recurrences, and the 5-year estimated disease-free survival rate was 99%. There was only one minor complication, proctitis, which responded to conservative treatment (194).

P.1372

In a GOG study of surgical and pathologic risk factors and outcomes, none of the three recurrences in the vaginal radiation implant group was vaginal or pelvic, whereas 7.4% of recurrences in the pelvic radiation therapy group were vaginal, and 18.2% of recurrences were vaginal in the group that did not receive adjuvant radiation. The investigators concluded that postoperative vaginal cuff irradiation reduced local recurrence and had a therapeutic ratio superior to whole-pelvis irradiation in patients at risk for isolated vaginal cuff recurrence (88).

In the past, postoperative vaginal irradiation was most commonly administered using low-dose-rate radium or cesium sources via colpostats to deliver a surface dose of 6,000 to 7,000 cGy to the upper vagina. More recently, afterloading outpatient techniques using high-dose-rate iridium sources have been employed (195,196,197,198,199). Morbidity is low, although vaginal stenosis and dyspareunia may be a problem for postmenopausal patients in the absence of regular vaginal dilation. **Patients most likely to benefit from vaginal irradiation are those who have surgical stage I grade 1 and 2 tumors with superficial (less than 50%) myometrial invasion (stage Ib G1,2) or grade 3 tumors with no invasion (stage Ia G3) and patients with stage IIa G1,2 disease with superficial myometrial invasion.**

External Pelvic Irradiation

External pelvic irradiation decreases the risk of pelvic recurrence after hysterectomy in certain high-risk groups. Patients found to benefit most from adjuvant

postoperative whole-pelvis irradiation are those with cervical involvement, pelvic lymph node metastases, or pelvic disease outside the uterus (adnexa, parametria), and patients with clinical stage I disease who are at significant risk for nodal metastasis (grade 3 tumors with any degree of myometrial invasion, grade 1 and 2 tumors with more than 50% myometrial invasion, large [>2 cm] grade 2 and 3 tumors with superficial myometrial invasion, and any grade tumor with LVSI) (200).

In a study of 41 endometrial cancer patients treated with postoperative pelvic irradiation (5,000-5,040 cGy) who had grade 3 tumors or deep myometrial invasion and histologically negative para-aortic lymph nodes (pelvic lymph nodes not sampled), 4 patients (9.7%) developed recurrences. Only one of the recurrences (2.4%) was within the treatment field, however, and the 5-year estimated disease-free survival rate was 88% (194). In the GOG study, the pelvic recurrence rate was higher in the surgery-only group of patients (31.8%) than in the patients who received postoperative external beam radiation therapy (16.8%) (88).

In 1980, the first randomized study was performed to evaluate the possible benefit of postoperative pelvic irradiation in clinical stage I endometrial cancer (105). After total abdominal hysterectomy and bilateral salpingo-oophorectomy, all 540 patients received vaginal vault radium and were then randomized to receive either 4,000 cGy of whole-pelvis irradiation or no further therapy. The addition of pelvic irradiation did not affect the overall 5-year survival rate. Patients receiving pelvic irradiation had a lower pelvic failure rate but a higher distant failure rate. Of note, patients with grade 3 tumors and more than 50% myometrial invasion had a lower rate of death from cancer if they received postoperative pelvic irradiation (18.2% versus 27.5%). This study has been criticized for a lack of complete surgical staging (no lymph node biopsies were performed) and the relatively low dose of external-beam irradiation (4,000 cGy) used.

The GOG recently published a prospective, randomized study of surgery alone versus surgery plus adjuvant pelvic irradiation in intermediate-risk endometrial cancer (stages Ib to IIb occult). Of 392 patients accrued to the study, more than 80% were actually low-risk patients (90.6% stage I, 81.6% grade 1-2, 82% $<50\%$ myometrial invasion). **Disease recurrence was reduced by 58% ($p=0.007$) with the use of postoperative pelvic irradiation.** After 2 years, the cumulative recurrence rate was 12% in the group with no postoperative treatment compared with 3% in the group that received pelvic irradiation. The pelvic failure rate was 8.9% in the surgery-alone group compared with 1.6% in the postoperative pelvic irradiation group. **Overall survival rates also were improved,**

although not significantly, in patients receiving postoperative pelvic irradiation compared with those treated only with surgery (92% versus 86%, respectively) (201).

Another randomized trial of surgery and postoperative pelvic radiotherapy versus surgery alone for 714 patients with stage I endometrial carcinoma was carried out by the Netherlands PORTEC Study Group. Eligibility criteria were stage IC, grade 1 to 2, and stage IB, grade 2 to 3; patients with stage IB, grade 3, made up only 10% of the study population, and lymph node biopsies and peritoneal cytology were not required. **Local-regional recurrences developed in 14% of the surgery group, compared with 4% of the postoperative pelvic irradiation group. Overall, the 5-year survival rate was no different between the two groups (85% versus 81%, respectively) (202).**

Postoperative whole-pelvis external-beam irradiation usually involves the delivery of 4,500 to 5,040 cGy in 180 cGy daily fractions over 5 to 6 weeks to a field encompassing the upper one half of the vagina inferiorly, the lower border of the L4 vertebral body superiorly, and 1 cm lateral to the margins of the bony pelvis. The dose of radiation at the surface of the vaginal apex usually is boosted to 6,000 to 7,000 cGy by a variety of techniques. The most frequently reported side effects are gastrointestinal, usually abdominal cramps and diarrhea, although more serious complications such as bleeding, proctitis, bowel obstruction, and fistula can occur and may require surgical correction. The urinary system may also be affected in the form of hematuria, cystitis, or fistula. The overall complication rate ranges from 25% to 40%; however, the rate of serious complications requiring surgical intervention is about 1.5% to 3%.

Patients at high risk for recurrence may benefit from pelvic irradiation. The pelvic failure rate is reduced and, at least in patients with grade 3 tumors and deep myometrial invasion, survival rates also appear to be improved. Patients with cervical extension and extrauterine pelvic disease, including adnexal spread, parametrial involvement, and pelvic lymph node metastases, in the absence of extrapelvic disease, also should benefit from postoperative pelvic irradiation.

Extended-field Irradiation

Patients with histologically proven para-aortic node metastases who have no other evidence of disease spread outside the pelvis should be treated with extended-field irradiation. The entire pelvis, common iliac lymph nodes, and para-aortic lymph nodes are included within the radiation field. The para-aortic radiation dose is limited to 4,500 to 5,000 cGy. **Extended-**

field radiotherapy appears to improve survival in patients with endometrial cancer who have positive para-aortic lymph nodes (88,203,204,205,206).

Five-year survival rates of 47% and 43% have been reported for patients with surgically confirmed para-aortic lymph node metastases only and for those with para-aortic as well as pelvic lymph node metastases, respectively, using postoperative extended-field irradiation. Only one case of severe enteric morbidity occurred in 48 patients, a complication rate of 2% (203). In a GOG study, 37 of 48 patients with positive para-aortic nodes received postoperative para-aortic irradiation, 36% of whom remained tumor free at 5 years (88). A comparison of patients with positive para-aortic nodes treated with *megestrol acetate* alone versus *megestrol acetate* and extended-field irradiation showed that the survival rate in the patients receiving extended-field irradiation was significantly better: 53% versus 12.5%, respectively (204). In another study of 18 patients with positive para-aortic nodes, 5-year survival rates were 67% for microscopic nodal disease and 17% for gross nodal disease (205).

Whole-abdomen Irradiation

Whole-abdomen irradiation therapy usually is reserved for patients with stage III and IV endometrial cancer. It may also be considered for patients who have papillary serous or mixed mllerian tumors, which have a propensity for upper-abdominal

P.1374

recurrence (207,208,209,210,211,212). The recommended dose to the whole abdomen is 3,000 cGy in 20 daily fractions of 150 cGy, with kidney shielding at 1,500 to 2,000 cGy, along with an additional 1,500 cGy to the para-aortic lymph nodes and 2,000 cGy to the pelvis. Gastrointestinal side effects, including nausea, vomiting and diarrhea, sometimes make it necessary to interrupt therapy, but it is rare for patients to discontinue treatment because of these symptoms. Hematologic toxicity can be expected to occur during whole-abdomen irradiation, but it is usually mild. The incidence of late complications, mainly chronic diarrhea and small bowel obstruction, generally is low (5% to 10%).

In a series of 27 patients treated with surgical stage III endometrial cancer with whole-abdomen irradiation, patients with spread to the adnexa, positive peritoneal cytology, or both had a 5-year, relapse-free survival of 90%, whereas all patients with macroscopic disease beyond the adnexa had recurrence (207). Similar results were reported by others (208,209). Some have advocated the use of adjuvant whole-abdomen radiotherapy for patients with high-risk stage

I and II endometrial carcinoma, including those with deep myometrial invasion, high-grade tumors, and papillary serous histology, because of the high proportion of recurrences in the upper abdomen. A 5-year recurrence-free survival rate of 85% has been reported (210,211). With whole-abdomen irradiation in patients at increased risk for intra-abdominal metastatic disease, such as those with nonnodal extrauterine disease and papillary serous histology, an actuarial 5-year relapse-free survival rate of 70% has been reported, with no significant toxicity (212). Similarly, others have noted a 3-year disease-free survival rate of 79% in patients with stage III and IV endometrial adenocarcinoma treated with whole-abdomen irradiation (213). Still other reports of using adjuvant postoperative whole-abdomen irradiation in early-stage uterine papillary serous carcinoma suggest a reduction in recurrence rates (214,215,216). Unfortunately, most recurrences are in the upper abdomen in all of these patients, despite this type of radiotherapy. **It is reasonable to use whole-abdomen irradiation postoperatively to treat patients with adnexal or upper-abdominal disease, such as in the omentum, that has been completely excised and in patients who are at very high risk for intra-abdominal recurrence, such as those with papillary serous tumors. It should not be used in patients with gross residual intraperitoneal disease.**

Progestins

Because most endometrial cancers have both estrogen and progesterone receptors and progestins have been successfully used to treat metastatic endometrial cancer, postoperative adjuvant progestin therapy has been attempted to reduce the risk of recurrence. This therapy is attractive because it provides systemic treatment and has few side effects. Unfortunately, **several large randomized, placebo-controlled studies have failed to identify a benefit for adjuvant progestin therapy** (217,218,219,220,221,222).

Conversely, in a series of 25 patients with positive peritoneal cytology as their only evidence of disease spread outside the uterus who were treated with adjuvant progestin for 1 year postoperatively (223), 22 patients had a second-look laparoscopy, and only one patient was found to have persistent intraperitoneal malignant cells. No patient had evidence of recurrent cancer. Therefore, progestins may have a role in treating positive peritoneal cytology in this setting (224).

Chemotherapy

Adjuvant cytotoxic chemotherapy has been studied in a few trials. The GOG treated 181 patients who had poor prognostic factors with postoperative irradiation and then randomly assigned patients to receive no further therapy or *doxorubicin* (*Adriamycin*) chemotherapy. After 5 years of observation, there was no difference in recurrence rates between the two groups (225). Researchers at the M. D. Anderson Cancer Center treated 62 high-risk patients with postoperative adjuvant *cisplatin*, *doxorubicin*, and *cyclophosphamide* (PAC) chemotherapy. The presence of extrauterine disease was the only significant risk factor for recurrence, and no benefit to adjuvant chemotherapy could be found (226,227).

P.1375

More recently, use of adjuvant postoperative chemotherapy has been studied in patients with surgical stage III/IV disease. **The GOG compared whole-abdomen irradiation versus *doxorubicin/cisplatin* chemotherapy in 388 patients with advanced endometrial cancer who had undergone maximal surgical resection of disease to less than 2cm. Patients who received chemotherapy had a 13% improvement in 2-year progression-free survival (50% versus 46%) and an 11% improvement in overall 2-year survival (70% versus 59%) compared with patients treated with whole-abdomen irradiation.** Although this study was the first to suggest an improvement in outcome for use of adjuvant chemotherapy compared with radiation, toxicity was more prevalent with chemotherapy; patients with gross residual disease were assigned to the radiation arm, almost guaranteeing failure; and overall, 55% of patients experienced a recurrence or progression during the study period (228).

Clinical Stage II

Endometrial cancer involving the cervix either contiguously or by lymphatic spread has a poorer prognosis than disease confined to the corpus

(229,230,231,232,233,234,235,236,237,238,239,240,241,242,243,244,245,246,247).

Preoperative assessment of cervical involvement is difficult. **Endocervical curettage has relatively high false-positive (50%-80%) and false-negative rates.** Histologic proof of cancer infiltration of the cervix or presence of obvious tumor on the cervix is the only reliable means of diagnosing cervical involvement, although ultrasonography, hysteroscopy, or MRI may show cervical invasion.

The relatively small number of true stage II cases in reported series and the lack of

randomized, prospective studies preclude formulation of a definitive treatment plan. **Three areas must be addressed in any treatment plan:**

- **For optimal results, the uterus should be removed in all patients.**
- **Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these lymph nodes.**
- **Because the incidence of disease spread outside the pelvis to the para-aortic lymph nodes, adnexal structures, and upper abdomen is higher than in stage I disease, attention should be directed to evaluating and treating extrapelvic disease.**

Two approaches have usually been used in the treatment of clinical stage II disease:

- **Radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy**
- **Combined radiation and surgery (external pelvic irradiation and intracavitary radium or cesium followed in 6 weeks by total abdominal hysterectomy and bilateral salpingo-oophorectomy)**

An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of allowing accurate surgical—pathologic information to be obtained. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. In addition, reported results are no better than those with combined radiation and less radical surgical therapy (247). The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

The most common, **traditional approach to the management of clinical stage II endometrial cancer has been to use external and intracavitary irradiation followed by**

P.1376

extrafascial hysterectomy. This combined approach has resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients (230,231,232,233,234,235,236,237,238). Patients who have medically inoperable disease are usually treated with external-beam irradiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors (187) (see Table 33.13).

Another method of management of clinical stage II endometrial cancer that is gaining favor is an initial surgical approach followed by irradiation. This method is based on the difficulty in establishing the preoperative diagnosis of cervical involvement in the absence of a gross cervical tumor, the evidence that radiation is equally effective when given after hysterectomy, and the high incidence of extrapelvic disease when the cervix is involved. Exploratory laparotomy with an extrafascial or modified radical hysterectomy, bilateral salpingo-oophorectomy, peritoneal washings for cytology, resection of grossly enlarged pelvic nodes, and selective high common iliac and lower para-aortic lymphadenectomy are performed. These procedures are followed by appropriate pelvic or extended-field external and intravaginal irradiation, depending on the results of surgical staging. Excellent results have been reported using this treatment scheme (241,242,243,244).

Clinical Stages III and IV

Clinical stage III disease accounts for about 7% to 10% of all endometrial carcinomas (248,249,250,251,252,253,254,255). Patients usually have clinical evidence of disease spread to the parametria, pelvic sidewall, or adnexal structures; less frequently, there is spread to the vagina or pelvic peritoneum. **Treatment for stage III endometrial carcinoma must be individualized, but initial operative evaluation and treatment should be considered because of the high risk for occult lymph node metastases and intraperitoneal spread when disease is known to extend outside of the uterus into the pelvis.** In the presence of an adnexal mass, surgery should be performed initially to determine the nature of the mass. Surgery should also be performed to determine the extent of disease and to remove the bulk of the disease if possible. This procedure should include peritoneal washings for cytologic examination, selective para-aortic and pelvic

lymphadenectomy, removal of any enlarged lymph nodes, biopsy or excision of any suspicious areas within the peritoneal cavity, and partial omentectomy and peritoneal biopsies. Except in patients with bulky parametrial disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. **The goal of surgery is eradication of all macroscopic disease because this finding is of major prognostic importance in the management of patients with clinical stage III disease.** Postoperative therapy can then be tailored to the extent of disease.

Results of therapy depend on the extent and nature of disease. A 5-year survival rate of 54% has been reported for all patients with stage III disease; however, the survival was 80% when only adnexal metastases were present, compared with 15% when other extrauterine pelvic structures were involved (248). Patients with surgical—pathologic stage III disease have a much better survival rate (40%) than those with clinical stage III disease (16%) (237). Patients who are treated with combined surgery and irradiation fare better than patients who receive radiation therapy alone (255).

Stage IV endometrial adenocarcinoma, in which tumor invades the bladder or rectum or extends outside the pelvis, makes up about 3% of cases (255,256,257,258,259). **Treatment of stage IV disease is patient dependent but usually involves a combination of surgery, radiation therapy, and systemic hormonal therapy or chemotherapy.** One objective of surgery and radiation therapy is to achieve local disease control in the pelvis to provide palliative relief of bleeding, discharge, and complications involving the bladder and rectum. In one report, control of pelvic disease was achieved in 28% of 72 patients with stage IV disease treated with radiation alone or in combination with surgery, progestins, or both (256). **Several reports have noted a positive impact of cytoreductive surgery on survival, the median**

P.1377

survival being about 3 times greater with optimal cytoreduction (18–34 months versus 8–11 months, respectively) (257,258,259). Pelvic exenteration may be considered in the very rare patient in whom disease is limited to the bladder, rectum, or both (260,261).

Recurrent Disease

About one fourth of patients treated for early endometrial cancer develop recurrent disease. More than one half of the recurrences develop within 2 years, and about three fourths occur within 3 years of initial treatment. The distribution

of recurrences is dependent in large part on the type of primary therapy: surgery alone versus surgery plus local or regional radiotherapy. In a GOG study of 390 patients with surgical stage I disease, vaginal and pelvic recurrences were noted to make up 53% of all recurrences in the group treated with surgery alone, whereas only 30% of recurrences were vaginal or pelvic in the group treated with combined surgery and radiotherapy (88). Therefore, after combined surgery and radiotherapy (vaginal or external beam), 70% or more of patients with treatment failures have distant metastases, and most of these patients do not have evidence of local or pelvic recurrence. The most common sites of extrapelvic metastases are the lung, abdomen, lymph nodes (aortic, supraclavicular, inguinal), liver, brain, and bone. In general, patients with isolated vaginal recurrences fare better than those with pelvic recurrences, who in turn have a better chance of cure than those with distant metastases. Patients who initially have well-differentiated tumors or who develop recurrent cancer more than 3 years after the primary therapy also tend to have an improved prognosis.

In a 1984 report on 379 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital from 1960 to 1976 (262), site of recurrence was local or regional in 190 patients (50%), distant in 108 patients (28%), and local and distant in 81 patients (21%). The median time of recurrence was 14 months for patients with local recurrences and 19 months for patients with distant metastases. Of all recurrences, 34% were detected within 1 year, and 76% were detected within 3 years of primary treatment. At the time of diagnosis of recurrence, 32% of patients had no symptoms. **Vaginal bleeding was the most common symptom associated with local recurrence, and pelvic pain was most often present with pelvic recurrence.** Hemoptysis was the initial symptom in 32% of patients with lung metastases, but 45% of cases of lung metastases were asymptomatic and picked up on routine chest x-ray. Only 9% of patients with metastases at other sites did not have symptoms; most had pain (37%) or other symptoms such as anorexia, nausea and vomiting, or ascites related to intra-abdominal carcinomatosis, neurologic symptoms such as seizures from brain metastases, or jaundice caused by liver metastases.

Overall, only 29 (7.7%) of the 379 patients were alive without evidence of disease from 3 to 19 years. This included 22 patients (12%) with local or pelvic recurrence, 5 patients (5%) with distant metastases, and 2 patients (2%) with both local and distant recurrences. The best results were obtained in the 42 patients with vaginal vault recurrences who were treated with radiotherapy, resulting in a 24% survival rate. None of the 78 patients with pelvic soft tissue recurrence survived. Three patients (7%) with only lung metastases treated with progestins, two patients with lymph node metastases treated with combined radiotherapy and progestins, and two patients with local recurrence and lung metastases treated

with radiotherapy, surgery, and progestins survived.

Surgery

A small subset of patients who develop recurrent endometrial cancer may benefit from surgical intervention. Pelvic or vaginal recurrence in patients who have not received prior pelvic irradiation is best treated with external irradiation plus some type of brachytherapy. Surgical resection of a metastatic nodule greater than 2 cm in diameter before irradiation, however, may improve local control. Pretherapy investigation for extrapelvic metastasis in these patients may include surgical evaluation of the peritoneal cavity and retroperitoneal lymph nodes for evidence of subclinical metastases.

P.1378

In one small series, upper-abdominal disease was found at laparotomy in 3 (37.5%) of 8 patients with presumed localized pelvic recurrence. Presence of subclinical extrapelvic metastases was associated with larger pelvic tumor size (>2 cm) and elevated serum CA125 levels (263). A few patients with intraperitoneal recurrence may benefit from laparotomy to relieve intestinal obstruction. Tumor-reductive surgery may be performed before administration of whole-abdomen radiation therapy or systemic hormonal therapy or chemotherapy.

Isolated central pelvic recurrence after irradiation is rare. In patients with this type of recurrence, exploratory laparotomy may be performed with the plan to proceed with pelvic exenteration if there is no evidence of disease outside the pelvis and no lymph node metastases. Exenterative surgery for recurrent endometrial cancer in the pelvis is of value in selected patients because of the high incidence of associated occult extrapelvic metastases. Of 36 patients who underwent pelvic exenteration for recurrent endometrial carcinoma at Memorial Sloan-Kettering Cancer Center, 75% died of their cancer within 1 year of operation, and only 14% were alive after 5 years (261).

Radiation Therapy

Patients with isolated local or regional recurrences after initial surgical treatment of endometrial cancer should be treated with radiotherapy (191,264-271). The best local control and subsequent cure are usually achieved by a combination of external-beam radiation therapy followed by a brachytherapy boost to deliver a total tumor dose of at least 6,000 cGy. Women with low-volume disease limited to the pelvis have the best outcome.

For patients with isolated vaginal recurrence treated with irradiation, reported survival rates range from 24% to 45%. Conversely, for those patients who undergo irradiation of the pelvic extension of their disease, lower survival rates (0%-24%) have been reported. Significant factors that determine control of pelvic disease and survival in patients with locally recurrent endometrial cancer include initial endometrial cancer grade 1, younger age at recurrence, recurrent tumor size 2 cm or less, time from initial treatment to recurrence of more than 1 year, vaginal versus pelvic disease, and radiation therapy that included brachytherapy vaginal boost.

Hormone Therapy

The use of progestational agents for treatment of metastatic endometrial cancer was first described in 1961, when researchers observed an objective response rate of 29% in 21 patients (272). In a report from 1974, a beneficial response was observed in 35% of 308 patients (273). Subsequent reports have noted somewhat less optimistic response rates, probably as a result of more strictly applied criteria for objective responses (274,275,276,277) (Table 33.15). Reports from Roswell Park Cancer Center and the Mayo Clinic observed objective response rates of 16% and 11%, respectively, with an additional 15% to 40% of patients exhibiting stable disease for at least 3 months (274,275). In 1986 the GOG

P.1379

initially reported on the use of oral *medroxyprogesterone acetate* for treatment of patients with advanced or recurrent endometrial cancer (276). Of 219 patients with measurable disease, 8% had a complete response, 6% had a partial response, 52% had stable disease, and 34% developed progressive disease within 1 month.

The mean survival time for the entire group was 10.4 months. In a follow-up study comparing two different doses of oral *medroxyprogesterone acetate*, similar response rates were achieved (26% for 200 mg/day and 18% for 1,000 mg/day) (277). The type, dose, and route of administration of the progestin seemed to have no effect on response in these studies.

Table 33.15 Response to Progestin Therapy in Advanced or Recurrent Endometrial Cancer

<i>Study</i>	<i>Progestin</i>	<i>No. of Patients</i>	<i>Response Rate (%)</i>	
Piver et al. (274)	<i>HPC</i>	1,000 mg/wk IM	51	14
	<i>MPA</i>	1,000 mg/wk IM	37	19
Podratz et al. (275)	<i>HPC</i>	1-3 g/wk IM	33	9
	<i>MA</i>	320 mg/d PO	81	11
Thigpen et al. (276,277)	<i>MPA</i>	150 mg/d PO	219	14
		200 mg/d PO	138	26
		1,000 mg/d PO	140	18

HPC, hydroxyprogesterone caproate (Delalutin); MPA, medroxyprogesterone acetate (Provera, Depo-Provera); MA, megestrol acetate (Megace); IM, intramuscular; PO, oral.

The response of metastatic endometrial carcinoma to progestin therapy is related to several clinical and pathologic factors. **Higher response rates are observed in well-differentiated tumors.** A 20.5% response in low-grade tumors and only 1.4% response in high-grade tumors have been noted (275). Likewise, the probability of an objective response to progestin therapy is about 70% for tumors that are estrogen- and progesterone-receptor positive, compared with about 5% to 15% for tumors that are negative for both receptors. A longer disease-free interval is associated with higher response rates to progestins. The response rate to progestins has been found to range from 6% in patients with an interval from primary treatment to recurrence of less than 6 months to 65% in patients in whom disease recurred more than 5 years after initial treatment (274). Other observed but less well-documented factors that may have an adverse effect on response to progestins are disease recurrence within a prior radiation field, large tumor burden, and advanced primary versus recurrent disease (274,275).

Tamoxifen, a nonsteroidal antiestrogen with some estrogenic properties, has been evaluated for treatment of metastatic endometrial carcinoma based on experience in using this agent in breast cancer treatment. Its use as either a single agent or in combination with a progestin is related to its ability to inhibit the binding of estradiol to the estrogen receptor and to increase progesterone receptors. **In a review of eight studies using *tamoxifen*, 20 to 40 mg/day, in patients with metastatic endometrial carcinoma, the overall response rate was 22%, with a range of 0% to 53% (278). Responses to *tamoxifen* were more likely to be observed in patients with low-grade, hormone receptor–positive tumors who had**

a prior response to progestin therapy. In an attempt to reverse the hormone receptor downregulation seen with progestin therapy, *tamoxifen* has been given along with progestins, but the overall responses to combined *tamoxifen* and progestin therapy have been similar to those noted for single-agent progestin therapy.

Progestins are currently recommended as initial treatment for all patients with recurrent endometrioid tumors with hormone receptor-positive tumors. Radiation therapy, surgery, or both should be used whenever feasible for treatment of localized recurrent cancer such as vaginal, pelvic, bone, and peripheral lymph node disease; however, these patients should also be given long-term progestin therapy unless they are known to have a progesterone-receptor—negative tumor. Patients with nonlocalized recurrent tumors, especially if progesterone receptors are known to be positive, are candidates for progestin therapy, either *megestrol acetate*, 80 mg twice daily, or *medroxyprogesterone acetate*, 50 to 100 mg three times daily. Progestin therapy should be continued for at least 2 to 3 months before assessing response. **If a response is obtained, the progestin should be continued for as long as the disease is static or in remission. In the presence of a relative contraindication to high-dose progestin therapy (e.g., prior or current thromboembolic disease, severe heart disease, or inability of the patient to tolerate progestin therapy), *tamoxifen*, 20 mg twice daily, is recommended.** Failure to respond to hormonal therapy is an indication for initiating chemotherapy.

Chemotherapy

Although several chemotherapeutic agents or combinations of agents are capable of inducing objective responses and even remissions in patients with metastatic endometrial carcinoma, response and survival times are short, and all cytotoxic therapy should be

P.1380

considered palliative (278,279,280). The most active chemotherapeutic agents are *doxorubicin*, the *platinum* compounds *cisplatin* and *carboplatin*, and *paclitaxel* (*Taxol*). *Doxorubicin*, 50 to 60 mg/m² every 3 weeks (281,282,283); *cisplatin*, 60 to 75 mg/m² every 3 weeks (284,285); and *carboplatin*, 350 to 400 mg/m² every 4 weeks (286,287) have been associated with response rates of 21% to 29%. *Paclitaxel*, 250 mg/m² as a 24-hour infusion with granulocyte colony-stimulating factor support (287), or 175 mg/m² as a 3-hour infusion every 3 weeks (288,289,290), has produced response rates of about 36%. Alkylating agents such as *cyclophosphamide* and *melphalan*, *fluorouracil*, *altretamine* (*hexamethylmelamine*)

(291), *liposomal doxorubicin* (292), and *topotecan* (293,294) have shown activity against endometrial cancer. Most responses obtained with use of these agents have been partial, generally averaging only 3 to 6 months, with the median survival time ranging from 4 to 8 months.

Combination chemotherapy regimens employing *doxorubicin* and *cisplatin* (283,295); *cyclophosphamide*, *doxorubicin*, and *cisplatin* (296,297); *paclitaxel* and *cisplatin* with or without *doxorubicin* (298,299); and *carboplatin* and *paclitaxel* (300) have resulted in response rates ranging from 38% to 76%. Despite these fairly impressive response rates, most responses have been partial, with durations of 4 to 8 months, and the median survival time has generally been less than 12 months.

Response to chemotherapy in patients with metastatic endometrial cancer does not appear to be affected by prior or concurrent progestin therapy. Metastatic site, age, disease-free interval, histology, and tumor grade also appear to have no effect on chemotherapy response. However, patients with long disease-free intervals and better performance status may live longer.

Treatment Results

Comprehensive survival data for endometrial cancer are provided by FIGO (301). Survival in relation to clinical and surgical stage is shown in Table 33.16 and in relation to surgical stage and grade in Table 33.17. **The overall 5-year survival rate was 76%. Patients who underwent surgical staging had much better 5-year survival rates than those staged clinically across all stages** (respectively): stage I, 87% versus 54%; stage II, 76% versus

41%; stage III, 57% versus 23%; stage IV, 18% versus 12%. Survival in surgical stage I disease ranged from more than 90% for stage Ia grades 1 and 2 and stage Ib grades 1 and 2 to 63% for stage Ic grade 3.

Follow-up after Treatment

History and physical examination remain the most effective methods of follow-up in patients treated for endometrial cancer (302,303,304,305). **Patients should be examined every 3 to 4 months during the first 2 years and every 6 months thereafter. About one half of patients discovered to have recurrent cancer have symptoms, and 75% to 80% of recurrences are detected initially on physical examination. Particular attention should be given to peripheral lymph nodes, the abdomen, and the pelvis.** Very few asymptomatic recurrences are detected by vaginal cytology.

Chest x-ray every 12 months is an important method of posttreatment surveillance. **Almost one half of all asymptomatic recurrences are detected by chest x-ray.** Other radiologic studies, such as intravenous pyelography and CT scans, are not indicated for routine follow-up of patients who do not have symptoms.

Serum CA125 measurement has been suggested for posttreatment surveillance of endometrial cancer (305,306,307). Elevated CA125 levels have been documented in patients with recurrent tumor, and these levels have correlated with the clinical course of disease. However, CA125 levels may be normal in the presence of small recurrences, making the utility of CA125 measurements for follow-up of patients after treatment of early-stage disease suspect. Determinations of CA125 should be obtained in patients with elevated levels at the time of diagnosis or with known extrauterine disease.

Estrogen Therapy after Treatment of Endometrial Cancer

A history of endometrial cancer has long been considered a contraindication to estrogen therapy because of the concern that occult metastatic disease might be activated by estrogen. Although this is a reasonable concern, the magnitude of this risk has never been quantified

and, in fact, **there is no evidence that estrogen therapy after apparently**

successful treatment of endometrial cancer increases the risk for cancer recurrence.

In a nonrandomized, retrospective follow-up study of 221 patients with clinical stage I endometrial cancer, 47 patients who had received estrogen after treatment were compared with 174 who had not been treated with estrogen. There were no significant differences between the two groups with respect to known risk factors for cancer recurrence. There were 26 (14.9%) recurrences in the patients not treated with estrogen, compared with only 1 (2.1%) recurrence in the patients treated with estrogen. Moreover, in the group not receiving estrogen, there were 26 deaths (16 from cancer and 10 from intercurrent disease), compared with only 1 death among those taking estrogen (308). Similarly in another report, no recurrent cancers and no intercurrent deaths were found in 44 women who took estrogen after treatment for endometrial cancer, compared with eight recurrences and eight intercurrent deaths (five from myocardial infarction) in 99 women who did not take estrogen (309). In a subsequent study of 123 surgical stage I and II endometrial cancer patients, 62 (50.5%) who received estrogen therapy postoperatively were identified. After controlling for risk factors for recurrence, there was no detectable difference in recurrence rate or time to recurrence between those patients who had received estrogen therapy and those who had not (310). More recently, a retrospective cohort study of matched treatment-control pairs found two recurrences (1%) among the 75 women using estrogen, compared with 11 recurrences (14%) in the 75 women not using estrogen after primary therapy for endometrial cancer (311). In all of these studies, however, most patients did not commence estrogen therapy immediately after surgery.

Many women who have been successfully treated for endometrial cancer suffer side effects of estrogen deficiency, such as vasomotor instability, vaginal dryness, and dyspareunia, as well as the long-term risk of osteoporosis. Because of the risk of hormone therapy for all women, its use in women previously treated for endometrial cancer should be considered carefully after the patient has been counseled about risks, benefits, and options. A compromise between immediate postoperative estrogen therapy and no hormone therapy might be to withhold estrogen for 1 to 3 years after treatment, the time in which most recurrences develop, thereby minimizing the chances of administering estrogen to patients with residual cancer. **Alternatively, topical estrogen alone can be used judiciously to treat vaginal symptoms. Symptomatic relief of hot flashes can be achieved by prescribing progestins such a *medroxyprogesterone acetate*, 10 mg orally daily or 150 mg intramuscularly every 3 months, or nonhormonal agents such as *Bellergal*, *clonidine*, and *venlafaxine*.**

Uterine Sarcoma

Uterine sarcomas are relatively rare tumors of mesodermal origin. They constitute 2% to 6% of uterine malignancies (312,313,314). There is an increased incidence of uterine sarcomas after radiation therapy to the pelvis for either carcinoma of the cervix or a benign condition. The relative risk of uterine sarcoma after pelvic radiotherapy has been estimated to be 5.38, with an interval of usually 10 to 20 years (315). Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread, and management.

Classification

The three most common histologic variants of uterine sarcoma are endometrial stromal sarcoma (ESS), leiomyosarcoma, and malignant mixed müllerian tumor (MMMT) of both homologous and heterologous type (316) (Table 33.18). Variations in the relative incidences of uterine sarcomas occur in different published series, probably

P.1383

related to the strictness of criteria used to classify smooth muscle and endometrial stromal tumors as sarcomas. In general, leiomyosarcoma and MMMT each make up about 40% of tumors, followed by ESS (15%) and other sarcomas (5%), although MMMT predominates in more recent reports. Staging of uterine sarcomas is based on the FIGO system for endometrial carcinoma (see Table 33.6 and 33.7).

Table 33.18 Classifications of Uterine Sarcomas

I. Pure nonepithelial tumors

Endometrial Stromal Tumors

Stromal tumors occur primarily in perimenopausal women between ages 45 and 50 years; about one third occur in postmenopausal women. There is no relationship to parity, associated diseases, or prior pelvic radiotherapy. These tumors are rare in African-American women. The most frequent symptom is abnormal uterine bleeding; abdominal pain and pressure caused by an enlarging pelvic mass occur less often, and some patients do not have symptoms. Pelvic examination usually reveals regular or irregular uterine enlargement, sometimes associated with rubbery parametrial induration. The diagnosis may be determined by endometrial biopsy, but the usual preoperative diagnosis is uterine leiomyoma. At surgery, the diagnosis is suggested by the presence of an enlarged uterus filled with soft, gray-white to yellow necrotic and hemorrhagic tumors with bulging surfaces associated with wormlike elastic extensions into the pelvic veins.

Endometrial stromal tumors are composed purely of cells resembling normal endometrial stroma. They are divided into three types on the basis of mitotic activity, vascular invasion, and observed differences in prognosis: (i) endometrial stromal nodule, (ii) endometrial stromal sarcoma, and (iii) high-grade or undifferentiated sarcoma.

Endometrial stromal nodule is an expansive, noninfiltrating, solitary lesion confined to the uterus with pushing margins, no lymphatic or vascular invasion, and usually less than 5 mitotic figures per 10 high-power microscopic fields (5 MF/10 HPF). These tumors should be considered benign because there have been no recurrences or tumor-associated deaths reported after surgery (317,318).

Endometrial stromal sarcoma (formerly termed low-grade ESS or endolymphatic stromal myosis) is distinguished from high-grade ESS or undifferentiated endometrial sarcoma microscopically by a mitotic rate of less than 10 MF/10 HPF as well as clinically by a more protracted course. Recurrences typically occur late, and local recurrence is more common than distant metastases (319,320,321,322,323). Although endometrial stromal sarcoma often behaves in a histologically aggressive fashion, it lacks the aneuploid DNA content and high proliferative index associated with high-grade stromal sarcoma. Flow cytometric analysis can be used to differentiate the two conditions and predict response to therapy.

Endometrial stromal sarcoma has extended beyond the uterus in 40% of cases at the time of diagnosis, but the extrauterine spread is confined to the pelvis in two thirds of the cases. Upper-abdominal, pulmonary, and lymph node metastases are uncommon. Recurrence occurs in almost one half of cases at an average interval of about 5 years after initial therapy. Prolonged survival and even cure are not uncommon even after the development of recurrent or metastatic disease.

Optimum initial therapy for patients with endometrial stromal sarcoma consists of surgical excision of all grossly detectable tumor. Total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. The adnexa should always be removed because of the propensity for tumor extension into the parametria, broad ligaments, and adnexal structures as well as the possible stimulating effect of estrogen from retained ovaries on the tumor cells. A beneficial effect of radiation therapy has been reported, and pelvic irradiation is recommended for inadequately excised or locally recurrent pelvic disease (319). There is also evidence that endometrial stromal sarcoma is hormone dependent or responsive.

(323). Recurrent or metastatic lesions may also be amenable to surgical excision. Long-term survival and apparent cures have been noted in patients with pulmonary metastases (324).

High-grade ESS or undifferentiated endometrial sarcoma is a highly malignant neoplasm. Histologically, it exhibits greater than 10 MF/10 HPF and often completely lacks recognizable stromal differentiation. This tumor has a much more aggressive clinical course and poorer prognosis than endometrial stromal sarcoma (316,319,325,326,327). The 5-year disease-free survival is about 25%. Treatment of undifferentiated endometrial sarcoma should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy. The poor therapeutic results obtained to date suggest that radiation therapy, chemotherapy, or both should be used in combination with surgery. These tumors, unlike endometrial stromal sarcoma, are not responsive to progestin therapy.

Uterine tumor resembling ovarian sex-cord tumor (UTROSCT) is a rare variant of endometrial stromal sarcoma in which benign glands and epithelial cells are found. Immunohistochemically, these tumors express cytokeratin, epithelial membrane antigen, vimentin, and smooth muscle actin. Although some of these tumors have infiltrative margins, almost all of them behave benignly. The so-called mixed UTROSCT have a significant endometrial stromal sarcoma component and tend to behave more aggressively (328,329).

Leiomyosarcoma

The median age for women with leiomyosarcoma (43 to 53 years) is somewhat lower than that for other uterine sarcomas, and premenopausal patients have a better chance of survival. This malignancy has no relationship with parity, and the incidence of associated diseases is not as high as in MMMT or endometrial adenocarcinoma. African-American women have a higher incidence and a poorer prognosis than women of other races. A history of prior pelvic radiation therapy can be elicited in about 4% of patients with leiomyosarcoma. The incidence of sarcomatous change in benign uterine leiomyomas is reported to be between 0.13% and 0.81% (330,331,332,333,334,335,336,337,338,339,340).

Presenting symptoms, which usually are of short duration (mean, 6 months) and not specific to the disease, include vaginal bleeding, pelvic pain or pressure, and awareness of an abdominopelvic mass. The principal physical finding is the presence of

a pelvic mass. The diagnosis should be suspected if severe pelvic pain accompanies a pelvic tumor, especially in a postmenopausal woman. Endometrial biopsy, although not as useful as in other sarcomas, may establish the diagnosis in as many as one third of cases when the lesion is submucosal.

Survival rates for patients with uterine leiomyosarcoma range from 20% to 63% (mean, 47%). The pattern of tumor spread is to the myometrium, pelvic blood vessels and lymphatics, contiguous pelvic structures, abdomen, and then distantly, most often to the lungs. The number of mitoses in the tumor has traditionally been the most reliable microscopic indicator of malignant behavior (see Fig. 33.8).

Generally, tumors with less than 5 MF/10 HPF behave in a benign fashion, and tumors with more than 10 MF/10 HPF are frankly malignant with a poor prognosis. Tumors with 5 to 10 MF/10 HPF, termed *cellular leiomyomas* or *smooth muscle tumors of uncertain malignant potential*, are less predictable. Therefore, in addition to mitotic index greater than 10, other histologic indicators used to classify uterine smooth muscle tumors as malignant are severe cytologic atypia and coagulative tumor cell necrosis (341). Uterine smooth muscle tumors with any two of these three features are associated with a poor prognosis. Gross presentation of the tumor at the time of surgery is also an important prognostic indicator. Tumors with infiltrating tumor margins or extension beyond the uterus are associated with poor prognosis, whereas tumors less than 5 cm, originating within myomas, or with pushing margins are associated with prolonged survival.

Five other clinical pathologic variants of uterine smooth muscle tumors deserve special comment: (i) myxoid leiomyosarcoma, (ii) leiomyoblastoma, (iii) intravenous leiomyomatosis, (iv) benign metastasizing uterine leiomyoma, and (v) disseminated peritoneal leiomyomatosis.

***Myxoid leiomyosarcoma* is characterized grossly by a gelatinous appearance and apparent circumscribed border.** Microscopically, the tumors have a myxomatous stroma and extensively invade adjacent tissue and blood vessels (342). The mitotic rate is low (0-2 MF/10 HPF), which belies their aggressive behavior and poor prognosis. Surgical excision by hysterectomy is the mainstay of treatment. The low mitotic rate and abundance of intracellular myxomatous tissue suggest that these tumors would not be responsive to radiation therapy or chemotherapy.

***Leiomyoblastoma* includes smooth muscle tumors designated as epithelioid leiomyomas, clear cell leiomyomas, and plexiform tumorlets (343,344).** This group of

atypical smooth muscle tumors is distinguished by the predominance of rounded rather than spindle-shaped cells and by a clustered or cordlike pattern. These lesions should be regarded as specialized low-grade leiomyosarcomas with fewer than 5 MF/10 HPF. Leiomyoblastoma is treated with hysterectomy, and the prognosis is excellent.

Figure 33.8 Leiomyosarcoma of the uterus. Interlacing bundles of spindle cells have fibrillar cytoplasm, irregular and hyperchromatic nuclei, and multiple mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

P.1386

Intravenous leiomyomatosis is characterized by the growth of histologically benign smooth muscle into venous channels within the broad ligament and then into uterine and iliac veins (345,346,347,348). The intravascular growth takes the form of visible, wormlike projections that extend out from a myomatous uterus into the parametria toward the pelvic sidewalls. It may be confused with low-grade stromal sarcoma. Symptoms are related to the associated uterine myomas. Most patients are in the late fifth and early sixth decades of life. The prognosis is excellent, even when tumor is left in pelvic vessels. Late local recurrences can occur, and deaths from extension into the inferior vena cava or metastases to the heart have been reported. Estrogen may stimulate the proliferation of these intravascular tumors. Treatment should be total abdominal hysterectomy and bilateral salpingo-oophorectomy with removal of as much of the tumor as possible.

Benign metastasizing uterine leiomyoma is a rare condition in which a histologically benign uterine smooth muscle tumor acts in a somewhat malignant fashion and produces benign metastases, usually to the lungs or lymph nodes (349). In most instances, intravenous leiomyomatosis is not apparent. The metastasizing myomas are capable of growth at distant sites, whereas the intravenous tumors spread only by direct extension within blood vessels. Both experimental and clinical evidence suggests that

P.1387

these tumors are stimulated by estrogen. Therefore, removing the source of estrogen, by castration or withdrawal of exogenous estrogen, or by treatment with progestins, *tamoxifen*, or a gonadotropin agonist, has an ameliorating effect (350). Surgical treatment should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy as well as resection of pulmonary metastases, if possible.

Disseminated peritoneal leiomyomatosis is a rare clinical entity characterized by benign smooth muscle nodules scattered throughout the peritoneal cavity (351). This condition probably arises as a result of metaplasia of subperitoneal mesenchymal stem cells to smooth muscle, fibroblasts, myofibroblasts, and decidual cells under the influence of estrogen

and progesterone. Most reported cases have occurred in 30- to 40-year-old women who are or who have recently been pregnant or who have a long history of oral contraceptive use. Intriguing features of this disease are its grossly malignant appearance, benign histology, and favorable clinical outcome. Intraoperative diagnosis requires frozen-section examination. Extirpative surgery, including total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and excision of as much gross disease as possible may be indicated in menopausal women. Removal of the source of excess estrogen, treatment with progestins, or both has resulted in regression of unresected tumor masses. Almost all patients have a good prognosis.

Malignant Mixed Müllerian Tumors

Malignant mixed müllerian tumors are composed histologically of a mixture of sarcoma and carcinoma. The carcinomatous element is usually glandular, whereas the sarcomatous element may resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (352,353,354,355).

Almost all of these tumors occur after menopause, at a median age of 62 years.

The incidence is higher in African-American women. These tumors are often found in association with other medical conditions, such as obesity, diabetes mellitus, and hypertension. A history of previous pelvic irradiation can be obtained in 7% to 37% of patients.

The most frequent presenting symptom is postmenopausal bleeding, which occurs in 80% to 90% of cases. Other less common symptoms are vaginal discharge, abdominal or pelvic pain, weight loss, and passage of tissue from the vagina. The duration of symptoms usually is only a few months. On physical examination, uterine enlargement is present in 50% to 95% of patients, and a polypoid mass may be seen within or protruding from the endocervical canal in up to 50% of patients. Diagnosis can usually be determined by biopsy of an endocervical mass or endometrial curettage.

The tumor grows as a large, soft, polypoid mass filling and distending the uterine cavity; necrosis and hemorrhage are prominent features. The myometrium is invaded to various degrees in almost all cases. The most frequent areas of spread are the pelvis, lymph nodes, peritoneal cavity, lungs, and liver. This metastatic pattern suggests that these neoplasms spread by local extension and regional lymph node metastasis in a manner similar to that of

endometrial adenocarcinoma, although they behave more aggressively.

The most important single factor affecting prognosis in patients with MMMT is the extent of tumor at the time of treatment. One study noted that in patients with tumor apparently confined to the uterine corpus (stage I), the 2-year survival rate was 53%, whereas the survival rate dropped to 8.5% when disease had extended to the cervix, vagina, or parametria (stage II and III); no patients with disease outside the pelvis (stage IV) survived (356). In another study, 5-year survival for patients with disease confined to the corpus (74%) was significantly greater than for those with more advanced disease (24%) (357).

P.1388

Unfortunately, disease has extended outside the uterus in 40% to 60% of cases at the time of diagnosis, indicating the highly malignant nature of this lesion. Even when disease is believed to be confined to the uterus preoperatively and potentially is still curable, surgical and pathologic staging identifies extrauterine spread of disease in a significant number of cases. In one study, 55% of women with clinical stage I MMMT had a higher surgical—pathologic stage. Only 28% of tumors were actually confined to the uterine corpus, 16% had extension to the cervix, and 56% showed extrauterine spread (358). In a significant number of patients, lymph node metastases and positive peritoneal cytology has been found with early-stage MMMT (357,359,360). Deep myometrial invasion, which is present in about one half of stage I cases, is associated with poor prognosis. Almost all patients in whom tumor involves the outer one half of the myometrium die from the disease. Patients who die from MMMT tend to have larger tumors and a higher incidence of LVSI. Patients with a history of prior pelvic irradiation generally have a poorer prognosis. Overall, the 5-year survival rate for patients with MMMT is about 20% to 30%.

Adenosarcoma is an uncommon variant of MMMT (361,362). It consists of an admixture of benign-appearing neoplastic glands and a sarcomatous stroma. Most patients present with postmenopausal vaginal bleeding, and the disease is diagnosed or suspected based on endometrial curettage. Most adenosarcomas are well circumscribed and limited to the endometrium or superficial myometrium. The treatment is hysterectomy and bilateral salpingo-oophorectomy, with or without adjuvant radiotherapy. Because recurrences, mostly in the form of local pelvic or vaginal disease, have been reported in 40% to 50% of cases, adjuvant postoperative intravaginal or pelvic irradiation has been recommended.

Treatment

Recurrences develop in more than one half of cases of uterine sarcoma, even when disease is apparently localized at the time of treatment (363,364,365). At least one half of recurrences occur outside the pelvis, with isolated pelvic failures accounting for less than 10% of recurrences. The most common sites of recurrence are the abdomen and lungs. These data emphasize that the major limitation to cure of uterine sarcomas is distant spread.

Based on this type of evidence, treatment of most stage I and II uterine sarcomas should include hysterectomy, bilateral salpingo-oophorectomy, and treatment of the pelvic lymphatics by irradiation or surgery. Strong consideration should also be given to the use of adjuvant chemotherapy to decrease the incidence of distant metastases. Stage III uterine sarcomas are probably best treated by an aggressive combined approach of surgery, radiation therapy, and chemotherapy. Stage IV disease must be treated with combination chemotherapy.

Surgery

The first step in the treatment of early uterine sarcoma should be exploratory laparotomy. Because extirpative survey is the most important aspect of treatment, and knowledge of the extent and spread of the disease is important for further management, one should not forego or delay surgery by using radiation therapy or chemotherapy first. At the time of surgery, the peritoneal cavity should be carefully explored and peritoneal washings obtained. Special attention should be given to the pelvic and para-aortic lymph nodes; selected lymphadenectomies should be performed with ESS and MMT, but are not necessary in leiomyosarcoma, in which the risk of lymph node metastases is low. **Total abdominal hysterectomy is the standard procedure, and bilateral salpingo-oophorectomy should also be performed in all patients except premenopausal women with leiomyosarcoma.** Based on the surgical and pathologic findings, additional therapy with radiation therapy or chemotherapy can then be planned. Rarely, a patient may be cured by excision of an isolated pulmonary metastasis (366,367).

Radiation Therapy

Most studies have found adjuvant preoperative or postoperative radiation therapy to be of value in decreasing pelvic recurrences and thereby increasing quality of life in

patients with localized ESS and MMMT, but not with leiomyosarcoma (368,369,370,371,372,373,374,375,376). Radiation therapy thus appears to have a role used in combination with surgery in the treatment of MMMT and ESS confined to the pelvis. By increasing the disease-free progression interval and pelvic control, radiation therapy probably increases the overall survival to some degree.

Chemotherapy

Several chemotherapeutic agents have been found to have activity in sarcomas, including *vincristine*, *actinomycin D*, *cyclophosphamide*, *doxorubicin*, *dimethyl triazeno imidazole carboxamide (dacarbazine, DTIC)*, *cisplatin*, *ifosfamide* *paclitaxel*, *gemcitabine*, and *liposomal doxorubicin* (377). *Doxorubicin* appears to be the most active single agent in the treatment of leiomyosarcoma, producing a 25% response rate (378). *Ifosfamide* also has some activity to a lesser degree (379). On the other hand, *cisplatin* and *ifosfamide* have demonstrated clear activity in MMMT, with responses rates of 18% to 42% and 32%, respectively (380,381,382). *Doxorubicin* has demonstrated less than a 10% response rate in MMMT (378). *Paclitaxel* yielded an 18% response rate with MMMT (383), but had limited activity in leiomyosarcomas (384). *Gemcitabine* (385) and *liposomal doxorubicin* (386) have shown activity in leiomyosarcomas.

Combination chemotherapy with *doxorubicin* and *DTIC*, or these two drugs plus *vincristine* and *cyclophosphamide*, has been reported to yield somewhat higher response rates (387,388,389). Similarly, *ifosfamide* has been combined with *mesna uroprotection*, *doxorubicin*, and *DTIC* to treat metastatic pure sarcomas (390). More recently, *gemcitabine* has been combined with *docetaxel* for treatment of metastatic leiomyosarcoma, yielding an overall response rate of 53%, including patients previously treated with *doxorubicin* (391). Combined *ifosfamide* and *cisplatin* chemotherapy has resulted in a higher response rate (54% versus 36%) and a longer progression-free survival than *ifosfamide* chemotherapy alone for treatment of advanced MMMT (392). **A combination of *paclitaxel* and *carboplatin* for treatment of advanced uterine MMMT was recently reported to result in a complete response rate of 80% (four fifths) and a median progression-free interval of 18 months** (393).

Adjuvant Treatment

Because of the relatively low survival rate in localized uterine sarcomas and the high incidence

of failure resulting from subsequent distant metastasis, adjuvant treatment programs employing chemotherapy have been tested (394,395,396,397). Unfortunately, **most reports have been unable to show a clear improvement in survival by the addition of postoperative adjuvant chemotherapy in early uterine sarcoma**. The GOG conducted a trial of postoperative adjuvant *doxorubicin* in stage I and II uterine sarcoma patients. Of the 75 patients randomized to receive *doxorubicin*, 41% developed a recurrence, compared with 53% of 81 patients receiving no adjuvant chemotherapy, but these differences were not significant (394). Other smaller, nonrandomized adjuvant chemotherapy studies employing *cyclophosphamide*, *cisplatin* plus *doxorubicin*, and *ifosfamide* plus *cisplatin* reported recurrence rates of 33%, 24%, and 31%, respectively (395,396,397).

- **Human papillomavirus (HPV) infection is the causal agent of cervical cancer.**
- **Screening programs are effective at decreasing the incidence of cervical cancer.**
- **Although the most common histologic type of cervical cancer is squamous, the relative and absolute incidence of adenocarcinoma is increasing.**
- **Cervical cancer is clinically staged, although modern radiographic modalities such as computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, or positron emission tomography (PET) may be beneficial for individual treatment planning.**
- **Treatment of cervical cancer is based on stage of disease. In general, early stage disease (I–IIa) can be treated with either radical surgery or radiation therapy. Advanced stage disease (IIb–IV) is best treated with chemoradiation.**
-

Vaginal cancer is a rare disease with many similarities to cervical cancer. Radiation therapy is the mainstay of treatment for most patients; however, select patients may be treated with radical surgery.

Cervical cancer ranks as the third most common gynecologic neoplasm in the United States, behind cancer of the corpus and ovary, mainly as a result of the effectiveness of screening programs. **Worldwide, cervical carcinoma continues to be a significant health care problem. In third world countries, where limited health care resources exist, cervical carcinoma remains a significant cause of mortality.** Because cervical cancer is preventable, it is imperative that gynecologists and other primary care providers who administer health care to women be familiar with screening techniques, diagnostic procedures, and risk factors for cervical cancer as well as management of preinvasive disease. Vaginal cancer is a rare tumor that shares a similar epidemiology and risk factor profile as cervical cancer.

P.1404

Cervical Cancer

Epidemiology and Risk Factors

Invasive cancer of the cervix is considered a preventable disease because it has a long preinvasive state, cervical cytology screening programs are currently available, and the treatment of preinvasive lesions is effective. In spite of the preventable nature of this disease, however, 9710 new cases of invasive cervical cancer resulting in 3700 deaths were anticipated in the United States in 2006 (1). Nationally, the lifetime probability of developing cervical cancer is 1:128. Although screening programs in the United States are well established, it is estimated that 30% of cervical cancer cases will occur in women who have never had a Pap test. In developing countries, this percentage approaches 60% (2). In spite of these statistics, the worldwide incidence of invasive disease is decreasing, and cervical cancer is being diagnosed earlier, leading to better survival rates (1,3). The mean age for cervical cancer in the United States is 47 years, and the distribution of cases is bimodal, with peaks at 35 to 39 years and 60 to 64 years of age (1).

There are numerous risk factors for cervical cancer: young age at first intercourse (<16 years), multiple sexual partners, cigarette smoking, race, high parity, and lower socioeconomic status. The relationship to oral contraceptive use has been debated. Some investigators have proposed that use of oral contraceptives may increase the incidence of cervical glandular abnormalities (4,5); however, this hypothesis has not been consistently supported. Many of these risk factors are linked to sexual activity and exposure to sexually transmitted diseases. Infection with the herpes virus was previously thought to be the initiating event in cervical cancer; however, infection with human papillomavirus (HPV) has now been determined to be the causal agent in the development of cervical cancer, with herpes virus and *Chlamydia trachomatis* likely acting as cofactors. The role of human immunodeficiency virus (HIV) in cervical cancer is thought to be mediated through immune suppression. The Centers for Disease Control and Prevention have described cervical cancer as an acquired immune deficiency syndrome (AIDS)—defining illness in patients infected with HIV (6).

The initiating event in cervical dysplasia and carcinogenesis is infection with HPV. HPV infection has been detected in up to 99% of women with squamous cervical carcinoma (7). There are more than 100 different types of HPV, and more than 30 of which can affect the lower genital tract. There are 14 high-risk HPV subtypes; two of the high-risk subtypes, 16 and

18, are found in up to 62% of cervical carcinomas. The mechanism by which HPV affects cellular growth and differentiation is through the interaction of viral E6 and E7 proteins with tumor suppressor genes p53 and Rb, respectively. Inhibition of p53 prevents cell cycle arrest and cellular apoptosis, which normally occurs when damaged DNA is present, whereas inhibition of Rb disrupts transcription factor E2F, resulting in unregulated cellular proliferation (8). Both steps are essential for the malignant transformation of cervical epithelial cells.

Evaluation

Vaginal bleeding is the most common symptom occurring in patients with cancer of the cervix. Most often, this is postcoital bleeding, but it may occur as irregular or postmenopausal bleeding as well. Patients with advanced disease may present with a malodorous vaginal discharge, weight loss, or obstructive uropathy. In asymptomatic women, cervical cancer is most commonly identified through evaluation of abnormal cytologic screening tests.

Initially, all women suspected of having cervical cancer should have a general physical examination performed to include evaluation of the supraclavicular, axillary, and inguinofemoral lymph nodes to exclude the presence of metastatic disease. On pelvic

P.1405

examination, a speculum is inserted into the vagina, and the cervix is inspected for suspicious areas (Fig. 34.1). The vaginal fornices should also be closely inspected. With invasive cancer, the cervix is usually firm and expanded, and these features should be confirmed by digital examination. Rectal examination is also important to help establish cervical consistency and size, particularly in patients with endocervical carcinomas. Additionally, rectal examination is the only way to determine cervical size if the vaginal fornices have been obliterated by menopausal changes or by the extension of disease. Parametrial extension of disease is best determined by the finding of nodularity beyond the cervix on rectal examination.

Figure 34.1 Gross appearance of cervical cancer on examination.

When obvious tumor growth is present, a cervical biopsy is usually sufficient for diagnosis. If gross disease is not present, a colposcopic examination with cervical biopsies and endocervical curettage is warranted. If the diagnosis cannot be established conclusively with colposcopy and directed biopsies, cervical conization may be necessary.

Colposcopic Findings of Invasion

Colposcopic examination is mandatory for patients with suspected early invasive cancer based on cervical cytology and a grossly normal-appearing cervix. Colposcopic findings that suggest invasion are (i) abnormal blood vessels, (ii) irregular surface contour with loss of surface epithelium, and (iii) color tone change. Colposcopically directed biopsies may permit the diagnosis of frank invasion and thus avoid the need for diagnostic cone biopsy, allowing treatment to be administered without delay. If there is debate about the depth of invasion based on the cervical biopsies, and if the clinical stage may be upstaged to stage Ia2 or Ib1, the patient should undergo a conization. In the presence of a large cervical biopsy specimen showing invasion greater than 3 mm or two biopsy specimens separated by 7 mm showing invasive cervical carcinoma, therapy should proceed without delay, and the patient could undergo radical surgery or radiation therapy.

P.1406

Abnormal Blood Vessels

Abnormal vessels may be looped, branched, or reticular. **Abnormal looped vessels are the most common colposcopic finding and arise from the punctated and mosaic vessels present in cervical intraepithelial neoplasia (CIN).** As the neoplastic growth process proceeds and the need for oxygen and nutrition increases, angiogenesis occurs as a result of tumor and local tissue production of VEGF, PDGF, EGF, and other cytokines, resulting in the proliferation of blood vessels and neovascularization. Punctate vessels push out over the surface of the epithelium in an erratic fashion, producing the looped, corkscrew, or J-shaped pattern of abnormal vessels characteristic of invasive disease. Abnormal blood vessels also arise from the cervical stroma and are pushed to the surface as the underlying cancer invades. The normally branching cervical stromal vessels are best observed over nabothian cysts. In this area, the branches are generally at acute angles, with the caliber of vessels becoming smaller after branching, much like the arborization of a tree. The abnormal branching blood vessels seen with cancer tend to form obtuse or right angles, with the caliber sometimes enlarging after branching. Sharp turns, dilations, and luminal narrowing also characterize these vessels. The surface epithelium may be lost in these areas, leading to irregular surface contour and friability.

Abnormal reticular vessels represent the terminal capillaries of the cervical epithelium. Normal capillaries are best seen in postmenopausal women with atrophic epithelium. When cancer involves this epithelium, the surface is eroded, and the capillary network is exposed. These vessels are very fine and short, and appear as small comma-shaped vessels without an organized pattern. They are not specific to invasive cancer; atrophic cervicitis may also have this appearance.

Irregular Surface Contour

Abnormal surface patterns are observed as tumor growth proceeds. The surface epithelium ulcerates as the cells lose intercellular cohesiveness secondary to loss of desmosomes. Irregular contour also may occur as a result of papillary characteristics of the lesion. **This finding can be confused with a benign HPV papillary growth on the cervix. For that reason, biopsies should be performed on all papillary cervical growths to avoid missing invasive disease.**

Color Tone

Color tone may change as a result of increasing vascularity, surface epithelial necrosis, and in some cases, production of keratin. The color tone is yellow-orange rather than the expected pink of intact squamous epithelium or the red of the endocervical epithelium.

Adenocarcinoma

Adenocarcinoma of the cervix does not have a specific colposcopic appearance. All of the aforementioned blood vessels may be seen in these lesions as well. Because adenocarcinomas tend to develop within the endocervix, endocervical curettage is required as part of the colposcopic examination.

Histologic Appearance of Invasion

Cervical conization is required to assess correctly the depth and the linear extent of involvement when microinvasion is suspected. Early invasion is characterized by a protrusion of malignant cells from the stromal–epithelial junction. This focus consists of cells that appear better differentiated than the adjacent noninvasive cells and have abundant pink-staining cytoplasm, hyperchromatic nuclei, and small- to medium-sized nucleoli (9). **These early invasive lesions form tongue-like processes without measurable volume and are classified as International Federation of Gynecology and Obstetrics (FIGO) stage Ia1.** With further progression, more tongue-like processes and isolated malignant cells appear in the stroma, followed by a proliferation of fibroblasts (desmoplasia) and a bandlike infiltration of chronic inflammatory cells (Fig. 34.2). **With increasing depth of invasion, lesions occur at multiple sites, and the growth becomes measurable by depth and linear extent. Lesions that are smaller than 3 mm are classified as FIGO stage Ia1. Lesions that are 3 to 5 mm or more in depth and up to 7 mm in linear**

extent are classified as FIGO stage Ia2 (10). As the depth of stromal invasion increases, the risk of capillary lymphatic space involvement is increased. Dilated capillaries, lymphatic spaces, and foreign-body multinucleated giant cells containing keratin debris are often seen in the stroma.

P.1407

Figure 34.2 Microinvasive squamous carcinoma. Multiple irregular tongue-like processes and isolated nests of malignant cells are seen, some surrounded by clear spaces, simulating capillary lymphatic invasion. This is an artifact caused by tissue shrinkage. The depth of stromal invasion is measured from the basement membrane of the overlying cervical intraepithelial neoplasia (CIN). In this case, it is 1.2 mm.

The depth of invasion should be measured with a micrometer from the base of the epithelium to the deepest point of invasion. **Depth of invasion is a significant predictor for the development of pelvic lymph node metastasis and tumor recurrence. Although lesions that have invaded 3 mm or less rarely metastasize, patients in whom lesions invade between 3 to 5 mm have positive pelvic lymph nodes in 3% to 8% of cases (11).** Although the significance of the cutoff at 3 mm has not been identified completely, it has been postulated that small capillary—lymphatic spaces at this level are incapable of facilitating the transport of malignant cells. Uneven shrinkage of tissue by fixative often creates space between the tumor nests and the surrounding fibrous stroma, simulating vascular lymphatic invasion (see Fig. 34.2). Therefore, suspected vascular—lymphatic involvement with invasion of less than 3 mm should be interpreted with care. A lack of endothelial lining indicates that the space is a fixation artifact rather than true vascular invasion.

Staging

Cervical cancer is a clinically staged disease. The FIGO staging system is the current standard and is applicable to all histologic types of cervical cancer. The current FIGO staging system is presented in Table 34.1 and Figure 34.3. The staging procedures allowed by FIGO are listed in Table 34.2. **When there is doubt concerning the stage to which a**

P.1408

P.1409

cancer should be allocated, the earlier stage should be selected. After a clinical stage

is assigned and treatment has been initiated, the stage must not be changed because of subsequent findings by either extended clinical staging or surgical staging.

The "upstaging" of patients during treatment will produce an erroneous perception of improvement in the results of treatment of low-stage disease. Following is a breakdown of the incidence of cervical cancer by stage at diagnosis: 38%, stage I; 32%, stage II; 26%, stage III; and 4%, stage IV (3,10,12).

Table 34.1 FIGO Staging of Carcinoma of the Cervix Uteri

Preinvasive Carcinoma	
Stage 0	Carcinoma <i>in situ</i> , intraepithelial carcinoma (cases of stage 0 should not be included in any therapeutic statistics).
Invasive Carcinoma	
Stage I^a	Carcinoma strictly confined to the cervix (extension to the corpus should be disregarded).
	Stage Ia Preclinical carcinomas of the cervix, that is, those diagnosed only by microscopy.
	Stage Ia1 Lesion with ≤ 3 mm invasion.
	Ia2 Lesions detected microscopically that can be measured. The upper limit of the measurement should show a depth of invasion of >3 – 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates, and a second dimension, the horizontal spread, must not exceed 7 mm. Larger lesions should be staged as Ib.
	Ib Lesions invasive > 5 mm.
	Stage Ib1 Lesion ≤ 4 cm.
	Ib2 Lesions > 4 cm.
Stage II^b	The carcinoma extends beyond the cervix but has not extended onto the wall.
	The carcinoma involves the vagina, but not the lower one third.
	Stage IIa No obvious parametrial involvement.
	IIb Obvious parametrial involvement.
Stage III^c	The carcinoma has extended onto the pelvic wall. On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower one third of the vagina. All cases with hydronephrosis or nonfunctioning kidney.
	Stage IIIa No extension to the pelvic wall.
	IIIb Extension onto the pelvic wall and/or hydronephrosis or nonfunctioning kidney.
Stage IV^d	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to stage IV.
	Stage IVa Spread to the growth to adjacent organs.
	IVb Spread to distant organs.

^a The diagnosis of both stages Ia1 and Ia2 should be based on microscopic examination of removed tissue, preferably a cone, which must include the entire lesion. The depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates. The second dimension, the horizontal spread, must not exceed 7 mm. Vascular space involvement, either venous or lymphatic, should not alter the staging but should be specifically recorded because it may affect treatment decisions in the future. Lesions of greater size should be staged as Ib. As a rule, it is impossible to estimate clinically whether a cancer of the cervix has extended to the corpus. Extension to the corpus should therefore be disregarded.

^b A patient with a growth fixed to the pelvic wall by a short and indurated, but not nodular, parametrium should be allotted to stage IIb.

At clinical examination, it is impossible to decide whether a smooth, indurated parametrium is truly cancerous or only inflammatory. Therefore, the case should be assigned to stage III only if the parametrium is nodular to the pelvic wall or the growth itself extends to the pelvic wall.

^cThe presence of hydronephrosis or nonfunctioning kidney due to stenosis of the ureter by cancer permits a case to be allotted to stage III even if, according to other findings, it should be allotted to stage I or II.

^dThe presence of the bullous edema, as such, should not permit a case to be allotted to stage IV. Ridges and furrows into the bladder wall should be interpreted as signs of submucous involvement of the bladder if they remain fixed to the growth at palpation (ie, examination from the vagina or the rectum during cystoscopy). A cytologic finding of malignant cells in washings from the urinary bladder requires further examination and a biopsy specimen from the wall of the bladder.

Additional Staging Modalities

Various investigators have used lymphangiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and positron emission tomography (PET) in an attempt to improve the accuracy of clinical staging (12,13,14,15,16,17).

Table 34.2 Staging Procedures

P.1410

Unfortunately, these modalities in general suffer from poor sensitivity and high false-negative rates. Evaluation of the para-aortic lymph nodes with lymphangiography is associated with a false-positive rate of 20% to 40% and a false-negative rate of 10% to 20% (12,13,14). Overall, lymphangiography has a sensitivity of 79% and specificity of 73% (18). Computed tomography has poor sensitivity (34%) but excellent specificity (97%) (18). The accuracy of CT scanning is 80% to 85%; the false-negative rate is 10% to 15%, and the false-positive rate is 20% to 25% (15,16,17). Ultrasound has a high false-negative rate (30%), low sensitivity (19%), but high specificity (99%) (18). Early MRI data showed that MRI results were comparable to those of CT scanning (19), a finding confirmed on meta-analysis (20). However, **a recent systematic review comparing CT scan with MRI has shown that MRI is significantly more sensitive with equivalent specificity.** Additionally, MRI has excellent sensitivity on T2-weighted images for the detection of parametrial disease (21). As a result, MRI has become the preferred study to evaluate tumor size, lymph node metastasis, and local tumor extension.

Position emission tomography scans are increasingly being utilized either alone or in conjunction with CT or MRI to detect metastatic disease; however, large prospective data series are limited. Early studies suggest that PET may be more useful than other techniques for the detection of abdominal and extrapelvic disease, with comparable or better sensitivity (76%–100%) and specificity (94%) (22,23). In addition, PET scans may be a better predictor of treatment outcome. Although early studies show promise for the use of PET

P.1411

scans in evaluating cervical cancer, the sensitivity for detecting metastatic disease less than 1 cm in size appears to be limited (24).

When abnormalities are noted on CT, MRI, or PET, radiographic guided fine-needle aspirations (FNA) can be performed to confirm metastatic disease and individualize treatment planning. Because these tests are not generally available throughout the world and the interpretation of results can be variable, these studies are not currently used for staging. They may, however, be useful in individual treatment planning.

The clinical staging system developed by FIGO is based on the belief that cervical cancer is a local disease until rather late in its course. Unfortunately, **the accuracy of clinical staging is limited, and surgical evaluation, although not practical or feasible in all patients, can more accurately identify metastatic disease.** Surgical staging has been advocated by providers who believe that surgical information details the extent of disease, allowing the treatment to be tailored to the individual (25). However, other providers believe that surgical staging should be limited to patients who are enrolled in clinical trials. These beliefs are based on the lack of randomized controlled studies demonstrating a survival benefit in patients who have had surgical staging.

Pathology

Squamous Cell Carcinoma

Invasive squamous cell carcinoma is the most common variety of invasive cancer in the cervix. Histologically, variants of squamous cell carcinoma include **large cell keratinizing, large cell nonkeratinizing, and small cell types** (26). Large cell keratinizing tumors consist of tumor cells forming irregular infiltrative nests with laminated keratin pearls in the center. Large cell nonkeratinizing carcinomas reveal individual cell keratinization but do not form keratin pearls (Fig. 34.4). The category of small cell carcinoma

P.1412

includes poorly differentiated squamous cell carcinoma and small cell anaplastic carcinoma. If possible, these two tumors should be differentiated. The former contains cells that have small-to medium-sized nuclei and more abundant cytoplasm than those of the latter. The designation of small cell anaplastic carcinoma should be reserved for lesions resembling oat cell carcinoma of the lung. Small cell anaplastic carcinoma infiltrates diffusely and consists of tumor cells that have scanty cytoplasm, round to oval small nuclei, coarsely granular chromatin, and high mitotic activity. The nucleoli are absent or small. **Immunohistochemistry or electron microscopy can differentiate the small cell neuroendocrine tumors.** Patients with the large cell type of carcinoma, with or without keratinization, have a better prognosis than those with the small cell variant. Furthermore, small cell anaplastic carcinomas behave more aggressively than poorly differentiated squamous carcinomas that contain small cells. Infiltration of parametrial tissue and pelvic lymph node metastasis affect the prognosis.

Figure 34.4 Invasive squamous cell carcinoma, large cell nonkeratinizing type. Tumor cells form irregular nests and have abundant eosinophilic cytoplasm and distinct cell borders indicative of squamous differentiation.

Other less common variants of squamous carcinoma include **verrucous carcinoma** and **papillary (transitional) carcinoma**. Verrucous carcinomas may resemble giant condyloma acuminatum, are locally invasive, and rarely metastasize. Papillary carcinomas histologically resemble transitional cells of the bladder and may have more typical squamous cell invasion at the base of the lesion. Papillary carcinomas behave and are treated in a manner similar to traditional squamous cell cancers, except that late recurrences have been noted.

Adenocarcinoma

In recent years, there has been an increasing number of cervical adenocarcinomas reported in women in their 20s and 30s. Although the total number of cases of adenocarcinoma has been relatively stable, this disease is being seen with increasing frequency in young women, especially as the number of cases of invasive squamous cell carcinoma decreases. Older reports indicated that 5% of all cervical cancers were adenocarcinomas (27), whereas newer reports show a proportion as high as 18.5% to 27% (28,29).

Adenocarcinoma *in situ* (AIS) is believed to be the precursor of invasive adenocarcinoma, and it is not surprising that the two often coexist (30). In addition to AIS, intraepithelial or invasive squamous neoplasia occurs in 30% to 50% of cervical adenocarcinomas (31). A squamous intraepithelial lesion may be observed colposcopically on the ectocervix and the coexistent adenocarcinoma often is higher in the cervical canal.

Patients with AIS who are treated with conization should undergo close clinical follow-up. Endocervical curettage, often used in surveillance, may miss residual or invasive disease, and false-negative rates as high as 50% have been reported (32). In addition, skip lesions not resected at the time of conization may be present. For these reasons, hysterectomy should be considered the standard therapy for patients who have completed their childbearing. In two reports, however, patients with negative cone biopsy margins were followed conservatively, with few requiring repeat surgical procedures (33,34). Because cervical AIS tends to affect women during their reproductive years, a thorough discussion of risks and benefits should take place, and treatment should be individualized.

Adenocarcinoma of the cervix is managed in the same a manner to that used for squamous cell carcinoma. Previously, it was believed that adenocarcinoma was associated with a worse prognosis and outcome when compared with squamous cell carcinoma. A study of 203 women with adenocarcinoma and 756 women with squamous carcinoma supported this assertion (29). This study showed 5-year survival rates of 90% versus 60%, 62% versus 47%, and 36% versus 8% for stages I, II, and III, respectively. Although some have attributed these rates to a relative resistance to radiation, they are more likely a reflection of the tendency of adenocarcinomas to grow endophytically and to be undetected until a large volume of tumor is present. When adjusted for stage, however, it now appears that

P.1413

P.1414

there is no difference in prognosis between the two histologic subtypes. Adenocarcinoma may be detected by cervical sampling, but less reliably so than squamous carcinomas. A definitive diagnosis may require cervical conization.

The clinical features of stage I adenocarcinomas have been well studied (28,35,36,37). These studies have identified size of tumor, depth of invasion, grade of tumor, and age of the patient as significant correlates of lymph node metastasis and survival. When matched with squamous carcinomas for lesion size, age, and depth of invasion, the incidence of lymph node metastases and the survival rate appear to be the same (36,37). **Patients with stage I adenocarcinomas can be selected for treatment according to the same criteria as for those with squamous cancers** (36).

The choice of treatment for bulky stage I and II tumors is controversial. Treatment with radiation alone has been advocated by some (38), whereas others support radiation plus extrafascial hysterectomy (39,40). In 1975, Rutledge et al. (39) reported an 85.2% 5-year survival rate for all patients with stage I disease treated with radiation alone and an 83.8% survival rate for those who had radiation plus surgery. The central persistent disease rate was 8.3%, compared with 4% for those who had radiation plus surgery. In stage II disease, the 5-year survival rate was 41.9% for radiation alone and 53.7% for radiation plus surgery. **A subsequent report revealed no significant difference in survival among patients treated with radiation alone or radiation plus extrafascial hysterectomy** (41).

Invasive adenocarcinoma may be pure (Fig. 34.5A and B) or mixed with squamous cell carcinoma. Within the category of pure adenocarcinoma, the tumors are quite heterogeneous (26), with a wide range of cell types, growth patterns, and differentiation. **About 80% of cervical adenocarcinomas are made up predominantly of cells of the endocervical type with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary.** Within each cell type, the growth patterns and nuclear abnormalities vary according to the degree of differentiation. In well-differentiated tumors, tall columnar cells line the well-formed branching glands and

papillary structures, whereas pleomorphic cells tend to form irregular nests and solid sheets in poorly differentiated neoplasms. The latter may require mucicarmine and periodic acid—Schiff (PAS) staining to confirm their glandular differentiation.

There are several special variants of adenocarcinoma. **Minimal deviation**

adenocarcinoma (adenoma malignum) is an extremely well-differentiated form of adenocarcinoma in which the branching glandular pattern strongly simulates that of the normal endocervical glands. In addition, the lining cells have abundant mucinous cytoplasm and uniform nuclei (42,43). Because of this, the tumor may not be recognized as malignant in small biopsy specimens, thereby causing considerable delay in diagnosis.

Special immunohistochemical staining may be required to establish the diagnosis. Earlier studies reported a dismal outcome for women with this tumor, but more recent studies have found a favorable prognosis if the disease is detected early (44). Although rare, similar tumors have also been reported in association with endometrioid, clear, and mesonephric cell types (45).

An entity described as **villoglandular papillary adenocarcinoma** also deserves special attention (46). It primarily affects young women, some of whom are pregnant or users of oral contraceptives. Histologically, the tumors have smooth, well-defined borders, are well differentiated, and are either *in situ* or superficially invasive. Follow-up information is encouraging. None of these tumors has recurred after cervical conization or hysterectomy, and no metastasis has been detected among women undergoing pelvic nodal dissection. This tumor appears to have limited risk for spread beyond the uterus.

Figure 34.5A and B Invasive adenocarcinoma of the cervix, well-differentiated. Irregular glands are lined with tall columnar cells with vacuolated mucinous cytoplasm resembling endocervical cells. Nuclear stratification, mild nuclear atypism, and mitotic figures are evident.

P.1415

Adenosquamous Carcinoma

Carcinomas with a mixture of malignant glandular and squamous components are known as **adenosquamous carcinomas**. Patients with adenosquamous carcinoma of the cervix have been reported to have a poorer prognosis than those with pure adenocarcinoma or squamous carcinoma (47). Whether this is true when corrected for size of lesion is controversial (35,36).

In mature adenosquamous carcinomas, the glandular and squamous carcinomas are readily identified on routine histologic evaluation and do not cause diagnostic problems. In poorly differentiated or immature adenosquamous carcinomas, however, glandular differentiation can be appreciated only with special stains, such as mucicarmine and PAS. In one study (45), 30% of squamous cell carcinomas demonstrated mucin secretion when stained with mucicarmine. These squamous cell carcinomas with mucin secretion have a higher incidence of pelvic lymph node metastases than do squamous cell carcinomas without mucin secretion (45), and they are similar to the signet-ring variant of adenosquamous carcinoma (48).

Glassy cell carcinoma has been recognized as a poorly differentiated form of adenosquamous carcinoma (48). Individual cells have abundant eosinophilic, granular, ground-glass cytoplasm, large round to oval nuclei, and prominent nucleoli. The stroma is infiltrated by numerous lymphocytes, plasma cells, and eosinophils. Approximately half of these tumors contain glandular structures or stain positive for mucin. The poor diagnosis of this tumor is linked to understaging and resistance to radiotherapy.

Other variants of adenosquamous carcinoma include **adenoid basal carcinoma** and **adenoid cystic carcinoma**. Adenoid basal carcinoma simulates the basal cell carcinoma of the skin (49). Nests of basaloid cells extend from the surface epithelium deep into the underlying tissue. Cells at the periphery of tumor nests form a distinct parallel nuclear arrangement, so-called peripheral palisading. An "adenoid" pattern occasionally develops, with "hollowed-out" nests of cells. Mitoses are rare, and the tumor often extends deep into the cervical stroma.

Adenoid cystic carcinoma of the cervix behaves much like such lesions elsewhere in the body. The tumors tend to invade into the adjacent tissues and metastasize late, often 8 to 10 years after the primary tumor has been removed. Like other adenoid cystic tumors, they may metastasize directly to the lung. The pattern simulates that of the adenoid basal tumor, but there is a cystic component, and the glands of the cervix are involved (49). Mitoses may be seen but are not numerous.

Sarcoma

The most important sarcoma of the cervix is **embryonal rhabdomyosarcoma**, which occurs in children and young adults. The tumor has grapelike polypoid nodules, known as botryoid sarcoma, and the diagnosis depends on the recognition of rhabdomyoblasts (50). **Leiomyosarcomas** and **mixed mesodermal tumors** involving the cervix may be primary but are more likely to be secondary to uterine tumors. **Cervical adenosarcoma** has been described as a low-grade tumor with a good prognosis (50). If recurrence develops, it is generally a central recurrence that may be treated with resection and hormonal therapy.

Malignant Melanoma

On rare occasions, melanosis has been seen in the cervix. Thus, **malignant melanoma** may arise de novo in this area. Histopathologically, it simulates melanoma elsewhere, and the prognosis depends on the depth of invasion into the cervical stroma.

Neuroendocrine Carcinoma

The classification of neuroendocrine cervical carcinoma includes four histologic subtypes: **(i) small cell, (ii) large cell, (iii) classical carcinoid, and (iv) atypical carcinoid** (51).

P.1416

Neuroendocrine tumors of the cervix are rare, and treatment regimens have been based on small case series of patients.

Small cell (neuroendocrine type) carcinoma of the cervix is aggressive in nature and is similar to cancer arising from the bronchus (52). The hallmark of neuroendocrine tumors is their aggressive malignant behavior with the propensity to metastasize. At the time of diagnosis, it is usually disseminated, with bone, brain, liver, and bone marrow being the most common sites of metastases. In one study of 11 patients with disease apparently confined to the cervix, a high rate of lymph node metastasis was noted (53). Pathologically, the diagnosis is aided by the finding of neuroendocrine granules on electron microscopy as well as by immunoperoxidase studies that are positive for a variety of neuroendocrine proteins such as calcitonin, insulin, glucagon, somatostatin, gastrin, and adrenocorticotrophic hormone (ACTH). In addition to the traditional staging for cancer of the cervix, these patients should undergo bone, liver, and brain scanning as well as bone marrow aspiration and biopsy to evaluate the possibility of metastatic disease. Therapy generally consists of surgery, chemotherapy, and radiation. Because patients with early-stage disease have distant metastases, multimodal therapy is recommended. The main active chemotherapeutic agent is *etoposide*.

Local therapy alone gives almost no chance of cure of small cell carcinoma. Regimens of combination chemotherapy have improved the median survival rates in small cell bronchogenic carcinoma, and these regimens are now being used for treatment of small cell carcinoma of the cervix. Combination chemotherapy may consist of *vincristine, doxorubicin, and cyclophosphamide* (VAC) or *VP-16 (etoposide) and cisplatin* (EP) (54). Patients must be monitored carefully because they are at high risk for developing

recurrent metastatic disease (55).

Patterns of Spread

Cancer of the cervix spreads by (i) direct invasion into the cervical stroma, corpus, vagina, and parametrium; (ii) lymphatic metastasis; (iii) blood-borne metastasis; and (iv) intraperitoneal implantation. The incidence of pelvic and para-aortic nodal metastasis is shown in Table 34.3.

The cervix is commonly involved in cancer of the endometrium and vagina. The latter is rare, and most lesions that involve the cervix and vagina are designated **cervical primaries**. Consequently, the clinical classification is that of cervical neoplasia extending to the vagina, rather than vice versa. Endometrial cancer may extend into the cervix by three modes: direct extension from the endometrium, submucosal involvement by lymph

P.1417

vascular extension, and multifocal disease. The latter is most unusual, but occasionally a focus of adenocarcinoma may be seen in the cervix, separate from the endometrium. This lesion should not be diagnosed as metastasis but rather as multifocal disease. Malignancies involving the peritoneal cavity (e.g., ovarian cancer) may be found in the cul-de-sac and extend directly into the vagina and cervix. Carcinomas of the urinary bladder and colon occasionally extend into the cervix. Cervical involvement by lymphoma, leukemia, and carcinoma of the breast, stomach, and kidney is usually part of the systemic pattern of spread for these malignancies. Isolated metastasis to the cervix in such cases may be the first sign of a primary tumor elsewhere in the body.

Table 34.3 Incidence of Pelvic and Para-aortic Nodal Metastasis by Stage

Stage	No. of Patients	Positive Pelvic Nodes (%)	Positive Para-aortic Nodes (%)
Ia1 (≤3 mm)	179 ^a	0.5	0
Ia2 (>3–5 mm)	84 ^a	4.8	<1
Ib	1,926 ^b	15.9	2.2
IIa	110 ^c	24.5	11
IIb	324 ^c	31.4	19
III	125 ^c	44.8	30
IVa	23 ^c	55	40

^cReferences 12, 13, 83, 86, 87, 91, 118

Treatment Options

The treatment of cervical cancer is similar to the treatment of any other type of malignancy in that both the primary lesion and potential sites of spread should be evaluated and treated. The therapeutic modalities for achieving this goal include primary treatment with surgery, radiotherapy, chemotherapy, or chemoradiation. **Whereas radiation therapy can be used in all stages of disease, surgery is limited to patients with stage I to IIa disease. The 5-year survival rate for stage I cancer of the cervix is approximately 85% with either radiation therapy or radical hysterectomy.** A recent study using the National Cancer Institute's Surveillance Epidemiology and End Results data showed by an intent-to-treat analysis that patients in the surgery arm had an improved survival when compared with patients in the radiation arm (56). In general, optimal therapy consists of radiation or

surgery alone to limit the increased morbidity that occurs when the two treatment modalities are combined. There have recently been great strides in the treatment of cervical carcinoma, including adjuvant chemoradiation in patients discovered to have high-risk cervical carcinoma after radical hysterectomy and in patients with locally advanced cervical carcinoma.

Surgery

There are advantages to the use of surgery instead of radiotherapy, particularly in younger women for whom conservation of the ovaries is important. Chronic bladder and bowel problems that require medical or surgical intervention occur in up to 8% of patients undergoing radiation therapy (57). Such problems are difficult to treat because they result from fibrosis and decreased vascularity. This is in contrast to surgical injuries, which in general are easily repaired and without long-term complications. Sexual dysfunction is less likely to occur after surgical therapy than radiation because of vaginal shortening, fibrosis, and atrophy of the epithelium associated with radiation. Surgical therapy shortens the vagina, but gradual lengthening can be brought about by sexual activity. The epithelium does not become atrophic because it responds either to endogenous estrogen or to exogenous estrogens if the patient is postmenopausal.

In general, radical hysterectomy is reserved for women who are in good physical condition. Advanced chronologic age should not be a deterrent. With improvements in anesthesia, elderly patients withstand radical surgery almost as well as their younger counterparts (58). **Generally, it is prudent not to operate on lesions that are larger than 4 cm in diameter because these patients will require postoperative radiation therapy.** When selected in this manner, the urinary fistula rate is less than 2% (59), and the operative mortality rate is less than 1% (60). A summary of the management of cervical cancer is presented in Table 34.4.

If radiation therapy is needed, ovarian function may be preserved by transposing the ovaries out of the planned radiation field. While transposition may provide some protection, some studies suggest that normal ovarian function is preserved in fewer than 50% of patients (61,62). Additionally, metastasis to the ovaries occurs in 0.5% of cases of squamous cell cancer and 1.7% of cases of adenocarcinomas of the cervix, so ovarian preservation at the time of surgery may incur a small risk (63).

Table 34.4 Management of Invasive Cancer of the Cervix

Stage Ia1	≤ 3 mm invasion, no LVSI	Conization or type I hysterectomy
	≤ 3 mm invasion, w/LVSI	Radical trachelectomy or type II radical hysterectomy with pelvic lymph node dissection
Ia2	$>3-5$ mm invasion	Radical trachelectomy or type II radical hysterectomy with pelvic lymphadenectomy
Ib1	>5 mm invasion, <2 cm	Radical trachelectomy or type III radical hysterectomy with pelvic lymphadenectomy
Ib2	>5 mm invasion, >2 cm	Type III radical hysterectomy with pelvic lymphadenectomy
	>5 mm invasion	Type III radical hysterectomy with pelvic and para-aortic lymphadenectomy or primary chemoradiation
Stage IIa		Type III radical hysterectomy with pelvic and para-aortic lymphadenectomy or primary chemoradiation
IIb, IIIa, IIIb		Primary chemoradiation

Stage IVA	Primary chemoradiation or primary exenteration
IVb	Primary chemotherapy \pm 6 radiation LVSI, lymphovascular space invasion.

Cone Biopsy of the Cervix

Cone biopsy of the cervix serves both a diagnostic and therapeutic role in cervical cancer. The procedure is indicated to confirm the diagnosis of cancer, as well as to definitively treat stage Ia1 disease when preservation of fertility is desired. For effective treatment, there must be no evidence of lymph—vascular space invasion, and both endocervical margins and curettage findings must be negative for cancer or dysplasia. Because stage Ia1 cancers have less than a 1% risk of lymph node metastasis, lymphadenectomy is not necessary. If the endocervical margin or curettage is positive for dysplasia or malignancy, further treatment is necessary as these findings are strong predictors of residual disease. For squamous cell carcinoma, the risk of residual disease is 4% if both the endocervical margin and curettage are negative for dysplasia or malignancy, 22% if the endocervical margin alone is positive, and 33% if both are positive (64). In cases of adenocarcinoma in situ, the status of the cone margins is particularly important, with residual preinvasive and invasive disease noted in up to 25% and 3%, respectively, of cases with negative margins, and up to 80% and 7%, respectively, in cases with positive margins (65,66).

Simple (Extrafascial) Hysterectomy

Type I hysterectomy is an appropriate therapy for patients with stage Ia1 tumors without lymph—vascular space invasion who are not desirous of future fertility. In such cases, lymphadenectomy is not recommended. If lymph—vascular space invasion is found, a modified radical hysterectomy with pelvic lymphadenectomy is appropriate and effective therapy.

Radical Trachelectomy

Radical trachelectomy is a procedure that is gaining popularity as a surgical management option for women with stage 1a2 and 1b1 disease who desire uterine preservation and fertility. This procedure may be performed vaginally or abdominally (Fig. 34.6), and it usually is accompanied by pelvic lymphadenectomy and cervical cerclage placement. The risk of positive pelvic lymph nodes with stage 1a2 cancer may be as high as 8%, indicating the need for lymphadenectomy. Lymphadenectomy may be performed either laparoscopically or by the open laparotomy technique. Experience with this therapeutic modality is limited, and it is uncertain if long-term outcome is similar to that of

traditionally therapy, although early results are promising. **Patients who are ideal candidates for this procedure have tumors less than 2 cm in diameter, negative lymph nodes, and no lymph—vascular space involvement.** There are limited data on subsequent pregnancy outcomes after radical trachelectomy; however, successful outcomes have been reported. In one study, there were 102 pregnancies and 65 live births in 92 women who had radical trachelectomy. Increased rates of preterm birth, preterm premature rupture of membranes, and miscarriages have been noted. (67,68).

Figure 34.6 Abdominal radical trachelectomy.

Although radical trachelectomy and lymphadenectomy are performed with curative intent, it should be remembered that the risk of recurrence after such procedures depends on risk factors being well-defined. If recurrence develops, definitive therapy with surgery or radiation is necessary.

Radical Hysterectomy

The **radical hysterectomy** (Fig. 34.7A and B) performed most often in the United States is that described by Meigs in 1944 (69). **The operation includes pelvic lymph node dissection along with removal of most of the uterosacral and cardinal ligaments and the upper one third of the vagina. This operation has been referred to as the type III radical hysterectomy (70).**

The **hysterectomy described by Wertheim is less extensive than a radical hysterectomy and removes the medial half of the cardinal and uterosacral ligaments (70). This procedure is often referred to as the modified radical or type II hysterectomy.** Wertheim's original operation did not include pelvic lymph node dissection but instead included selective removal of enlarged lymph nodes. **The modified radical hysterectomy (type II) differs from the radical hysterectomy (type III) in the following ways:**

- The uterine artery is transected at the level of the ureter, thus preserving the ureteral branch to the ureter.

- The cardinal ligament is not divided near the sidewall but instead is divided at about its midportion near the ureteral dissection.
- The anterior vesicouterine ligament is divided, but the posterior vesicouterine ligament is conserved.
- A smaller margin of vagina is removed.

Figure 34.7A Radical hysterectomy. An intraoperative photograph showing the lateral dissection during a radical hysterectomy. Note the ureter running beneath the uterine artery (tissue in the clamp).

Figure 34.7B Radical hysterectomy specimen.

Radical hysterectomies can be further classified as extended radical hysterectomy (type IV and type V). In the type IV operation, the periureteral tissue, superior vesicle artery, and as much as three fourths of the vagina are removed (70). In the type V operation, portions of the distal ureter and bladder are resected. This procedure is rarely performed because radiotherapy should be used when such extensive disease is encountered (70).

The abdomen is opened through either a midline incision or a low transverse incision after the methods of Maylard or Cherney. The low transverse incision requires division of the rectus muscles and provides excellent exposure of the lateral pelvis. It allows adequate pelvic node dissection and wide resection of the primary tumor. After the abdomen is entered, the peritoneal cavity is explored to exclude metastatic disease. The stomach is palpated to ensure that it has been decompressed to facilitate packing of the intestines. The liver is palpated, and the omentum is inspected for metastases. Both kidneys are palpated to ensure their proper placement and lack of congenital and other abnormalities. The para-aortic nodes are palpated transperitoneally.

During exploration of the pelvis, the fallopian tubes and ovaries are inspected for any abnormalities. **In premenopausal patients, the ovaries are generally conserved.** The peritoneum of the vesicouterine fold and the rectouterine pouch should be inspected for signs of tumor extension or implantation. The cervix is then palpated between the thumb anteriorly and the fingers posteriorly to determine its extent, and the cardinal ligaments are palpated for evidence of lateral tumor extension or nodularity.

Lymphadenectomy

After inspection of the abdomen and pelvis, the pelvic and para-aortic lymph nodes should be inspected and palpated. Lymph nodes suspicious for gross disease should

be excised and evaluated by frozen section. If metastatic disease is identified, consideration should be given to abandoning radical surgery in favor of primary chemoradiation therapy. If the patient has no gross evidence of metastatic disease, the pelvic lymphadenectomy is begun.

Pelvic Lymphadenectomy

The pelvic lymph node dissection is begun by opening the round ligaments at the pelvic sidewall and developing the paravesical and pararectal spaces. The ureter is elevated on the medial flap by a Deaver retractor to expose the common iliac artery. The common iliac and external iliac nodes are dissected, with care taken to avoid injuring the genitofemoral nerve, which lies laterally on the psoas muscle. At the bifurcation of the common iliac artery, the external iliac node chain is divided into lateral and medial portions.

The lateral chain is stripped free from the artery to the circumflex iliac vein distally. A hemaclip is placed across the distal portion of the lymph node chain to reduce the incidence of lymphocyst formation. The medial chain is then dissected. The obturator lymph nodes are dissected next; for this procedure, the lymph nodes are grasped just under the external iliac vein, and traction is applied medially. Although in most patients both the obturator artery and vein are dorsal to the obturator nerve, 10% have an aberrant vein arising from the external iliac vein. The node chain is separated from the nerve and vessels and clipped caudally. Dissection continues cephalad to the hypogastric artery. The cephalad portion of the obturator space should be entered lateral to the external iliac artery and

P.1422

medial to the psoas muscle, where the remainder of the obturator node tissue can be dissected as far cephalad as the common iliac artery. In general, drainage of the pelvic and para-aortic lymph node beds is not performed because of the increase in complications in patients in whom drains have been used (71).

Patients who have bulky cervical tumors or grossly positive pelvic nodes, or for whom frozen section evaluation will be performed, should then undergo para-aortic lymph node evaluation to determine the full extent of disease and to guide adjuvant therapy.

Para-aortic Lymph Node Evaluation

The bowel is packed to expose the peritoneum overlying the bifurcation of the aorta. The peritoneum is incised medial to the ureter and over the right common iliac artery. A retractor is placed retroperitoneally to expose the aorta and the vena cava. Any enlarged para-aortic lymph nodes are removed, hemaclips are applied for hemostasis, and specimens are sent for analysis by frozen section. If the lymph nodes are positive for metastatic cancer, an option is to discontinue the operation and treat the patient with radiation therapy (69). If the lymph nodes are negative for disease, the left side of the aorta is palpated through the peritoneal incision with a finger passed under the inferior mesenteric artery. The lymph nodes on this side of the aorta are more lateral and nearly behind the aorta and the common iliac artery. If the left para-aortic lymph nodes appear healthy and the cervical tumor is small with no suspicious pelvic lymph nodes, these additional lymph nodes are not submitted for frozen-section analysis. If they are removed, they may be dissected through the incision made for the right para-aortic nodes, or they may be dissected after reflection of the sigmoid colon medially.

Development of Pelvic Spaces

The pelvic spaces are developed by sharp and blunt dissection (Fig. 34.8).

The paravesical space is bordered by the following structures:

- The obliterated umbilical artery running along the bladder medially
- The obturator internus muscle along the pelvic sidewall laterally
- The cardinal ligament posteriorly
- The pubic symphysis anteriorly

The attachments of the vagina to the tendinous arch form the floor of the paravesical space.

The pararectal space is bordered by the following structures:

- The rectum medially
- The cardinal ligament anteriorly

- **The hypogastric artery laterally**
- **The sacrum posteriorly**

The coccygeus (levator ani) muscle forms the floor of the pararectal space.

The development of these spaces before pelvic lymphadenectomy will aid in identification and dissection of the pelvic lymph nodes as well as dissection of the ureter as it passes into the vesicouterine ligament tunnel.

Dissection of the Bladder

The dissection of the bladder from the anterior part of the cervix and vagina is a critical step. Occasionally, tumor extension into the base of the bladder (which cannot be detected with cystoscopy) precludes adequate mobilization of the bladder flap, leading to the abandonment of the operation. Therefore, this portion of the operation should be undertaken early in the procedure. The bladder should be mobilized off of the upper third of the vagina to remove the tumor safely and with adequate margins.

Dissection of the Uterine Artery

The superior vesicle artery is dissected away from the cardinal ligament at a point near the uterine artery. **The uterine artery, which usually arises from the superior vesicle artery, is thus isolated and divided, preserving the superior vesicle arteries.** The uterine vessels are then brought over the ureter by application of gentle traction. Occasionally, the uterine vein passes under the ureter.

Dissection of the Ureter

The ureter is dissected free from the medial peritoneal flap at the level of the uterosacral ligament. As the ureter passes near the uterine artery, there is a consistent arterial branch from the uterine artery to the ureter. This branch is sacrificed in the standard radical (type III) hysterectomy but preserved in the modified radical (type II) hysterectomy. Dissection of the ureter from the vesicouterine ligament (ureteral tunnel) may now be accomplished. If the patient has a deep pelvis, ligation of the uterosacral and cardinal ligaments may be undertaken first to bring the ureteral tunnel dissection closer to the operator. The roof of the ureteral tunnel is the anterior vesicouterine ligament. It should be ligated and divided to expose the posterior ligament. **The posterior ligament is also divided in the radical (type III) hysterectomy but conserved in the modified radical (type II) hysterectomy.**

Posterior Dissection

The peritoneum across the cul-de-sac is incised, exposing the uterosacral ligaments. **The rectum is rolled free from the uterosacral ligaments, which**

are divided midway to the sacrum in a radical (type III) hysterectomy and near the rectum in the modified radical (type II) operation. This allows the operator to develop the cardinal ligament separate from the rectum. A surgical clamp is placed on the cardinal ligament at the lateral pelvic sidewall in a radical hysterectomy and at the level of

the ureteral bed in the modified radical procedure. A clamp is placed on the specimen side to maintain traction and to ensure that the full cardinal ligament is excised with the specimen. A right-angled clamp then is placed caudad to this clamp across the paravaginal tissues. A second paravaginal clamp is usually needed to reach the vagina.

The vagina is entered anteriorly, and a suitable margin of proximal vagina is removed with the specimen. More vaginal epithelium can be excised if necessary, depending on the previous colposcopic findings. The vaginal edge may be sutured in a hemostatic fashion and left open with a drain from the pelvic space or closed with a suction drain placed percutaneously. The ureteral fistula and pelvic lymphocyst rates from these two techniques are similar.

Complications of Radical Hysterectomy

Acute Complications

The acute complications of radical hysterectomy include (72):

- Blood loss (average, 0.8 liters)
- Ureterovaginal fistula (1%–2%)
- Vesicovaginal fistula (1%)
- Pulmonary embolus (1%–2%)
- Small bowel obstruction (1%)
- Febrile morbidity (25%–50%)

Febrile morbidity is most often caused by pulmonary infection (10%) and is seen frequently with pelvic cellulitis (7%) and urinary tract infection (6%). Wound infection, pelvic abscess, and phlebitis all occur in fewer than 5% of patients (73).

Subacute Complications

The subacute effects of radical hysterectomy are postoperative bladder dysfunction and lymphocyst formation. For the first few days after radical hysterectomy, bladder volume is decreased, and filling pressure is increased. The sensitivity to filling is diminished, and the patient is unable to initiate voiding. The cause of this dysfunction is unclear. It is important to maintain adequate bladder drainage during this time to prevent overdistention. Bladder drainage is usually accomplished with a suprapubic catheter. It is more comfortable for the patient and allows the physician to perform cystometrography and determine residual urine volume without the need for frequent catheterization. In addition, the patient is able to accomplish voiding trials at home by clamping the catheter, voiding, and releasing to check the residual urine level. Cystometrography may be performed 3 to 4 weeks after surgery. For the catheter to be discontinued, the patient must be able to sense the fullness of the bladder, initiate voiding, and void with a residual urine level of less than 75 to 100 mL. Otherwise, voiding trials should continue at home until these criteria can be fulfilled.

Lymphocyst formation occurs in fewer than 5% of patients (73), and the cause is uncertain. Adequate drainage of the pelvis after radical hysterectomy may be an important step in prevention. However, routine placement of retroperitoneal drains has not been shown to reduce this morbidity (71). Ureteral obstruction, partial venous obstruction, and thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion

P.1425

of the lymphocyst wall and placement of either large bowel or omentum into the lymphocyst should be performed.

Chronic Complications

The most common chronic effect of radical hysterectomy is bladder hypotonia or, in extreme instances, atony. This condition occurs in about 3% of patients, regardless of the method of bladder drainage used (74,75). It may be a result of bladder denervation and not simply a problem associated with bladder overdistention (76). Voiding every 4 to 6 hours, increasing intra-abdominal pressure with Credés maneuver, and intermittent self-catheterization may be used to manage bladder hypotonia.

Ureteral strictures are uncommon in the absence of postoperative radiation therapy, recurrent cancer, or lymphocyst formation (59). If the stricture is associated with lymphocyst formation, treatment of the lymphocyst usually alleviates the problem. Strictures that occur after radiation therapy should be managed with ureteral stenting. If a ureteral stricture is noted in the absence of radiotherapy or lymphocyst formation, recurrent carcinoma is the most common cause. A CT scan of the area of obstruction should be obtained and cytologic assessment by FNA should be performed if there is a target lesion to exclude carcinoma. If the results of these tests are negative, a ureteral stent may be placed to relieve the stricture. Close observation for recurrent carcinoma is necessary, and the diagnosis of recurrence may ultimately require laparotomy.

Nerve-Sparing Radical Hysterectomy

Nerve-sparing radical hysterectomies have been described in recent years in an attempt to diminish the bladder dysfunction, sexual dysfunction, and colorectal motility disorders commonly encountered after traditional radical hysterectomy.

Multiple techniques have been described involving the identification of the pelvic autonomic nerves at the sacral promontory followed by various surgical methods of nerve preservation as the nerves transit the cardinal ligaments. These techniques are promising and have been shown in small series to reduce postoperative bladder dysfunction (77,78).

Laparoscopic Radical Hysterectomy

Laparoscopic-assisted radical vaginal hysterectomy is being performed with increasing frequency in highly selected patients. In one large series of 200 women with stage Ia1–IIb cervical cancer treated with laparoscopic lymphadenectomy followed by radical vaginal hysterectomy, the authors found a 5-year survival rate comparable to patients treated with a similar abdominal approach and a comparable rate of intraoperative complications (79).

The use of laparoscopy in cervical cancer patients is appealing because it may lead to less blood loss, improved cosmetic results, shorter duration of hospitalization, and faster recovery.

Sentinel Lymph Node Evaluation

Sentinel lymph node detection has become an integral part of the management strategy for breast cancer and melanoma and is currently being investigated as a diagnostic tool in multiple human malignancies, including carcinoma of the cervix. The sentinel node is a specific lymph node (or nodes) that is the first to receive drainage from a malignancy and is a primary site of nodal metastasis. In theory, the presence or absence of metastatic disease in the sentinel node should reflect the status of the nodal basin as a whole. Thus, a negative sentinel lymph node would allow omission of lymphadenectomy of the involved nodal basin. Sentinel lymph nodes are detected through perilesional injection of radiolabeled technetium-99 or blue dye followed by intraoperative identification of the sentinel lymph nodes utilizing handheld gamma probes or visual identification of blue-stained nodes. These techniques are primarily applicable in patients with early-stage disease and

P.1426

clinically negative lymph nodes, in whom lymph node status may influence the extent of the procedure or the use of adjuvant treatment.

Although data utilizing sentinel lymph node detection techniques in cervical cancer are limited, several interesting conclusions can be drawn from completed studies. Sentinel nodes can be detected in 80% to 100% of cervical cancer patients and have been detected by both laparotomy and laparoscopic techniques with equivalent detection rates. A combination of dye and radiolabeled techniques appears to be superior for the detection of sentinel lymph nodes over either technique used alone. Test sensitivity of 65% to 87% can be expected with a 90% to 97% negative predictive value. The likelihood of detecting sentinel nodes may depend on the tumor volume, the time from injection to retrieval of the sentinel nodes, and the volume of dye or radiolabeled tracer injected. Sentinel node detection rates do not appear to be influenced by prior cold knife cone biopsy. False-negative results have been reported. **The role of sentinel node detection in cervix cancer is purely investigational at this time; although the technique is promising, complete lymphadenectomy, when indicated, remains the standard of care** (80).

Postoperative Management

Prognostic Variables for Early-Stage Cervical Cancer (Ia2–IIa)

The survival of patients with early-stage cervical cancer after radical hysterectomy and pelvic lymphadenectomy depends on the presence or absence of several intermediate and high-risk pathologic factors (72,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95).

Intermediate-risk factors for recurrent disease:

- **Large tumor size**
- **Cervical stromal invasion to the middle or deep one third**
- **Lymph—vascular space invasion**

High-risk factors for recurrent disease:

- **Positive or close margins**
- **Positive lymph nodes**
- **Microscopic parametrial involvement**

Patients treated with radical hysterectomy that have intermediate- or high-risk factors have a 30% and 40% risk, respectively, of recurrence within 3 years (96,97,98).

Lesion Size

Lesion size is an independent predictor of survival. Patients with lesions smaller than 2 cm have a survival rate of approximately 90%, and patients with lesions larger than 2 cm have a 60% survival rate (84). When the primary tumor is larger than 4 cm, the survival rate drops to 40% (82,93). An analysis of a Gynecologic Oncology Group prospective study of 645 patients showed a 94.6% 3-year disease-free survival rate for patients with occult lesions, 85.5% for those with tumors smaller than 3 cm, and 68.4% for patients with tumors larger than 3 cm (94).

Depth of Invasion

Patients in whom depth of invasion is less than 1 cm have a 5-year survival rate of approximately 90%, but the survival rate falls to 63% to 78% if the depth of invasion is more than 1 cm (72,94,98).

P.1427

Parametrial Spread

Patients with spread to the parametrium have a 5-year survival rate of 69%, compared with 95% when the parametrium is negative. When the parametrium is involved and pelvic lymph nodes are also positive, the 5-year survival rate falls to 39% to 42% (85,95).

Lymph—Vascular Space Involvement

The significance of the finding of lymph—vascular space involvement is somewhat controversial. Several reports have shown a 50% to 70% 5-year survival rate when lymph—vascular space invasion is present and a 90% 5—year survival rate when invasion is absent (72,84,88,99,100,101,102,103). Others have found no significant difference in survival if the study is controlled for other risk factors (93,94,104,105,106). Lymph—vascular space involvement may be a predictor of lymph node metastasis and not an independent predictor of survival.

Lymph Nodes

The most dependent variable associated with survival is the status of the lymph

nodes. Patients with negative nodes have an 85% to 90% 5-year survival rate (94,107), whereas the survival rate for those with positive nodes ranges from 20% to 74%, depending on the number of nodes involved and the location and size of the metastases (90,91,92,98,107,108,109).

Data on lymph node status can be summarized as follows:

- When the common iliac lymph nodes are positive, the 5-year survival rate is about 25%, compared with about 65% when only the pelvic lymph nodes are involved (99,110,111).
- Bilateral positive pelvic lymph nodes portend a less favorable prognosis (22%–40% survival rate) than unilateral positive pelvic nodes (59%–70%) (110,111).
- The presence of more than three positive pelvic lymph nodes is accompanied by a 68% recurrence rate, compared with 30% to 50% when three or fewer lymph nodes are positive (90,108).
- Patients in whom tumor emboli are the only findings in the pelvic lymph node have an 82.5% 5-year survival rate, whereas the survival rate is 62.1% and 54% with microscopic invasion and macroscopic disease, respectively (81).

Given the high risk of recurrent disease in surgically treated patients with early-stage cervical cancer who exhibit intermediate- or high-risk pathologic factors, adjuvant radiation or chemoradiation therapy should be considered.

Primary Radiation Therapy

Radiotherapy can be used to treat all stages of cervical cancer, with cure rates of about 70% for stage I, 60% for stage II, 45% for stage III, and 18% for stage IV (3).

A comparison of surgery and radiation for treatment of low-stage disease is shown in Table 34.5. Primary radiation treatment plans generally consist of a combination of external teletherapy to treat the regional lymph nodes and to decrease the tumor volume, and brachytherapy delivered by intracavitary applicators or interstitial implants to provide a treatment boost to the central tumor. Intracavitary therapy alone may be used in patients with early disease when the incidence of lymph node metastasis is negligible.

The treatment sequence depends on tumor volume. Stage Ib lesions smaller than 2 cm may be treated first with an intracavitary source to treat the primary lesion, followed by external therapy to treat the pelvic lymph nodes. Larger lesions require external radiotherapy first to shrink the tumor and to reduce the anatomic distortion caused by the cancer. Such

P.1428

a treatment strategy enables the therapist to achieve better intracavitary dosimetry. **The usual doses delivered are 7,000 to 8,000 cGy to point A (defined as 2 cm superior to the external cervical os and 2 cm lateral to the internal uterine canal) and 6,000 cGy to point B (defined as 3 cm lateral to point A),** limiting the bladder and rectal dosage to less than 6,000 cGy. To achieve this level, it is necessary to adequately pack the bladder and bowel away from the intracavitary source. Localization films and careful calculation of dosimetry are mandatory to optimize the dose of radiation and to reduce the incidence of bowel and bladder complications. Local control depends on delivering an adequate dose to the tumor from the intracavitary source.

Table 34.5 Comparison of Surgery versus Radiation for Stage Ib/IIa Cancer of the Cervix		
	<i>Surgery</i>	<i>Radiation</i>
Survival	85%	85%
Serious complications	Urologic fistulas 1%–2%	Intestinal and urinary strictures and fistulas 1.4%–5.3%
Vagina	Initially shortened, but may lengthen with regular intercourse	Fibrosis and possible stenosis, particularly in postmenopausal patients
Ovaries	Can be conserved	Destroyed
Chronic effects	Bladder atony in 3%	Radiation fibrosis of bowel and bladder in 6%–8%
Applicability	Best candidates are younger than 65 years of age, <200 lb, and in good health	All patients are potential candidates
Surgical mortality	1%	1% (from pulmonary embolism during intracavitary therapy)

Although brachytherapy has traditionally been prescribed using a low-dose rate technique, high-dose rate techniques are becoming more popular, and controversy currently exists over which technique is superior. Low-dose rates typically use Cs-137 as the source, whereas high-dose rates use Ir-192. Proponents of high-dose rate techniques argue that the exposure of radiation to medical personnel is less, ambulatory therapy is possible, and total treatment time is less. Advocates of low-dose rate techniques cite literature suggesting that complication rates are higher with higher-dose rate therapy. **Several published trials have shown that although there may be slight stage-related differences in survival between patients treated with low- and high-dose rate regimens, overall the techniques have comparable survival and complication rates** (112,113,114).

As noted, clinical staging is imprecise and fails to accurately predict disease extension to the para-aortic nodes in 7% of patients with stage Ib, 18% with stage IIb, and 28% with stage III disease (115). Such patients will have "geographic" treatment failures if standard pelvic radiotherapy ports are used. As a result, treatment plans for these patients are individualized based on CT scans and biopsies of the para-aortic lymph nodes for consideration of extended-field radiotherapy. The routine use of extended-field radiation for "prophylactic para-aortic radiation" without documentation of distant metastasis to the para-aortic nodes has been evaluated and is typically not practiced because of the increased enteric morbidity associated with this treatment modality.

Intensity Modulated Radiation Therapy

A relatively new method of providing external beam therapy, known as intensity modulated radiation therapy (IMRT), may be a significant therapeutic development. This technique uses computer-generated algorithms that accurately distinguish between target treatment volumes and normal tissue. The radiation beam intensity is then modulated to optimize the delivery of radiation to the specified treatment volume while sparing adjacent normal tissue. The result appears to be much more accurate treatment of

the tumor with minimal toxicity. Emphasizing this point is a recent study in 40 gynecologic

cancer patients in which IMRT was used. Excellent coverage of the planned treatment volume was obtained, with no patient suffering grade 3 toxicity, and only 60% of patients suffering grade 2 toxicity compared with a historical rate of 90% toxicity with conventional techniques (116). This technique is especially promising for treating cervical cancer because it allows higher doses to be delivered much more precisely, allowing patients who are unable to undergo brachytherapy because of pelvic anatomy and tumor geometry a chance for curative therapy. Studies utilizing IMRT in treating patients with cervical cancer are limited, but experience with this technique is increasing.

Adjuvant Radiation

In an effort to improve survival rates, postoperative radiotherapy has been recommended for patients with high- and intermediate-risk factors such as metastasis to pelvic lymph nodes (72,82,99,107), invasion of paracervical tissue (85,86), deep cervical invasion (117), or positive surgical margins (108,118). Although most authors agree that postoperative radiotherapy is necessary in the presence of positive surgical margins, the use of radiation in patients with other high-risk factors is controversial. Increasing evidence supports the use of adjuvant radiation, however. Particularly controversial but best studied is the use of radiation in the presence of positive pelvic lymph nodes. The rationale for treatment is the knowledge that pelvic lymphadenectomy does not remove all of the nodal and lymphatic tissue and subsequent radiotherapy can sterilize remaining cancer. The hesitancy to recommend postoperative radiotherapy relates to the significant rate of postradiation bowel and urinary tract complications (119). Most of the data currently available are retrospective. However, a randomized study by the Gynecologic Oncology Group comparing radiation with no further treatment for patients at high risk for recurrence with negative pelvic nodes revealed a 30% serious complication rate, 16% reoperation rate, and a 2% mortality rate as a result of treatment-related complications (120).

Based on retrospective studies, it appears that postoperative radiation therapy for positive pelvic nodes can decrease pelvic recurrence but does not improve 5-year actuarial survival rates. One multi-institutional study showed no difference in survival in patients with three or fewer positive pelvic nodes (59% versus 60%) (98). However, there seemed to be a benefit when radiotherapy was given to those with more than three positive nodes.

In a study of 60 pairs of irradiated and nonirradiated women matched for age, lesion size, number, and location of positive nodes after radical hysterectomy (121), no significant difference was found in projected 5-year survival rates (72% for surgery alone, 64% for surgery plus radiation). The proportion of recurrences confined to the pelvis was 67% in patients treated with surgery only and 27% in patients treated with postoperative radiation ($p = 0.03$). In a Cox regression analysis of 320 women who underwent radical hysterectomy, 72 of whom received postoperative radiation (91), there was a significant decrease in pelvic recurrence but no survival benefit. A multi-institutional retrospective study was performed of 185 women with positive pelvic nodes after radical hysterectomy, 103 of who received postoperative radiotherapy (93). Multivariate analysis disclosed that radiotherapy was not an independent predictor of survival, whereas age, lesion diameter, and number of positive nodes were found to influence survival. These authors concluded that additional treatment is needed to improve survival rates. Because survival is limited by distant recurrence, the addition of chemotherapy to postoperative radiotherapy has been proposed. A 75% disease-free survival rate was reported at 3 years in 40 high-risk patients given *cisplatin*, *vinblastine*, and *bleomycin* after radical hysterectomy, and a 46% disease-free survival rate was found in 79 comparable patients who refused treatment (122). Only 4 (11.8%) of 34 patients with positive pelvic nodes had recurrences, whereas disease recurred in 8 (33%) of 24 untreated patients

with positive nodes. An 82% rate of disease-free survival was reported at 2 years among 32 patients who were treated postoperatively with radiation therapy plus *cisplatin* and *bleomycin* (123).

The location of lymph node metastases is apparently relevant to postirradiation recurrence rates. When common iliac lymph nodes are involved, the survival rate drops to 20% (100). As the number of positive pelvic nodes increases, the percentage of positive common iliac and low para-aortic nodes increases (ie, 0.6% when pelvic lymph nodes are negative, 6.3% with one positive pelvic node, 21.4% with two or three positive nodes, and 73.3% with four or more positive nodes) (100). This information has been used to recommend extended-field radiotherapy to patients with positive pelvic lymph nodes in an attempt to treat undetected extrapelvic nodal disease (100). A 3-year disease-free survival rate of 85% occurred in patients with positive pelvic nodes, and a survival rate of 51% occurred in patients with positive common iliac nodes; these rates are better than the survival rates of 50% and 23%, respectively, for historical control groups receiving radiotherapy to the pelvis alone.

The Gynecologic Oncology Group reported the results of a randomized controlled trial on patients with cervical cancer treated by radical hysterectomy and found to have at least two of the following risk factors: capillary lymphatic space invasion, more than one third stromal invasion, and large tumor burden (121). A total of 277 patients were entered into the study, with 140 patients randomized to no further therapy and 137 patients randomized to adjuvant pelvic radiotherapy. **Patients with these risk factors who were treated postoperatively with radiation therapy had a statistically significant (47%) decrease in recurrent disease.** The study results have not had adequate follow-up to show a statistically significant decrease in mortality. The data, however, demonstrate improved survival rates. The morbidity with combination therapy was acceptable, with a low rate of enteric and urinary complications. A second Gynecologic Oncology Group study of patients with high-risk cervical cancer randomized patients to concurrent chemoradiation therapy or radiation therapy alone (96), as discussed below.

Concurrent Chemoradiation

Radiation therapy fails to achieve tumor control in 20% to 65% of patients with advanced cervical cancer. Chemotherapy, despite its relative lack of success in treating patients with cervical cancer, has been studied as neoadjuvant treatment in combination with surgery. **Concomitant use of chemotherapy and radiation has been studied extensively by the Gynecologic Oncology Group, and results of five randomized studies have been reported.** The concept of chemoradiation encompasses the benefits of systemic chemotherapy with the benefits of regional radiation therapy. Additionally, **the use of chemotherapy to sensitize cells to radiation therapy has been shown to improve local—regional control.** These new results have changed the way cervical cancer is treated in many medical centers.

An intergroup trial involving the Gynecologic Oncology Group, the Southwestern Oncology Group, and the Radiation Therapy Oncology Group evaluated postoperative chemoradiation therapy in patients with stage Ia2, Ib, or IIa cervical cancer who were found to have positive pelvic lymph nodes, positive parametrial extension, or positive vaginal margins at the completion of radical hysterectomy (123). A total of 243 patients were assessed in this trial, with 127 receiving chemoradiation (*cisplatin*, *5-FU*, radiation therapy) and 116 receiving radiation. **The results of this trial showed a statistically significant improvement in progression-free survival and overall survival at 43 months for the patients receiving concurrent chemoradiation.** The 4-year survival rates for the patients receiving

chemoradiation versus radiation alone were 81% and 71%, respectively. The toxicity levels in the two groups were acceptable, with a higher rate of hematologic toxicity in the concurrent chemoradiation arm. **This study showed that in patients with these high-risk factors after radical hysterectomy for stage Ia2, Ib, and IIa disease, chemoradiation is the postoperative treatment of choice.**

Concurrent chemoradiation was also evaluated in patients with advanced cervical carcinoma. Gynecologic Oncology Group protocol 85 was a prospective study that enrolled

P.1431

patients with stage IIb to IVa cervical cancer and compared concurrent chemoradiation (124). There were 177 patients treated with *cisplatin*, 5-FU, and radiation. These patients were compared with 191 patients treated with *hydroxyurea* and radiation. The median follow-up of patients who were alive at the time of the analysis was 8.7 years. Patients who received concurrent chemoradiation and were treated with *cisplatin* and 5-FU had a statistically significant improvement in progression-free interval and overall survival (122). Hematologic toxicity levels in the two groups were similar. **This study showed that *cisplatin*-based concurrent chemoradiation was a superior treatment when compared with *hydroxyurea* and concurrent radiation.**

Gynecologic Oncology Group protocol 120 was initiated to evaluate patients with negative para-aortic nodes and cervical carcinoma stage IIb to IVa treated with concurrent chemoradiation. The treatment arms in this study consisted of radiation plus weekly *cisplatin*; or *cisplatin*, 5-FU, and *hydroxyurea*; or *hydroxyurea*. There were 176 patients in the weekly *cisplatin* arm; 173 patients in the *cisplatin*, 5-FU, and *hydroxyurea* arm; and 177 patients in the *hydroxyurea* arm (125). The two treatment arms with *cisplatin*-based chemotherapy and radiation showed an improvement in progression-free interval and overall survival at a median follow-up of 35 months. The relative risks for progression of disease or death were 0.55 and 0.57, respectively, for patients treated with *cisplatin*-based chemotherapy and radiation, compared with the patients treated with *hydroxyurea* and radiation (126). **This study confirmed the findings of GOG 85 and again suggested that *cisplatin*-based concurrent chemoradiation is the treatment of choice for patients with advanced-stage cervical cancer.**

A third Gynecologic Oncology Group trial evaluated patients with stage Ib to IVa cervical cancer. Of the patients enrolled in this study, 70% had stage Ib or IIa disease (127). A total of 403 patients were enrolled and evaluated. The 5-year survival rates were 73% in patients treated with chemoradiation and 58% in patients treated with radiation therapy alone. The cumulative rates of disease-free survival at 5 years were 67% in patients treated with concurrent chemoradiation and 40% in patients treated with radiation therapy alone. Survival and progression-free intervals for patients receiving concurrent chemoradiation were significantly improved (127). **The results of this study suggested that chemoradiation is the treatment of choice for stage IIb to IVa disease and that those patients with stage Ib2 and IIa disease may also benefit from chemoradiation.**

A Gynecologic Oncology Group study of chemoradiation comparing concurrent *cisplatin* and radiation with radiation alone in patients with bulky Ib cervical cancer also included adjuvant hysterectomy after completion of the radiation (127). There were 183 patients assigned to the concurrent chemotherapy and radiation arm, and 186 patients treated with radiation alone. The median duration of follow-up was 36 months, with disease recurrence detected in 37% of the patients treated with radiation alone, compared with 21% who were treated with concurrent chemoradiation (126). The 3-year survival rates were 83% in the group who received concurrent chemoradiation and 74% in the group that received radiation alone (126). The study also included adjuvant hysterectomy after completion of radiation treatment. However, because the results did not show an improvement in survival

by using adjuvant hysterectomy, the authors concluded that adjuvant hysterectomy would not be part of their recommendations. **This study supported the results of previous studies and showed that patients with bulky stage Ib and IIa cervical cancer treated with concurrent chemoradiation had survival rates superior to those treated with radiation alone. These two studies suggest that patients with bulky stage Ib and IIa disease should have primary treatment consisting of chemoradiation, with the chemotherapy agent being weekly cisplatin.**

Surgical Staging Before Radiation

Surgical staging procedures designed to discover positive lymph nodes have been devised. Transperitoneal exploration was initially used, but was associated with a

P.1432

16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (128,129). When transperitoneal exploration was routinely employed, the subsequent radiotherapy dose to the para-aortic chain was 5,500 to 6,000 cGy, which is now known to be excessive. Intestinal morbidity was predominately a result of postsurgical adhesions entrapping the intestine in the radiotherapy field, resulting in bowel exposure to the full dose of radiation. In the absence of postsurgical adhesions, the small bowel would move in and out of the radiotherapy field and receive a lesser dose. **To avoid these complications, extraperitoneal dissection of the para-aortic nodes is now recommended, and the radiation dose should be reduced to 5,000 cGy or less (130,131). When such an approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients (132,133), and the 5-year survival rate is 15% to 26% in patients with positive para-aortic nodes (17,133).** Survival appears to be related to the amount of disease in the para-aortic nodes and to the size of the primary tumor. In patients whose metastases to the para-aortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (134,135). Surgical staging techniques have improved to include laparoscopic assessment of the para-aortic and pelvic lymph nodes. Studies have demonstrated benefit from surgical staging with improved survival and changes in treatment plans in 40% of patients (131,132).

Management of Grossly Positive Para-aortic Lymph Nodes

The management of patients with macroscopic or grossly positive para-aortic lymph nodes discovered at the time of surgery or by imaging studies is controversial. It is likely that grossly positive nodes are beyond the ability of radiation therapy alone to sterilize. Therefore, to improve survival, additional therapy is required. In a representative study of the multiple reports in the literature (25), lymph node metastases were noted in 133 of 266 patients. Pelvic and para-aortic nodes were positive in 44 patients and positive para-aortic nodes were noted in only 2 patients. Five- and ten-year survival rates were similar for patients with macroscopically positive resectable nodes and microscopically positive nodes. Patients with unresectable nodal disease had a worse survival rate than those with resectable disease. All patients underwent extraperitoneal lymph node resections and subsequent radiotherapy. There was a 10% incidence of severe morbidity related to radiation use. Consistent with other reports in the literature, this study showed that **extraperitoneal debulking lymphadenectomy confers a survival advantage similar to that enjoyed by patients with micrometastatic disease without additional morbidity (25).**

Prophylactic Para-aortic Radiation Therapy

Prophylactic extended-field radiation therapy is an alternative to surgical staging of

the para-aortic lymph node chain in women with advanced cervical cancer judged to be at high risk but without radiological or clinical evidence of para-aortic lymph node involvement. This treatment strategy was evaluated in 441 patients with stage I—III disease (136). High rates of gastrointestinal toxicity were noted in the treatment group. There was no difference in disease-free survival or overall survival between the control and treated groups, although treated patients had fewer para-aortic failures. A lack of difference in survival rates in this study may be related to high local and regional failure rates, suggesting that ideal patients for prophylactic radiotherapy would be those in whom there is a high likelihood of achieving pelvic control. A survival benefit was noted in a study by the Radiation Therapy Oncology Group (137), in which 367 patients with stage Ib—IIb disease were randomized to pelvic radiotherapy versus pelvic and extended field radiotherapy. The extended field treatment arm suffered more grade 4 and 5 toxicity, confirming previous studies. Complicating the issue is another study from the Radiation Therapy Oncology Group that revealed that in locally advanced cervical cancer, pelvic radiation therapy with concurrent *cisplatin* chemotherapy was superior to extended-field radiation therapy (138).

P.1433

The appropriate role of prophylactic para-aortic radiation therapy is still under investigation.

Supraclavicular Lymph Node Biopsy

Although not standard practice, the performance of a supraclavicular lymph node biopsy has been advocated in patients with positive para-aortic lymph nodes before the initiation of extended-field irradiation as well as in patients with a central recurrence before exploration for possible exenteration. The incidence of metastatic disease in the supraclavicular lymph nodes in patients with positive para-aortic lymph nodes is 5% to 30% (139). Cytologic assessment by FNA can obviate the need for an excisional biopsy and thus should be performed if any enlarged nodes are present. If the scalene lymph nodes are found to be positive, the disease is incurable, and treatment is palliative.

Complications of Radiation Therapy

Perforation of the uterus may occur at the time of insertion of the uterine tandem. This is a problem particularly for elderly patients and those who have had a previous diagnostic conization procedure. When perforation is recognized, the tandem should be removed, and the patient should be observed for bleeding or signs of peritonitis. Survival may be decreased in patients who have had uterine perforation (140), possibly because these patients have more extensive uterine disease. Fever may occur after insertion of the uterine tandem and ovoids. Fever most often results from infection of the necrotic tumor and occurs 2 to 6 hours after insertion of the intracavitary system. If uterine perforation has been excluded by ultrasonography, intravenous broad-spectrum antibiotic coverage, usually with a cephalosporin, should be administered. If the fever does not decrease promptly or if the temperature is higher than 38.5°C, an aminoglycoside and a *Bacteroides* species—specific antibiotic should administered. If fever persists or if the patient shows signs of septic shock or peritonitis, the intracavitary system must be removed. Antibiotics are continued until the patient has recovered, and the intracavitary application is delayed for 1 to 2 weeks.

Acute Morbidity

The acute effects of radiotherapy are caused by ionizing radiation on the epithelium of

the intestine and bladder and occur after administration of 2,000 to 3,000 cGy.

Symptoms include diarrhea, abdominal cramps, nausea, frequent urination, and occasionally bleeding from the bladder or bowel mucosa. Bowel symptoms can be treated with a low-gluten, low-lactose, and low-protein diet. Antidiarrheal and antispasmodic agents may also help. Bladder symptoms may be treated with antispasmodic medication. Severe symptoms may require a week of rest from radiotherapy.

Chronic Morbidity

The chronic effects of radiotherapy result from radiation-induced vasculitis and fibrosis and are more serious than the acute effects. These complications occur several months to years after radiotherapy has been completed. The bowel and bladder fistula rate after pelvic radiation therapy for cervical cancer is 1.4% to 5.3% (57,59). Other serious toxicity (e.g., bowel bleeding, stricture, stenosis, or obstruction) occurs in 6.4% to 8.1% of patients (57,59).

Proctosigmoiditis

Bleeding from proctosigmoiditis should be treated with a low-residue diet, antidiarrheal medications, and steroid enemas. In extreme cases, a colostomy may be required to rest the bowel completely. Occasionally resection of the rectosigmoid must be performed.

Rectovaginal Fistula

Rectovaginal fistulas or rectal strictures occur in fewer than 2% of patients. The successful closure of fistulas with bulbocavernosus flaps (141) or sigmoid colon transposition (142) has been reported. Occasionally, resection with anastomosis is feasible. Diversion resulting in colostomy may be the optimal therapy in patients who have poor vascular supply to the pelvis and a history of an anastomotic leak or breakdown from prior repairs.

P.1434

Small Bowel Complications

Patients with previous abdominal surgery are more likely to have pelvic adhesions and thus sustain more radiotherapy complications in the small bowel. The terminal ileum may be particularly susceptible to chronic damage because of its relatively fixed position at the cecum. Patients with small bowel complications typically have a long history of crampy abdominal pain, intestinal rushes, and distention characteristic of partial small bowel obstruction. Often, low-grade fever and anemia accompany the symptoms.

Patients who have no evidence of disease should be treated aggressively with total parenteral nutrition, nasogastric suction, and early surgical intervention after the anemia has resolved and good nutritional status has been attained. The type of procedure performed depends on individual circumstances (143). Small bowel fistulas that occur after radiotherapy rarely close spontaneously while total parenteral nutrition is maintained. Recurrent cancer should be excluded; aggressive fluid replacement, nasogastric suction, and wound care should be instituted. Fistulography and a barium enema should be performed to exclude a combined large and small bowel fistula. The fistula-containing loop of bowel may be either resected or isolated and left *in situ*. In the latter case, the fistula will act as its own mucous fistula.

Urinary Tract

Chronic urinary tract complications occur in 1% to 5% of patients and depend on the dose of radiation to the base of the bladder. Vesicovaginal fistulas are the most common complication and usually require supravescicular urinary diversion. Occasionally, a small fistula can be repaired with either a bulbo cavernosus flap or an omental pedicle. Ureteral strictures are usually a sign of recurrent cancer, and a cytologic sample should be obtained at the site of the obstruction using FNA guided by a CT scan. If the findings are negative, the patient should undergo exploratory surgery to evaluate the presence of recurrent disease. If radiation fibrosis is the cause, ureterolysis may be possible or indwelling ureteral stents may be passed through the open urinary bladder to relieve obstruction.

Chemotherapy

Neoadjuvant Chemotherapy

Randomized trials have been initiated by the Gynecologic Oncology Group and other large centers to determine the efficacy of neoadjuvant chemotherapy. **In the era of effective chemoradiation therapy, there is no evidence that neoadjuvant chemotherapy offers superior results or a survival advantage over standard therapy.**

Chemotherapy for Advanced Disease

Chemotherapy has been studied in advanced cervical cancer with mixed results.

Single-agent chemotherapy has been the standard for advanced or recurrent disease. Active agents include *cisplatin*, *carboplatin*, *paclitaxol*, and *ifosfamide*, but response rates are only 10% to 20% with a median duration of only 4 to 6 months. More recently, a number of trials have been performed to determine whether multiagent chemotherapy is superior. The Gynecologic Oncology Group 149 studied patients with histologically confirmed, advanced stage (IVb), recurrent or persistent squamous cell cancer of the cervix and randomized these patients to one of two combination chemotherapy treatment arms. Of the 287 patients, 146 patients were randomized to the *cisplatin* and *ifosfamide* arm, and 141 patients received *cisplatin*, *ifosfamide*, and *bleomycin*. There were no differences in overall survival, progression-free survival, response rates, or overall toxicity between the two combination chemotherapy regimens (144). In another trial sponsored by the Gynecologic Oncology Group, single-agent *cisplatin* was compared to *cisplatin* plus either *dibromodulcitol* or *ifosfamide* plus *mesna*. In this trial, the combination of *cisplatin* plus *ifosfamide* had a better response rate (31% versus 18%) and median time to progression (4.6 months versus 3.2 months) compared with single agent *cisplatin*. Toxicity was notably higher in the combination regimen, and there was no overall survival advantage demonstrated (145). Recently, the Gynecologic

P.1435

Oncology Group published the results of a study comparing single-agent *cisplatin* to *cisplatin* plus *paclitaxel* in women with stage IVb squamous cell cancer of the cervix. Although the response rate (36% versus 19%) and progression-free survival (4.8 months versus 2.8 months) were greater for the combination regimen, there was only a 1-month increase in overall survival (146). Finally, the regimen of *methotrexate*, *vinblastine*, *doxorubicin*, and *cisplatin* (MVAC), which had received considerable attention because of preliminary studies suggesting high response rates, was evaluated in **Gynecologic Oncology Group protocol 179**. In this study, MVAC was compared to *cisplatin* alone, and *cisplatin* combined with *topotecan*. The MVAC arm was prematurely closed because of excessive toxicity, and the remaining *cisplatin* arms were compared. **Although the combination of *cisplatin* and *topotecan* was superior to *cisplatin* alone, the improvement in overall survival was**

only 3 months. The combination arm had a higher complete response rate, overall response rate, progression-free survival, and overall survival. Based on these results, the GOG has initiated a trial comparing *topotecan*, *paclitaxel*, *vinorelbine*, and *gemcitabine* each in combination with *cisplatin*. Overall, it appears that multiagent regimens offer an improved response rate and slightly higher overall survival but with increased toxicity.

Treatment of Cervical Cancer by Stage

Stage Ia

Until 1985, no FIGO recommendation existed concerning the size of lesion or the depth of invasion that should be considered microinvasive (stage Ia). This led to considerable confusion and controversy in the literature. Over the years, as many as 18 different definitions have been used to describe "microinvasion." In 1974, the Society of Gynecologic Oncologists recommended a definition that is now accepted by FIGO: **A microinvasive lesion is one in which neoplastic epithelium invades the stroma to a depth of less than 3 mm beneath the basement membrane and in which lymphatic or blood vascular involvement is not demonstrated.** The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node metastases or recurrence and who therefore may be treated with less than radical therapy.

Diagnosis must be determined on the basis of a cone biopsy of the cervix. The treatment decision rests with the gynecologist and should be determined based on a review of the conization specimen with the pathologist. It is important that the pathologic condition be described in terms of (i) depth of invasion, (ii) width and breadth of the invasive area, (iii) presence or absence of lymph—vascular space invasion, and (iv) margin status. These variables are used to determine the degree of radicality of the operation and whether the regional lymph nodes should be treated (10).

Stage Ia1 \leq 3 mm Invasion

Lesions with invasion less than or equal to 3 mm have less than 1% incidence of pelvic node metastases. Within this group, it appears that the patients most at risk for nodal metastases or central pelvic recurrence are those with definitive evidence of tumor emboli in lymph vascular spaces (72,147). Therefore, patients with less than 3 mm invasion and no lymph—vascular space invasion may be treated with extrafascial hysterectomy without lymph node dissection. Therapeutic conization appears to be adequate therapy for these patients if childbearing capability is desired. Surgical margins and postconization endocervical curettage must be free of disease. If there is lymph—vascular space invasion, a type I (extrafascial) or II (modified radical) hysterectomy with pelvic lymph node dissection should be considered.

Treatment of microinvasive cervical adenocarcinoma has been complicated by a lack of agreement on approaches. Recent reports have shown that patients with stage Ia1

P.1436

cervical adenocarcinoma may be treated in a fashion similar to patients with this stage and a squamous lesion. Some providers disagree with this interpretation because of the difficulty of establishing a pathologic diagnosis of microinvasion from a glandular lesion. **Patients diagnosed with microinvasive cervical adenocarcinoma should have expert pathologic assessment before considering treatment with extrafascial hysterectomy or conization.**

Stage Ia2 3–5 mm Invasion

Lesions with invasion of >3 to 5 mm have a 3% to 8% incidence of pelvic node metastases (147,148,149); thus, pelvic node dissection is necessary for these lesions. The primary tumor may be treated with a modified radical hysterectomy (type II) or a radical trachelectomy if preservation of fertility is desired. If intermediate- or high-risk pathologic factors are identified in the surgical specimen, adjuvant radiation or chemoradiation therapy is recommended, respectively.

Stage Ib1 and Ib2 Invasive Cancer

Stage Ib lesions are subdivided into stage Ib1, which denotes lesions that are 4 cm or smaller in maximum diameter, and stage Ib2, which denotes lesions that are larger than 4 cm. These patients may be managed with either radical trachelectomy or a type III radical hysterectomy, with pelvic lymphadenectomy. Radical trachelectomy should be restricted to candidates with low-risk disease, an absence of lymph–vascular space invasion, and tumor size less than 2 cm. The para-aortic lymph node chain must be evaluated, especially if pelvic nodal disease is encountered. Adjuvant radiation therapy is recommended if intermediate-risk factors are identified postoperatively. Adjuvant chemoradiation is indicated if high-risk features are found.

Alternatively, primary chemoradiation therapy with curative intent is appropriate. A comparison of radical hysterectomy with radiation has resulted in similar survival rates for the two treatment modalities. Several studies comparing patients treated by either radical hysterectomy or radiation therapy showed similar survival rates and outcomes for both groups (81,150). However, patients treated with type III radical hysterectomy who subsequently received postoperative radiation had a higher rate of intestinal and urinary morbidity compared with patients treated with either modality alone. Therefore, some clinicians advocate using radiation and avoiding surgery in these patients because many will require adjuvant postoperative radiation.

Bulky Stage Ib2 and IIa Invasive Cancer

Patients with bulky Ib2 and IIa disease may be treated with either primary chemoradiation or radical surgery. Because many of these patients will be found to have intermediate- or high-risk factors postoperatively, strong consideration should be given to primary chemoradiation. If surgical therapy is desired, a type III radical hysterectomy with pelvic and para-aortic lymphadenectomy, followed by adjuvant chemoradiation if intermediate- or high-risk factors are present, is appropriate therapy. This option has benefits of complete surgical staging and ovarian preservation, if desired. Disadvantages of primary surgery include increased morbidity if multimodality therapy is utilized (150).

Stage IIb to IIIb Invasive Cancer

Therapy for patients with stage IIb or greater cervical cancer has traditionally been radiation therapy. Primary pelvic radiotherapy fails to control disease progression in 30% to 82% of patients with advanced cervical carcinoma (3). Two thirds of these failures occur in the pelvis (151). A variety of agents have been used in an attempt to increase the effectiveness of radiation therapy in patients with large primary tumors. **Because chemoradiation has been shown to be superior to radiation therapy alone, chemoradiation is now the preferred treatment strategy for these patients, with cisplatin the**

chemotherapy agent of choice. Nodal involvement, particularly the para-aortic lymph nodes, is the most important factor related to survival (see section on Concurrent Chemoradiation.)

Stage IVa and IVb Cancer

Although primary exenteration may be considered for patients with direct extension to the rectum or bladder, it is rarely performed. For patients with extension to the bladder, the survival rate with radiation therapy is as high as 30%, with a urinary fistula rate of only 3.8% (152). The presence of tumor in the bladder may prohibit cure with radiation therapy alone; thus, consideration must be given to removal of the bladder on completion of external beam radiation treatment. This is particularly true if the disease persists at that time and the geometry is not conducive to brachytherapy. Rectal extension is less commonly observed but may require diversion of the fecal stream before chemoradiation to avoid septic episodes from fecal contamination. In certain clinical situations, such as with patients who have stage IVa disease and present with vesicovaginal or rectovaginal fistula, urinary or rectal diversion may be performed, followed by chemoradiation. **Patients with stage IVb cervical carcinoma are candidates for chemotherapy and palliative pelvic radiation therapy. Control of symptoms with the least morbidity is of primary concern in this patient population.**

Patient Evaluation and Follow-up after Therapy

Patients who receive radiotherapy should be closely monitored to assess treatment response. Tumors may be expected to regress for up to 3 months after radiotherapy. During the pelvic examination, progressive shrinkage of the cervix and possible stenosis of the cervical os and surrounding upper vagina is expected and should be noted. During rectovaginal examination, careful palpation of the uterosacral and cardinal ligaments for nodularity is important. Cytologic assessment by FNA of suspicious areas should be performed to allow early diagnosis of persistent disease. In addition to the pelvic examination, the supraclavicular and inguinal lymph nodes should be carefully examined, and cervical or vaginal assessment should be performed every 3 months for 2 years and then every 6 months for the next 3 years. Endocervical curettage may be performed in patients with large central tumors.

Radiography of the chest may be performed yearly in patients who have advanced disease. Metastasis to the lung has been reported in 1.5% of cases. Solitary nodules are present in 25% of cases with metastasis. Resection of a solitary nodule in the absence of other persistent disease may yield some long-term survivors (153). Although intravenous pyelography (IVP) is not a part of routine postradiotherapy surveillance, it should be performed if a pelvic mass is detected or if urinary symptoms warrant evaluation. The finding of ureteral obstruction after radiotherapy in the absence of a palpable mass may indicate unresectable pelvic sidewall disease, but this finding should be confirmed, usually by FNA cytologic assessment (154).

Patients who have had radical hysterectomy and who are at high risk for recurrence may benefit from early recognition of recurrence because they might be saved with radiation therapy. In these patients, a routine CT urogram 6 to 12 months after surgery may be beneficial. After radical hysterectomy, about 80% of recurrences are detected within 2 years (155). In general, the larger the primary lesion, the shorter the median time is to recurrence (156).

Special Considerations

Cervical Cancer during Pregnancy

The incidence of invasive cervical cancer associated with pregnancy is 1.2 in 10,000 (157). A Pap test should be performed on all pregnant patients at the initial prenatal visit, and any grossly suspicious lesions should be biopsied. Diagnosis is often delayed during pregnancy because bleeding is attributed to pregnancy-related complications. **If the result of the Pap test is positive for malignant cells, and invasive cancer cannot be diagnosed using colposcopy and biopsy, a diagnostic conization procedure may be necessary.**

P.1438

Conization in the first trimester of pregnancy is associated with an abortion rate as high as 33% (158,159), as well as hemorrhagic and infectious complications. Because conization subjects the mother and fetus to complications, it should be performed only in the second trimester and only in patients with colposcopy findings consistent with cancer, biopsy-proven microinvasive cervical cancer, or strong cytologic evidence of invasive cancer. Inadequate colposcopic examination may be encountered during pregnancy in patients who have had prior ablative therapy. Close follow-up throughout pregnancy may allow the cervix to evert and develop an ectropion, allowing satisfactory colposcopy in the second or third trimester. Patients with obvious cervical carcinoma may undergo cervical biopsy and clinical staging similar to that of nonpregnant patients.

After conization, there appears to be no harm in delaying definitive treatment until fetal maturity is achieved in patients with stage Ia cervical cancer (158,160,161).

Patients with less than 3 mm of invasion and no lymphatic or vascular space involvement may be followed to term. Historically, these patients were allowed to deliver vaginally, and a hysterectomy was performed 6 weeks postpartum if further childbearing was not desired. However, in a multivariate analysis of 56 women with cervical cancer diagnosed during pregnancy and 27 women with cervical cancer diagnosed within 6 months of delivery, vaginal delivery was the most significant predictor of recurrence (162). In addition, most recurrences after vaginal delivery involved distant sites. The ideal delivery method for these patients is not known definitively; however, strong consideration should be given to performing a cesarean birth in women with cervical cancer of any stage (162). If vaginal delivery is chosen, close inspection of the episiotomy site is required during follow-up because of rare reports of metastatic cervical cancer at these locations (163).

Patients with 3 to 5 mm of invasion and those with lymph—vascular space invasion may also be followed to term or delivered early after establishment of fetal pulmonary maturity (158,161). They may be delivered by cesarean birth, followed immediately by modified radical hysterectomy and pelvic lymphadenectomy. **Patients with more than 5 mm invasion should be treated as having frankly invasive carcinoma of the cervix.** Treatment depends on the gestational age of the pregnancy and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestation and 90% for those delivered at 32 weeks of gestation. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. Although timing is controversial, it is probably unwise to delay therapy for longer than 4 weeks (160,161). The recommended treatment is classic cesarean delivery followed by radical hysterectomy with pelvic lymph node dissection. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with stage II—IV cervical cancer should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean birth, and therapy is begun postoperatively. If the pregnancy is in the first trimester, external radiation therapy can be started with the expectation that spontaneous abortion will occur before the delivery of

4,000 cGy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken.

The clinical stage is the most important prognostic factor for cervical cancer during pregnancy. Overall survival is slightly better because an increased proportion of these patients have stage I disease. For patients with advanced disease, there is evidence that pregnancy impairs the prognosis (158,161). The diagnosis of cancer in the postpartum period is associated with a more advanced clinical stage and a corresponding decrease in survival (162).

P.1439

Cancer of the Cervical Stump

Cancer of the cervical stump was more common many decades ago when supracervical hysterectomy was popular; however, as this operation has gained new popularity, this situation may again become more common. Early-stage disease is treated surgically, with very little change in technique from that used when the uterus is intact (164). Radical parametrectomy with upper vaginectomy and pelvic lymphadenectomy is the standard procedure. Advanced-stage disease may present a therapeutic problem for the radiotherapist if the length of the cervical canal is less than 2 cm. This length is necessary to allow satisfactory placement of the uterine tandem. If the uterine tandem cannot be placed, radiation therapy can be completed with vaginal ovoids or with an external treatment plan in which lateral ports are used to augment the standard anterior and posterior ports. Such a technique will reduce the dosage to the bowel and bladder and thus reduce the incidence of complications.

Pelvic Mass

The origin of a pelvic mass must be clarified before treatment is initiated. A CT urogram can exclude a pelvic kidney, and a barium enema helps to identify diverticular disease or carcinoma of the colon. An abdominal x-ray film may show calcifications typically associated with benign ovarian teratomas or uterine leiomyomas. Pelvic ultrasonography differentiates between solid and cystic masses and indicates uterine or adnexal origin. Solid masses of uterine origin are most often leiomyomas and generally do not need further investigation.

Pyometra and Hematometra

An enlarged fluid-filled uterine cavity may be a pyometra or a hematometra. The hematometra can be drained by dilation of the cervical canal and will not interfere with treatment. The pyometra also should be drained, and the patient should be given antibiotics to cover *Bacteroides* species, anaerobic *Staphylococcus* and *Streptococcus* species, and aerobic coliform bacterial infection. Placement of a large mushroom catheter through the cervix has been advocated, but the catheter itself may become obstructed, leading to further occlusion of the drainage. Repeated dilation of the cervix with aspiration of pus every 2 to 3 days is more effective.

If the disease is stage I, a radical hysterectomy and pelvic lymphadenectomy may be performed. However, a pyometra is usually found in patients with advanced disease, and thus radiotherapy is required. External-beam therapy can begin when the pyometra has healed. Patients often have a significant amount of pus in the uterus or a tubo-ovarian abscess without signs of infection; therefore, a normal temperature and a normal white blood cell count do not necessarily exclude infection. Repeat physical examination or pelvic ultrasonography is necessary to ensure adequate drainage.

Cervical Carcinoma after Extrafascial Hysterectomy

When invasive cervical cancer is found after simple hysterectomy, further treatment is predicated on the extent of disease. Microinvasive disease in patients at low risk for lymph node metastasis does not require further treatment. Invasive disease may be treated with radiotherapy or reoperation involving a pelvic node dissection and radical excision of parametrial tissue, cardinal ligaments, and the vaginal stump (165).

Reoperation

Reoperation is indicated particularly for a young patient who has a small lesion and in whom preservation of ovarian function is desirable. It is not indicated for patients who have positive margins or obvious residual disease (165). Survival rates after radical reoperation are similar to those after radical hysterectomy for stage I disease.

Radiation Therapy

Survival after radiotherapy depends on the volume of disease, the status of the surgical margins, and the length of delay from surgery to radiotherapy.

P.1440

Patients with microscopic disease have a 95% to 100% 5-year survival rate; the 5-year survival rate is 82% to 84% in those with macroscopic disease and free margins, 38% to 87% in those with microscopically positive margins, and 20% to 47% in those with obvious residual cancer (166,167,168). A delay in treatment of more than 6 months is associated with a 20% survival rate (168).

Acute Hemorrhage

Occasionally, a large lesion can produce life-threatening hemorrhage. A biopsy of the lesion should be performed to verify neoplasia, and a vaginal pack soaked in Monsel's solution (*ferric subsulfate*) should be packed tightly against the cervix. After proper evaluation, **external radiation therapy can be started with the expectation that control of bleeding may require 8 to 10 daily treatments at 180 to 200 cGy/day.** Broad-spectrum antibiotics should be used to reduce the incidence of infection. If the patient becomes febrile, the pack should be removed. Rapid replacement of the pack may be necessary, and a fresh pack should be immediately available. This approach to management of hemorrhage in patients previously untreated is preferable to exploration and vascular ligation.

Occasionally, vascular embolization under fluoroscopic control may be required in severe cases, and this procedure may obviate a laparotomy. However, vascular occlusion ultimately may lead to decreased blood flow and oxygenation of the tumor, compromising the effectiveness of subsequent radiotherapy.

Ureteral Obstruction

Treatment of bilateral ureteral obstruction and uremia in previously untreated patients should be determined on an individual basis. Transvesical or percutaneous ureteral catheters should be placed in patients with no evidence of distant disease, and radiotherapy with curative intent should be instituted. Patients with metastatic disease beyond curative treatment fields should be presented with the options of ureteral stenting, palliative radiotherapy, and chemotherapy. With aggressive management, a median survival rate of 17 months may be achieved for these patients (169).

Barrel-shaped Cervix

The expansion of the upper endocervix and lower uterine segment by tumor has been referred to as a **barrel-shaped cervix**. **Patients with tumors larger than 6 cm in diameter have a 17.5% central failure rate when treated with radiotherapy alone because the tumor at the periphery of the lower uterine segment is too far from the standard intracavitary source to receive an adequate tumoricidal dose** (170). Attempts have been made to overcome this problem radiotherapeutically by means of interstitial implants into the tumor with a perineal template, but high central failure rates have also been reported with this technique (171).

One approach is to use a combination of radiotherapy and surgery for treatment of patients with a barrel-shaped cervix. An extrafascial hysterectomy is performed 2 to 3 months after the completion of radiation therapy in an effort to resect a small, centrally persistent tumor. The dose of external radiotherapy is reduced to 4,000 cGy, and a single intracavitary treatment is given, which is followed by an extrafascial hysterectomy (172,173). This method appears to result in a lower rate of central failure (2%), although it is not clear that the overall survival rate is improved. **There is disagreement concerning the need for extrafascial hysterectomy**, and the Gynecologic Oncology Group is undertaking a randomized study to compare adjuvant hysterectomy with radiotherapy alone in patients who have no evidence of occult metastases in the para-aortic nodes (see Stage Ib and IIa discussion).

The narrow upper vagina of older patients may preclude the use of an intracavitary source of radiation. Such patients must receive their entire course of therapy from external sources, leading to a higher central failure rate and more significant bowel and bladder morbidity. If stage I disease is present in such a patient, a radical hysterectomy with pelvic

P.1441

lymphadenectomy is preferable if the patient's medical condition allows such an approach. There may be a role for IMRT in the management of such tumors.

Recurrent Cervical Cancer

Treatment of recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Patients who have been treated initially with surgery should be considered for radiation therapy, and those who have had radiation therapy should be considered for surgical treatment. Chemotherapy is palliative only and is reserved for patients who are not considered curable by either surgery or radiation therapy.

Radiotherapy for recurrence after surgery consists primarily of external treatment. Vaginal ovoids also may be placed in patients with isolated vaginal cuff recurrences. Patients with a regional recurrence may require interstitial implantation with a Syed type of template in addition to external therapy. A 25% survival rate can be expected in patients treated with radiation for a postsurgical recurrence (155).

Radiation Retreatment

Retreatment of recurrent pelvic disease by means of radiotherapy with curative intent is confined to patients who have had suboptimal or incomplete primary therapy. This may allow the radiotherapist to deliver curative doses of radiation to the tumor. The proximity of the bladder and rectum to the cancer and the relative sensitivity of these organs to radiation injury are the major deterrents to retreatment with radiation. The insertion of multiple interstitial radiation sources into locally recurrent cancer through a perineal template may

help overcome these dosimetric considerations (165,174). The fistula rates are high, however, and the consequences must be considered seriously before interstitial therapy is initiated. In general, for patients considered curable with interstitial implant therapy, pelvic exenteration is a better treatment choice. Palliative radiotherapy can be given to patients with localized metastatic lesions that are deemed incurable. Painful bony metastases, central nervous system lesions, and severe urologic or vena caval obstructions are specific indications.

Surgical Therapy

Surgical therapy for postirradiation recurrence is limited to patients with central pelvic disease. A few carefully selected patients with small-volume disease limited to the cervix may be treated with an extrafascial or radical hysterectomy. However, the difficulty of assessing tumor volume and the 30% to 50% rate of serious urinary complications in these previously irradiated patients have led most gynecologic oncologists to recommend pelvic exenteration as a last chance for cure (175,176).

Exenteration

There are three types of exenterative procedures: (i) an anterior exenteration (removal of the bladder, vagina, cervix, and uterus), (ii) a posterior exenteration (removal of the rectum, vagina, cervix, and uterus), and (iii) a total exenteration (removal of both bladder and rectum with the vagina, cervix, and uterus [Fig. 34.9]). A total exenteration that includes a large perineal phase includes the entire rectum and leaves the patient with a permanent colostomy as well as a urinary conduit (**infralevator**). In selected patients, a total exenteration may take place above the levator muscle (**supralevator**), leaving a rectal stump that may be anastomosed to the sigmoid, thus avoiding a permanent colostomy.

Preoperative Evaluation and Patient Selection

It is imperative to search for metastatic disease before undergoing an exenteration. The presence of metastatic disease in this setting is considered a contraindication to exenterative procedures. Physical examination includes careful palpation of the peripheral lymph nodes with FNA

P.1442

cytologic sampling of any nodes that appear suspicious. A random biopsy of nonsuspicious supraclavicular lymph nodes has been advocated by some clinicians but is not routinely practiced (139,177). A CT scan of the lung can detect disease missed on routine radiographic examination of the chest. Abdominal and pelvic CT scans are helpful in the detection of liver metastases and enlarged para-aortic nodes. Cytologic study of any abnormality should be undertaken with CT-guided FNA. If a positive cytologic diagnosis is obtained, it will obviate the need for exploratory laparotomy.

Figure 34.9 Pelvic exenteration.

Extension of the tumor to the pelvic sidewall is a contraindication to exenteration; however, this may be difficult for even the most experienced examiner to determine because of radiation fibrosis. If any question of resectability arises, exploratory laparotomy and parametrial biopsies should be offered (178,179,180,181). **The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction is nearly always pathognomonic of unresectable disease on the pelvic sidewall.** Preoperatively, the patient should be prepared for a major operation. Total parenteral nutrition may be necessary to place the patient in an anabolic state for optimal healing. A bowel preparation, preoperative antibiotic administration, and prophylaxis for deep venous thrombosis with low-dose heparin or pneumatic calf compression should be undertaken (182). Surgical mortality increases with age, and the operation should rarely be considered in a patient who is older than 70 years. Other medical illnesses should be taken into account. When life expectancy is limited, exenterative surgery is unwise.

Anterior Exenteration

Candidates for anterior exenteration are those in whom the disease is limited to the cervix and anterior portion of the upper vagina. Proctoscopic examination should be performed because a positive finding would mandate a total exenteration. However, a negative proctoscopic examination finding does not exclude disease in the rectal muscularis, and findings at laparotomy still must be considered. Generally, the presence of disease in the posterior vaginal mucosa directly over the rectum mandates removal of the underlying rectum.

Posterior Exenteration

A posterior exenteration is rarely performed for recurrent cervical cancer. It is indicated, however, for the patient with an isolated posterior vaginal recurrence in which dissection of the ureters through the cardinal ligaments will not be necessary.

Total Exenteration

Total exenteration with a large perineal phase is indicated when the disease extends to the lower part of the vagina (see Fig. 34.9). Because distal vaginal lymphatics may empty into the nodal basins of the inguinal region, these nodes should be carefully evaluated preoperatively. A supralelevator total exenteration with low rectal anastomosis is indicated in the patient whose disease is confined to the upper vagina and cervix (183,184). Samples from margins of the rectal edge should be obtained for frozen-section evaluation because occult metastases to the muscularis may occur.

The development of techniques to establish continent urinary diversion has helped improve a woman's physical appearance after exenteration (185,186,187).

When both a rectal anastomosis and a continent diversion are performed, the patient will not have a permanent external appliance. Associated psychological trauma in such cases may be avoided. **Every effort should be made to create a neovagina simultaneously with the exenteration** (188). This procedure helps in the reconstruction of the pelvic floor after extirpation of the pelvic viscera. Regardless whether a neovagina is constructed, it is desirable to mobilize the omentum on the left gastroepiploic artery to create a new pelvic floor.

Surgical mortality from exenterative procedures has steadily decreased to an acceptable level of less than 10%. Common causes of postoperative death are sepsis, pulmonary thromboembolism, and hemorrhage. Fistulas of the gastrointestinal and genitourinary tract are serious surgical complications, with a 30% to 40% mortality rate despite attempts at surgical repair. The risk for fistula formation has decreased because nonirradiated segments of bowel have been used for formation of the urinary conduit (182). **The 5-year survival rate is 33% to 60% for patients undergoing anterior exenteration and 20% to 46% for those undergoing total exenteration** (178,179,180,181,182,183,184,185,186,187,188). Survival rates are worse for patients with recurrent disease (larger than 3 cm), invasion into the bladder, positive pelvic lymph nodes, and recurrence diagnosed within 1 year after radiotherapy (181). The 5-year survival rate of patients with positive pelvic lymph nodes is less than 5%; thus, the performance of an extensive lymphadenectomy in the irradiated field is not warranted. Discontinuation of the procedure is advisable if any nodes are positive for metastatic cancer. Patients who have any disease in the peritoneal cavity have no chance of survival.

Laterally Extended Endopelvic Resection

Locally recurrent cervical cancer in a previously irradiated field is associated with a dismal prognosis. Exenterative therapy has traditionally been reserved for the highly select patient with centrally recurrent disease, a selection criteria that excludes most patients with recurrence. Recently, a new technique called **laterally extended endopelvic resection (LEER)** procedure has been described, which offers a new surgical treatment option for patients with recurrent disease involving the pelvic sidewall. The LEER procedure involves extending the lateral resection plane of the traditional pelvic exenteration to include resection of the internal iliac vessels; the endopelvic portion of the obturator internus muscle; and the coccygeus, iliococcygeus, and pubococcygeus muscles. Extension of the surgical plane allows for resection of lateral tumors with a negative margin. Experience with it is limited (189).

Chemotherapy for Recurrent Cervical Cancer

Recurrent cervical cancer is not considered curable with chemotherapy. The delivery of chemotherapy to recurrent tumor in a prior radiated field may be compromised because of altered blood supply caused by radiation. **Topotecan and cisplatin has been reported to have response rates of 15% to 20%, with a median duration of 6 to 9 months (190).**

P.1444

Many other agents have shown activity against cervical cancer and may be used in attempt to help control symptoms. **Several clinical trials with various drugs (e.g., paclitaxel, topotecan, cisplatin, and carboplatin) have shown response rates of up to 45%. Most responses are partial (191), and complete responses are unusual and are generally limited to patients with chest metastases,** in whom the dose of drug delivered to the disease is stronger than that delivered to the fibrotic postirradiated pelvis (192).

Palliative Therapy

Palliative therapy for patients with incurable disease consists of radiation or chemotherapy or both. **Palliative radiation therapy is intended to relieve symptoms of pain or bleeding associated with advanced disease and may be administered as either external beam therapy (teletherapy) or brachytherapy.** Special care should be given to previously irradiated sites because additional radiation therapy may be associated with unacceptable morbidity. Single or multiagent palliative chemotherapy may also be used with variable response rates. Symptomatic recurrent disease within previously irradiated fields may not respond well to palliative chemotherapy.

Vaginal Carcinoma

Primary vaginal cancer is a relatively uncommon tumor, representing only 1% to 2% of malignant neoplasms of the female genital tract (193,194). The incidence of invasive vaginal cancer is 0.42 per 100,000 women, and it has remained relatively unchanged since the 1980s (195). Primary vaginal cancer should be differentiated from cancers metastatic to the vagina, which constitute the majority of vaginal cancers (80% to 90%) (196).

Staging

The FIGO staging of vaginal cancer dictates that a tumor extending to the vagina from the cervix be regarded as a cancer of the cervix, whereas a tumor involving both the vulva and the vagina should be classified as a cancer of the vulva.

The FIGO staging for vaginal carcinoma is shown in Table 34.6. **Staging is performed by clinical examination** and, if indicated, cystoscopy, proctoscopy, and chest and skeletal radiography. Information derived from lymphangiography, CT, MRI, or PET cannot be used to change the FIGO stage; however, it can be used for planning treatment. Unfortunately, 75% of patients present with stage II–IV disease, complicating the treatment and subsequent cure rates (197,198,199).

Table 34.6 FIGO Staging of Vaginal Cancer

Stage 0	Carcinoma <i>in situ</i> , intraepithelial carcinoma.
Stage I	The carcinoma is limited to the vaginal wall.
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	The carcinoma has extended to the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum.
	IVa Spread of the growth to adjacent organs.
	IVb Spread to distant organs.
FIGO, International Federation of Gynecology and Obstetrics.	

P.1445

Surgical staging and resection of enlarged lymph nodes may be indicated in selected patients. FIGO staging does not include a category for microinvasive disease. Because vaginal cancer is rare, and treatment is generally by radiotherapy, there is very little information concerning the spread of disease in relation to depth of invasion, lymph—vascular space invasion, and size of the lesion.

Etiology

The cause of squamous cell carcinoma of the vagina is unknown. The association of cervical cancer with HPV suggests that vaginal cancer may have a similar association (200).

Human papillomavirus has been recovered from 80% of precursor lesions and 60% of squamous cell cancers of the vagina (53,54). In addition, as many as 30% of women with vaginal cancer have a history of cervical cancer treated within the previous 5 years (201,202,203). As with cervical cancer, there appears to be a premalignant phase called **vaginal intraepithelial neoplasia (VAIN)** (see Chapter 17). **The exact incidence of progression to invasive vaginal cancer from VAIN is not known;** however, there are documented cases of invasive disease occurring despite adequate treatment of VAIN (204,205).

By convention, any new vaginal carcinoma developing at least 5 years after cervical cancer should be considered a new primary lesion. There are three possible mechanisms for the occurrence of vaginal cancer after cervical neoplasia:

- Residual disease in the vaginal epithelium after treatment of the cervical neoplasia
- New primary disease arising in a patient with increased susceptibility to lower genital tract carcinogenesis (the role of HPV in this setting is suspected)
- Increased susceptibility to carcinogenesis caused by radiation therapy

Screening

Routine screening of all patients for vaginal cancer is inappropriate. For women who have had a cervical or vulvar neoplasm, the Pap test is an important part of routine follow-up with each physician visit, as these patients are at an increased lifetime risk for developing

vaginal cancer. It is recommended that Pap test surveillance for vaginal cancer be performed yearly after the patient has completed surveillance for cancer of the cervix or vulva. **For women who have had a hysterectomy for benign disease and have no antecedent history of CIN 2–3, performance of Pap testing is unnecessary. If the patient has a history of cervical dysplasia or cervical cancer, yearly screening is recommended.**

When adjusted for age and prior cervical disease, the incidence of vaginal cancer is not increased in women who have had hysterectomy for benign disease (206). Because primary vaginal tumors tend to be multicentric, the entire vaginal mucosa should be considered at risk. Therefore, in addition to screening cytology, careful bimanual examinations of the entire vagina and vulva is recommended for women at high risk.

Symptoms

Painless vaginal bleeding and discharge are the most common symptoms of vaginal cancer. With more advanced tumors, urinary retention, bladder spasm, hematuria, and frequency of urination may occur. Tumors developing on the posterior vaginal wall may produce rectal symptoms, such as tenesmus, constipation, or blood in the stool.

Diagnosis

The diagnostic workup includes a complete history and physical examination, careful speculum examination and palpation of the vagina, and bimanual pelvic and rectal

P.1446

examinations. **It is important to rotate the speculum to obtain a careful view of the entire vagina because posterior wall lesions frequently occur and may be overlooked.**

In early squamous cell lesions, the diagnosis is often suggested by an abnormal Pap test result; however, this is not true for clear cell adenocarcinomas, which are characterized by submucosal growth. In these cases, the diagnosis is suggested by cytologic findings in only 33% of cases. Visually suspicious areas in the vagina should be evaluated with a targeted biopsy using the same instruments as those used for cervical biopsies. Careful palpation of the vagina may be helpful in detecting submucosal irregularities. **The most common site of vaginal cancer is in the upper one third of the vagina on the posterior wall.**

The developing tumor may be missed during initial inspection because of obscured visualization caused by the blades of the speculum (207). Colposcopy is valuable in evaluating patients with abnormal Pap test results, unexplained vaginal bleeding, or ulcerated erythematous patches in the upper vagina. A colposcopically targeted biopsy may not allow a definitive diagnosis, and a partial vaginectomy may be necessary to determine invasion. Occult invasive carcinoma may be detected by such an excision, particularly in patients who have a history of prior hysterectomy in whom the vaginal vault closure may bury some of the vaginal epithelium at risk for cancer (208).

Pathology

Cancer of the vagina spreads most often by direct extension into the pelvic soft tissues and adjacent organs. Metastases to the pelvic and para-aortic lymph nodes may occur in advanced disease. Lesions in the lower one third of the vagina may spread directly to the inguinal femoral lymph nodes as well as the pelvic nodes (209). Hematogenous dissemination to the lungs, liver, or bone may occur as a late phenomenon.

Squamous cell carcinomas are the most common form of vaginal cancer, occurring in 80% to 90% of cases. These tumors most commonly occur in the upper one third, posterior wall of the vagina. The mean age of patients with squamous cell cancer is 60 years

(210,211). Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (212,213,214). Other histologic subtypes include adenocarcinoma and sarcoma.

Primary adenocarcinoma of the vagina is rare, constituting 9% of primary tumors of the vagina. The most common adenocarcinoma of the vagina is metastatic, originating from the colon, endometrium, ovary, or, rarely, pancreas and stomach.

In general, adenocarcinomas affect a younger population of women, regardless of whether they were exposed to *diethylstilbestrol (DES) in utero* (215). Adenocarcinomas may arise in wolffian rest elements, periurethral glands, and foci of endometriosis (216). In women exposed to *DES in utero*, adenocarcinoma may develop in vaginal adenosis.

Diethylstilbestrol was used in the United States from 1940 until 1971 to maintain high-risk pregnancies in women with a history of spontaneous abortions. In 1970, seven young women were reported with clear cell adenocarcinoma of the vagina (Fig. 34.10); later, an association between this cancer and maternal ingestion of *DES* during pregnancy was identified (217). Subsequently, more than 500 cases of clear cell cancer of the vagina and cervix have been reported to the Registry for Research on Hormonal Transplacental Carcinogenesis.

The estimated risk for developing clear cell adenocarcinoma for an exposed offspring is 1 in 1,000 or less. The mean age of diagnosis is 19 years (218). Clear cell adenocarcinoma in women with a history of *in utero* exposure to *DES* typically presents in the exocervix or anterior, upper one third of the vagina. These tumors vary greatly in size and are most frequently exophytic and superficially invasive. Stage is the most important prognostic factor. Other statistically significant factors include a tubulocystic growth pattern,

P.1447

size less than 3 cm², and less than 3 mm of stromal invasion. Because the use of *DES* in pregnant women was discontinued in 1971, most of these tumors probably have been discovered. It is uncertain, however, what will happen to this cohort of women as they move into their fifth, sixth, and seventh decades of life. Continued surveillance of these women is indicated.

Figure 34.10 Vaginal clear cell carcinoma. Note the formation of tubules with hobnail cells lining the lumen. These cells are characterized by nuclear protrusion into the apical cytoplasm.

Ninety-seven percent of cases of vaginal clear cell adenocarcinoma are associated with adenosis. Adenosis is characterized by the presence of persistent müllerian-type glandular epithelium. Although adenosis is the most common histologic abnormality in women exposed to *DES in utero*, adenosis can also be found in women without a history of exposure. Adenosis typically appears as red, grapelike clusters in the vagina.

Malignant melanoma of the vagina is rare and extremely lethal, occurring most often in white women. The average age of these patients is 58 years (219). Most lesions are deeply invasive, corresponding to a Clark level IV when compared with the staging for vulvar melanomas. The most common location of these tumors is in the lower one third of the vagina (220). Melanomas have a wide variety of size, color, and growth patterns (218,221). Radical excision (vaginectomy, hysterectomy, and pelvic lymphadenectomy) has been the mainstay of treatment. The goal of treatment is to avoid local (vaginal) recurrence, which is the most common site of recurrence (219,220). The need to dissect regional lymph nodes is uncertain. Because the disease is deeply invasive, hematogenous spread is the most common lethal recurrence. There is no difference in overall survival of patients with local as opposed to radical excision (219). The survival rate is approximately 10% at 5 years.

The most common benign and malignant mesenchymal tumors of the vagina in adult women are smooth muscle tumors (222). Vaginal sarcomas are usually fibrosarcomas or

leiomyosarcomas and are extremely rare. Radical local excision, followed by adjuvant chemotherapy or radiation therapy, is the indicated treatment.

Figure 34.11 Embryonal rhabdomyosarcoma of the vagina (botryoid sarcoma). This lesion consists of primitive mesenchymal cells and rhabdomyoblasts, which have abundant eosinophilic cytoplasm. With further differentiation, cross striations may become evident.

The most common malignant mesenchymal tumor of the vagina in children and infants is botryoid rhabdomyosarcoma (Fig. 34.11). Botryoid sarcoma is usually found in the vagina during infancy and early childhood, in the cervix during the reproductive years, and in the corpus uteri during postmenopausal years. Preoperative chemotherapy with *vincristine*, *actinomycin D*, and *cyclophosphamide*, followed by conservative surgery or radiation, has led to improved survival.

Treatment

Treatment selection is based on the clinical examination, CT scan results, chest radiography results, age, and condition of the patient. Most tumors are treated by radiation therapy. Surgery is limited to highly selective cases.

Women with stage I disease involving the upper posterior vagina may be treated by radical vaginectomy and pelvic lymphadenectomy. If the uterus is *in situ*, it is removed as a radical hysterectomy specimen. When margins are clear and lymph nodes are negative, no additional therapy is necessary. Patients with stage IV disease with either rectovaginal or vesicovaginal fistula may be candidates for primary pelvic exenteration with pelvic and para-aortic node dissection (218). Low rectal anastomosis, continent urinary diversion, and vaginal reconstruction are indicated and are more successful in these nonirradiated patients than in patients who receive prior radiation therapy (188).

Women with central pelvic recurrence after radiation therapy are candidates for pelvic exenteration similar to that used for cervical cancer. Surgical staging with

resection of enlarged lymph nodes followed by radiation therapy may improve the control of pelvic disease.

Radiation therapy is the treatment of choice for all patients except those described previously. Small superficial lesions may be treated with intracavitary radiation alone (218). Larger, thicker lesions should be treated first with external teletherapy to decrease tumor volume and to treat the regional pelvic nodes, followed by intracavitary and interstitial therapy to deliver a high dose to the primary tumor (211,219). If the uterus is intact and the lesion involves the upper vagina, an intrauterine tandem and ovoids can be used. If the uterus has been previously removed, a vaginal cylinder may be used for superficial irradiation. When brachytherapy is used, high- and low-dose rate techniques have been described. If the lesion is more than 0.5 cm thick, interstitial radiation techniques can improve the dose distribution to the primary tumor. Surgical exploration or laparoscopy at the time of insertion of Syed interstitial implants defines more precisely the placement of the needles and ensures that needles do not pass into adherent loops of bowel. Extended-field radiation may be used for vaginal cancer in a manner similar to its use for cervical carcinoma, although there is no experience reported with the use of this technique in the treatment of vaginal cancer. Likewise, there is no reported experience with combination chemoradiation treatment. However, **concurrent use of 5-FU and cisplatin has been highly successful in anal and cervical cancer and thus should be considered for treatment of vaginal cancer.**

Sequelae

The proximity of the rectum, bladder, and urethra leads to a major complication rate of 10% to 15% for both surgery and radiation treatment. For large tumors, the risk of bladder or bowel fistula is significant. Radiation cystitis and proctitis are common, as are rectal strictures or ulcerations. Radiation necrosis of the vagina occasionally occurs, requiring débridement, and often leads to fistula formation. Vaginal fibrosis, stenosis, and stricture are common after radiation therapy. **Use of vaginal dilators and resumption of regular sexual relations should be encouraged, along with the use of topical estrogen to maintain adequate vaginal function.**

Survival

The overall 5-year survival rate for patients with vaginal cancer is 42% (Table 34.7). Even for patients with stage I disease, the 5-year survival rate is less than 70%, which is 15% lower than that for comparable stages of cervical or vulvar cancer (220,221,222,223,224). Most recurrences are in the pelvis, either from enlarged regional nodes or from large central tumors. Radiation techniques, including interstitial implants with Syed applicator and combination chemoradiation, are the mainstay of therapy. Careful evaluation of patients who receive radiation therapy to detect central recurrence may allow some

P.1450

patients to be saved by pelvic exenteration. Because of the rarity of vaginal cancer, these patients should be treated in a center that is familiar with the complexity of treatment and modalities of therapy.

Table 34.7 Primary Vaginal Carcinoma: 5-year Survival

Stage	No. of Patients	No. Surviving 5 Years	Percentage
I	172	118	68.6
II	236	108	45.8
III	203	62	30.5
IV	114	20	17.5
Total	725	308	42.5

Ovarian and Fallopian Tube Cancer

Jonathan S. Berek

Sathima Natarajan

- **The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age. About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant. The average age of patients with borderline tumors is approximately 46 years.**
- **Ovarian cancer has been associated with low parity and infertility. Because parity is inversely related to the risk of ovarian cancer, having at least one child**

is protective of the disease, with a risk reduction of 0.3 to 0.4.

- Oral contraceptive use reduces the risk of epithelial ovarian cancer. Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer).
- Given the false-positive results for both CA125 and transvaginal ultrasonography, particularly in premenopausal women, these tests are not cost-effective and should not be used routinely to screen for ovarian cancer.
- Most epithelial ovarian cancer is sporadic, with familial or hereditary patterns accounting for 5% to 10% of all malignancies. Hereditary ovarian cancers in general occur in women approximately 10 years younger than those with nonhereditary tumors.
- Most hereditary ovarian cancer is associated with germline mutations in the *BRCA1* gene; a small proportion of inherited disease is associated with mutations in the gene *BRCA2*. The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated. The value of prophylactic salpingo-oophorectomy in these patients has been documented.
- The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. Patients with advanced-stage disease should undergo "debulking" or cytoreductive surgery to remove as much of the tumor and its metastases as possible, if the patient is medically stable. The performance of a debulking operation as early as possible in the course of the patient's treatment should be considered the standard of care.
- Combination chemotherapy with *carboplatin* and *paclitaxel* is the treatment of choice for patients with high-risk, low-stage disease. For advanced-stage epithelial ovarian cancer, the choice of intravenous versus intraperitoneal platinum and taxane chemotherapy should be individualized.
- In the first two decades of life, almost 70% of ovarian tumors are of germ

cell origin, and one third of these are malignant. In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly.

- **The most common types of malignant germ cell tumors are dysgerminomas, immature teratomas, and endodermal sinus tumors. Preservation of fertility should be standard in most patients. The most effective chemotherapy is *bleomycin, etoposide, and cisplatin* (BEP) combination.**
- **Stromal tumors include granulosa cell tumors, which are low-grade malignancies. In premenopausal women, they can be treated conservatively. Adjuvant chemotherapy is of unproven value.**
- **Metastatic tumors to the ovaries are most frequently from the breast and gastrointestinal tract.**
- **Fallopian tube carcinomas are treated the same as ovarian cancer, with staging, cytoreductive surgery, and platinum and taxane chemotherapy.**

Of all the gynecologic cancers, ovarian malignancies represent the greatest clinical challenge. Epithelial cancers are the most common ovarian malignancies, and because they are usually asymptomatic until they have metastasized, patients have advanced disease at diagnosis in more than two thirds of the cases. Ovarian cancer represents a major surgical challenge, requires intensive and often complex therapies, and is extremely demanding of the patient's psychological and physical energy. It has the highest fatality-to-case ratio of all the gynecologic malignancies. There are more than 20,000 new cases annually in the United States, and more than 15,000 women can be expected to succumb to their illness (1). Ovarian cancer is the seventh most common cancer in women in the United States, accounting for 3% of all malignancies and 6% of deaths from cancer in women, and almost one third of invasive malignancies of the female genital organs. Ovarian cancer is the fifth most common cause of death from malignancy in women. **A woman's risk at birth of having ovarian cancer sometime in her life is 1% to 1.5%, and that of dying from ovarian cancer almost 0.5%** (2).

Epithelial Ovarian Cancer

Approximately 90% of ovarian cancers are derived from tissues that come from the coelomic epithelium or mesothelium (2). The cells are a product of the primitive mesoderm, which can undergo metaplasia. A classification of the histologic types of epithelial tumors of the ovary is presented in Table 35.1. Neoplastic transformation can occur when the

cells are genetically predisposed to oncogenesis or exposed to an oncogenic agent or both (3).

Table 35.1 Epithelial Ovarian Tumors	
<i>Histologic Type</i>	<i>Cellular Type</i>

<i>VII. Undifferentiated</i>	<i>Anaplastic</i>
<i>VIII. Unclassified</i>	<i>Mesothelioma, etc.</i>
From Seroy SF, Scully RE, Sobin LH. <i>International histological classification of tumours no. 9. Histological typing of ovarian tumors.</i> Geneva, Switzerland: World Health Organization, 1973, with permission.	

Pathology

Invasive Cancer

Seventy-five percent of epithelial cancers are of the serous histologic type. Less common types are mucinous (20%), endometrioid (2%), clear cell, Brenner, and undifferentiated carcinomas; each of the last three types represents less than 1% of epithelial lesions (2). Each tumor type has a histologic pattern that reproduces the mucosal features of a section of the lower genital tract (3). For example, the serous or papillary pattern has an appearance similar to that of the glandular epithelial lining and fallopian

P.1460

tube. Mucinous tumors contain cells that resemble the endocervical glands, and the endometrioid tumors resemble the endometrium.

Borderline Tumors

An important group of tumors to distinguish is the *tumor of low malignant potential*, also called the *borderline tumor*. Borderline tumors are lesions that tend to remain confined to the ovary for long periods, occur predominantly in premenopausal women, and are associated with a very good prognosis (2,3,4,5,6,7,8). They are encountered most frequently in women between the ages of 30 and 50 years, whereas invasive carcinomas occur more often in women between the ages of 50 and 70 years (2).

Although uncommon, metastatic implants may occur with borderline tumors. Such implants have been divided into *noninvasive* and *invasive* forms. The latter group has a higher likelihood of developing into progressive, proliferative disease in the peritoneal cavity, which can lead to intestinal obstruction and death (2,6).

The criteria for the diagnosis of borderline tumors (Fig. 35.1) are as follows (7):

- **Epithelial hyperplasia in the form of pseudostratification, tufting, cribriform, and micropapillary architecture**
- **Nuclear atypia and increased mitotic activity**
- **Detached cell clusters**
- **Absence of destructive stromal invasion (i.e., without tissue destruction)**

Figure 35.1 Borderline malignant serous tumor of the ovary. Complex papillary fronds are lined with pseudostratified columnar cells. The epithelium and the stroma are clearly separated by a basement membrane, indicating no stromal invasion.

It should be emphasized that about 20% to 25% of borderline tumors spread beyond the ovary. **The diagnosis of borderline tumor versus malignant ovarian tumor must be based on the histologic features of the primary tumor (7).**

Classification of Epithelial Ovarian Tumors

Serous Tumors

Serous tumors develop by invagination of the surface ovarian epithelium and are so classified because they secrete serous fluid (as do tubal secretory cells).

Psammoma bodies, more correctly foci of foreign material, frequently are associated with these invaginations and may be a response to irritative agents that produce adhesion formation

and the entrapment of the surface epithelium. In the wall of the mesothelial invaginations, papillary ingrowths are common, representing the early stages of development of a papillary serous cystadenoma. There are many variations in the proliferation of these mesothelial inclusions. Several foci may be lined with flattened inactive epithelium; in adjacent cavities, papillary excrescences are present, often resulting from local irritants (2).

Borderline Serous Tumors

Approximately 10% of all ovarian serous tumors fall into the category of a tumor of low malignant potential or borderline tumor, and 50% occur before the age of 40 years.

As many as 10% of women with ovarian serous borderline tumors have extraovarian implants, and some will eventually die of the disease (9). Although multiple foci of disease have been documented in the abdominal cavity with secondary deposits in the pelvis, omentum, and adjacent tissues, including lymph nodes, metastases outside the abdominal cavity are rare. Death can occur as the result of intestinal obstruction (10,11,12).

The implants are divided histologically into *invasive* and *noninvasive implants* (6,10). In the noninvasive implants, papillary proliferations of atypical cells involve the peritoneal surface and form smooth invaginations (6). The invasive implants resemble well-differentiated serous carcinoma and are characterized by atypical cells forming irregular glands with sharp borders. Bell et al. (6) have reported that only three of 50 women with noninvasive implants died, whereas four of six women with invasive implants died. In the series of McCaughey et al., two of 13 patients with noninvasive implants and all five patients with invasive implants died (9). Others have noted no differences in prognosis (10,11).

Rare examples of borderline malignant serous tumors with foci of microinvasion have been reported by Bell and Scully (12). Most patients are young, International Federation of Gynecology and Obstetrics (FIGO) stage I, and sometimes pregnant. Only one of 30 such patients died of disease, and she had stage III disease.

Malignant Serous Carcinomas

In malignant serous tumors, stromal invasion is present (2). The grade of tumor should be identified. In well-differentiated serous adenocarcinomas, papillary and glandular structures predominate (Fig. 35.2); poorly differentiated neoplasms are characterized by solid sheets of cells, nuclear pleomorphism, and high mitotic activity; and moderately differentiated carcinomas are intermediate between these two lesions. Laminated, calcified psammoma bodies are found in 80% of serous carcinomas. ***Serous psammocarcinoma is a rare variant of serous carcinoma characterized by massive psammoma body formation and low-grade cytological features.*** At least 75% of the epithelial nests are associated with psammoma body formation. Patients with serous psammocarcinoma have a protracted clinical course and a relatively favorable prognosis; their clinical course more closely resembles that of serous borderline tumor than serous carcinoma.

Figure 35.2 Well-differentiated serous papillary adenocarcinoma of the ovary. Clusters and papillae of malignant cells are in direct contact with fibrous stroma indicative of stromal invasion.

Mucinous Tumors

These cystic ovarian tumors have loculi lined with mucin-secreting epithelium. The lining epithelial cells contain intracytoplasmic mucin and resemble those of endocervix, gastric pylorus, or intestina. **They represent about 8% to 10% of epithelial ovarian tumors.** They may reach enormous size, filling the entire abdominal cavity (2).

Borderline Mucinous Tumors

The mucinous tumor of low malignant potential is often a diagnosis difficult to make. Although it is common to find a rather uniform pattern from section to section in the serous borderline

tumor, this is not true in the mucinous tumors. **Frequently, well-differentiated mucinous epithelium may be seen immediately adjacent to a poorly differentiated focus. Therefore, it is important to take multiple sections from many areas in the mucinous tumor to identify the most malignant alteration.**

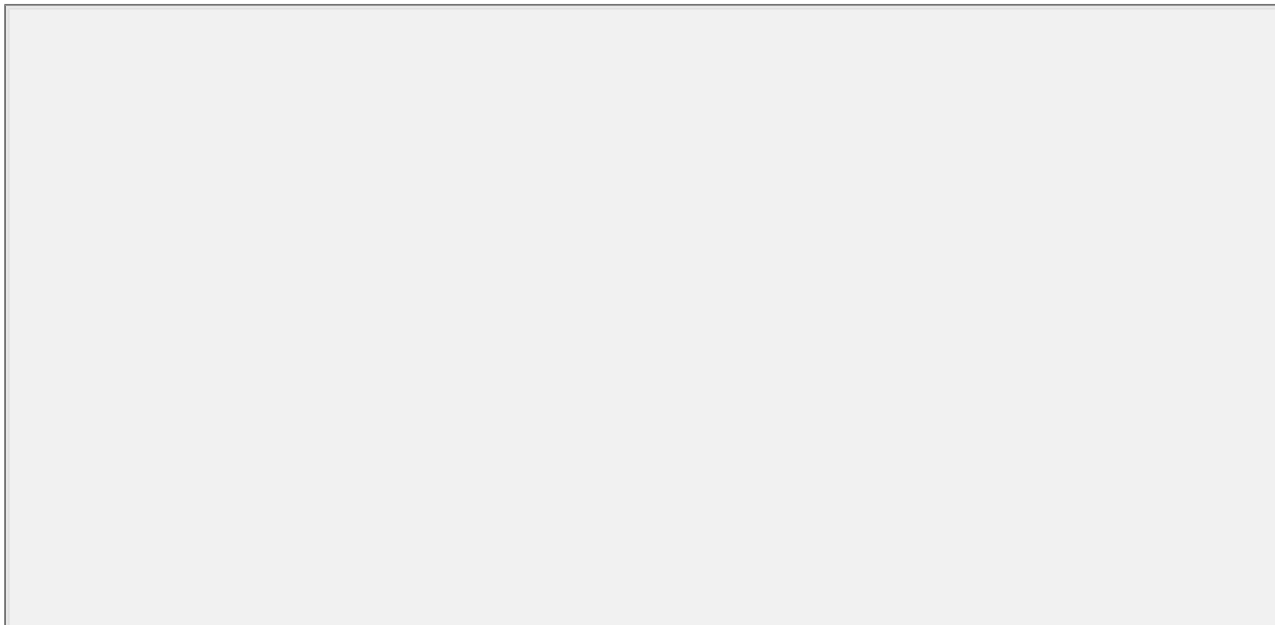

Malignant Mucinous Carcinomas

Bilateral tumors occur in 8% to 10% of cases. The mucinous lesions are intraovarian in 95% to 98% of cases (Fig. 35.3). **Because most ovarian mucinous carcinomas contain intestinal-type cells, they cannot be distinguished from metastatic carcinoma of the gastrointestinal tract on the basis of histology alone.** Primary ovarian neoplasms rarely metastasize to the mucosa of the bowel, although they commonly involve the serosa, whereas gastrointestinal lesions frequently involve the ovary by direct extension of vascular lymphatic spread.

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a clinical term used to describe the finding of abundant mucoid or gelatinous material in the pelvis and abdominal cavity surrounded by fibrous tissue. It is **most commonly secondary to a well-differentiated**

appendiceal carcinoma or other gastrointestinal primary, and less commonly, a mucocele of the appendix.

Figure 35.3 Mucinous adenocarcinoma of the ovary. Irregular glandular spaces are lined with a layer of tall columnar cells with abundant mucinous cytoplasm, resembling endocervical cells. The nuclei are mildly atypical.

Endometrioid Tumors

Endometrioid lesions constitute 6% to 8% of epithelial tumors. Endometrioid neoplasia includes all the benign demonstrations of endometriosis. In 1925, Sampson (13) suggested that certain cases of adenocarcinoma of the ovary probably arose in areas of endometriosis. The adenocarcinomas are similar to those seen in the uterine corpus. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be demonstrated (Fig. 35.4).

Borderline Endometrioid Tumors

The endometrioid tumor of low malignant potential has a wide morphologic

spectrum. Tumors may resemble an endometrial polyp or complex endometrial hyperplasia with glandular crowding. When there are back-to-back glands with no intervening stroma, the tumor is classified as a well-differentiated endometrioid carcinoma. Some borderline endometrioid tumors have a prominent fibromatous component. In such cases, the word *adenofibroma* is used.

Malignant Endometrioid Carcinomas

Endometrioid tumors are characterized by an adenomatous pattern with all the potential variations of epithelia found in the uterus.

Multifocal Disease

The *endometrial* or endometrioid tumors afford the greatest opportunity to evaluate multifocal disease. **Endometrioid carcinoma of the ovary is associated in 15% to 20% of the cases with carcinoma of the endometrium. Identification of multifocal disease is important, because patients with disease metastatic from the**

uterus to the ovaries have a 30% to 40% 5-year survival, whereas those with synchronous multifocal disease have a 75% to 80% 5-year survival (14). When the histologic appearance of endometrial and ovarian tumors is different, the two tumors most likely represent two separate primary lesions. When they appear similar, the endometrial tumor can be considered a separate primary tumor if it is well differentiated and only superficially invasive.

Figure 35.4 Endometrioid cancer. Round to tubular glands lined by stratified columnar cells with confluent growth pattern.

Clear Cell Carcinomas

Several basic histologic patterns are present in the clear cell adenocarcinoma (i.e., tubulocystic, papillary, reticular, and solid). The tumors are made up of clear and hobnail cells that project their nuclei to the apical cytoplasm. The tall clear cells have abundant clear or vacuolated cytoplasm, hyperchromatic irregular nuclei, and nucleoli of various sizes (Fig. 35.5). **Focal areas of endometriosis and endometrioid carcinoma sometimes occur.** The clear cell carcinoma seen in the ovary is histologically identical to that seen in the uterus or vagina of the young patient who has been exposed to diethylstilbestrol (DES) *in utero*. Nuclei of clear cell carcinoma range from grade 1 to grade 3, but pure grade 1 tumors are extremely rare. **Almost invariably high-grade (grade 3) nuclei are identified. Hence, clear cell carcinoma is not graded.**

Brenner Tumors

Borderline Brenner Tumors

Borderline, or proliferating, Brenner tumors have been described. In such cases, the epithelium does not invade the stroma. Some investigators subclassify those tumors that resemble low-grade papillary transitional cell carcinoma of the urinary bladder as proliferating tumors and those with a higher grade of transitional cell carcinoma *in situ* as borderline malignant Brenner tumors (15). Complete surgical removal usually results in cure.

P.1465

Figure 35.5 Clear cell mesonephroid carcinoma of the ovary. Note the solid variant of clear cell carcinoma with sheets of cells that have clear cytoplasm ("hobnail" cells).

These are rare and are defined as **benign Brenner tumors coexisting with invasive transitional cells or another type of carcinoma**. In malignant Brenner tumors there is stromal invasion associated with a benign or borderline Brenner tumor component.

Transitional Cell Tumors

The designation *transitional cell tumor* refers to a **primary ovarian carcinoma resembling transitional cell carcinoma of the urinary bladder without a recognizable Brenner tumor**. An important finding is that those ovarian carcinomas that contain more than 50% of transitional cell carcinoma are more sensitive to chemotherapy and have a more favorable prognosis than other poorly differentiated ovarian carcinomas of comparable stage (16,17). Transitional cell tumors differ from malignant Brenner tumors in that they are more frequently diagnosed in an advanced stage and, therefore, are associated with a poorer survival rate (18).

Small cell carcinoma occurs mainly in young women, who may have symptoms of hypercalcemia. Immunohistochemical stains are helpful to differentiate this tumor from a lymphoma, leukemia, or sarcoma.

Peritoneal Carcinomas

Primary peritoneal tumors are histologically indistinguishable from primary ovarian serous tumors. In the case of *borderline serous peritoneal tumors* and *serous peritoneal carcinomas*, the ovaries are normal or minimally involved, and the tumors affect predominantly the uterosacral ligaments, pelvic peritoneum, or omentum. The overall prognosis for borderline serous peritoneal tumors is excellent and comparable to that of ovarian borderline serous tumors (19,20,21). In the review of 38 cases of peritoneal borderline serous

P.1466

tumors from the literature, 32 women had no persistent disease, four were well after resection of recurrence, one developed an invasive serous carcinoma, and one died from the effects of the tumor (19).

Peritoneal serous carcinomas have the appearance of a moderately to poorly differentiated serous ovarian carcinoma. Primary peritoneal endometrioid carcinoma is less common.

The primary malignant transformation of the peritoneum has been called primary peritoneal carcinoma or primary peritoneal papillary serous carcinoma. Peritoneal carcinoma simulates ovarian cancer clinically. In patients for whom exploratory surgery is performed, there may be microscopic or small macroscopic cancer on the surface of the ovary and extensive disease in the upper abdomen, particularly in the

omentum. **This phenomenon can thus produce a condition in which so-called ovarian cancer can arise in a patient whose ovaries were surgically removed many years earlier** (22).

Mesotheliomas

Peritoneal malignant mesotheliomas fall into the following four categories (2,23):

(i) fibrosarcomatous, (ii) tubulopapillary (papillary-alveolar), (iii) carcinomatous, and (iv) mixed. These lesions appear as multiple intraperitoneal masses and can develop after hysterectomy and bilateral salpingo-oophorectomy for benign disease.

Malignant mesotheliomas should be distinguished from ovarian tumor implants and primary peritoneal müllerian neoplasms.

Clinical Features

More than 80% of epithelial ovarian cancers are found in postmenopausal women (Fig. 35.6).

The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age (2,3,24). The age-specific incidence of ovarian epithelial cancer rises precipitously from 20 to 80 years of age and subsequently declines (24). These cancers are relatively uncommon in women younger than age 45. Fewer than 1% of epithelial ovarian cancers occur before the age of 21 years, two thirds of ovarian malignancies in such patients being germ cell tumors (2,24,25). **About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant** (2,3).

The average age of patients with borderline tumors is approximately 46 years (2,3,5). Eighty to ninety percent of ovarian cancers, including borderline forms, occur after the age of 40 years, whereas 30% to 40% of malignancies occur after the age of 65 years. The chance that a primary epithelial tumor will be of borderline or invasive malignancy in a patient younger than 40 years is approximately 1 in 10, but after that age it rises to one in three (2,3). Fewer than 1% of epithelial ovarian cancers occur before the age of 20 years, with two thirds of ovarian malignancies in such patients being germ cell tumors.

Etiology

Ovarian cancer has been associated with low parity and infertility (26). Although there have been a variety of epidemiologic variables correlated with ovarian cancer, such as talc use, galactose consumption, and tubal ligation (see Chapter 4), none has been so strongly correlated as prior reproductive history and duration of the reproductive career (26,27). Early menarche and late menopause increase the risk of ovarian cancer (27). These factors and the relationship of parity and infertility to the risk of ovarian cancer have led to the hypothesis that suppression of ovulation may be an important factor. **Theoretically,**

this process might lead to a higher probability of spontaneous mutations that can unmask germline mutations or otherwise lead to the oncogenic phenotype (see Chapter 6).

Prevention

Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective of the disease, with a risk reduction of 0.3 to 0.4. Oral contraceptive use reduces the risk of epithelial ovarian cancer (26). Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a

50% reduction in the likelihood of development of ovarian cancer). Women who have had two children and have used oral contraceptives for 5 or more years have a relative risk of ovarian cancer as low as 0.3, or a 70% reduction (28). **Therefore, the oral contraceptive pill is the only documented method of chemoprevention for ovarian cancer, and it should be recommended to women for this purpose. When counseling patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is also important for women with a strong family history of ovarian cancer** (see discussion below).

Fenretinide (4-hydroxyretinoic acid), a vitamin A derivative, has been given to women with unilateral breast cancer in an effort to reduce the risk of contralateral breast cancer. In a prospective, randomized, placebo-controlled trial conducted in Italy (29), women with unilateral breast cancer were given for 6 months either *fenretinide* orally or a placebo. In the treatment group, no ovarian cancers developed, whereas there were six cases of ovarian cancer in the control group. A larger trial is ongoing in an attempt to verify these data.

The performance of a prophylactic salpingo-oophorectomy reduces, but does not eliminate, the risk of ovarian and fallopian tube cancers (19,22). Because the entire peritoneum is at risk, peritoneal carcinomas can occur even after prophylactic

P.1468

oophorectomy. **In premenopausal women at low risk for ovarian cancer, a thorough discussion of the risks and benefits of oophorectomy should be undertaken. The ovaries may provide protection from cardiovascular and orthopedic diseases, and long-term mortality may not be decreased by the performance of prophylactic oophorectomy** (30).

Screening

The value of tumor markers and ultrasonography to screen for epithelial ovarian cancer has not been clearly established by prospective studies. Screening results with transabdominal ultrasonography have been encouraging (31,32,33), but specificity has been limited. However, advances in transvaginal ultrasonography have been shown to have a very high (>95%) sensitivity for the detection of early-stage ovarian cancer, although this test alone might require as many as 10 to 15 laparotomy procedures be performed for each case of ovarian cancer detected (31,32). Routine annual pelvic examinations have had disappointing results in the early detection of ovarian cancer (34). Transvaginal color-flow Doppler to assess the vascularity of the ovarian vessels has been shown to be a useful adjunct to ultrasonography (35,36), but it has not been shown to be useful in screening.

CA125 has been shown to contribute to the early diagnosis of epithelial ovarian cancer (37,38,39,40,41,42,43). **Regarding the sensitivity of the test, CA125 can detect 50% of patients with stage I disease** (37,42). **Data suggest that the specificity of CA125 is improved when the test is combined with transvaginal ultrasonography** (44) or

when the CA125 levels are followed over time (43,44). These data have encouraged the development of prospective screening studies in Sweden and the United Kingdom (39,40). In these studies, patients with elevated CA125 levels (>30 U/mL) have undergone abdominal ultrasonography, and 14 ovarian cancers have been discovered among 27,000 women screened. About four laparotomies were performed for each case of cancer detected.

A randomized trial of nearly 22,000 women aged 45 years or older was performed in the United Kingdom (44). **The patients were assigned to either a control group of routine pelvic examination** (n = 10,977) **or to a screening group** (n = 10,958). The screening consisted of three annual screens that involved measurement of serum CA125 levels, pelvic ultrasonography if the CA125 was 30 U/mL or higher, and referral for gynecologic examination if the ovarian volume was 8.8 mL or greater on the ultrasonography. Of the 468 women in the screened group with an elevated CA125, 29 were referred for surgery, six cancers were discovered, and 23 had false-positive screening results, yielding a positive predictive value of 20.7%. During a 7-year follow-up period, cancer developed in 10 additional women in the screened group, as it did in 20 women in the control group. Although the median survival of women in whom cancer developed in the screened group was 72.9 months, compared with 41.8 months in the control group ($p = 0.0112$), the number of deaths did not differ significantly between the control and screened groups (18/10,977 versus 9/10,958; relative risk 2.0 [0.78 to 5.13]). Therefore, these data show that a multimodal approach to ovarian cancer screening is feasible, but a larger trial is necessary to determine whether this approach affects mortality. Such a three-arm randomized trial is ongoing in the United Kingdom, and the anticipated accrual is approximately 50,000 women per study arm and 100,000 women in the control arm. Based on the risk of ovarian cancer (ROC) algorithm, patients in the third group will be referred for transvaginal ultrasonography and/or surgery (45). Women will be screened for 3 years and studied for 7 years. **This trial may demonstrate more definitively the feasibility of screening for ovarian cancer as well as the impact of early detection on survival.**

A new approach is the use of proteomic patterns to identify ovarian cancer using surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) technology

P.1469

(46). In a study using this technology, the sensitivity for predicting ovarian cancer was 100% with a specificity of 95% and a positive predictive value of 94%. The assay correctly identified all 18 women with stage I tumors. This technology is in the early phases of development and validation, and its efficacy has yet to be demonstrated in large population-based studies.

Another new approach is the measurement of *plasma DNA levels* and *allelic imbalance* by a technique known as digital single nucleotide polymorphism (SNP) analysis. In a study by Chang et al. (47), this analysis had a 87% (13 of 15) positive correlation in stages I and II patients, and a 95% (37 of 39) correlation in patients with stages III and IV disease.

Given the false-positive results for both CA125 and transvaginal

ultrasonography, particularly in premenopausal women, these tests are not cost-effective and should not be used routinely to screen for ovarian cancer (48). In the future, new markers or technologies may improve the specificity of ovarian cancer screening, but proof of this will require a large, prospective study (41,42). Screening in women who have a familial risk may have a better yield, but additional study is necessary (48,49).

Genetic Risk for Epithelial Ovarian Cancer

The lifetime risk of ovarian carcinoma for women in the United States is about 1.4% (1,2,3). The risk of ovarian cancer is higher than that in the general population in women with certain family histories (50,51,52,53,54,55,56,57,58,59). **Most epithelial ovarian cancer is sporadic, with familial or hereditary patterns accounting for 5% to 10% of all malignancies** (51).

Hereditary Ovarian Cancer

BRCA1 and BRCA2

Most hereditary ovarian cancer is associated with mutations in them *BRCA1* gene, located on chromosome 17 (50). **A small proportion of inherited disease is associated with germline mutations in another gene, *BRCA2*, located on chromosome 13** (52). Discovered through linkage analyses, these two genes are associated with the genetic predisposition to both ovarian and breast cancer. There may be other yet undiscovered genes that predispose to ovarian and breast cancer (59).

In the past, it had been thought that there were two distinct syndromes associated with a genetic risk, *site-specific hereditary ovarian cancer* and *hereditary breast-ovarian cancer syndrome*. However, it is now believed that these groups essentially represent a continuum of mutations with different degrees of penetrance within a given family (54,59). In addition, there is a higher-than-expected risk of ovarian and endometrial cancer in the *Lynch II syndrome*, known also as the ***hereditary nonpolyposis colorectal cancer syndrome (HNPCC syndrome)*** (60).

The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated (54). There are numerous distinct mutations that have been identified on each of these genes, and the mutations have different degrees of penetrance that may account for the preponderance of either breast cancer, ovarian cancer, or both, in any given family. **Based on analysis of women who have a mutation in the *BRCA1* gene and are from high-risk families, the lifetime risk of ovarian cancer may be as high as 28% to 44%, and the risk has been calculated to be as high as 27% for those women with a *BRCA2* mutation** (51,52,58). **The risk of breast cancer in women with a *BRCA1* or *BRCA2***

Hereditary ovarian cancers in general occur in women approximately 10 years younger than those with nonhereditary tumors (51). Because the median age of epithelial ovarian cancer is in the mid- to late 50s, a woman with a first- or second-degree relative who had premenopausal ovarian cancer may have a higher probability of carrying an affected gene.

Breast and ovarian cancer may exist in a family in which there is a combination of epithelial ovarian and breast cancers, affecting a mixture of first- and second-degree relatives. Women with this syndrome tend to have these tumors at a young age, and the breast cancers may be bilateral. If two first-degree relatives are affected, this pedigree is consistent with an autosomal dominant mode of inheritance (44,50).

Founder Effect

There is a higher carrier rate of *BRCA1* and *BRCA2* mutations in women of Ashkenazi Jewish descent and in Icelandic women (56,57,59). There have been three specific mutations carried by the Ashkenazi population, 185delAG and 5382insC on *BRCA1*, and 6174 delT on *BRCA2*. **The total carrier rate for a patient of Ashkenazi Jewish descent to have at least one of these three mutations is 1 in 40, or 2.5%**, and thus there is a substantial risk in this population. The increased risk is a result of the *founder effect*, in which a higher rate of mutations occurs in a defined geographic area.

Pedigree Analysis

The risk of carrying a germline mutation that predisposes to ovarian cancer depends on the number of first- and/or second-degree relatives (or both) with a history of epithelial ovarian carcinoma or breast cancer (or both), and on the number of malignancies that occur at an earlier age. The degree of risk is difficult to determine precisely unless a full pedigree analysis is performed.

- **In families with two first-degree relatives (i.e., mother, sister, or daughter) with documented premenopausal epithelial ovarian cancer, the risk that a female first-degree relative has an affected gene could be as high as 35% to 40%** (52).
- **In families with a single first-degree relative and a single second-degree relative (i.e., grandmother, aunt, first cousin, or granddaughter) with epithelial ovarian cancer, the risk that a woman has an affected gene also may be increased. The risk may be two- to 10-fold higher than in those without a familial history of the disease** (52).

- **In families with a single postmenopausal first-degree relative with epithelial ovarian carcinoma, a woman may not have an increased risk of having an affected gene because the case is most likely to be sporadic. However, if the ovarian cancer occurs in a premenopausal relative, this could be significant, and a full pedigree analysis should be undertaken.**
- **Women with a primary history of breast cancer have twice the expected incidence of subsequent ovarian cancer (51).**

Hereditary Nonpolyposis Colon Cancer, or Lynch II Syndrome

HNPCC syndrome, which includes multiple adenocarcinomas, involves a combination of familial colon cancer (known as the Lynch I syndrome); a high rate of ovarian, endometrial, and breast cancers; and other malignancies of the gastrointestinal and genitourinary systems (60). The mutations that have been associated with this syndrome

P.1471

are *MSH2*, *MLH1*, *PMS1*, and *PMS2*. The risk that a woman who is a member of one of these families will develop epithelial ovarian cancer depends on the frequency of this disease in first- and second-degree relatives, although these women appear to have at least 3 times the relative risk of the general population. A full pedigree analysis of such families should be performed by a geneticist to determine the risk more accurately.

Management of Women at High Risk for Ovarian Cancer

The management of a woman with a strong family history of epithelial ovarian cancer must be individualized and depends on her age, her reproductive plans, and the extent of risk. In all of these syndromes, women at risk benefit from a thorough pedigree analysis. A geneticist should evaluate the family pedigree for at least three generations. Decisions about management are best made after careful study and, whenever possible, verification of the histologic diagnosis of the family members' ovarian cancer.

The value of testing for *BRCA1* and *BRCA2* has been clearly established, and there are guidelines for testing (54,59,61). The importance of genetic counseling cannot be overemphasized because the decision is complex. The American Society of Clinical Oncology has offered guidelines that emphasize careful evaluation by geneticists, careful maintenance of medical records, and a clear understanding in a genetic screening clinic of how to counsel and manage these patients. Concerns remain over how the information should be used, the

impact on insurability, how the results will be interpreted, and how the information will be used within a specific family (e.g., to counsel children).

Although there are some conflicting data, the behavior of breast cancers arising in women with germline mutations in *BRCA1* or *BRCA2* is comparable to that of sporadic tumors (53). **Women with breast cancer who carry these mutations, however, are at a greatly increased risk of ovarian cancer as well as a second breast cancer: the lifetime risk of ovarian cancer is 54% for women who have a *BRCA1* mutation and 23% for those with a *BRCA2* mutation, and for the two groups together, there is an 82% lifetime risk of breast cancer** (62).

Although recommended by the National Institutes of Health Consensus Conference on Ovarian Cancer (63), **the value of screening with transvaginal ultrasonography, CA125 levels, or other procedures has not been clearly established in women at high risk.** Bourne and co-workers (49) have shown that, using this approach, tumors can be detected approximately 10 times more often than in the general population, and thus they recommend screening in high-risk women.

Data derived from a multicenter consortium of genetic screening centers indicate that the use of the oral contraceptive pill is associated with a lower risk for development of ovarian cancer in women who have a mutation in either *BRCA1* or *BRCA2* (64). The risk reduction is significant: in women who have taken oral contraceptives for 5 or more years, the relative risk of ovarian cancer is 0.4, or a 60% reduction in the incidence of the disease.

Prophylactic Oophorectomy in High-risk Women

The value of prophylactic salpingo-oophorectomy in these patients has been documented (65,66,67,68,69,70,71). Women at high risk for ovarian cancer who undergo prophylactic oophorectomy have a risk of harboring occult neoplasia: in one series of 98 such operations, 3 (3.1%) patients had a low-stage ovarian malignancy (67). **The protection against ovarian cancer is excellent: the performance of a prophylactic salpingo-oophorectomy reduced the risk of *BRCA*-related gynecologic cancer by 96%** (68). Although the risk of ovarian cancer is significantly diminished, there remains the small risk of peritoneal carcinoma, a tumor for which women who have mutations in *BRCA1* and *BRCA2* may have a higher predisposition. In these series, the subsequent development of peritoneal

carcinoma was 0.8% and 1 %, respectively (66,67). **In addition, the risk of developing subsequent breast cancer was reduced by 50% to 80%.** Women at high risk for ovarian cancer who undergo prophylactic oophorectomy have a risk of harboring occult neoplasia. In one series of 42 such operations, four patients (9.5%) had a malignancy, one of which was noted at surgery and three that were microscopic; all were smaller than 5 mm (66).

The role of hysterectomy is more controversial. Although most studies show no increase in

the rate of uterine and cervical tumors, there are some reports of an increase of papillary serous tumors of the endometrium (71). Women on *tamoxifen* are at higher risk for benign endometrial lesions (e.g., polyps) and endometrial cancer. Therefore, **it is reasonable to consider the performance of a prophylactic hysterectomy in conjunction with salpingo-oophorectomy**, and this decision should be individualized.

The survival of women who have a *BRCA1* or *BRCA2* mutation and develop ovarian cancer is longer than that for those who do not have a mutation. In one study, the median survival for mutation carriers was 53.4 months compared with 37.8 months for those with sporadic ovarian cancer from the same institution (72).

Recommendations

Current recommendations for management of women at high risk for ovarian cancer are summarized as follows (61,63,70):

- **Women who appear to be at high risk for ovarian or breast cancer should undergo genetic counseling and, if the risk appears to be substantial, may be offered genetic testing for *BRCA1* and *BRCA2*.**
- **Women who wish to preserve their reproductive capacity can undergo screening by transvaginal ultrasonography every 6 months**, although the efficacy of this approach is not clearly established.
- **Oral contraceptives should be recommended** to young women before they embark on an attempt to have a family.
- **Women who do not wish to maintain their fertility or who have completed their families should be recommended to undergo prophylactic bilateral salpingo-oophorectomy.** The risk should be clearly documented, preferably established by *BRCA1* and *BRCA2* testing, before oophorectomy is performed. These women should be counseled that this operation does not offer absolute protection, because peritoneal carcinomas occasionally can occur after bilateral oophorectomy (19,22,71).
- **In women who also have a strong family history of breast or ovarian cancer, annual mammographic screening should be performed beginning at age 30 years.**
- **Women with a documented HNPCC syndrome should be treated as above, but in**

and endometrial biopsy (60,68).

Symptoms

The majority of women with epithelial ovarian cancer have vague and nonspecific symptoms. (3,73,74,75). In early-stage disease, the patient may experience irregular menses if she is premenopausal. If a pelvic mass is compressing the bladder or rectum, she may report urinary frequency or constipation (73,74,75). Occasionally, she may perceive lower

P.1473

abdominal distention, pressure, or pain, such as dyspareunia. Acute symptoms, such as pain secondary to rupture or torsion, are unusual.

In advanced-stage disease, patients most often have symptoms related to the presence of ascites, omental metastases, or bowel metastases. The symptoms include abdominal distention, bloating, constipation, nausea, anorexia, or early satiety. Premenopausal women may report irregular or heavy menses, whereas vaginal bleeding may occur in postmenopausal women (72). In one survey of 1,725 with ovarian cancer, 95% recalled symptoms before diagnosis, including 89% with stage I and II disease and 97% with stages III and IV disease (74). Some 70% had abdominal or gastrointestinal symptoms, 58% pain, 34% urinary symptoms, and 26% pelvic discomfort.

Signs

The most important sign of epithelial ovarian cancer is the presence of a pelvic mass on physical examination. A solid, irregular, fixed pelvic mass is highly suggestive of an ovarian malignancy. If, in addition, an upper abdominal mass or ascites is present, the diagnosis of ovarian cancer is almost certain. Because the patient usually reports abdominal symptoms, she may not have a pelvic examination, and a tumor may be missed.

In patients who are at least 1 year past menopause, the ovaries should have become atrophic and not palpable. It has been proposed that any palpable pelvic mass in these patients should be considered potentially malignant, a situation that has been referred to as the postmenopausal palpable ovary syndrome (76). This concept has been challenged, because subsequent authors have reported that only about 3% of palpable masses measuring <5 cm in postmenopausal women are malignant (49).

Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries. A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomas, can simulate

ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory (e. g., diverticular) disease or neoplastic colonic mass, must be excluded (3). A pelvic kidney can simulate ovarian cancer.

Serum CA125 levels have been shown to be useful in distinguishing malignant from benign pelvic masses (77). For a postmenopausal patient with an adnexal mass and a very high serum CA125 level (>200 U/mL), there is a 96% positive predictive value for malignancy. For premenopausal patients, however, the specificity of the test is low because the CA125 level tends to be elevated in common benign conditions.

For the premenopausal patient, a period of observation is reasonable provided the adnexal mass does not have characteristics that suggest malignancy (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). Generally, an interval of no more than 2 months is allowed, during which hormonal suppression with the oral contraceptive may be used. If the lesion is not neoplastic it should regress, as measured by pelvic examination and pelvic ultrasonography. If the mass does not regress or if it increases in size, it must be presumed to be neoplastic and must be removed surgically.

The size of the lesion is important. If a cystic mass is >8 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient has been taking clomiphene citrate or other agents to induce ovulation (31,32,33,34). Patients whose lesions are suggestive of malignancy (i.e., predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with adnexal masses.

P.1474

Ultrasonographic signs of malignancy include an adnexal pelvic mass with areas of complexity, such as irregular borders, multiple echogenic patterns within the mass, and dense multiple irregular septae. Bilateral tumors are more likely to be malignant, although the individual characteristics of the lesions are of greater significance.

Transvaginal ultrasonography may have a somewhat better resolution than transabdominal ultrasonography for adnexal neoplasms (78,79,80,81). Doppler color flow imaging may enhance the specificity of ultrasonography for demonstrating findings consistent with malignancy (82,83,84).

In the premenopausal patient, a period of observation is reasonable, provided the adnexal mass is not clinically suspicious (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). Generally, an interval of 2 months is allowed for observation. The size of the lesion is of importance. If a complex cystic mass is more than 8 to 10 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient has been taking *clomiphene citrate* or other agents to induce ovulation (85,86,87). If the lesion is not neoplastic, it should remain stable or regress, as measured by pelvic examination and pelvic ultrasonography. If a mass does not regress, or if it increases in size or complexity, it must be presumed to be neoplastic and removed surgically.

In postmenopausal women with unilocular cysts measuring 8 to 10 cm or less and normal serial CA125 levels, expectant management is acceptable, and this approach may decrease the number of surgical interventions (85,86,87).

Premenopausal patients whose lesions are clinically suspicious (i.e., large, predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with complex adnexal masses of any size.

The diagnosis of an ovarian cancer requires an exploratory laparotomy. The preoperative evaluation of the patient with an adnexal mass is outlined in Figure 14.20 (see Chapter 14).

Before the planned exploration, the patient should undergo routine hematologic and biochemical assessments. A preoperative evaluation in a patient undergoing laparotomy should include a radiograph of the chest. Abdominal and pelvic computed tomography (CT) or magnetic resonance imaging (MRI) are of limited value for a patient with a definite pelvic mass (88,89,90). A CT or MRI should be performed for patients with ascites and no pelvic mass to look for liver or pancreatic tumors. The findings only rarely preclude laparotomy (88). The value of PET scanning is still being evaluated (91,92). If the hepatic enzyme values are normal, the likelihood of liver disease is low. Liver-spleen scans, bone scans, and brain scans are unnecessary unless symptoms or signs suggest metastases to these sites.

The preoperative evaluation should exclude other primary cancers metastatic to the ovary. A barium enema or colonoscopy is indicated in selected patients with symptoms and signs suspicious for colon cancer. This study should be performed for any patient who has evidence of occult blood in the stool or of intestinal obstruction. An upper gastrointestinal radiographic series or gastroscopy is indicated if there are upper gastrointestinal symptoms such as nausea, vomiting, or hematemesis (3,93). Bilateral mammography is indicated if there is any breast mass, because occasionally breast cancer metastatic to the ovaries can simulate primary ovarian cancer.

A Pap test should be performed, although its value for the detection of ovarian cancer is very limited. Patients who have irregular menses or postmenopausal vaginal bleeding should have endometrial biopsy and endocervical curettage to exclude the presence of uterine or endocervical cancer metastatic to the ovary.

Differential Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries (85,86,87). **A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomata, can simulate ovarian cancer.** Nongynecologic causes of a pelvic tumor, such as an inflammatory or neoplastic colonic mass, must be excluded (94). A pelvic kidney can

simulate ovarian cancer.

Patterns of Spread

Ovarian epithelial cancers spread primarily by exfoliation of cells into the peritoneal cavity, by lymphatic dissemination, and by hematogenous spread.

Transcoelomic

The most common and earliest mode of dissemination of ovarian epithelial cancer is by exfoliation of cells that implant along the surfaces of the peritoneal cavity. The cells tend to follow the circulatory path of the peritoneal fluid. The fluid tends to move with the forces of respiration from the pelvis, up the paracolic gutters, especially on the right, along the intestinal mesenteries, to the right hemidiaphragm. Therefore, metastases are typically seen on the posterior cul-de-sac, paracolic gutters, right hemidiaphragm, liver capsule, the peritoneal surfaces of the intestines and their mesenteries, and the omentum. The disease seldom invades the intestinal lumen but progressively agglutinates loops of bowel, leading to a functional intestinal obstruction. This condition is known as carcinomatous ileus (3).

Lymphatic

Lymphatic dissemination to the pelvic and para-aortic lymph nodes is common, particularly in advanced-stage disease (95,96,97). Spread through the lymphatic channels of the diaphragm and through the retroperitoneal lymph nodes can lead to dissemination above the diaphragm, especially to the supraclavicular lymph nodes (95). Burghardt et al. (97) reported that 78% of patients with stage III disease have metastases to the pelvic lymph nodes. In another series (95), the rate of para-aortic lymph nodes positive for metastasis was 18% in stage I, 20% in stage II, 42% in stage III, and 67% in stage IV.

Hematogenous

Hematogenous dissemination at the time of diagnosis is uncommon. Spread to vital organ parenchyma, such as the lungs and liver, occurs in only about 2% to 3% of patients. Most patients with disease above the diaphragm when diagnosed have a right pleural effusion (3). Systemic metastases are seen more frequently in patients who have survived for some years. Dauplat et al. (98) reported that distant metastasis consistent with stage IV disease ultimately occurred in 38% of the patients whose disease was originally intraperitoneal.

Prognostic Factors

The outcome of treatment can be evaluated in the context of prognostic factors, which can be grouped into pathologic, biologic, and clinical factors (99).

Pathologic Factors

The morphology and histologic pattern, including the architecture and grade of the lesion, are important prognostic variables (3). Histologic type has not generally been believed to be of prognostic significance, but several papers recently have contained suggestions that clear cell carcinomas are associated with a prognosis worse than that of other histologic types (99,100).

Histologic grade, as determined either by the pattern of differentiation or by the extent of cellular anaplasia and the proportion of undifferentiated cells, seems to be of prognostic significance (101,102,103,104). However, studies of the reproducibility of grading ovarian cancers

P.1476

have shown a high degree of intraobserver and interobserver variation (105,106). **Because there is significant heterogeneity of tumors and observational bias, the value of histologic grade as an independent prognostic factor has not been clearly established.** Baak et al. (107) have presented a standard grading system based on morphometric analysis, and the system seems to correlate with prognosis, especially in its ability to distinguish low-grade or borderline patterns from other tumors.

Biologic Factors

Several biologic factors have been correlated with prognosis in epithelial ovarian cancer. Using flow cytometry, Friedlander et al. (108) showed that ovarian cancers were commonly aneuploid. Furthermore, they and others showed that there was a high correlation between FIGO stage and ploidy; low-stage cancers tend to be diploid and high-stage tumors tend to be aneuploid (108,109,110,111,112). **Patients with diploid tumors have a significantly longer median survival than those with aneuploid tumors:** 5 years versus 1 year, respectively (108). Multivariate analyses have demonstrated that **ploidy is an independent prognostic variable** and one of the most significant predictors of survival (108). Flow cytometric analysis also provides data on the cell cycle, and the proliferation fraction (S phase) determined by this technique has correlated with prognosis in some studies (108,109,110,111,112).

More than 100 proto-oncogenes have been identified, and studies have focused on the amplification or expression of these genetic loci and their relationship to the development and progression of ovarian cancer (113,114). For example, Slamon et al. (115) reported that 30% of epithelial ovarian tumors expressed HER-2/*neu* oncogene and that this group had a poorer prognosis, especially patients with more than five copies of the gene. Berchuck et al. (116) reported a similar incidence (32%) of HER-2/*neu* expression. In their series, patients whose tumors expressed the gene had a poorer median survival (15.7 months versus 32.8 months). Others have not substantiated this

finding (117,118,119,120,121,122), and a review of the literature by Leary et al. (118) revealed an overall incidence of HER-2/*neu* expression of only 11%. Thus, **the prognostic value of HER-2/*neu* expression in ovarian cancer is unclear, and further study is required.**

The most commonly expressed tumor suppressor gene in ovarian cancer is *p53* (123,124,125). Indeed, as many as one half of all epithelial ovarian cancers have evidence of mutated *p53* in the tumor. Other tumor suppressor genes that are being evaluated are *ras* and *PTEN* (126,127,128).

The *in vitro* clonogenic assay has been studied in relation to ovarian cancer. A significant inverse correlation has been reported between clonogenic growth *in vitro* and survival (129,130,131). Multivariate analysis has found that clonogenic growth in a semisolid culture medium is a significant independent prognostic variable (131). The use of an **"extreme drug resistance assay"** has been suggested as a possible means of directing therapy by defining platinum-sensitive and resistant tumors *in vitro* (132). **Further study will be needed to evaluate the clinical usefulness of these assays.**

Clinical Factors

In addition to stage, the extent of residual disease after primary surgery, the volume of ascites, patient age, and performance status are all independent prognostic variables (133,141). Among patients with stage I disease, Dembo et al. (138) showed, in a multivariate analysis, that tumor grade and dense adherence to the pelvic peritoneum had a significant adverse impact on prognosis, whereas intraoperative tumor spillage or rupture did not. Sjövall et al. (139) confirmed that **ovarian cancers that undergo intraoperative rupture or spillage do not worsen prognosis, whereas tumors found to have already ruptured preoperatively do have a poorer prognosis.** A multivariate analysis of these and several other studies was performed by Vergote et al. (141), who found that **for early-stage disease, poor prognostic variables were tumor grade, capsular penetration, surface excrescences, and malignant ascites, but not iatrogenic rupture.**

Initial Surgery for Ovarian Cancer

Staging

Ovarian epithelial malignancies are staged according to the FIGO system listed in Table 35.2 (24). The FIGO staging is based on findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases.

The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. For patients

in whom exploratory laparotomy does not reveal any macroscopic evidence of disease on inspection and palpation of the entire intra-abdominal space, a careful search for microscopic spread must be undertaken. In earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60% (142). Since then, survival rates of 90% to 100% have been reported for patients who were properly staged and were found to have stage Ia or Ib disease (143,144).

Table 35.2 FIGO Staging for Primary Carcinoma of the Ovary

Stage I	Growth limited to the ovaries.
Ia	Growth limited to one ovary; no ascites containing malignant cells. No tumor on the external surface; capsule intact.
Ib	Growth limited to both ovaries; no ascites containing malignant cells. No tumor on the external surfaces; capsules intact.
Ic^a	Tumor either stage Ia or Ib but with tumor on the surface of one or both ovaries; or with capsule ruptured; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage II	Growth involving one or both ovaries with pelvic extension.
IIa	Extension and/or metastases to the uterus and/or fallopian tubes.
IIb	Extension to other pelvic tissues.
IIc^a	Tumor either stage IIa or IIb but with tumor on the surface of one or both ovaries; or with capsule(s) ruptured; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastasis equals stage III. Tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum.
IIIa	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces.
IIIb	Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter. Nodes negative.
IIIc	Abdominal implants >2 cm in diameter or positive retroperitoneal or inguinal nodes or both.
Stage IV	Growth involving one or both ovaries with distant metastasis. If pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV. Parenchymal liver metastasis equals stage IV.

These categories are based on findings at clinical examination or surgical exploration or both. The histologic characteristics are to be considered in the staging, as are results of cytologic testing as far as effusions are concerned. It is desirable that a biopsy be performed on suspicious areas outside the pelvis.

FIGO, International Federation of Obstetrics and Gynecology.

^a To evaluate the impact on prognosis of the different criteria for allotting cases to stage Ic or IIc, it would be of value to know if rupture of the capsule was (i) spontaneous or (ii) caused by the surgeon and if the source of malignant cells detected was (i) peritoneal washings or (ii) ascites.

Technique for Surgical Staging

In patients whose preoperative evaluation suggests a probable malignancy, a midline or paramedian abdominal incision is recommended to allow adequate access to the upper abdomen (3,142). When a malignancy is unexpectedly discovered in a patient who has a lower transverse incision, the rectus muscles can be either divided or detached from the symphysis pubis to allow better access to the upper abdomen. If this is not sufficient, the incision can be extended on one side to create a "J" incision (3).

The ovarian tumor should be removed intact, if possible, and a frozen histologic section should be obtained. If ovarian malignancy is present and the tumor is apparently confined to the ovaries or the pelvis, thorough surgical staging should be performed.

Staging involves the following steps (3,142):

- **Any free fluid, especially in the pelvic cul-de-sac, should be submitted for cytologic evaluation.**
- **If no free fluid is present, peritoneal washings should be performed by instilling and recovering 50 to 100 mL of saline from the pelvic cul-de-sac, each paracolic gutter, and beneath each hemidiaphragm.** Obtaining the specimens from under the diaphragms can be facilitated with the use of a rubber catheter attached to the end of a bulb syringe.
- **A systematic exploration of all the intra-abdominal surfaces and viscera is performed,** proceeding in a clockwise fashion from the cecum cephalad along the paracolic gutter and the ascending colon to the right kidney, the liver and gallbladder, the right hemidiaphragm, the entrance to the lesser sac at the para-aortic area, across the transverse colon to the left hemidiaphragm, down the left gutter and the descending colon to

the rectosigmoid colon. The small intestine and its mesentery from the Treitz ligament to the cecum should be inspected.

- **Any suspicious areas or adhesions on the peritoneal surfaces should be biopsied.** If there is no evidence of disease, multiple intraperitoneal biopsies should be performed. Tissue from the peritoneum of the pelvic cul-de-sac, both paracolic gutters, the peritoneum over the bladder, and the intestinal mesenteries should be taken for biopsy.
- **The diaphragm should be sampled either by biopsy or by scraping with a tongue depressor and obtaining a sample for cytologic assessment.** Biopsies of any irregularities on the surface of the diaphragm can be facilitated by use of the laparoscope and the associated biopsy instrument.
- **The omentum should be resected from the transverse colon, a procedure called an *infracolic omentectomy*.** The procedure is initiated on the underside of the greater omentum, where the peritoneum is incised just a few millimeters away from the transverse colon. The branches of the gastroepiploic vessels are clamped, ligated, and divided, along with all the small branching vessels that feed the infracolic omentum. If the gastrocolic ligament is palpably normal, it does not need to be resected.
- **The retroperitoneal spaces should be explored to evaluate the pelvic and para-aortic lymph nodes.** The retroperitoneal dissection is performed by incision of the peritoneum over the psoas muscles. This may be performed on the ipsilateral side only for unilateral tumors. Any enlarged lymph nodes should be resected and submitted for frozen section. If no metastases are present, a formal pelvic lymphadenectomy should be performed. The para-aortic area should be explored.

Results

Metastases in apparent stage I and II epithelial ovarian cancer occur in as many as 3 in 10 patients whose tumors appear to be confined to the pelvis but who have occult metastatic disease in the upper abdomen or the retroperitoneal lymph nodes (96,143,144,145,146,147,148,149,150,151,152). In a review of the literature (142), occult metastases were found in biopsies of the diaphragm in 7.3% of such patients, biopsies of the omentum in 8.6%, the pelvic lymph nodes in 5.9%, the aortic lymph nodes in 18.1%, and in 26.4% of peritoneal washings.

The importance of careful initial surgical staging is emphasized by the findings of a

cooperative national study (143) in which 100 patients with apparent stage I and II disease who were referred for subsequent therapy underwent additional surgical staging. In this series, 28% of the patients initially believed to have stage I disease were "upstaged" and 43% of those believed to have stage II disease had more advanced lesions. **A total of 31% of the patients were upstaged as a result of additional surgery, and 77% were reclassified as having stage III disease. Histologic grade was a significant predictor of occult metastasis.** Sixteen percent of the patients with grade 1 lesions were upstaged, compared with 34% with grade 2 disease and 46% with grade 3 disease.

Borderline Tumors

The principal treatment of borderline (low malignant potential) ovarian tumors is surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. **After a frozen section has determined that the histology is borderline, premenopausal patients who desire preservation of ovarian function may undergo a conservative operation, a unilateral oophorectomy (3,153,154).** In a study of patients who underwent unilateral ovarian cystectomy only for apparent stage I borderline serous tumors, Lim-Tan et al. (154) found that this conservative operation was also safe; only 8% of the patients had recurrences 2 to 18 years later, all with curable disease confined to the ovaries. Recurrence was associated with positive margins of the removed ovarian cyst (154). Thus, hormonal function and fertility can be maintained (3,153,154). For patients in whom an oophorectomy or cystectomy has been performed and a borderline tumor is later documented in the permanent pathology, no additional immediate surgery is necessary.

Stage I

After a comprehensive staging laparotomy, only a minority of women will have local disease (FIGO stage I). There are over 20,000 women diagnosed yearly with epithelial ovarian cancer in the United States, and nearly 4,000 of these have disease confined to the ovaries (1,155). The prognosis for these patients depends on the clinical-pathologic features, as outlined below. Because of this emphasis on the importance of surgical staging, the rate of lymph node sampling has increased in the United States, with a study showing that for women with stage I and II disease, the percentage having lymph nodes sampled increased from 38% to 59% from 1991 to 1996 (156).

The primary surgical treatment for stage I epithelial ovarian cancer is surgical, and patients should undergo total abdominal hysterectomy, bilateral salpingo-oophorectomy, and surgical staging (142,143). In certain circumstances, a unilateral salpingo-oophorectomy may be performed. Based on the findings at surgery and the pathologic evaluation, patients with stage I ovarian cancer can be grouped into low-risk and high-risk categories (Table 35.3).

Stage I Low-risk

Fertility Preservation in Early-stage Ovarian Cancer

For patients who have undergone a thorough staging laparotomy and for whom there is no evidence of spread

P.1480

beyond the ovary, abdominal hysterectomy and bilateral salpingo-oophorectomy are appropriate therapy. The uterus and the contralateral ovary can be preserved in women with stage Ia, grade 1 to 2 disease who desire to preserve fertility.

The conditions of the women should be monitored carefully with routine periodic pelvic examinations and determinations of serum CA125 levels. Generally, the other ovary and the uterus are removed at the completion of childbearing.

Table 35.3 Prognostic Variables in Early-stage Epithelial Ovarian Cancer

<i>Low Risk</i>	<i>High Risk</i>
Low grade	High grade
Non—clear cell histologic type	Clear cell histologic type
Intact capsule	Tumor growth through capsule
No surface excrescences	Surface excrescences
No ascites	Ascites
Negative peritoneal cytologic findings	Malignant cells in fluid
Unruptured or intraoperative rupture	Preoperative rupture
No dense adherence	Dense adherence
Diploid tumor	Aneuploid tumor

From **Berek JS, Hacker NF**, eds. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005, with permission.

Guthrie et al. (152) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No untreated patients who had stage Ia, grade 1 cancer died of their disease; thus, adjuvant radiation and chemotherapy are unnecessary. Furthermore, the Gynecologic Oncology Group (GOG) carried out a prospective, randomized trial of observation versus *melphalan* for patients with stage Ia and Ib, grade 1–2 disease (100). Five-year survival for each group was 94% and 96%, respectively, confirming that no further treatment is needed for such patients.

Stage I High-risk

For patients whose disease is more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings, complete surgical

staging must be performed (3). The surgery should include the performance of a hysterectomy and bilateral salpingo-oophorectomy in addition to the staging laparotomy. Additional therapy is indicated, and although the optimal therapy for these patients is not known, most patients are treated with chemotherapy, as outlined below.

Advanced-Stage Ovarian Cancer

The surgical management of all patients with advanced-stage disease is approached in a similar manner, with modifications made for the overall status and general health of the patient, as well as the extent of residual disease present at the time treatment is initiated. A treatment scheme is outlined in Figure 35.7. Most patients subsequently receive combination chemotherapy for an empiric number of cycles.

Cytoreductive Surgery for Advanced-stage Disease

If the patient is medically stable, she should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible

(157,156,157,158,159,160,161,162,163,164,165,166,167,168,169,170,171,172,173,174,175,176,177,178,179,180,181,182,183,184)

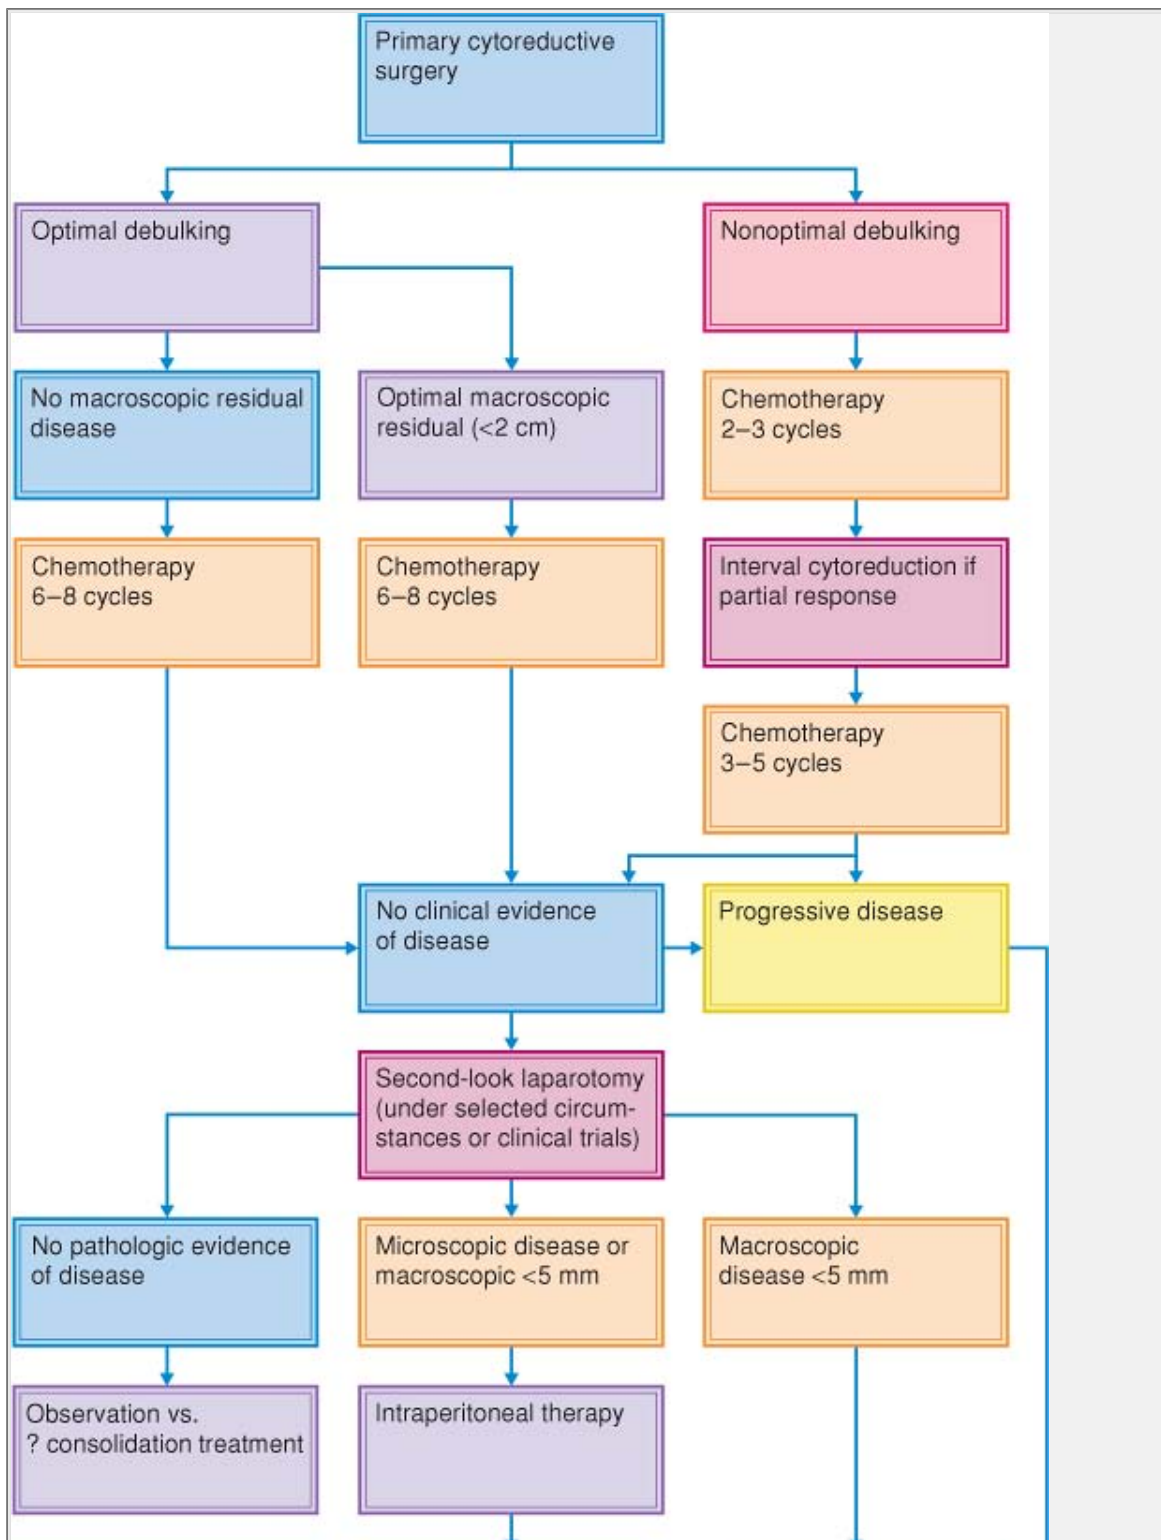

(see Fig 35.7). **The operation to remove the primary tumor as well as the associated metastatic disease is**

P.1481

referred to as "*debulking*" or cytoreductive surgery. The operation typically includes the performance of a total abdominal hysterectomy and bilateral salpingo-oophorectomy, along with a complete omentectomy and resection of any metastatic lesions from the peritoneal surfaces or from the intestines. The pelvic tumor often directly involves the rectosigmoid colon, the terminal ileum, and the cecum (Fig. 35.8). In a minority of

P.1482

patients, most or all of the disease is confined to the pelvic viscera and the omentum, so that removal of these organs will result in extirpation of all gross tumor, a situation that is associated with a reasonable chance of prolonged progression-free survival.

Experimental protocols
or palliative care

Figure 35.7 Treatment scheme for patients with advanced-stage ovarian cancer.

*Under selected circumstances or clinical trials. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005: 460, with permission.)

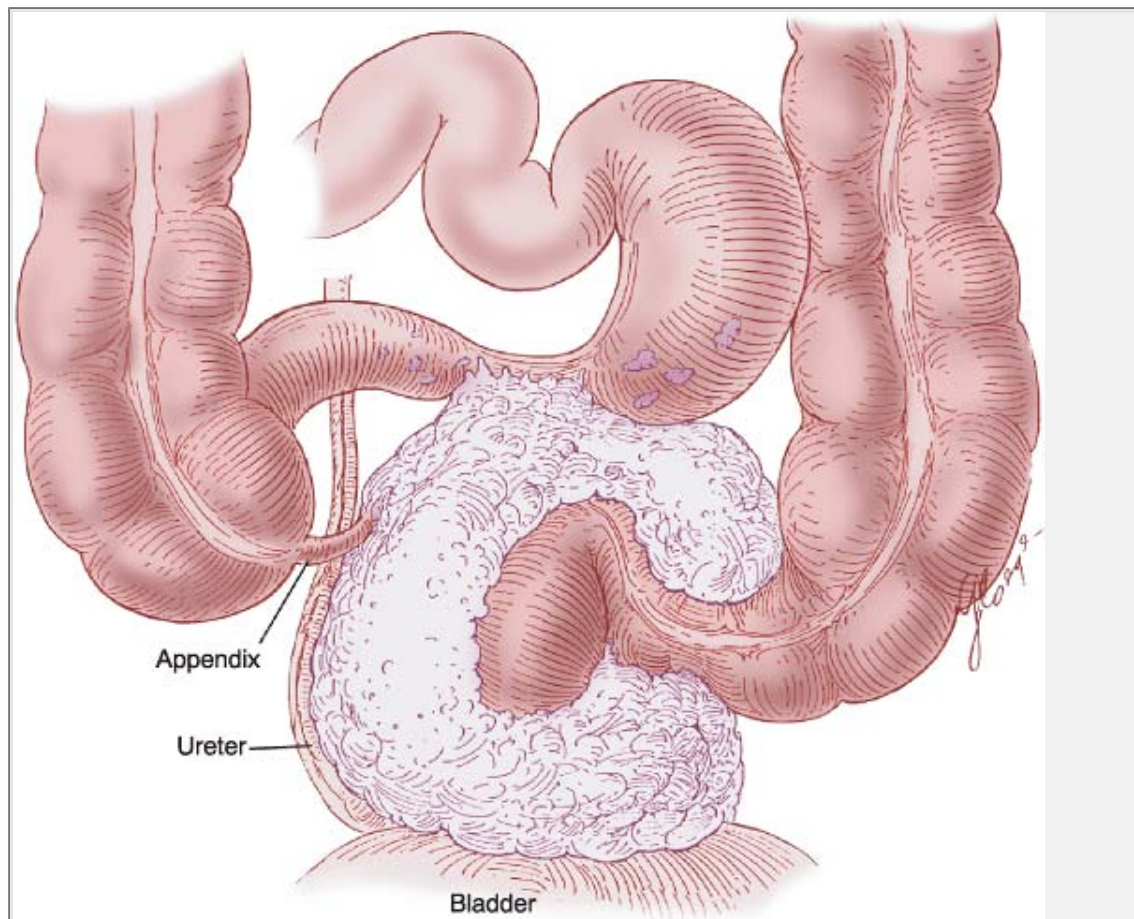

Figure 35.8 Extensive ovarian carcinoma involving the bladder, rectosigmoid, and ileocecal area. (From **Heintz APM, Berek JS.** *Cytoreductive surgery for ovarian carcinoma*. In: **Piver MS**, ed. *Ovarian malignancies*. Edinburgh, UK: Churchill Livingstone, 1987: 134, with permission.)

The removal of bulky tumor masses may reduce the volume of ascites present.

Often, ascites will completely disappear after removal of the primary tumor and a large omental "cake." Also, removal of the omental cake often alleviates the nausea and early satiety that many patients experience. Removal of intestinal metastases may restore adequate intestinal function and lead to an improvement in the overall nutritional status of the patient, thereby facilitating the patient's ability to tolerate subsequent chemotherapy.

A large, bulky tumor may contain areas that are poorly vascularized, and such areas will be exposed to suboptimal concentrations of chemotherapeutic agents. Similarly, these areas are poorly oxygenated, so that radiation therapy, which requires adequate oxygenation to achieve maximal cell kill, will be less effective. Thus, surgical removal of these bulky tumors may eliminate areas that are most likely to be relatively resistant to treatment.

In addition, larger tumor masses tend to be composed of a higher proportion of cells that are either nondividing or in the "resting" phase (i.e., G_0 cells, which are essentially resistant to the therapy). A low growth fraction is characteristic of bulky tumor masses, and cytoreductive surgery can result in smaller residual masses with a relatively higher growth fraction.

P.1483

Goals of Cytoreductive Surgery

The principal goal of cytoreductive surgery is removal of all of the primary cancer and, if possible, all metastatic disease. If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status. Griffiths (157) initially proposed that all metastatic nodules should be reduced to <1.5 cm in maximal diameter and showed that survival was significantly longer in patients for whom this was achieved.

Subsequently, Hacker and Berek (158,159,160) showed that patients whose largest residual lesions were <5 mm had a superior survival rate, which was substantiated by Van Lindert et al. (161). The median survival of patients in this category was 40 months, compared with 18 months for patients whose lesions were <1.5 cm and 6 months for patients with nodules >1.5 cm. **Patients whose disease has been completely resected to no macroscopic (microscopic only) residual disease have the best overall survival** (162) (Fig. 35.9). **Approximately 60% of patients in this category will be free of disease at 5 years.**

The resectability of the metastatic tumor is usually determined by the location of the disease. Optimal cytoreduction is difficult to achieve in the presence of extensive disease on the diaphragm, in the parenchyma of the liver, along the base of the small-bowel mesentery, in the lesser omentum, or in the porta hepatis.

The ability of cytoreductive surgery to influence survival is limited by the extent of metastases before cytoreduction, presumably because of the presence of phenotypically resistant clones of cells in large metastatic masses. A patient

shorter survival than those with smaller areas of disease (160,162). Extensive carcinomatosis, the presence of ascites, and poor tumor grade, even with lesions that measure <5 mm, may also shorten the survival (163,164,165,166).

Figure 35.9 Survival of patients with stage IIIc epithelial ovarian cancer based on the maximal size of residual tumor after exploratory laparotomy and tumor resection.

(From Pecorelli S, Odicino F, Maisonneuve P, et al. Carcinoma of the ovary. Annual Report of the Results of Treatment of Gynaecological Cancer. *J Epidemiol Biostat* 1998; 3: 75–102, with permission.)

Exploration

The supine position on the operating table may be sufficient for surgical exploration of most patients. However, for those with extensive pelvic disease for whom a low resection of the colon may be necessary, the low lithotomy position should be used. Debulking operations should be performed through a vertical incision to gain adequate access to the upper abdomen as well as to the pelvis.

After the peritoneal cavity is opened, ascitic fluid, if present, should be evacuated. In some centers, fluid is submitted for *in vitro* research studies, such as molecular analyses. In cases of massive ascites, careful attention must be given to hemodynamic monitoring, especially for patients with borderline cardiovascular function.

The peritoneal cavity and retroperitoneum are thoroughly inspected and palpated to assess the extent of the primary tumor and the metastatic disease. All abdominal viscera must be palpated to exclude the possibility that the ovarian disease is metastatic, particularly from the stomach, colon, or pancreas. If optimal status is not considered achievable, extensive bowel and urologic resections are not indicated, except to overcome a bowel obstruction. However, removal of the primary tumor and omental cake is usually both feasible and desirable.

Pelvic Tumor Resection

The essential principle of removal of the pelvic tumor is to use the retroperitoneal approach. To accomplish this, the retroperitoneum is entered laterally, along the surface of the psoas muscles, which avoids the iliac vessels and the ureters. The procedure is initiated by division of the round ligaments bilaterally if the uterus is present. The peritoneal incision is extended cephalad, lateral to the ovarian vessels within the infundibulopelvic ligament, and caudally toward the bladder. With careful dissection, the retroperitoneal space is explored, and the ureter and pelvic vessels are identified. The pararectal and paravesicular spaces are identified and developed as described in Chapter 34.

The peritoneum overlying the bladder is dissected to connect the peritoneal incisions anteriorly. The vesicouterine plane is identified, and with careful sharp dissection the bladder is mobilized from the anterior surface of the cervix. The ovarian vessels are isolated, doubly ligated, and divided.

Hysterectomy, which is often not a simple operation, is then performed. The ureters must be carefully displayed to avoid injury. During this procedure, the uterine vessels can be identified. The hysterectomy and resection of the contiguous tumor are completed by ligation of the uterine vessels and the remainder of the tissues within the cardinal ligaments.

Because epithelial ovarian cancers tend not to invade the lumina of the colon or bladder, it is usually feasible to resect pelvic tumors without having to resect portions of the lower colon or the urinary tract (167,168). Resection of a small portion of the bladder may be required and, if so, a cystotomy should be performed to assist in resection of the disease (168).

Intestinal Resection

The disease may involve focal areas of the small or large intestine, and resection should be performed if it would permit the removal of all or most of the abdominal metastases and the patient will be left with optimal disease at the end of the cytoreduction. Apart from the rectosigmoid colon, the most frequent sites of

intestinal metastasis are the terminal ileum, the cecum, and the transverse colon. Resection of one or more of these segments of bowel may be necessary (167,169).

If the disease surrounds the rectosigmoid colon and its mesentery, it may be necessary to remove that portion of the colon to clear the pelvic disease (Fig. 35.10) (167). After the pararectal space is identified in such patients, the proximal site of colonic involvement is

identified, the colon and its mesentery are divided, and the rectosigmoid is removed along with the uterus *en bloc*. A reanastomosis of the colon is performed.

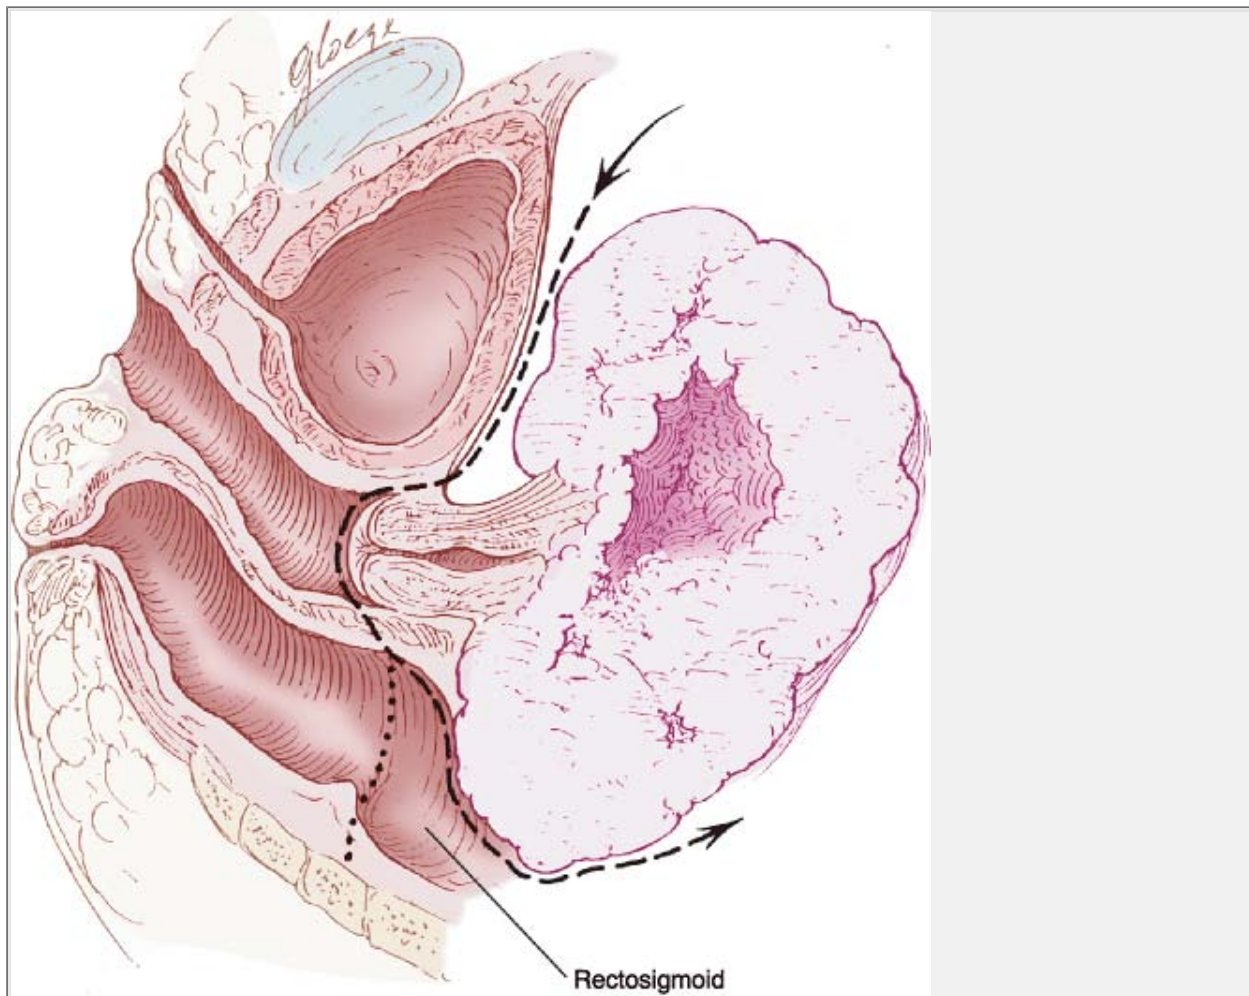

Figure 35.10 The resection of the pelvic tumor may include removal of the uterus, tubes, and ovaries, as well as portions of the lower intestinal tract. The *arrows* represent the plane of resection. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005:465, with permission.)

Omentectomy

Advanced epithelial ovarian cancer often completely replaces the omentum, forming an "omental cake." This disease may be adherent to the parietal peritoneum of the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the transverse colon. The peritoneum is incised to open the appropriate plane, which is developed by sharp dissection along the serosa of the transverse colon. Small vessels are ligated with hemoclips. The omentum is then separated from the greater curvature of the stomach by ligation of the right and left gastroepiploic arteries and ligation of the short gastric arteries (Fig. 35.11).

The disease in the gastrocolic ligament can extend to the hilus of the spleen and splenic flexure of the colon on the left and to the capsule of the liver and the hepatic flexure of the colon on the right. Usually, the disease does not invade the parenchyma of the liver or spleen, and a plane can be found between the tumor and these organs. However, it will occasionally be necessary to perform splenectomy to remove all the omental disease (170).

Figure 35.11 Separation of the omentum from stomach and transverse colon. *Arrow, the direction of the initial surgical approach.* (From **Heintz APM, Berek JS.** *Cytoreductive surgery for ovarian carcinoma.* In: **Piver MS,** ed. *Ovarian malignancies.* Edinburgh, UK: Churchill Livingstone, 1987: 134, with permission.)

Resection of Other Metastases

Other large masses of tumor that are located on the parietal peritoneum should be removed, particularly if they are isolated masses and their removal will permit optimal cytoreduction. Resection of extensive disease from the surfaces of the diaphragm is generally neither practical nor feasible, although solitary metastases may be resected, the diaphragm sutured, and a chest tube placed for a few days (170,171). The use of the Cavitron Ultrasonic Surgical Aspirator (CUSA) and the argon beam coagulator may help facilitate resection of small tumor nodules, especially those on flat surfaces (172,173).

Feasibility and Outcome

Although no randomized prospective study has ever been performed to define the value of primary cytoreductive surgery, all retrospective studies indicate that the diameter of the largest residual tumor nodule before the initiation of chemotherapy is significantly related to progression-free survival in patients with advanced ovarian cancer (176). In addition, quality of life is likely to be significantly enhanced by removal of bulky tumor masses from the pelvis and upper abdomen (179).

An analysis of the retrospective data available suggests that these operations are feasible for 70% to 90% of patients when performed by gynecologic oncologists (165,166). Major morbidity is in the range of 5% and operative mortality is in the range of 1% (169,174,175). Intestinal resection in these patients does not appear to increase the overall morbidity caused by the operation (169).

In a meta-analysis of 81 studies of women who underwent cytoreductive surgery for advanced ovarian cancer, Bristow et al. documented that the extent of debulking correlated with incremental benefits in survival, i.e., the greater the percentage of

P.1487

tumor reduction, the longer the survival: Each 10% increase in cytoreduction equaled a 5.5% increase in median survival (176). **Women whose cytoreduction was greater than 75% of their tumor burden had a median survival of 33.9 months compared with 22.7 months for women whose tumors were cytoreduced to less than 75%** ($p < 0.001$). The performance of a pelvic and para-aortic lymphadenectomy in patients with stage III disease does not prolong survival based on the results of a large prospective, randomized trial (177).

A prospective randomized study of "interval" cytoreductive surgery was carried out by the European Organization for the Research and Treatment of Cancer (EORTC).

Interval surgery was performed after three cycles of platinum-combination chemotherapy in patients whose primary attempt at cytoreduction was suboptimal. Patients in the surgical arm of the study demonstrated a survival benefit when compared with those who did not undergo interval debulking (178). Most of these patients had not had an aggressive attempt to debulk their tumor at their initial surgery. The risk of mortality was reduced by more than 40% in the group that was randomized to the debulking arm of the study. Based on these data, **the performance of a debulking operation as early as possible in the course of the patient's treatment should be considered the standard of care** (179).

A prospective phase III study of interval cytoreductive surgery was conducted by the GOG (180), but the study design was different because the patients entered on the trial had already undergone a maximal attempt at tumor resection at their initial surgery. The randomized findings showed no difference between the group who had an additional attempt at debulking after three cycles of chemotherapy compared with those who did not. The median survival of the 216 women who underwent interval cytoreduction was 32 months compared with 33 months for the 209 women who did not undergo surgical cytoreduction.

There is evidence that the survival of women with advanced ovarian cancer is improved when the surgeon is specifically trained to perform cytoreductive surgery (181,182,183,184) and when there is centralization of care (182). Therefore, **whenever feasible, patients with advanced ovarian malignancy should be referred to a subspecialty unit for primary surgery, and every effort should be made to attain as complete a cytoreduction as possible.**

Chemotherapy

Stage I Epithelial Ovarian Cancer

Early-stage, Low-risk

Guthrie et al. (152) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No patients who had stage Ia, grade 1 cancer who did not receive radiation or chemotherapy died of their disease; thus, adjuvant therapy is unnecessary. Furthermore, the GOG carried out a prospective, randomized trial of observation versus *melphalan* for patients with stage Ia and Ib, grades 1 and 2 disease (100). **Five-year survival for each group was 94% and 96%, respectively, confirming that adjuvant treatment did not improve survival. Therefore, no adjuvant chemotherapy is recommended for these patients.**

Early-stage, High-risk

In patients whose disease is high-risk, e.g., more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings, additional therapy is indicated. Most investigators recommend chemotherapy for these patients

P.1488

(185,186,187,188,189,190,191,192,193,194,195,196,197,198). Chemotherapy for patients with early-stage high-risk epithelial ovarian cancer can be either single agent or multiagent. Some researchers have questioned the wisdom of overly aggressive chemotherapy in women with early-stage disease, suggesting that the evidence for a durable impact on survival is marginal (187,188,194). Furthermore, the risk of leukemia with alkylating agents and platinum make the administration of adjuvant therapy risky unless there is a significant benefit (199,200).

Because *cisplatin*, *carboplatin*, *cyclophosphamide*, and *paclitaxel (Taxol)* are active single agents against epithelial ovarian cancer, these drugs have been administered in various combinations. There are some series in which *cisplatin* or *cyclophosphamide* (PC) or both have been used to treat patients with stage I disease (189,190,191). In a GOG trial of

three cycles of *cisplatin* and *cyclophosphamide* versus intraperitoneal chromic phosphate (³²P) in patients with stage Ib and Ic disease, the progression-free survival of women receiving the *platinum*-based chemotherapy was 31% higher than those receiving the radiocolloid (191). Similar results were also reported by a multicenter trial performed in Italy by the Gruppo Italiano Collaborativo Oncologica Ginecologica (GICOG) for progression-free survival, although there was no overall survival advantage. *Carboplatin* can be substituted for *cisplatin* in the therapy of these patients (197), although it is unclear if there is a survival benefit.

Two large parallel randomized phase III clinical trials were conducted on women with early-stage disease: the **International Collaborative Ovarian Neoplasm Trial 1 (ICON1)** and the **Adjuvant Chemotherapy Trial in Ovarian Neoplasia (ACTION)** (201,202).

In the ICON1 trial, 477 patients from 84 centers in Europe were entered. Patients of all stages were eligible for the trial if, in the opinion of the investigator, it was unclear whether adjuvant therapy would be of benefit. Most patients were said to have stages I and IIa disease but optimal **surgical staging was not required**, so it is likely an unquantified number of these women had stage III disease. Adjuvant platinum-based chemotherapy was given to 241 patients, and no adjuvant chemotherapy was given to 236 patients. **The 5-year survival was 73% in the group who received adjuvant chemotherapy compared with 62% in the control group** (HR=0.65, $p=0.01$) (202).

In the ACTION trial, **440 patients from 40 European centers were randomized; 224 patients received adjuvant platinum-based chemotherapy, and 224 patients did not** (201). **Patients with stages I and IIa, grades 2 and 3 were eligible. Only** about one third of the total group was optimally staged (**151 patients**). **In the observation arm, optimal staging was associated with a better survival [hazard ratio (HR) = 2.31, $p = 0.03$], and in the nonoptimally staged patients, adjuvant chemotherapy was associated with an improvement in survival (HR = 1.78, $p = 0.009$).** In optimally staged patients, no benefit of adjuvant chemotherapy was seen. **Therefore, in the ACTION trial, the benefit from adjuvant chemotherapy was limited to the patients with nonoptimal staging, suggesting that patients might only benefit if they had a higher likelihood of occult microscopic dissemination.**

When the data from the two trials were combined and analyzed (203), a total of 465 patients were randomized to receive platinum-based adjuvant chemotherapy and 460 to observation until disease progression. After a median follow-up of more than 4 years, the overall survival was 82% in the chemotherapy arm and 74% in the observation arm (HR = 0.67, $p = 0.001$). Recurrence-free survival was also better in the chemotherapy arm: 76% versus 65% (HR = 0.64, $p = 0.001$). The results of this analysis must be interpreted with caution, because most of the patients did not undergo thorough surgical staging, but **the findings suggest that platinum-based chemotherapy should be given to patients who have not been optimally staged.**

The current GOG trial includes patients with high-risk stage I and stage II disease, and consists

observation versus 26 weeks of weekly low-dose (40 mg/m²) *paclitaxel*. High-risk stage I is defined as stages Ia or Ib, grade 3, stage Ic, or clear cell carcinomas.

The recommendations for therapy follow:

- **Patients with high-grade, high-risk stage I epithelial ovarian cancer should be given adjuvant chemotherapy. The type depends on the patient's overall health and status.**
- **Treatment with *carboplatin* and *paclitaxel* chemotherapy for three to six cycles seems desirable in these patients, whereas a short course of a single agent, either *carboplatin* or *paclitaxel*, may be preferable for older women.**

Advanced-stage Epithelial Ovarian Cancer

Systemic multiagent chemotherapy is the standard treatment for metastatic epithelial ovarian cancer (204,205,206,207,208,209,210,211,212,213,214,215,216,217,218,219,220,221,222). After the introduction of *cisplatin* in the latter half of the 1970s, platinum-based combination chemotherapy became the most frequently used treatment regimen in the United States. *Paclitaxel* became available in the 1980s, and this drug was incorporated into the combination chemotherapy in the 1990s (204,205,206,207,208,209). Comparative trials of *paclitaxel*, *cisplatin*, and *carboplatin* are summarized below.

In a meta-analysis performed on studies of patients with advanced-stage disease, those patients given *cisplatin*-containing combination chemotherapy were compared with those treated with regimens that did not include *cisplatin* (213). Survival differences between the groups were seen from 2 to 5 years, with the *cisplatin* group having a slight survival advantage, but this difference disappeared by 8 years.

The major advance in the treatment of advanced-stage disease was the incorporation of *paclitaxel* into the chemotherapeutic regimens. A series of randomized, prospective clinical trials with *paclitaxel*-containing arms have defined the current recommended treatment protocol in advanced epithelial ovarian cancer (207,208,217,218).

Reporting the GOG data (Protocol 111), McGuire et al. showed that the combination of *cisplatin* (75 mg/m²) and *paclitaxel* (135 mg/m²) was superior to *cisplatin* (75 mg/m²) and *cyclophosphamide* (600 mg/m²), each given for six cycles (207). In suboptimally resected patients, the *paclitaxel*-containing arm produced a 36% reduction in mortality. These data were verified in a trial conducted jointly by the European Organization for the Research

and Treatment of Cancer (EORTC), the Nordic Ovarian Cancer Study Group (NOCOVA), and the National Cancer Institute of Canada (NCIC), in which patients with both optimal and suboptimal disease were treated (208). In this study, the *paclitaxel*-containing arm produced a significant improvement in both progression-free interval and overall survival in both optimal and suboptimal groups. **Based on these two studies, *paclitaxel* should be included in the primary treatment of all women with advanced-stage epithelial ovarian cancer, unless precluded by toxicity.**

A three-arm comparison of *paclitaxel* (T) versus *cisplatin* (P) versus PT in suboptimal stage III and IV patients (Protocol 132) showed equivalency in the three groups, but crossover from one drug to the other was permitted (209). The study essentially showed that the combination regimen was better tolerated than the sequential administration of the agents in suboptimally resected patients.

There is no evidence that increasing the dose of *cisplatin* >50 mg/m² improves survival (221,222,223).

The second-generation platinum analogue, *carboplatin*, was introduced and developed to have less toxicity than its parent compound, *cisplatin*. In early trials, *carboplatin* was shown to have lower overall toxicity (211). Fewer gastrointestinal side effects, especially

P.1490

nausea and vomiting, were observed than with *cisplatin*, and there was less nephrotoxicity, neurotoxicity, and ototoxicity. *Carboplatin* is, however, associated with a higher degree of myelosuppression.

The initial studies showed that *carboplatin* and *cisplatin* had approximately a 4:1 equivalency ratio. Thus, a standard single-agent dose of about 400 mg/m² has been used in most phase II trials (217,218,219). **The dose is calculated by using the area under the curve (AUC) and the glomerular filtration rate (GFR) according to the Calvert formula (223). The target AUC is 5 to 6 for untreated patients with ovarian cancer. Alternatively, a dose of approximately 350 to 450 mg/m² *carboplatin* can be used initially in patients with a normal serum creatinine and adjusted to toxicity.** A platelet nadir of approximately 50,000/mL is a suitable target (211).

Carboplatin and Paclitaxel

Two randomized, prospective clinical studies have compared the combination of *paclitaxel* and *carboplatin* to *paclitaxel* and *cisplatin* (217,218). In both studies, the efficacy and survivals were similar, but the toxicity was more acceptable with the *carboplatin*-containing regimen. In the first trial, GOG Protocol 158, the randomization was *carboplatin* AUC=7.5 and *paclitaxel* 175 mg/m² over 3 hours versus *cisplatin* 75 mg/m² and *paclitaxel* 135 mg/m² over 24 hours (Fig. 35.12). The disease progression-free survival of the *carboplatin*-containing arm was 22 months versus 21.7 months for the control arm (217). The gastrointestinal and neurotoxicity

of the *carboplatin* arm were appreciably lower than that of the *cisplatin* arm. A similar result was obtained in a large randomized trial in Germany (218), in which the dose of *carboplatin* was AUC = 6 and *paclitaxel* was 185 mg/m² over 3 hours compared with the same dose of *paclitaxel* and *cisplatin* 75 mg/m². Based on these data, **the preferred regimen in patients with advanced-stage disease has been the *paclitaxel* plus *carboplatin* combination** (219).

The International Collaborative Ovarian Neoplasm (ICON) 3 trial was a study of 2,074 women with all stages of ovarian cancer, including 20% who had stage I or II disease (224). ***Carboplatin* plus *paclitaxel* was compared with two non-*paclitaxel* regimens, *carboplatin* (70%), or CAP (30%).** The regimens were chosen before randomization and based on the clinical preference of the treating physician. One third of patients who received *carboplatin* or CAP subsequently received second-line *paclitaxel*, and this additional chemotherapy was often given before clinical progression. With a median follow-up of 51 months, the *carboplatin* plus *paclitaxel* and the control groups had a similar progression-free survival (0.93) and overall survival (0.98). **The median survival for the *paclitaxel* plus *carboplatin* and control groups was 36.1 and 35.4 months, respectively.** The median duration of progression-free survival was 17.3 and 16.1 months, respectively. **The researchers concluded that single agent *carboplatin* and CAP were as effective as *paclitaxel* and *carboplatin* for first-line chemotherapy.** Because *carboplatin* as a single agent had a lower toxicity than the other regimens and the median survival (33 months) was similar in the prior trial (ICON 2) that had compared *carboplatin* and CAP as first-line treatment (225), the researchers suggested that *carboplatin* alone was the preferred therapy. **However, the design of the study limits the validity of the results, because patients with FIGO stage I to IV disease were included, the extent of primary surgery was variable, and the study was not audited by an independent data monitoring committee. Also, the majority (85%) of patients who relapsed after single-agent *carboplatin* or *paclitaxel* subsequently received the other drug. Therefore, the study is not conclusive.**

Carboplatin and Docetaxel

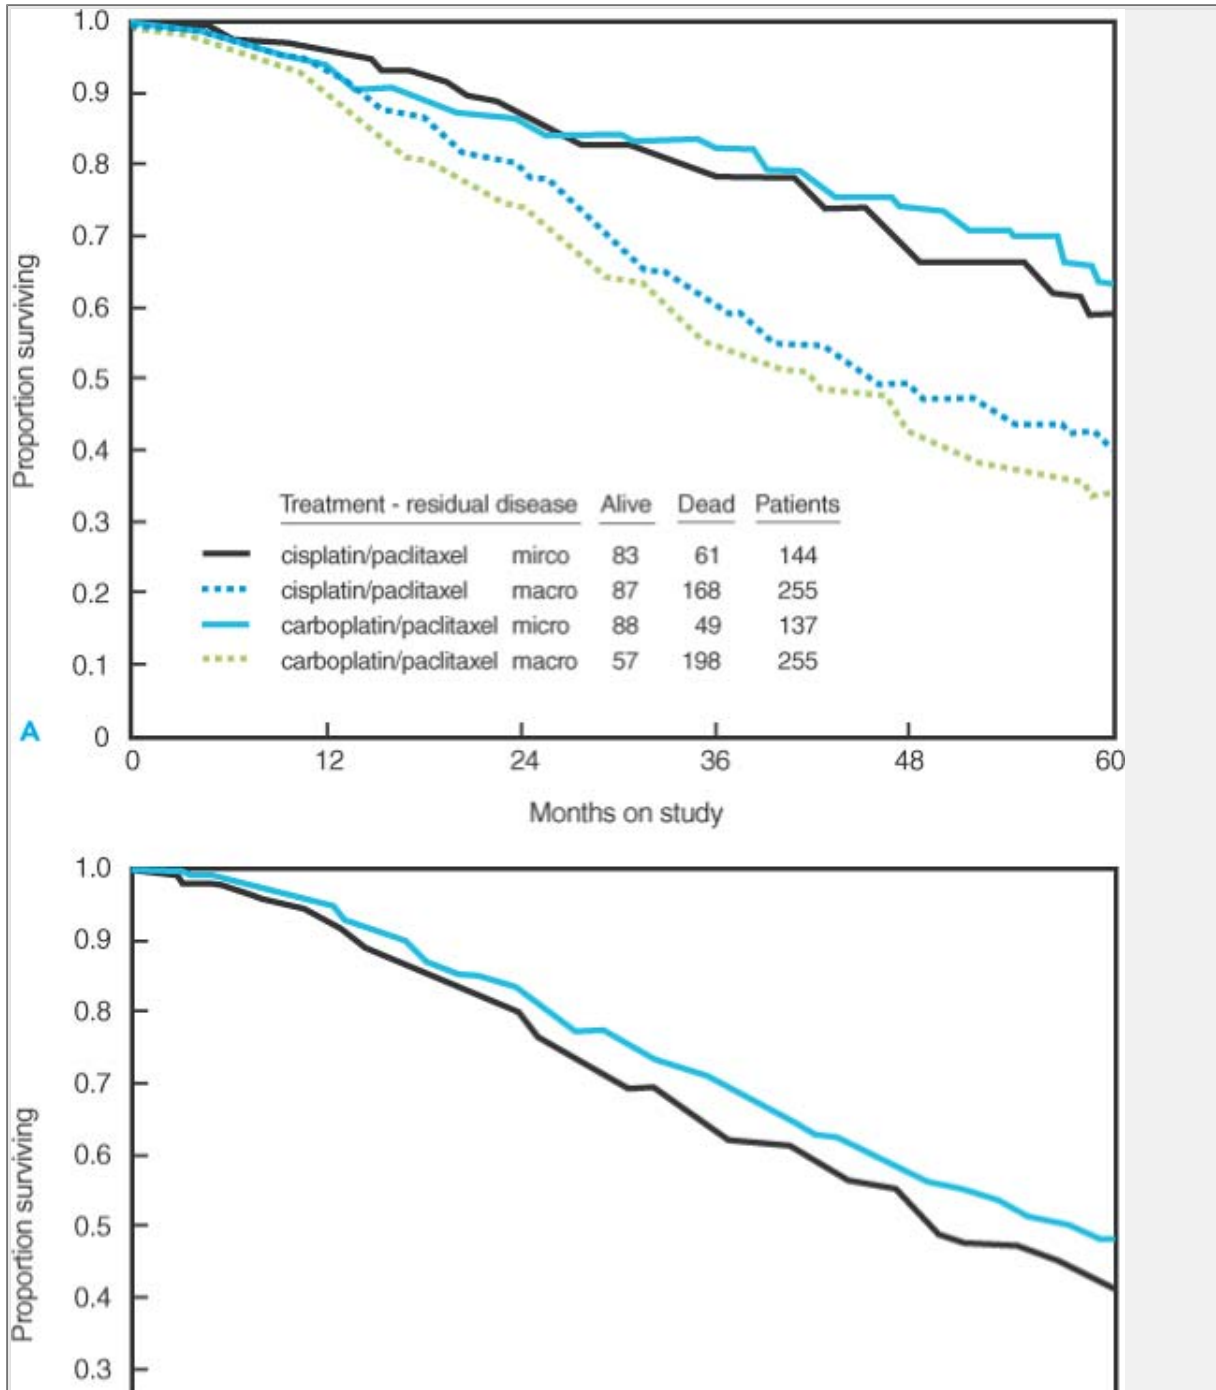

Docetaxel has a different toxicity profile from *paclitaxel*. The SCOT-ROC (Scottish Gynaecological Cancer Trials Group) study randomly assigned 1,077 women with stage Ic

P.1491

P.1492

to IV epithelial ovarian cancer to *carboplatin* with either *paclitaxel* or *docetaxel* (226). **The efficacy of *docetaxel* appeared to be similar to *paclitaxel*:** The median progression-free survival was 15.1 months versus 15.4 months, and **the *docetaxel* group had fewer neurologic effects, arthralgias, myalgias, and extremity weakness than the *paclitaxel* group.** However, the *docetaxel* plus *carboplatin* regimen was associated with significantly more myelosuppression and its consequences, i.e., serious infections

and prolonged grade 3 to 4 neutropenia. Therefore, additional study will be necessary to determine whether *docetaxel* should supplant *paclitaxel* in the primary treatment of epithelial ovarian cancer.

Figure 35.12 Survival of patients with stage III epithelial ovarian cancer treated with carboplatin and paclitaxel versus cisplatin and paclitaxel: a Gynecologic Oncology Group study. A: Survival by treatment. **B:** Survival by treatment group (micro vs. macro). (From **Ozols RF, Bundy BN, Greer BE, et al.** Phase III trial of carboplatin and paclitaxel compared with cisplatin and paclitaxel in patients with optimally resected stage III ovarian cancer: a Gynecologic Oncology Group Study. *J Clin Oncol* 2003;21:3194–3200, with permission). (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005: 477, with permission.)

Five-Arm Trial

An intergroup, international trial (GOG 182/SWOG 182/ICON 5) compared the standard combination of *carboplatin* and *paclitaxel* with these drugs in combination with *gemcitabine*, *topotecan*, or *liposomal doxorubicin* in sequential doublets or triplets (227,228). The study shows that the addition of any three drugs to the standard chemotherapy does not enhance outcome or survival (228).

Intraperitoneal Chemotherapy

A randomized, prospective GOG study (Protocol 104) of intraperitoneal *cisplatin* versus intravenous *cisplatin* (100 mg/m²), each given with 750 mg/m² *cyclophosphamide*, has been performed jointly by the Southwest Oncology Group (SWOG) and the GOG in patients with minimal residual disease (229). **The intraperitoneal *cisplatin* arm had a somewhat longer overall median survival than the intravenous arm, 49 versus 41 months ($p = 0.03$).** In the patients with minimal residual disease (< 0.5 cm maximal residual), however, there was no difference between the two treatments, 51 versus 46 months ($p = 0.08$).

In a follow-up GOG study (Protocol 114), the dose-intense arm was initiated by giving a moderately high dose of *carboplatin* (dose AUC = 9) for two induction cycles, followed by intraperitoneal *cisplatin* 100 mg/m² and intravenous *paclitaxel* 135 mg/m² over 24 hours, versus intravenous *cisplatin* 75 mg/m² and intravenous *paclitaxel* 135 mg/m² (230). The dose-intense arm results were slightly better—the disease progression-free median survival was 27.6 months compared with 22.5 months for the control arm ($p = 0.02$). However, there was

no difference in overall survival (52.9 months versus 47.6 months, $p = 0.056$). Thus, based on this study, it was unclear if dose intensification with intraperitoneal *cisplatin* would have a sustained long-term impact on the survival of these patients.

A third randomized prospective GOG study (Protocol 172) compared intraperitoneal *cisplatin* and *paclitaxel* versus intravenous *cisplatin* and *paclitaxel* (231). The combination of *cisplatin* 75 mg/m² and *paclitaxel* 135 mg/m² given intravenously every 3 weeks was compared with *paclitaxel* 135 mg/m² intravenous day 1, followed by *cisplatin* 100 mg/m² intraperitoneal day 2, and *paclitaxel* 60 mg/m² intraperitoneal day 8 every 3 weeks, each given for 6 cycles. **While 83% of the patients randomized to intravenous chemotherapy completed all 6 cycles of therapy, only 42% of those treated with intraperitoneal chemotherapy completed the 6 cycles, principally because of catheter-related complications. For patients in either group who could not complete the therapy because of *cisplatin*-related toxicity, the chemotherapy was switched to intravenous *carboplatin*.** Comparing the intravenous and intraperitoneal arms, the median duration of progression-free survival was 18.3 and 23.8 months, respectively ($p = 0.05$). **The median duration of overall survival in the intravenous-therapy and intraperitoneal-therapy groups was 49.7 and 65.6 months, respectively ($p = 0.03$)** (231). Quality of life was significantly worse in the intraperitoneal-therapy group before cycle 4 and 3-6 weeks after treatment but not one year after treatment. A summary of the intraperitoneal catheter related issues in this trial has been presented (232).

Based on these randomized trials, the intraperitoneal route of administration for *cisplatin* and *paclitaxel* chemotherapy in the primary treatment of optimally resected

P.1493

stage III ovarian cancer is an acceptable therapeutic alternative to intravenous chemotherapy with *carboplatin* and *paclitaxel* (233). **However, thus far there has been no randomized direct comparison of this intraperitoneal regimen to intravenous *carboplatin* and *paclitaxel* or to intraperitoneal *carboplatin* and *paclitaxel*. Intraperitoneal therapy can be used in patients with optimally resected tumors who have a good performance status and are in overall good health. Because intraperitoneal chemotherapy is more cumbersome and has a higher morbidity than intravenous therapy, the use of this technique of drug delivery should be individualized after thorough discussion with the patient.**

Neoadjuvant Chemotherapy

Some authors have suggested that, for patients with suboptimal stage III and stage IV disease, chemotherapy may be given in lieu of debulking surgery. A series performed by Schwartz et al. (234) suggested that the survival of these patients treated with neoadjuvant or cytoreductive chemotherapy was comparable to those patients historically treated in the same institution with debulking surgery followed by conventional chemotherapy. As other

authors have shown a benefit to debulking patients before chemotherapy (235,236), the issue would need to be resolved by a prospective clinical trial. However, two or three cycles of chemotherapy before cytoreductive surgery may be helpful in patients with massive ascites and large pleural effusions. The chemotherapy may dry up the effusions, improve the patient's performance status, and decrease postoperative morbidity, particularly chest morbidity.

Chemotherapeutic Recommendation in Advanced Epithelial Ovarian Cancer

For the treatment of advanced-stage epithelial ovarian cancer, the following is recommended (Table 35.4):

- **Combination chemotherapy with intraperitoneal *cisplatin* and *paclitaxel* or intravenous *carboplatin* and *paclitaxel* are the treatments of choice for patients with advanced disease. The advantages and disadvantages of the intraperitoneal versus intravenous routes of administration of these drugs should be discussed with the patient.**
- **The recommended doses and schedule for intraperitoneal chemotherapy are *paclitaxel* 135 mg/m² intravenous on day 1, followed by *cisplatin* 50-100 mg/m² intraperitoneal on day 2, followed by *paclitaxel* 60 mg/m² intraperitoneal on day 8, every 3 weeks for 6 cycles, as tolerated.**
- **The recommended doses and schedule for intravenous chemotherapy are: *carboplatin* (starting dose AUC = 5-6), and *paclitaxel* (175 mg/m²), every 3 weeks for 6-8 cycles.**
- **In patients who cannot tolerate combination chemotherapy, single-agent, intravenously administered *carboplatin* (AUC = 5-6) or *paclitaxel* 175 mg/m² can be given.**
- **In patients who have a hypersensitivity to *paclitaxel* or *carboplatin*, either desensitization can be performed, or an alternative active drug can be substituted (e. g., *docetaxel*, *liposomal doxorubicin*, *topotecan*, *etoposide*). *Etoposide* can be given orally.**

The treatment of all patients with advanced-stage disease is approached in a similar manner, with modifications based on the overall status and general health of

the patient, as well as the extent of residual disease present at the time treatment is initiated.

Table 35.4. Combination Chemotherapy for Advanced Epithelial Ovarian Cancer: Recommended Regimens				
Drugs	Dose (mg/m ²)*	Route	Interval (weeks)	Treatments (cycles)
Standard regimens				
Intraperitoneal chemotherapy				
<i>Paclitaxel</i>	135	IV	3, day 1	6
<i>Cisplatin</i>	50–100	IP	day 2	
<i>Paclitaxel</i>	60	IP	day 8	
Intravenous chemotherapy				
<i>Paclitaxel</i>	175	IV	3	6–8
<i>Carboplatin</i>	*AUC = 5–6	IV		
<i>Paclitaxel</i>	135	IV	3	6–8

**Drugs that can be substituted for *paclitaxel* if hypersensitivity to that drug occurs; the number of treatments administered as tolerated.

Immunotherapy

There is currently a great deal of interest in the use of immunotherapies in ovarian cancer. Cytokines have been used extensively in second-line therapy, and the activity of *interferon- α* , *interferon- γ* and *interleukin-2* has been demonstrated, as discussed below (3). In a recent trial of *interferon- γ* plus *cisplatin* combination chemotherapy versus chemotherapy alone, patients who received the *interferon* had a longer disease progression-free survival (237). A randomized, multicenter trial of first-line *carboplatin* and *paclitaxel* with or without *interferon- γ* has been conducted, and there is no survival advantage in the patients who received *interferon- γ* .

Hormonal Therapy

There is no evidence that hormonal therapy alone is appropriate primary therapy for advanced ovarian cancer. **The use of progestational agents in the treatment of recurrent well-differentiated endometrioid carcinomas is supported by the current data.** In one study, 30 evaluable patients with recurrent epithelial cancers were treated; 17 (57%) had an objective response, and three (10%) of these patients achieved a complete response (238). All responding patients had well-differentiated, estrogen receptor—positive tumors. A trial of *tamoxifen* in combination with multiagent chemotherapy is being conducted.

P.1495

Consolidation and Maintenance of Complete Clinical Response to First-line Chemotherapy

Because as many as 80% of women with advanced-stage disease who completely respond to their first-line chemotherapy will ultimately relapse, several trials have been conducted that administer a drug to these patients immediately following their primary treatment in an effort to decrease the relapse rate.

Paclitaxel

In a study conducted by the GOG and SWOG, 277 women with advanced ovarian cancer who had a complete clinical remission to first-line chemotherapy were randomized to receive 3 or 12 cycles of additional single-agent *paclitaxel* (175 or 135 mg/m² every 28 days) (239). Patients were excluded if they had developed grade 2 or 3 neurotoxicity during their initial chemotherapy. Because of cumulative toxicity, the mean number of actual cycles of *paclitaxel* received by the group assigned to receive 12 cycles was 9. The treatment-related grade 2 to 3 neuropathy was more common with longer treatment, 24% versus 14% of patients, respectively. **The study was closed after a median follow-up of only 8.5 months, and an interim analysis showed a significant 7-month prolongation in median progression-free survival (28 versus 21 months) with 9 versus 3 months of consolidation *paclitaxel*. However, there was no difference in median overall survival.** The rate of disease progression increased significantly after maintenance therapy was discontinued, which suggested that long-term survival would not be likely to be improved. Furthermore, it is unlikely that a survival benefit will be seen with longer follow-up, because patients assigned to three cycles were given the option of receiving an additional nine courses of *paclitaxel* after the study was discontinued (240). Another placebo-controlled, randomized trial using two formulations of *paclitaxel* is being conducted by the GOG.

Topotecan

Four additional treatment courses of *topotecan* were administered to patients following six cycles of *carboplatin* and *paclitaxel* in two randomized trials, one conducted in Italy (241) and the other in Germany (242). In the larger trial conducted in Germany, 1,059 evaluable patients were randomly assigned to six cycles of *paclitaxel* (175 mg/m² over 3 hours) and *carboplatin* (AUC 5) with (537 patients) or without (522 patients) four additional cycles of *topotecan* (1.25 mg/m² IV days 1 to 5 every 3 weeks) (242). In the Italian trial, 273 women were randomly assigned to receive four additional cycles (137 patients) of *topotecan* at a dose of 1 mg/m² on days 1 to 5 every 3 weeks or no further chemotherapy (136 patients) (241). **Preliminary reports suggest no significant differences in either progression-free or overall survival in patients who received four to six cycles of consolidation *topotecan*.**

Cisplatin

In a randomized clinical trial of intraperitoneal *cisplatin* for consolidation versus observation, there was no difference in survival between the treatment arms (243).

Immunotherapy

Trials of monoclonal antibodies directed toward ovarian cancer-associated antigens are being conducted. Monoclonal antibodies (MonAb) directed toward CA125 (OvaRex) (244) and toward the HMFG (human milk fat globulin) (245) tumor-associated antigens have been conducted. In a randomized, placebo-controlled trial of intravenous OvaRex (ant-CA125 MonAb) as consolidation/maintenance, Berek et al. reported that a subset of patients with optimal ovarian cancer who had achieved a prompt clinical remission after three cycles of chemotherapy (as indicated by a rapid decline in CA125) had a longer time to disease relapse (24 months) compared with those who received placebo (10.8 months) ($p = 0.06$) (244). A randomized trial of an intraperitoneally administered yttrium-labeled antimucin (HMFG) MonAb versus placebo was not associated with an improved overall survival after a negative second-look laparoscopy (245). However, the time to intraperitoneal relapse was effectively delayed by the IP MonAb, suggesting regional activity for the drug.

Summary

The clinical benefit of consolidation and maintenance chemotherapy and immunotherapy remains unclear. Patients and their physicians may consider prolonged single-agent *paclitaxel* an option, but it should not be considered the standard of care at this time.

Treatment Assessment

Many patients who undergo optimal cytoreductive surgery and subsequent

chemotherapy for epithelial ovarian cancer will have no evidence of disease at the completion of treatment. Tumor markers and radiologic assessments have proven to be too insensitive to exclude the presence of subclinical disease. Therefore, a second-look surgery has been performed to evaluate these patients (142,246,247,248,249,250,251,252,253,254,255). Most often, patients have undergone formal reassessment laparotomy, although the laparoscope has also been used in this circumstance (253,254,255). However, there is a 35% false-negative rate if laparoscopy is used for a second-look procedure (142,254).

Tumor Markers

Tumor markers are not reliable enough to predict accurately which patients with epithelial tumors will experience complete eradication of disease with a particular therapy. Carcinoembryonic antigen (CEA) levels are often elevated in patients with ovarian cancer, but the test is too nonspecific and insensitive to have much use in the management of these patients (42). The level of CA125, a surface glycoprotein associated with müllerian epithelial tissues, is elevated in about 80% of patients with epithelial ovarian cancers, particularly those with nonmucinous tumors. The levels frequently become undetectable after the initial surgical resection and one or two cycles of chemotherapy.

Levels of CA125 have been correlated with findings at second-look operations. Positive levels are useful in predicting the presence of disease, but negative levels are an insensitive determinant of the absence of disease. In a prospective study (256), the predictive value of a positive test was shown to be 100%; if the level of CA125 was positive (>35 U/mL), disease was always detectable in patients at the second-look procedure. The predictive value of a negative test was only 56%; if the level was <35 U/mL, disease was present in 44% of the patients at the time of the second-look surgery. **A review of the literature suggests that an elevated CA125 level predicts persistent disease at second-look surgery in 97% of the cases (257), but the CA125 level is not sensitive enough to exclude subclinical disease in many patients.**

Serum CA125 levels can be used during chemotherapy to follow those patients whose levels were positive at the initiation of therapy (3,257). The change in level generally correlates with response. Those patients with persistently elevated levels after three cycles of treatment most likely have persistent disease. When levels rise after treatment, almost invariably treatment has failed, and continuation of the current regimen is futile. A retrospective study has determined that a doubling of the CA125 level from its nadir in those patients with a persistently elevated level accurately predicts disease progression (258).

Radiologic Assessment

For patients with stage I to III epithelial ovarian cancer, radiologic tests generally have been of limited value in assessing the response to therapy for subclinical

disease. Ascites can be readily detected, but even quite large omental metastases can be missed on CT scan (259). If liver enzyme levels are abnormal, the liver can be evaluated with a CT scan or ultrasonography. A positive CT scan and fine-needle aspiration (FNA) cytology indicating tumor persistence could document persistent or recurrent disease, but the false-negative rate of a CT scan is about 45% (260). **Positron-emission tomography (PET) alone or with CT imaging may help in the detection of relapse, although the relative value of adding PET has not been established. There appears to be a higher false-positive rate with PET compared**

P.1497

with CT (90,91,92). MRI can be used as an alternative to CT in patients with allergies to the contrast medium (90).

Second-look Operations

A second-look operation is one performed on a patient who has no clinical evidence of disease after a prescribed course of chemotherapy to determine the response to therapy.

Second-look Laparotomy

The technique of the second-look laparotomy is essentially identical to that for the staging laparotomy (142). The operation should be performed through a vertical abdominal incision. The incision should be initiated below the level of the umbilicus, so that if pelvic disease is detected in the absence of any palpable upper abdominal disease, a smaller incision might suffice. The incision can be extended cranially as needed. After multiple cytologic specimens have been obtained, samples of the peritoneal surfaces should be collected for biopsy, particularly in any areas of previously documented tumor. These are the most important areas to sample for biopsy because they are most likely to give a positive result. Any adhesions or surface irregularities should be sampled. In addition, biopsy specimens should be taken from the pelvic side walls, the pelvic cul-de-sac, the bladder, the paracolic gutters, the residual omentum, and the diaphragm. A pelvic and para-aortic lymph node dissection should be performed for those patients whose nodal tissues have not been previously removed.

About 30% of patients with no evidence of macroscopic disease will have microscopic metastases (246,247,248,249). Also, for many patients with microscopic disease, it will be detected in only the occasional biopsy or cytologic specimen. Therefore, a large number of specimens (at least 20 to 30) should be obtained to minimize possibility of false-negative results of the operation. **In selected patients in whom gross residual tumor is discovered at second-look surgery, resection of isolated masses may be performed.** The removal of all macroscopic areas of disease might facilitate response to salvage therapies (261,262,263,264,265,266,267,268).

Second-look laparotomies have not been shown to influence patient survival

(250,251). **Therefore, they should be performed selectively, e.g., in patients receiving therapy in a setting where second-line therapies are undergoing clinical trials.**

The findings at second-look correlate with subsequent outcome and survival (142,246,247,248,249,250,251,252). Patients who have no histologic evidence of disease have a significantly longer survival than those in whom microscopic or macroscopic disease is documented at laparotomy (251,252). The attainment of negative findings with second-look surgery is not tantamount to a cure (252). Indeed, the reported probability that a patient will have a recurrence after a negative second-look laparotomy ranges from 30% to 50% at 5 years (142,246,247,248,249,250,251,252). Clearly, it is not possible to sample every potential site of disease. In addition, disease can become clinically apparent in sites that are occult, such as the liver parenchyma (98). Most recurrences after a negative second-look laparotomy occur in patients with poorly differentiated cancers (252).

Variables associated with the outcome of the second-look laparotomy are (i) initial stage, (ii) tumor grade, (iii) the size of the residual tumor and the size of the largest metastatic tumor before treatment, and (iv) the type of chemotherapy. No single variable or combination of variables is sufficiently predictive of the findings of a second-look laparotomy (3,142).

Second-look Laparoscopy

The laparoscope in epithelial ovarian cancer patients may be used to stage disease in patients who have undergone a prior laparotomy for a tumor that was incompletely staged. Second-look laparoscopy may also be useful for patients on experimental treatment protocols, especially second-line treatments that require some evaluation of

P.1498

response. The advantage of laparoscopy is that it is a less invasive operation; the disadvantage is that visibility may be limited by the frequent presence of intraperitoneal adhesions (3,253,254,255). The development of newer techniques for retroperitoneal lymphadenectomy has potentially increased the utility of the endoscopic approach to second look.

Second-line Therapy

Secondary Cytoreduction

Secondary cytoreduction maybe defined as an attempt at cytoreductive surgery at some stage following completion of first-line chemotherapy (261). Patients with progressive disease on chemotherapy are not suitable candidates for secondary cytoreduction, but patients who are clinically free of disease and undergo second-look laparotomy may benefit if all macroscopic residual disease can be resected (262,263,264). Patients with recurrent disease are occasionally candidates for surgical excision of their disease. **Tumor resection under**

these circumstances should be restricted to those who have a disease-free interval of at least 12, but preferably 24, months or those in whom all macroscopic disease can be resected, regardless of the disease free interval (261,262,263,264,265,266,267,268).

Second-line Chemotherapy

If disease persists at the time of second-look laparotomy, or if clinically progressive disease develops during primary therapy, patients usually have been switched to an alternative treatment, often a second-line chemotherapy. The response rates for second-line chemotherapies have been 15% to 35% for most drugs tested by the oral or intravenous route

(269,270,271,272,273,274,275,276,277,278,279,280,281,282,283,284,285,286,287,288,289,290,291,292).

Active drugs that have been used as single agents include *cisplatin*, *carboplatin*, *paclitaxel*, *docetaxel* (*Taxotere*), *topotecan*, *gemcitabine*, *etoposide* (*VP-16*), *doxorubicin* (*Doxil*), *vinorelbine* (*Navelbine*), *ifosfamide*, *5-fluorouracil* with *leucovorin*, and *hexamethylmelamine*.

Single-agent drugs are sometimes used for second-line chemotherapy because of their relative ease of administration and low toxicity.

Platinum-sensitive Disease

Second-line therapies have been categorized by whether the patients responded to their initial platinum-based chemotherapy. Although this concept has been variously defined, platinum sensitivity has been related to a disease progression-free interval of at least 6 months. Response rates after retreatment with *cisplatin* have been shown to be higher in patients whose time to clinical relapse after prior response to *cisplatin* is longer than 6 months, especially when it is 12 to 24 months (271,272,273). **Thus, the concept of platinum sensitivity is a continuum: The longer the interval, the higher the probability of a secondary response to secondary platinum-based chemotherapy.** *Carboplatin* is active as a second-line agent in patients who have responded to prior *cisplatin* treatment, and response rates in these patients have been 20% to 30% (271). The concept of platinum sensitivity and *paclitaxel* sensitivity should influence the choice of second-line chemotherapy.

In patients who have platinum-or *paclitaxel*-sensitive tumors, retreatment with a platinum drug or *paclitaxel* is appropriate. Second-line responses to *paclitaxel*, *carboplatin*, and *cisplatin* in those patients who have responded previously to *cisplatin* have been observed in 20% to 25% of patients. Furthermore, the length of a prior response to platinum-based chemotherapy is highly predictive of the upper limit of the duration of response to a subsequent platinum treatment using the same or similar drugs (274).

There are studies that suggest that a platinum plus *paclitaxel* may be better for second-line therapy than platinum alone (293,294). In a series of 25 women who relapsed 6 months or

longer after first-line *carboplatin* and *paclitaxel*, retreatment with the same combination of drugs resulted in a response rate of 91% and a median progression-free interval of more

than 9 months (294). Others suggest that single-agent therapy (*cisplatin* or *carboplatin*) should be considered the standard of care for platinum-sensitive relapsing disease (295,296). **In most studies, there is a lack of survival advantage and greater toxicity with multiagent compared with single-agent regimens**, although the combination of *carboplatin* and *paclitaxel* is well tolerated (297).

The use of combination platinum plus *paclitaxel* chemotherapy versus a single-agent platinum was tested in two multinational randomized phase III trials (298) and a randomized phase II study (299). In a report of the ICON4 (298) and AGO-OVAR-2.2 (299) trials, 802 women with platinum-sensitive ovarian cancer who relapsed after being treatment-free for at least 6 to 12 months were randomized to platinum -based chemotherapy (72% *carboplatin* or *cisplatin* alone; 17% CAP; 4% *carboplatin* plus *cisplatin*; and 3% *cisplatin* plus *doxorubicin*) or *paclitaxel* plus platinum-based chemotherapy (80% *paclitaxel* plus *carboplatin*; 10% *paclitaxel* plus *cisplatin*; 5% *paclitaxel* plus both *carboplatin* and *cisplatin*; and 4% *paclitaxel* alone). The AGO-OVAR-2.2 trial did not accrue its planned number of patients. In both trials, a significant proportion of the patients had not received *paclitaxel* as part of their initial chemotherapeutic regimen. **Combining the trials for analysis, there was a significant survival advantage for the *paclitaxel*-containing therapy** (HR = 0.82) with a median follow up of 42 months. **The absolute 2-year survival advantage was 7% (57% vs. 50%), and there was a 5-month improvement in median survival (29 vs. 24 months)**. Progression-free survival was better with the *paclitaxel* regimen (HR = 0.76); there was a 10% difference in 1-year progression-free survival (50% vs. 40%) and a 3-month prolongation in median progression-free survival (13 vs. 10 months). The toxicities were comparable, except there was a significantly higher incidence of grade 2 to 4 neurologic effects (20% vs. 1%) and alopecia (86% vs. 25%) in the *paclitaxel* group. Conversely, myelosuppression was significantly greater with the non-*paclitaxel*-containing regimens. **These data support the slight advantage of a second-line regimen containing both *paclitaxel* and a platinum agent compared with platinum-based therapy alone, especially in patients who have not received *paclitaxel* in their primary chemotherapeutic regimen.**

Platinum-resistant and Refractory Disease

In *cisplatin*-refractory patients, response rates to second-line *carboplatin* are less than 10% (270,272). The management of women who have platinum-resistant disease requires the use of non—cross-resistant agents. Single-agent therapy is typically used, because combination regimens are associated with more toxicity without additional benefit. There are a variety of active drugs; *paclitaxel*, *docetaxel*, *topotecan*, *liposomal doxorubicin*, *gemcitabine*, *oral etoposide*, and *tamoxifen* are the most frequently used. Other active agents include *vinorelbine*, *ifosfamide*, and *leucovorin-modulated 5-fluorouracil*. These agents have resulted

in second-line response rates of about 8% to 28% in patients with platinum-resistant disease (275,276,277,278,279,280,281,282,283,284,285,286,287,289,290,291,292).

Some researchers have used these drugs to prolong the "platinum-free interval," hoping that their use will allow the tumor to become platinum sensitive during the interval use of non-cross-resistant agents. The rationale for this method is that the platinum-free interval is equivalent to the treatment-free interval, and before the availability of other active drugs, these two terms were synonymous. However, there are no data to support the hypothesis that the interposition of another drug can produce an increased platinum sensitivity as a result of a longer interval since the last platinum treatment.

Single-agent *paclitaxel* shows objective responses in 24% to 30% in phase II trials of women with platinum-resistant ovarian cancer (300,301,302,303,304,305,306).

Weekly *paclitaxel* is active, and the toxicity, especially myelosuppression, is less than with the every-3-weeks regimens. *Docetaxel* also has some activity in these patients (307,308,309).

Topotecan is an active second-line treatment for patients with platinum-sensitive and platinum-resistant disease

(310,311,312,313,314,315,316,317,318,319,320,321,322,323,324,325). **Weekly**

***topotecan* administered at a dose of**

P.1500

4 mg/m²/week for 3 weeks with a week off every month produced a response rate similar to the 5-day regimen with considerably less toxicity; therefore, this is now considered the regimen of choice for this agent (325). *Liposomal doxorubicin* (*Doxil* in the United States and *Caelyx* in Europe) has activity in platinum- and taxane-refractory disease (326,327,328). **The predominant severe toxicity of *liposomal doxorubicin* is the hand-foot syndrome, also known as *palmar-plantar erythrodysesthesia* or *acral erythema*.**

This morbidity is observed in 20% of patients who receive 50 mg/m² every 4 weeks (326).

There have been two randomized trials comparing *liposomal doxorubicin* with *topotecan*. In a study of 237 women who relapsed after receiving one platinum-containing regimen, 117 of whom (49.4%) had platinum-refractory disease (328), *liposomal doxorubicin* 50 mg/m² over 1 hour every 4 weeks was compared with *topotecan* 1.5 mg/m²/day for 5 days every 3 weeks.

The two treatments had a similar overall response rate (20% vs. 17%), time to progression (22 vs. 20 weeks), and median overall survival (66 vs. 56 weeks).

The myelotoxicity was significantly lower in the *liposomal doxorubicin*-treated patients than with those receiving *topotecan* with grade 3 or 4 neutropenia (12% vs. 71%) and grade 3 or 4 thrombocytopenia (1% vs. 35%). However, with more long term follow-up of these patients (329), the median survival was 62.7 weeks for those treated with *liposomal doxorubicin* and 59.7 weeks for *topotecan*-treated patients ($p = 0.05$). In the subset of patients with platinum-sensitive disease, the median survival was 107.9 weeks for those treated with *liposomal doxorubicin* versus 70.1 weeks for *topotecan*-treated patients ($p = 0.017$), suggesting a slight advantage of the *liposomal doxorubicin* in this second-line setting.

Gemcitabine has been associated with response rates of 20% to 50%, with 15% to 30% in patients who are platinum resistant (330,331,332,333,334). Oral *etoposide* should be considered one of the principal drugs to be used in patients with *paclitaxel*- and platinum-resistant disease (335,336). Other active agents include hexamethylmelamine (337,338), capecitabine (339), 5-fluorouracil and leukovorin (340), and ifosfamide with mesna (341).

Hormonal Therapy

Tamoxifen has been associated with response rates of 15% to 20% in well-differentiated carcinomas of the ovary (342,343,344,345,346,346). The gonadotropin-agonist *leuprolide acetate* (*Lupron*) has been shown to produce a response rate of 10% in one series (347). Trials combining *tamoxifen* and *leuprolide acetate*, and *tamoxifen* and combination chemotherapy are being conducted (348). Aromatase inhibitors, e.g., *letrozole*, *anastrozole*, and *exemestane*, which have been shown to have activity in metastatic breast cancer, are being studied in relapsed ovarian cancer (349). One of the principal advantages of this class of agents is the very low toxicity (350).

Immunotherapy

Herceptin, an antibody directed toward the extracellular protein produced when the HER-2/*neu* oncogene is overexpressed, has been used extensively in breast cancer, where it has been shown to improve the response rate to chemotherapy in selected patients. Trials of this antibody in patients whose ovarian cancers overexpress erbB2 was conducted by the GOG, but only 11% of the tumors overexpressed the protein, and the response rate was only about 4% (351).

In addition to its use as a maintenance therapy (245), the OvaRex anti-CA125 monoclonal antibody is being used alone and in combination with a variety of cytotoxic agents in the treatment of patients with recurrent disease (352,353) .

Intraperitoneal Therapy

For patients with minimal residual (<5 mm) or microscopic disease confined to the peritoneal cavity, consideration can be given to intraperitoneal chemotherapy or immunotherapy. The failure of second-line intravenous chemotherapy to control residual disease has led to the use of intraperitoneal therapies for small, persistent disease.

Intraperitoneal Chemotherapy

Cytotoxic chemotherapeutic agents, such as *cisplatin*, *5-fluorouracil*, *cytosine arabinoside* (*Ara-C*), *etoposide* (*VP-16*), and *mitoxantrone*, have been used for patients with persistent

epithelial ovarian cancer (354,355,356,357,358,359,360,361,362,363), and complete responses have been seen in patients who begin treatment with minimal residual disease. **The surgically documented response rates reported with this approach are about 20% to 40% for carefully selected patients, and the complete response rate is about 10% to 20%.** *Cisplatin* seems to be the best drug, although various combinations of agents (e. g., *cisplatin* plus *etoposide*) have been shown to have significant activity (356,357). Although it has been suggested that this approach produces a significant subsequent improvement in survival (359), there are no prospective phase III data, and the patients so treated tend to be those with a more favorable prognosis regardless of subsequent therapy.

Intraperitoneal Immunotherapy

Another approach is the use of intraperitoneal immunotherapy such as *interferon* (364,365,366,367,368,369,370). *Interferon* has been found to have some activity for patients with minimal residual disease (364,365). Intraperitoneal administration *interferon- α* , *interferon- γ* , *tumor necrosis factor*, and *interleukin-2* has been performed. **The response rate for the intraperitoneal cytokines, *interferon- α* and *interferon- γ* , is the same as that for the cytotoxic agents (i.e., 28% to 50%) (364,365,366,367,368,369,370).** The intraperitoneal administration of *interferon- α* has produced a 32% (9 of 28) surgically documented complete response rate, and a 50% (14 of 28) total response rate for patients with minimal residual disease after primary combination chemotherapy with *cisplatin* (364,369). This experience was replicated in a multi-institutional trial in which the surgically documented complete response rate was 28% in platinum-sensitive patients (365).

The interferons have been combined with cytotoxic agents in an effort to increase the overall response rates. In several trials, the combination of *cisplatin* and *interferon- α* seemed to produce a 50% complete response rate, which was greater than that produced by either single agent (367,368,369). Surgically documented responses to intraperitoneal therapy have been generally limited to patients with minimal residual disease (i.e., < 5 mm maximal tumor dimension) and patients whose tumors have been responsive to *cisplatin* chemotherapy.

Candidates for Intraperitoneal Therapy

Intraperitoneal treatment is not suitable for all patients because it can be cumbersome, requiring catheters that remain functional. Neither patients with extensive intraperitoneal adhesions nor patients with extraperitoneal disease are appropriate candidates. On the basis of these issues and the failure to achieve responses in most patients with bulky, *platinum*-refractory disease, second-line intraperitoneal chemotherapy and immunotherapy should still be considered experimental (371).

High-dose Chemotherapy and Autologous Bone

Marrow Transplantation

The use of high-dose chemotherapy and either autologous bone marrow transplantation (ABMT) or peripheral stem cell protection has been tested in patients with advanced ovarian cancer (372,373,374,375). A phase III randomized trial of 57 patients treated with high-dose chemotherapy (*cyclophosphamide* 6,000 mg/m² and *carboplatin* 1,600 mg/m²) with peripheral blood stem cell support as consolidation versus 53 patients treated with conventional dose maintenance (*cyclophosphamide* 600 mg/m² and *carboplatin* 300 mg/m²) has been reported (374). Only 43 of the 57 (75%) women completed the high-dose therapy, whereas 48 of 53 (92%) completed the standard dose regimen, and there was no statistically significant difference in progression-free and overall survival between the two groups of patients. A nonrandomized trial of ABMT for consolidation in 96 patients conducted at the MD Anderson Cancer Center showed a 6-year survival of 37%, but it is unclear if this would be survival advantage (375).

P.1502

Radiation Therapy

Whole-abdominal radiation therapy given as a salvage treatment has been shown to be associated with a relatively high morbidity. The principal problem associated with this approach is the development of acute and chronic intestinal morbidity. As many as 30% of patients treated with this approach develop intestinal obstruction, which necessitated exploratory surgery with potential morbidity (376).

Intestinal Obstruction

Patients with epithelial ovarian cancer often develop intestinal obstruction, either at the time of initial diagnosis or, more frequently, in association with recurrent disease

(142,377,378,379,380,381,382,383,384,385,386,387,388,389,390,391,392,393). Obstruction may be related to a mechanical blockage or to carcinomatous ileus.

The intestinal blockage can be corrected in most patients whose obstruction appears at the time of initial diagnosis. However, the decision to perform an exploratory procedure to ease intestinal obstruction in patients with recurrent disease is more difficult. For patients whose life expectancy is very short (e.g., <2 months), surgical relief of the obstruction is not indicated (377). **In those whose projected life span is longer, features that predict a reasonable likelihood of correcting the obstruction include young age, good nutritional status, and the absence of rapidly accumulating ascites** (378).

For most patients with recurrent ovarian cancer who have intestinal obstruction, initial management should include proper radiographic documentation of the obstruction,

hydration, correction of any electrolyte disturbances, parenteral alimentation, and intestinal intubation. For some patients, the obstruction may be alleviated by this conservative approach. A preoperative upper gastrointestinal radiographic series and a barium enema will define possible sites of obstruction.

If exploratory surgery is deemed appropriate, the type of operation to be performed will depend on the site and the number of obstructions. **Multiple sites of obstruction are not uncommon in patients with recurrent epithelial ovarian cancer.** More than one half of the patients have small-bowel obstruction, one third have colonic obstruction, and one sixth have both (379,380,381,382,383). If the obstruction is principally contained in one area of the bowel (e.g., the terminal ileum), this area can either be resected or bypassed, depending on what is easier to accomplish safely. Intestinal bypass is generally less morbid than resection, and in patients with progressive cancer, the survival time after these two operations is the same (384,385,386,387,388,389,390).

If multiple obstructions are present, resection of several segments of intestine is usually not indicated, and intestinal bypass and/or colostomy should be performed. A gastrostomy may occasionally be useful in this circumstance (389), and this can usually be placed percutaneously (392).

Surgery for bowel obstruction in patients with ovarian cancer carries an operative mortality of about 10% and a major complications rate of about 30% (377,378,379,380,381,382,383,384,385,386,387,388,389,390). The need for multiple reanastomoses and prior radiation therapy increase the morbidity, which consists primarily of sepsis and enterocutaneous fistulae. The median survival ranges from 3 to 12 months, although about 20% of such patients survive longer than 12 months (391,392,393).

Survival

The prognosis for patients with epithelial ovarian cancer is related to several clinical variables. Survival analyses based on the most commonly used prognostic variables are presented (1,3,24,133,134,135,136,137). Including patients at all stages, patients younger than 50 years of age have a 5-year survival rate of about 40%, compared with about 15% for patients

older than 50 years. **The 5-year survival rate for carefully and properly staged patients with stage I disease is 76% to 93%, depending on the tumor grade. The 5-year survival for stage II is 60% to 74%. The 5-year survival rate for stage IIIa is 41%, for stage IIIb about 25%, for stage IIIc 23%, and for stage IV disease 11%** (Fig 35.13).

Figure 35.13 Survival of patients with epithelial ovarian cancer. The percentage of patients diagnosed at a particular stage is shown next to the 5-year survival by stage. *IP*, intraperitoneal. (From **Berek JS, Hacker NF**, eds. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005:492, with permission.)

An analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database reveals a trend toward improved survival for ovarian cancer in the United States during the last period of analysis (1988 to 1994). In this cohort, the survival for stage I was 93%, for stage II 70%, for stage III 37%, and for stage IV 25% (394). Compared with the interval 1983 to 1987, there was a statistically significant improvement in survival for stages I, III, and IV disease.

Survival of patients with borderline tumors is excellent, with stage I lesions having a 98% 15-year survival (24). When all stages of borderline tumors are included, the 5-year survival rate is about 86% to 90%.

Regarding patients with invasive cancer, the 5-year survival rate for grade 1 epithelial ovarian cancers is about 91%, compared with about 74% for grade 2 and 75% for grade 3 (24,394). For stage II disease, the survivals are 69%, 60%, and 51%, respectively, for grades 1, 2, and 3. Examining stage III to IV patients, the 5-year survivals for grades 1, 2, and 3,

respectively, are 38%, 25%, and 19%. Patients with stage III disease with microscopic residual disease at the start of treatment have a 5-year survival rate of about 40% to 75%, compared with about 30% to 40% for those with optimal disease and only 5% for those with nonoptimal disease (136,137,162). Patients whose Karnofsky's index (KI) is low (<70) have a significantly shorter survival than those with a KI >70 (24).

Nonepithelial Ovarian Cancers

Compared with epithelial ovarian cancers, other malignant tumors of the ovary are uncommon. **Nonepithelial malignancies of the ovary account for about 10% of all ovarian cancers** (2,3,395). Nonepithelial ovarian cancers include malignancies of germ cell origin, sex cord–stromal cell origin, metastatic carcinomas to the ovary, and a variety of extremely rare ovarian cancers (e.g., sarcomas, lipoid cell tumors). Although there are many similarities in the presentation, evaluation, and management of these patients, these tumors also have many unique qualities that require a special approach (2,395,396,397,398).

Germ Cell Malignancies

Germ cell tumors are derived from the primordial germ cells of the ovary. Their incidence is only about one tenth the incidence of malignant germ cell tumors of the testis, so most of the advances in the management of these tumors have been extrapolations from experience with the corresponding testicular tumors. Although malignant germ cell tumors can arise in extragonadal sites such as the mediastinum and the retroperitoneum, most germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads (2,3,395).

Classification

A histologic classification of ovarian germ cell tumors is presented in Table 32.5 (3,395). **Both α -fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies; therefore, the presence of circulating hormones can be**

clinically useful in the diagnosis of a pelvic mass and in monitoring the course of a patient after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are produced by up to 95% of dysgerminomas, and serial measurements of LDH may be useful for monitoring the disease. α_1 -Antitrypsin (AAT) can rarely be detected in association with germ cell tumors. When the histologic and immunohistologic identification of these substances in tumors is correlated, a classification

of germ cell tumors emerges (Fig. 35.14) (399).

Table 35.5 Histologic Typing of Ovarian Germ Cell Tumors	
1. Primitive germ cell tumors	3. Monodermal teratoma and somatic-type tumors associated with dermoid cysts
A. Dysgerminoma	A. Thyroid tumor
B. Yolk sac tumor	1. Struma ovarii
C. Embryonal carcinoma	a. Benign
D. Polyembryoma	b. Malignant
E. Non-gestational choriocarcinoma	B. Carcinoid
F. Mixed germ cell tumor	C. Neuroectodermal tumor
2. Biphasic or triphasic teratoma	D. Carcinoma
A. Immature teratoma	E. Melanocytic
B. Mature teratoma	F. Sarcoma
1. Solid	G. Sebaceous tumor
2. Cystic	H. Pituitary-type tumor
a. Dermoid cyst	I. Others (homunculus)
b. Fetiform teratoma

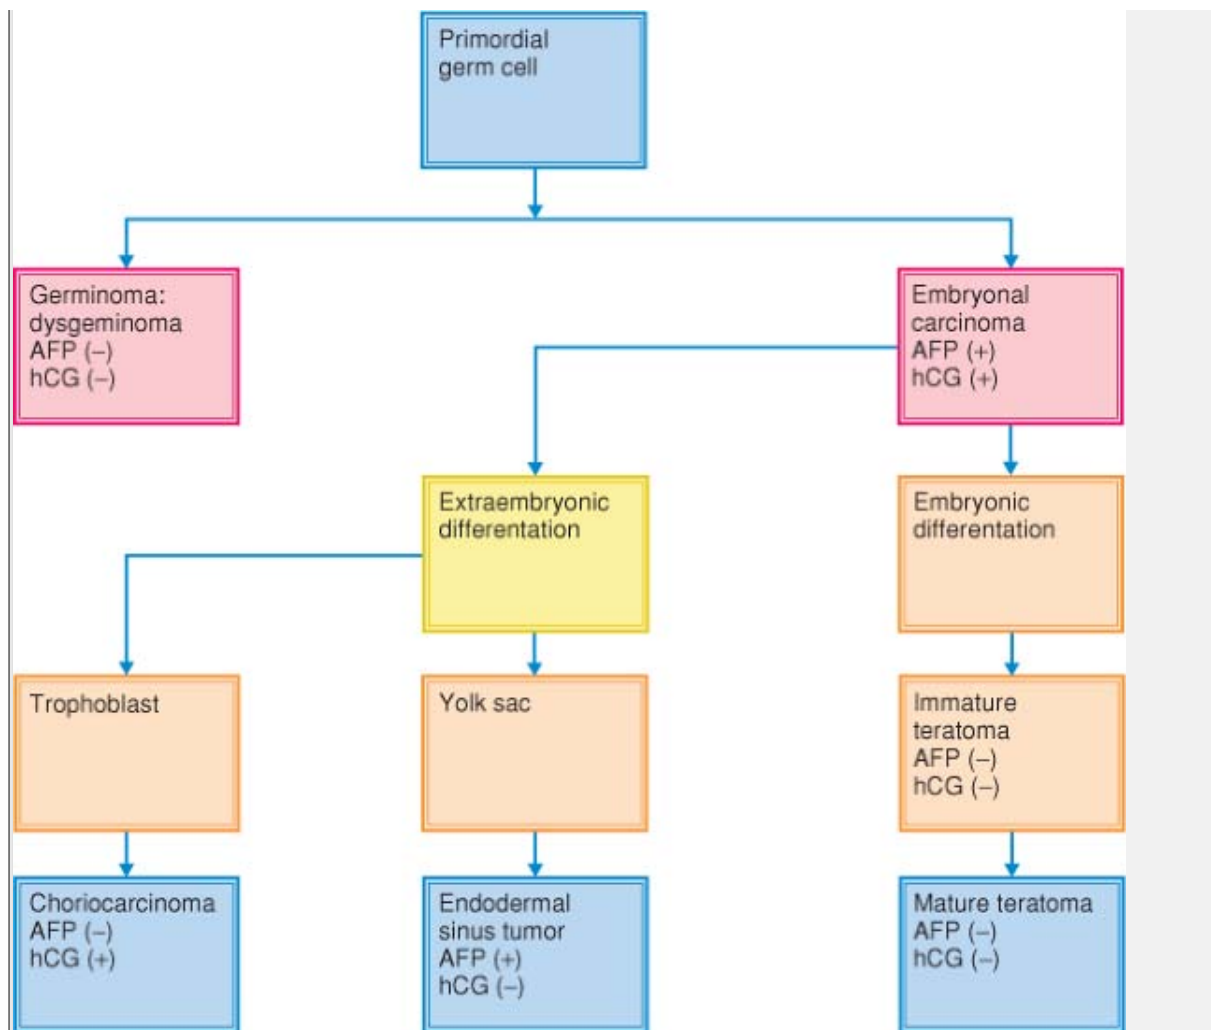

Figure 35.14 Relationship between types of pure malignant tumors. Germ cell tumors and their secreted marker substances. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2005:513, with permission.)

In this scheme, **embryonal carcinoma (a cancer composed of undifferentiated cells) synthesizes both hCG and AFP**, and this lesion is the progenitor of several other germ cell tumors (399). More differentiated germ cell tumors, such as the endodermal sinus tumor, which secretes AFP, and the choriocarcinoma, which secretes hCG, are derived from the extraembryonic tissues; the immature teratomas derived from the embryonic cells have lost the ability to secrete these substances. Pure germinomas do not secrete these markers.

Epidemiology

Although 20% to 25% of all benign and malignant ovarian neoplasms are of germ cell origin, only about 3% of these tumors are malignant (2,3). Germ cell malignancies account for fewer than 5% of all ovarian cancers in western countries. Germ cell malignancies represent up to 15% of ovarian cancers in Asian and African-American societies, where epithelial ovarian cancers are much less common.

In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one third of these are malignant (2,3,395). Germ cell tumors account for two thirds of the ovarian malignancies in this age group. Germ cell cancers also are seen in the third decade, but thereafter they become quite rare.

Clinical Features

Symptoms

In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly and often are characterized by subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities also may occur in menarcheal patients. Some young patients may misinterpret the early symptoms of a neoplasm as those of pregnancy, and this can lead to a delay in the diagnosis. Acute symptoms associated with torsion or rupture of the adnexa can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient can have abdominal distention (397).

Signs

For a patient with a palpable adnexal mass, the evaluation can proceed as outlined. Some patients with germ cell tumors will be premenarcheal and may require examination under anesthesia. **If the lesions are principally solid or a combination of solid and cystic, as might be noted on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible** (see Fig. 14.8 and Chapter 14). During the remainder of the physical examination, effort should be directed to searching for signs of ascites, pleural effusion, and organomegaly.

Diagnosis

Adnexal masses measuring 2 cm or larger in premenarcheal girls or 8 cm or larger in other premenopausal patients will usually require surgical exploration. For young patients, blood tests should include serum hCG and AFP titers, a complete blood count, and

liver function tests. A radiograph of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. **A karyotype should be obtained preoperatively for all premenarcheal girls because of the propensity of these tumors to arise in dysgenetic gonads** (396,400). A preoperative CT scan or MRI may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases; however, because these patients require surgical exploration, such extensive and time-consuming evaluation is unnecessary. If postmenarcheal patients have predominantly cystic lesions up to 8 cm in diameter, they may be observed or given oral contraceptives for two menstrual cycles (401).

Dysgerminoma

Dysgerminoma is the most common malignant germ cell tumor, accounting for about 30% to 40% of all ovarian cancers of germ cell origin (2,3,399). The tumors represent only 1% to 3% of all ovarian cancers, but they represent as many as 5% to 10% of ovarian cancers in patients younger than 20 years. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years, and they rarely occur after 50 years of age (2,3,397). Because these malignancies occur in young women, 20% to 30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Dysgerminomas are found in both sexes and may arise in gonadal or extragonadal sites. The latter include the midline structures from the pineal gland to the mediastinum and the retroperitoneum. Histologically, they represent abnormal proliferations of the basic

P.1507

germ cell. In the ovary, the germ cells are encapsulated at birth (the primordial follicle), and the unencapsulated or free cells die. If either of the latter processes fails, it is conceivable that the germ cell could free itself of its normal control and multiply indiscriminately.

Figure 35.15 Dysgerminoma of the ovary. Note that the lesion is principally solid with some cystic areas and necrosis.

The size of dysgerminomas varies widely, but they are usually 5 to 15 cm in diameter (2,3). The capsule is slightly bosselated, and the consistency of the cut surface is spongy and gray-brown in color (Fig. 35.15).

The histologic characteristics of the dysgerminoma are very distinctive. The large round, ovoid, or polygonal cells have abundant, clear, very-pale-staining cytoplasm, large and irregular nuclei, and prominent nucleoli (Fig. 35.16). Mitotic figures are seen in varying numbers, although they are usually numerous. Another characteristic feature is the arrangement of the elements in lobules and nests separated by fibrous septa, which are often extensively infiltrated with lymphocytes, plasma cells, and granulomas with epithelioid

cells and multinucleated giant cells. When necrosis is extensive, the lesion may be confused with tuberculosis. Occasional dysgerminomas may contain syncytiotrophoblastic giant cells and may be associated with precocious puberty or virilization. The presence of these cells does not seem to alter the behavior of the tumor (2,3).

Because the dysgerminoma is a germ cell tumor and parthenogenesis (stimulation of the basic germ cell to atypical division) is the most commonly accepted genesis for the more immature teratomas, it is logical that these two tumors may coexist. Choriocarcinoma,

P.1508

endodermal sinus tumor, and other extraembryonal lesions are also commonly associated with the dysgerminoma.

Figure 35.16 Dysgerminoma of ovary. Primitive germ cells are divided into clusters and lobules by fibrous septa rich in lymphocytes.

Approximately 5% of dysgerminomas are discovered in phenotypic women with

abnormal gonads (2,400,402). This malignancy can be associated with patients who have pure gonadal dysgenesis (46, XY, bilateral streak gonads), mixed gonadal dysgenesis (45, X/46, XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46, XY, testicular feminization). Therefore, for premenarcheal patients with a pelvic mass, the karyotype should be determined (see Chapter 26).

For most patients with gonadal dysgenesis, dysgerminomas arise in gonadoblastomas, which are benign ovarian tumors that are composed of germ cells and sex cord stroma. If gonadoblastomas are left *in situ* in patients with gonadal dysgenesis, more than 50% will develop into ovarian malignancies (402).

About 65% of dysgerminomas are stage I (i.e., confined to one or both ovaries) at diagnosis (2,3,403,404,405,406,407,408). **About 85% to 90% of stage I tumors are confined to one ovary; 10% to 15% are bilateral. In fact, dysgerminoma is the only germ cell malignancy that has this significant rate of bilaterality. Other germ cell tumors are rarely bilateral.**

For patients whose contralateral ovary has been preserved, disease can develop in 5% to 10% of the retained gonads over the next 2 years (2). This figure includes those not given additional therapy, as well as patients with gonadal dysgenesis.

In the 25% of patients who are diagnosed initially with metastatic disease, the tumor most commonly spreads via the lymphatic system. It can also spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination

P.1509

of cells throughout the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone; when metastasis to this site occurs, the lesions are seen principally in the lower vertebrae. Metastases to the lungs, liver, and brain are seen most often in patients with long-standing or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is usually a late manifestation of disease (403,404).

Treatment

The treatment of patients with early dysgerminoma is primarily surgical, including resection of the primary lesion and proper surgical staging. Chemotherapy or radiation is administered to patients with metastatic disease. Because the disease principally affects girls and young women, special consideration must be given to the preservation of fertility and use of chemotherapy as needed whenever possible.

An algorithm for the management of ovarian dysgerminoma is presented in Fig. 35.17.

Surgery

The minimal surgical operation for ovarian dysgerminoma is a unilateral oophorectomy (405). If there is a desire to preserve fertility, the contralateral ovary, fallopian tube, and uterus should be left *in situ*, even in the presence of metastatic disease, because of the sensitivity of the tumor to chemotherapy. If fertility need not be preserved, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy for patients with advanced disease (407,408). For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left *in situ* for possible future embryo transfer (402). Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.

In patients in whom the neoplasm appears on inspection to be confined to the ovary, a careful staging operation should be undertaken to determine the presence of any occult metastatic disease. All peritoneal surfaces should be inspected and palpated, and any suspicious lesions should be sampled for biopsy. Unilateral pelvic lymphadenectomy and at least careful palpation and biopsy of enlarged para-aortic nodes are particularly important parts of the staging. These tumors often metastasize to the para-aortic nodes around the renal vessels. Dysgerminoma is the only germ cell tumor that tends to be bilateral, and not all of the bilateral lesions are associated with obvious ovarian enlargement. Therefore, bisection of the contralateral ovary and excisional biopsy of any suspicious lesion are desirable (405,406,407,408). If a small contralateral tumor is found, it may be possible to resect it and preserve some normal ovary.

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred after unilateral salpingo-oophorectomy without surgical staging. The options for such patients are (i) repeat laparotomy for surgical staging, (ii) regular pelvic and abdominal CT scans, or (iii) adjuvant chemotherapy. As these are rapidly growing tumors, our preference is to perform regular surveillance. Tumor markers (LDH, AFP, and μ -hCG) should also be monitored in case occult mixed germ cell elements are present.

Radiation Therapy

Dysgerminomas are very sensitive to radiation therapy, and doses of 2,500 to 3,500 cGy may be curative, even for gross metastatic disease. Loss of fertility is a problem with radiation therapy, however, so radiation should rarely be used as first-line treatment (407).

Chemotherapy

There have been numerous reports of successful control of metastatic dysgerminomas with systemic chemotherapy, and this technique should now be regarded as the treatment of choice

the preservation of fertility (420,421,422,423).

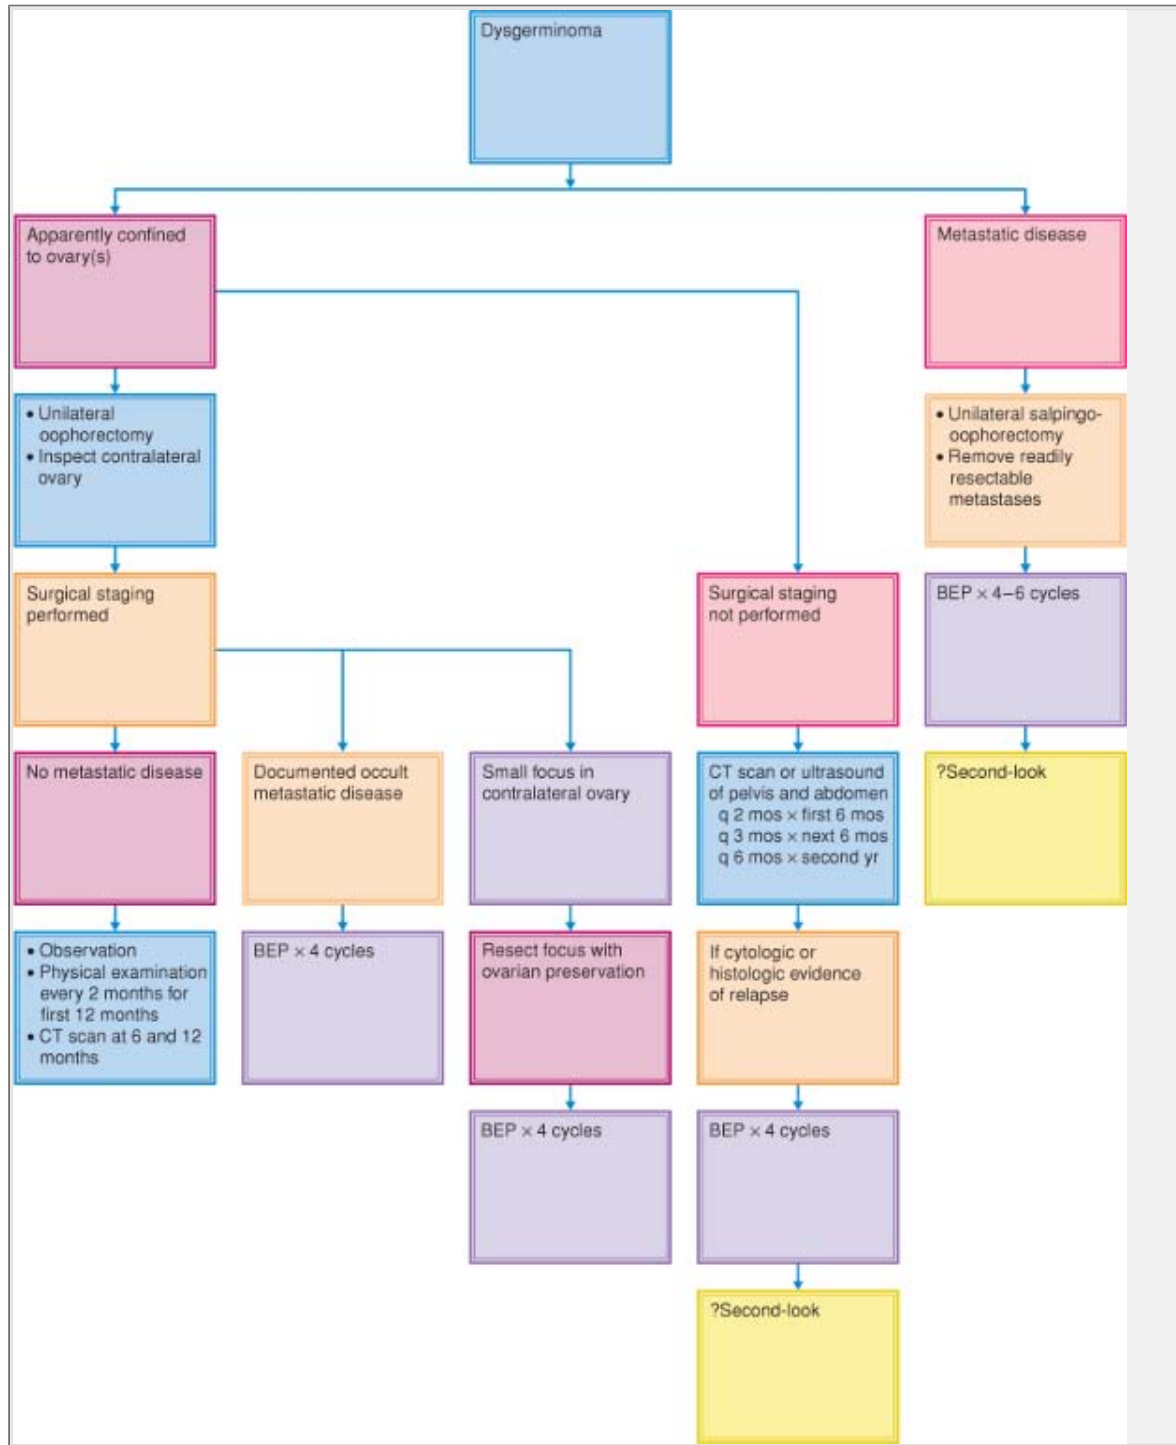

Figure 35.17 Management of dysgerminoma of the ovary. (From **Berek JS, Hacker NF.** *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005:518, with permission.)

Table 35.6 Combination Chemotherapy for Germ Cell Tumors of the Ovary	
Regimen and Drugs	Dose and Schedule ^a
BEP	
Bleomycin	15 units/m ² /week × 5; then on day 1 of course 4
Etoposide	100 mg/m ² /day × 5 days every 3 weeks
Cisplatin	20 mg/m ² /day × 5 days, or 100 mg/m ² /day × 1 day every 3 weeks
VBP	
Vinblastine	0.15 mg/kg days 1 and 2 every 3 weeks
Bleomycin	15 units/m ² /week × 5; then on day 1 of course 4
Cisplatin	100 mg/m ² on day 1 every 3 weeks
VAC	
Vincristine	1–1.5 mg/m ² on day 1 every 4 weeks
Actinomycin D	0.5 mg/day × 5 days every 4 weeks
Cyclophosphamide	150 mg/m ² /day × 5 days every 4 weeks

^aAll doses given intravenously.

P.1510

P.1511

The most frequently used chemotherapeutic regimens for germ cell tumors are **BEP (bleomycin, etoposide, and cisplatin)**, **VBP (vinblastine, bleomycin, and cisplatin)**, and **VAC (vincristine, actinomycin, and cyclophosphamide)** (407,408,409,410,411,412,413,414,415,416,417,418,419,420,421,422,423,424,425) (Table 35.6).

The GOG studied three cycles of the EC regimen, consisting of *etoposide* (120 mg/m² intravenously on days 1, 2, and 3 every 4 weeks) and *carboplatin* (400 mg/m² intravenously on day 1 every 4 weeks) for patients with completely resected ovarian dysgerminoma, stages Ib, Ic, II, or III (416). The results showed a sustained disease-free remission rate of 100%.

For patients with advanced, incompletely resected germ cell tumors, the GOG studied *cisplatin*-based chemotherapy in two consecutive protocols (409,410). In the first study, patients received four cycles of *vinblastine* (12 mg/m² every 3 weeks), *bleomycin* (20 units/m² intravenously every week for 12 weeks), and *cisplatin* (20 mg/m² per day intravenously for 5 days every 3 weeks). Patients with persistent or progressive disease at second-look

laparotomy were treated with six cycles of VAC. In the second trial, patients received three cycles of BEP initially, followed by consolidation with VAC, which was later discontinued in patients with dysgerminomas (410). The VAC consolidation after BEP in patients with tumors other than dysgerminoma is still being investigated, but VAC does not appear to improve the outcome of the BEP regimen. A total of 20 evaluable patients with stage III and IV dysgerminoma were treated in these two protocols, and 19 are alive and free of disease after 6 to 68 months (median = 26 months). Fourteen of these patients had a second-look laparotomy, and all findings were negative. Another study at MD Anderson Cancer Center (413) used BEP in 14 patients with residual disease, and all patients were free of disease during long-term follow-up. **These results suggest that patients with advanced-stage, incompletely resected dysgerminoma have an excellent prognosis when treated with cisplatin-based combination chemotherapy. The best regimen is four cycles of BEP based on the data from testicular cancers** (424,425).

There appears to be no need to perform a second-look laparotomy in patients with dysgerminoma whose macroscopic disease was all resected during the primary operation (426,427,428). In patients with macroscopic residual disease at the start of chemotherapy, we

P.1512

prefer to perform a second-look operation, because second-line therapy is available and the earlier persistent disease is identified, the better the prognosis should be.

Recurrent Disease

About 75% of recurrences occur within the first year after initial treatment (2,395,396,397), the most common sites being the peritoneal cavity and the retroperitoneal lymph nodes. These patients should be treated with either radiation or chemotherapy, depending on their primary treatment. Patients with recurrent disease who have had no therapy other than surgery should be treated with chemotherapy. If prior chemotherapy with BEP has been given, POMB-ACE (*vincristine, bleomycin, cisplatin, etoposide, actinomycin D, and cyclophosphamide*) may be used (Table 35.7), and consideration should be given to the use of high-dose chemotherapy (e.g., with *carboplatin* and *etoposide*). Alternatively, radiation therapy is effective for this disease, with the major disadvantage being loss of fertility if pelvic and abdominal irradiation is required.

Pregnancy

Because dysgerminomas tend to occur in young patients, they may coexist with pregnancy. When a stage Ia cancer is found, the tumor can be removed intact and the pregnancy continued. For patients with more advanced disease, continuation of the pregnancy

P.1513

depends on the gestational age of the fetus. Chemotherapy can be given in the second and third trimesters in the same dosages as given for the nonpregnant patient without apparent detriment to the fetus (420).

Table 35.7 POMB-ACE Chemotherapy for Germ Cell Tumors of the Ovary

POMB

Day 1	<i>Vincristine</i> 1 mg/m ² IV; <i>methotrexate</i> 300 mg/m ² as a 12-hr infusion,
Day 2	<i>Bleomycin</i> 15 mg as a 24-hr infusion; <i>folinic acid</i> rescue started at 24 hrs after the start of <i>methotrexate</i> in a dose of 15 mg every 12 hrs for 4 doses
Day 3	<i>Bleomycin</i> infusion 15 mg by 24-hr infusion
Day 4	<i>Cisplatin</i> 120 mg/m ² as a 12-hr infusion, given with hydration and 3 g magnesium sulfate supplementation

ACE

Days 1–5	<i>Etoposide</i> (VP16-213) 100 mg/m ² , days 1–5
Days 3, 4, 5	<i>Actinomycin D</i> 0.5 mg IV, days 3, 4, and 5
Day 5	<i>Cyclophosphamide</i> 500 mg/m ² IV, day 5

OMB

Day 1	<i>Vincristine</i> 1 mg/m ² IV; <i>methotrexate</i> 300 mg/m ² as a 12-hr infusion
Day 2	<i>Bleomycin</i> 15 mg by 24-hr infusion; <i>folinic acid</i> rescue started at 24 hrs after start of <i>methotrexate</i> in a dose of 15 mg every 12 hrs for 4 doses
Day 3	<i>Bleomycin</i> 15 mg by 24-hr infusion

IV, intravenous.

The sequence of treatment schedules is two courses of POMB followed by ACE. POMB is then alternated with ACE until patients are in biochemical remission as measured by human chorionic gonadotropin (hCG) and α -fetoprotein (AFP), placental alkaline phosphatase (PLAP), and lactate dehydrogenase (LDH). The usual number of courses of POMB is three to five. Following biochemical remission, patients alternate ACE with OMB until remission has been maintained for approximately 12 weeks. The interval between courses of treatment is kept to the minimum (usually 9 to 11 days). If delays are caused by myelosuppression after courses of ACE, the first 2 days of etoposide are omitted from subsequent courses of ACE.

From **Newlands ES, Southall PJ, Paradinas FJ, et al.** Management of ovarian germ cell tumours. In: **Williams CJ, Kaikorian JG, Green MR, et al.**, eds. *Textbook of uncommon cancer*. New York, NY: John Wiley and Sons, 1988:47, with permission.

Prognosis

For patients whose initial disease is stage Ia (i.e., a unilateral

encapsulated dysgerminoma), unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95% (406,407). The features that have been associated with a higher tendency to recur include lesions larger than 10 to 15 cm in diameter, age younger than 20 years, and a microscopic pattern that includes numerous mitoses, anaplasia, and a medullary pattern (2,399).

Although in the past, surgery for advanced disease followed by pelvic and abdominal irradiation resulted in a 5-year survival rate of 63% to 83%, cure rates of 85% to 90% for this same group of patients are now being reported with the use of VBP, BEP, or EC combination chemotherapy (407,408,409,410,411,412,413,414,415,416,417,418,419,420,421,422,423,424).

Immature Teratomas

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell malignancy. This lesion represents 10% to 20% of all ovarian malignancies seen in women younger than 20 years and 30% of the deaths from ovarian cancer in this age group (2). About 50% of pure immature teratomas of the ovary occur in women between the ages of 10 and 20 years, and they rarely occur in postmenopausal women.

Pathology and Grading

Of fundamental importance in the understanding of the teratoma is a recognition of the maturation of the various elements. If maturation continues along normal lines, the mature or adult teratoma results, and the prognosis is excellent. Conversely, abnormal maturation of these elements produces undisciplined growth that can be fatal. Teratomas containing immature elements, although relatively rare, have been recognized more commonly during the past two decades (Fig. 35.18). Among the tumors with embryonal elements, those containing neural tissues demonstrate most clearly the importance of the ability to mature. Gliomatosis peritonei is the most dramatic demonstration of the significance of maturation, because most patients with these tumors have survived, even with this disseminated disease (3).

Immature teratomas are classified according to a grading system (grades 1 to 3) that is based on the degree of differentiation and the quantity of immature tissue (429). A determination of the amount of undifferentiated neural tissue is of prognostic importance. A grade 1 tumor is one in which less than one low-power microscopic field (LPF) contains immature neural elements, a grade 2 tumor has one to three LPFs with immature elements, and a grade 3 tumor has more than three LPFs with these elements. **The prognosis can be correlated with the grade determined by the quantity of these immature neural elements; with a**

higher grade, there is a poorer prognosis (2,3).

Previously, most malignant teratomas were classified as secondary neoplasms developing in a primarily benign teratoma. During the last decade, lesions composed primarily of immature embryonal or extraembryonal elements have become more prevalent, and the basic demonstration of malignancy is the inability of the tissue to mature rather than the presence of individual cell anaplasia (i.e., the mitotic activity may be low). This unique aspect is demonstrated by an absence of aneuploidy in the few cases that have been studied (3).

Figure 35.18 Ovarian teratoma. This tumor contains both mature and immature neural elements with a neural tube–like structure near its center.

Malignant change in benign cystic teratomas has been recorded as occurring in 0.5% to 2% of cases, usually in patients older than 40 years of age (429). The most common malignancy developing in the initially benign teratoma is squamous cell carcinoma.

Other neoplasms have been reported (e.g., melanomas, which may arise from the skin or retinal anlage, and sarcomas, including leiomyosarcomas and mixed mesodermal tumors) (2). Carcinomas may arise from any of the epithelial elements.

Diagnosis

The preoperative evaluation and differential diagnosis of immature teratomas are the same as for other germ cell tumors. Some of these lesions will contain calcifications similar to those of mature teratomas, which can be detected by a radiograph of the abdomen or by ultrasonography. Rarely, they are associated with the production of steroid hormones and can be accompanied by sexual pseudoprecocity (395,396,397). Tumor markers are negative unless a mixed germ cell tumor is present.

Treatment

Surgery

In a premenopausal patient whose lesion appears to be confined to a single ovary, unilateral oophorectomy and surgical staging should be performed. For a postmenopausal patient, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary (3,429).

Any lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Bloodborne metastases to organ parenchyma, such as the lungs, liver, or brain, are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are poorly differentiated (i.e., grade 3).

P.1515

It is unclear whether debulking of metastatic implants enhances the response to combination chemotherapy (430,431,432,433,434,435,436,437). Unlike epithelial lesions, immature teratomas are much more chemosensitive. Because cure ultimately depends on the ability to deliver chemotherapy promptly, any surgical resection that may be potentially morbid and therefore delay chemotherapy should be resisted.

Chemotherapy

Patients with stage Ia, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. For patients whose tumors are stage Ia, grades 2 or 3, adjuvant chemotherapy should be used

(411,412,413,413,426,427,428,429,430,431,432,433,434,435,436,437,438,439,440,441,442,443,444).

Chemotherapy is also indicated for patients who have ascites, regardless of tumor grade. The most frequently used combination chemotherapeutic regimen in the past has been VAC (438,439,440). However, in a GOG study, the relapse-free survival rate in patients with incompletely resected disease was only 75% (440). The newer approach has been to incorporate *cisplatin* into the primary treatment of these tumors, and most of the experience has been with the VBP and BEP regimens (411,412,444). No direct comparison of these regimens with VAC has been reported, but the BEP combination can save some patients who have persistent or recurrent disease after VAC (434,435,444).

The GOG has been prospectively studying three courses of BEP therapy for patients with completely resected stage I, II, and III ovarian germ cell tumors (411,412,444). Overall, the toxicity has been acceptable, and 91 of 93 patients whose nondysgerminomatous tumors were treated are clinically free of disease. **Thus, the BEP regimen, which is used more extensively for testicular cancer, seems to be superior to the VAC regimen in the treatment of completely resected nondysgerminomatous germ cells tumors of the ovary.** Because some tumors can progress rapidly, treatment should be initiated as soon as possible after surgery, preferably within 7 to 10 days (445).

The switch from VBP to BEP has been prompted by the experience in patients with testicular cancer, in which the replacement of *vinblastine* with *etoposide* has been associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), especially less neurologic and gastrointestinal toxicity. Furthermore, the use of *bleomycin* seems to be important for this group of patients. In a randomized study of three cycles of *etoposide* plus *cisplatin* with or without *bleomycin* (EP versus BEP) in 166 patients with germ cell tumors of the testes, the BEP regimen had a relapse-free survival rate of 84% compared with 69% for the EP regimen ($p = 0.03$) (424). In addition, *cisplatin* may be slightly better than *carboplatin* in the setting of metastatic germ cell tumors. One hundred ninety-two patients with germ cell tumors of the testes were entered into a study of four cycles of *etoposide* plus *cisplatin* (EP) versus four cycles of *etoposide* plus *carboplatin* (EC). There have been three relapses with the EP regimen versus seven with the EC regimen, although the overall survival of the two groups is identical thus far (425). In view of these results, **BEP is the preferred treatment regimen for patients with gross residual disease and has replaced the VAC regimen for patients with completely resected disease.**

The necessity of adjuvant chemotherapy for all patients with resected immature teratomas is uncertain. Several reports support the successful management of these patients with surgery alone (436,437,446). In the largest series, an intergroup study from the Pediatric Oncology Group and the Children's Cancer Group, 73 children with immature teratoma (44 of ovarian origin) underwent surgery followed by surveillance. With a median follow-up of 35 months, the overall 3-year event-free survival rates for all patients and those with ovarian teratomas were 93% and 100%, respectively. Thirteen of the 44 girls with an immature ovarian teratoma had microscopic foci of yolk sac tumor in the teratoma; one

developed recurrent disease and was successfully salvaged with *cisplatin*-based chemotherapy. Of note, 82% of the tumors were grade 1 or 2; however, 92% of those with foci of yolk sac tumor were grade 2 or 3.

Patients who have immature teratomas with malignant squamous elements seem to have a poorer prognosis than those whose tumors are without these elements (415,446,447). The treatment in these patients is also the BEP regimen.

Radiation Therapy

Radiation therapy is generally not used in the primary treatment of patients with immature teratomas. Furthermore, there is no evidence that the combination of chemotherapy and radiation has a higher rate of disease control than chemotherapy alone. Radiation therapy should be reserved for patients with localized persistent disease after chemotherapy (407,426).

Second-look Laparotomy

The need for a second-look operation has been questioned (427,428). It seems not to be justified in patients who have received chemotherapy in an adjuvant setting (i.e., stage Ia, grades 2 and 3), because chemotherapy in these patients is so effective. Second-look laparotomy in patients with macroscopic residual disease at the start of chemotherapy may be of value in selected patients, because there are no reliable tumor markers for this disease and such patients are at higher risk of failure.

If a second-look operation is performed, sampling of any peritoneal lesions should be performed and the retroperitoneal lymph nodes should be evaluated carefully. If only mature elements are found during the second-look procedure, chemotherapy should be discontinued. If the presence of persistent immature elements is documented, alternative chemotherapy should be employed. An enlarged contralateral ovary may contain a benign cyst or a mature cystic teratoma, which may be managed with an ovarian cystectomy (395,397).

Prognosis

The most important prognostic feature of the immature teratoma is the grade of the lesion (2,429). In addition, the stage of disease and the extent of tumor at the initiation of treatment have an impact on the curability of the lesion. Patients whose tumors have been incompletely resected before treatment have a significantly lower probability of 5-year survival than those whose lesions have been completely resected (i.e., 94% versus 50%) (397). Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70% to 80%, and it is 90% to 95% for patients with surgically determined stage I

lesions (426,429,432).

The degree or grade of immaturity generally correlates with the metastatic potential and curability. The 5-year survival rates for all stages combined have been reported to be 82%, 62%, and 30% for patients with grades 1, 2, and 3, respectively (429). Occasionally, these tumors are associated with mature or low-grade glial elements that have implanted throughout the peritoneum, and such patients usually have a favorable long-term survival (2,3).

Endodermal Sinus Tumors

Endodermal sinus tumors (EST) have also been referred to as *yolk sac carcinomas* because they are derived from the primitive yolk sac (2,3). These lesions are the third most frequent malignant germ cell tumors of the ovary. ESTs occur in patients with a median age of 16 to 18 years (2,3,448). About one third of the patients are premenarcheal at the time of diagnosis. Abdominal or pelvic pain is the most frequent initial symptom, occurring in about 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients (396).

Pathology

The gross appearance of an EST is soft grayish-brown. Cystic areas caused by degeneration are present in these rapidly growing lesions. The capsule is intact in most cases.

Figure 35.19 Endodermal sinus tumor of the ovary. Note the classic Schiller-Duval body with its central vessel and mantle of endoderm.

The EST is unilateral in 100% of cases; thus, biopsy of the opposite ovary in such young patients is contraindicated. The association of such lesions with gonadal dysgenesis must be appreciated, and chromosomal analysis should be performed preoperatively in premenarcheal patients (3).

Microscopically, the characteristic feature is the endodermal sinus, or *Schiller-Duval body* (Fig. 35.19). The cystic space is lined with a layer of flattened or irregular endothelium into which projects a glomeruluslike tuft with a central vascular core. These structures vary throughout the tumor, and the reticular, myxoid elements represent undifferentiated mesoblast. The lining of the papillary infolding and the cavity is irregular, with an occasional cell containing clear, glassy cytoplasm, simulating the hobnail appearance of the epithelium in clear cell tumors. The association of EST with dysgerminoma must be emphasized if diagnosis and therapy are to be optimal (2,3).

Most EST lesions secrete AFP and, rarely, they may elaborate detectable AAT. AFP can be demonstrated in the tumor by means of the immunoperoxidase technique. There is a good correlation between the extent of disease and the level of AFP, although discordance also has been observed. The serum level of these markers, particularly AFP, is useful in monitoring the patient's response to treatment (448,449,450,451,452).

Treatment

Surgery

The treatment of the EST consists of surgical exploration, unilateral salpingo-oophorectomy, and a frozen section for diagnosis. The addition of a hysterectomy and contralateral salpingo-oophorectomy does not alter outcome (397,450). Any gross metastases should be removed, if possible, but thorough surgical staging is not indicated because all patients need chemotherapy. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median, 15 cm) in the GOG series (397,444).

P.1518

Bilaterality is not seen in these lesions, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71%, stage I; 6%, stage II; and 23%, stage III (452).

Chemotherapy

All patients with ESTs are treated with either adjuvant or therapeutic chemotherapy. Before the routine use of combination chemotherapy for this disease, the 2-year survival rate was only about 25%. After the introduction of the VAC regimen, this rate improved to 60% to 70%, indicating the chemosensitivity of most of these tumors (439,440). Furthermore, with conservative surgery and adjuvant chemotherapy, fertility can be preserved as with other germ cell tumors.

VPB is a more effective regimen than VAC in the treatment of EST, particularly in the treatment of measurable or incompletely resected tumors (444). In the GOG series, only about 20% of patients with residual metastatic disease responded completely to the VAC regimen, whereas about 60% of those treated with VBP had a complete response (412). In addition, this regimen may save some patients in whom VAC therapy has failed.

Workers at the Charing Cross Hospital in London have developed the POMB-ACE regimen for high-risk germ cell tumors of any histologic type (453) (see Table 35.7). This protocol introduces seven drugs into the initial management, which is intended to minimize the chances of developing drug resistance. Drug resistance is particularly relevant for patients

with massive metastatic disease, and the POMB-ACE regimen may be used as primary therapy for such patients as well as for those with liver or brain metastases. The POMB schedule is only moderately myelosuppressive, so the intervals between each course can be kept to a maximum of 14 days (usually 9 to 11 days), thereby minimizing the time for tumor regrowth between courses. When *bleomycin* is given by a 48-hour infusion, pulmonary toxicity is reduced. With a maximum of 9 years of follow-up, the Charing Cross group has seen no long-term side effects for patients treated with POMB-ACE. Children have developed normally, menstruation has been physiologic, and several have completed normal pregnancies.

***Cisplatin*-containing combination chemotherapy, preferably BEP or POMB-ACE, should be used as primary chemotherapy for ESTs.** The optimal number of treatment cycles has not been established. The GOG protocols have used three to four treatment cycles given every 4 weeks (444,453). Alternatively, three cycles can be given to patients with stage I and completely resected disease, and two further cycles can be given after negative tumor marker status is achieved by patients with macroscopic residual disease before chemotherapy.

Second-look Laparotomy

The value of a second-look operation has yet to be established in patients with an EST. It seems reasonable to omit the operation for patients with pure low-stage lesions and for patients whose AFP values return to normal and remain normal for the balance of their treatment (451,452). There have been reported cases in which the AFP has returned to normal despite persistent measurable disease; some of these cases have been mixed germ cell tumors (452). For patients whose **AFP** levels do not return to normal, persistent disease can be assumed and alternative chemotherapy (e.g., **POMB-ACE**) can be offered.

Rare Germ Cell Tumors of the Ovary

Embryonal Carcinoma

Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and

cytotrophoblastic cells. The patients are very young; ages ranged between 4 and 28 years (median, 14 years) in two series (454). Older patients have been reported (455). Embryonal carcinomas may secrete estrogens, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding (2). The clinical picture is otherwise similar to that of the EST. The primary lesions tend to be large, and about two thirds are confined to one ovary at the time of diagnosis. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy (451). **The treatment of embryonal carcinomas is the same as for the EST (i.e., a unilateral oophorectomy followed by combination chemotherapy with BEP)** (412,444). Radiation does not seem to

be useful for primary treatment.

Choriocarcinoma of the Ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries (456). Most patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient's response to treatment. **In the presence of high hCG levels, isosexual precocity has been seen to occur in about 50% of patients whose lesions appear before menarche** (456,457).

There are only a few limited reports on the use of chemotherapy for nongestational choriocarcinomas, but complete responses have been reported with the MAC (*methotrexate, actinomycin D, and cyclophosphamide*) regimen used in a manner described for gestational trophoblastic disease (458) (see Chapter 37). Alternatively, the BEP regimen can be used. The prognosis of ovarian choriocarcinomas has been poor, with most patients having metastases to organ parenchyma at the time of diagnosis.

Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of "embryoid bodies." This tumor replicates the structures of early embryonic differentiation (i.e., the three somatic layers: endoderm, mesoderm, and ectoderm) (2,399). The lesion tends to occur in very young, premenarcheal girls with signs of pseudopuberty and elevated AFP and hCG titers. Anecdotally, the VAC chemotherapeutic regimen has been reported to be effective (399).

Mixed Germ Cell Tumors

Mixed germ cell malignancies of the ovary contain two or more elements of the lesions described above. In one series (458), the most common component of a mixed malignancy was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16%. **The most frequent combination was a dysgerminoma and an EST. The mixed lesions may secrete either AFP, hCG, or both or neither of these markers, depending on the components.**

These lesions should be managed with combination chemotherapy, preferably BEP. The serum marker, if positive initially, may become negative during chemotherapy, but this finding may reflect regression of only a particular component of the mixed lesion. Therefore, for these patients, a second-look laparotomy may be indicated to determine the precise response to therapy if macroscopic disease was present at initiation of chemotherapy.

The most important prognostic features are the size of the primary tumor and the

relative size of its most malignant component (458). For stage Ia lesions smaller than 10 cm, survival is 100%. Tumors composed of less than one third EST, choriocarcinoma, or grade 3 immature teratoma also have an excellent prognosis, but it is less favorable when these components constitute most of the mixed lesions.

Late Effects of Treatment of Malignant Germ Cell Tumors of the Ovary

Although there are substantial data regarding late effects of *cisplatin*-based therapy in men with testicular cancer, sparse information is available for women with ovarian germ cell tumors. Among the adverse events from chemotherapy reported in men are renal and gonadal dysfunction, neurotoxicity, cardiovascular toxicity, and secondary malignancies.

Gonadal Function

An important cause of infertility in patients with ovarian germ cell tumors is unnecessary bilateral salpingo-oophorectomy and hysterectomy. **Although temporary ovarian dysfunction or failure is common with *platinum*-based chemotherapy, most women will resume normal ovarian function, and childbearing is usually preserved** (400,406,408,460,461,462,463,464). In one representative series of 47 patients treated with combination chemotherapy for germ cell malignancies, 91.5% resumed normal menstrual function, and there were 14 healthy live births and no birth defects (422). Factors such as older age at initiation of chemotherapy, greater cumulative drug dose, and longer duration of therapy all have an adverse effect on future gonadal function (461).

Secondary Malignancies

An important cause of late morbidity and mortality in patients receiving chemotherapy for germ cell tumors is the development of secondary tumors. ***Etoposide* in particular has been implicated in the development of treatment-related leukemias** (465,466).

The chance of developing treatment-related leukemia following *etoposide* is dose related. **The incidence of leukemia is approximately 0.4% to 0.5%** (representing a 30-fold increased likelihood) in patients receiving a cumulative *etoposide* dose of less than 2,000 mg/m²(465), compared with as much as 5% (representing a 336-fold increased likelihood) in those receiving more than 2,000 mg/m²(465). In a typical three- or four-cycle course of BEP, patients receive a cumulative *etoposide* dose of 1,500 or 2,000 mg/m², respectively.

Despite the risk of secondary leukemia, risk-benefit analyses have concluded that *etoposide*-containing chemotherapy regimens are beneficial in advanced germ cell tumors; one case of treatment-induced leukemia would be expected for every 20 additionally cured patients

who receive BEP as compared with PVB. The risk-benefit balance for low-risk disease, or for high-dose *etoposide* in the salvage setting, is less clear (466).

Sex Cord—stromal

Sex cord—stromal tumors of the ovary account for about 5% to 8% of all ovarian Tumors malignancies (2,3,395,396,467,468,469,470,471,472,473). This group of ovarian neoplasms is derived from the sex cords and the ovarian stroma or mesenchyme. The tumors usually are composed of various combinations of elements, including the “female” cells (i.e., granulosa and theca cells) and “male” cells (i.e., Sertoli and Leydig cells), as well as morphologically indifferent cells. A classification of this group of tumors is presented in Table 35.8.

Granulosa-stromal Cell Tumors

Granulosa-stromal cell tumors include granulosa cell tumors, thecomas, and fibromas. The granulosa cell tumor is a low-grade malignancy; rarely, thecomas and fibromas have morphologic features of malignancy and then may be referred to as fibrosarcomas.

Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder are found in women throughout their reproductive and postmenopausal years (470). Granulosa cell tumors are bilateral in only 2% of patients.

From **Young RE, Scully RE**. Ovarian sex cord–stromal tumors: recent progress. *Int J Gynecol Pathol* 1980;1:153, with permission.

Pathology

Granulosa cell tumors range from a few millimeters to 20 centimeters or more in diameter. **The tumors are rarely bilateral**, and they have a smooth, lobulated surface. The solid portions of the tumor are granular, frequently trabeculated, and are commonly yellow or gray-yellow in color. The granulosa-theca cell tumor is probably the most inaccurately diagnosed lesion of the female gonad. Of 477 ovarian tumors from the Emil Novak Ovarian Tumor Registry diagnosed initially as granulosa-theca cell tumors, almost 15% were reclassified after histologic review. Lesions misdiagnosed as granulosa cell tumors included metastatic carcinomas, teratoid tumors, and poorly differentiated mesothelial tumors (467).

The classic granulosa cell is round or ovoid with scant cytoplasm. The nucleus contains compact, finely granular cytoplasm suggesting hyperchromatism (3). "Coffee bean" grooved nuclei are common, as are mitoses, thus simulating the corresponding elements in the normal, mature follicle. Conversely, if the epithelial elements are bizarre with atypical mitoses, the lesion should not be categorized as a poorly differentiated granulosa cell tumor but instead as an undifferentiated mesothelial neoplasm. **In the most common variety, the granulosa cells show a tendency to arrange themselves in small clusters or rosettes around a central cavity, so there is a resemblance to primordial follicles (i.e., Call-Exner bodies)** (Fig. 35.20). The stroma is similar to the theca and may be luteinized. In children and adolescents, the granular cell tumors are often cystic, contain luteinized cells, and can be associated with precocious puberty.

Diagnosis

Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder is distributed throughout the reproductive and postmenopausal years (470,471,472,473). They are bilateral in only 2% of patients.

Figure 35.20 Granulosa cell tumor of the ovary. Note the classic Call-Exner bodies with a minimal stromal component in this tumor of folliculoid pattern. (Arrow points to an example.)

Of the rare prepubertal lesions, 75% are associated with sexual pseudoprecocity because of the estrogen secretion (470). For women of reproductive age, most patients have menstrual irregularities or secondary amenorrhea, and cystic hyperplasia of the endometrium is frequently present. For postmenopausal women, abnormal uterine bleeding is frequently the initial symptom. Indeed, the estrogen secretion in these patients can be sufficient to stimulate the development of endometrial cancer. **Endometrial cancer occurs in association with granulosa cell tumors in at least 5% of cases, and 25% to 50% are associated with endometrial hyperplasia** (2,456,467,468,469,470,470,472).

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in about 10% of cases, and rarely a pleural effusion is present (467,468,469,470). Granulosa tumors tend to be hemorrhagic; occasionally, they

rupture and produce a hemoperitoneum.

Granulosa cell tumors are usually stage I at diagnosis but may recur 5 to 30 years after initial diagnosis (469). The tumors may also spread hematogenously, and metastases can develop in the lungs, liver, and brain years after initial diagnosis. When granulosa cell tumors do recur, they can progress quite rapidly. Malignant thecomas are extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (467). **Inhibin is secreted by some granulosa cell tumors and is a useful marker for the disease** (474,475,476,477,478). An elevated serum inhibin level in a premenopausal woman presenting with amenorrhea and infertility is suggestive of a granulosa cell tumor (479).

Treatment

The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy; radiation and

P.1523

chemotherapy are reserved for the treatment of recurrent or metastatic disease (470,471,472,473,474,475,476,476,480,481,482,483).

Surgery

Because granulosa cell tumors are bilateral in only about 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage Ia tumors in children or in women of reproductive age (468). At the time of laparotomy, if a granulosa cell tumor is identified by frozen section, a staging operation is performed, including an assessment of the contralateral ovary. If the opposite ovary appears enlarged, it should be sampled for biopsy. For perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. **For premenopausal patients in whom the uterus is left *in situ*, an endometrial biopsy should be performed because of the possibility of a coexistent adenocarcinoma of the endometrium** (470).

Radiation Therapy

There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic irradiation may help to palliate isolated pelvic recurrences (470,481).

Chemotherapy

There is no evidence that adjuvant chemotherapy will prevent recurrence of disease (483,484,485,486). Metastatic lesions and recurrences have been treated with a variety

of antineoplastic drugs. Although the data are inconclusive, four to six cycles of BEP in selected patients with stage III/IV disease is an acceptable regimen (480). In a GOG study, 37% (14 of 30) patients treated with BEP had a negative second-look laparotomy, and completely responding patients had a median time to progression of 24.4 months (487). The use of hormonal agents, such as progestins, antiestrogens, and aromatase inhibitors, have been suggested, but there are limited data available to suggest effectiveness (480).

Prognosis

Granulosa cell tumors have a prolonged natural history and a tendency toward late relapse, reflecting their low-grade biology. As such, 10-year survival rates of about 90% have been reported, with 20-year survival rates dropping to 75% (468,469,470,470,479,480). Most histologic types have the same prognosis, but patients with the more poorly differentiated diffuse or sarcomatoid type tend to do worse (467).

The DNA ploidy of the tumors has recently been correlated with survival. Holland and colleagues (484) reported DNA aneuploidy in 13 of 37 patients (35%) with primary granulosa cell tumors. The presence of residual disease was found to be the most important predictor of progression-free survival, but DNA ploidy was an independent prognostic factor. **Patients with residual-negative DNA diploid tumors had a 10-year progression-free survival of 96%.**

Juvenile granulosa cell tumors of the ovary are rare and make up less than 5% of ovarian tumors in childhood and adolescence (488). About 90% are diagnosed in stage I, and they have a favorable prognosis. The juvenile subtype behaves less aggressively than the adult type. Advanced-stage tumors have been successfully treated with platinum-based combination chemotherapy, e.g., BEP (480,487).

Sertoli-Leydig Tumors

Sertoli-Leydig tumors occur most frequently in the third and fourth decades of life; 75% of the lesions are seen in women younger than 40 years. These lesions are extremely rare and account for less than 0.2% of ovarian cancers (2). Sertoli-Leydig cell tumors are most frequently low-grade malignancies, although occasionally a poorly differentiated variety may behave more aggressively (489).

The tumors typically produce androgens, and clinical virilization is noted in 70% to 85% of patients (489). Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, deepening of the voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulphate (2,492). Rarely, the Sertoli-Leydig tumor can be associated with manifestations of estrogenization (i.

e., isosexual precocity, irregular, or postmenopausal bleeding).

Treatment

Because these low-grade lesions are only rarely bilateral (<,1%), the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary for patients who are in their reproductive years (3,470). For older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate (490,491).

There are insufficient data to document the utility of radiation or chemotherapy for patients with persistent disease, but some responses in patients with measurable disease have been reported with pelvic irradiation and the VAC chemotherapy regimen (3,397).

Prognosis

The 5-year survival rate is 70% to 90%, and recurrences thereafter are uncommon (3,492). Most fatalities occur in the presence of poorly differentiated lesions XS.

Uncommon Ovarian Cancers

There are several varieties of malignant ovarian tumors that together constitute only 0.1% of ovarian malignancies (2). Two of these lesions are the lipoid (or lipid) cell tumors and the primary ovarian sarcomas.

Lipoid Cell Tumors

Lipoid cell tumors are believed to arise in adrenal cortical rests that reside in the vicinity of the ovary. More than 100 cases have been reported, and bilateral disease has been noted in only a few (2). Most are associated with virilization and, occasionally, with obesity, hypertension, and glucose intolerance reflecting corticosteroid secretion. Rare cases of estrogen secretion and isosexual precocity have been reported.

Most of these tumors have benign or low-grade behavior, but about 20%, most of which are initially larger than 8 cm in diameter, are associated with metastatic lesions. Metastases are usually in the peritoneal cavity but rarely occur at distant sites. The primary treatment is surgical extirpation of the primary lesion. There are no data regarding the effectiveness of radiation or chemotherapy for this disease.

Sarcomas

Malignant mixed mesodermal sarcomas of the ovary are extremely rare; only about 100 cases have been reported. Most lesions are heterologous, and 80% occur in postmenopausal women. The signs and symptoms are similar to those of most ovarian

malignancies. These lesions are biologically aggressive, and most patients have evidence of metastases.

There is no effective treatment for ovarian sarcomas, and most patients die within 2 years. *Doxorubicin*, with or without *cyclophosphamide*, has produced an occasional partial response, and *cisplatin* is currently undergoing clinical trials (493,494,495,496,497). For patients in whom all macroscopic disease can be resected, we have observed disease-free survival of more than 3 years in two patients treated with six cycles of *cisplatin* and *epirubicin*.

Small Cell Carcinomas

This rare tumor occurs at an average age of 24 years (range 2 to 46 years) (498). The tumors are all bilateral. Approximately two thirds of the tumors are accompanied by paraendocrine hypercalcemia. This tumor accounts for one half of all of the cases of hypercalcemia associated with ovarian tumors. About 50% of the tumors have spread beyond the ovaries when they are diagnosed (498).

The management of these malignancies consists of surgery followed by platinum-based chemotherapy or radiation therapy or both. In addition to the primary treatment of the disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates or *calcitonin*. The prognosis tends to be poor, with most patients dying within 2 years of diagnosis in spite of treatment.

Metastatic Tumors

About 5% to 6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract (499,500,501,502,503,504,505,506,507,508,509,510,511,512,513,514,515). The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous or lymphatic spread, or by transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.

Gynecologic

Nonovarian cancers of the genital tract can spread by direct extension or they may metastasize to the ovaries. Tubal carcinoma involves the ovaries secondarily in 13% of cases (2,3), usually by direct extension. Under some circumstances, it is difficult to know whether the tumor originated in the tube or in the ovary when both are involved. Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are of an advanced clinical stage or are adenocarcinomas. Although adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in as many as 5%

of cases, two synchronous primary tumors probably occur with greater frequency (514). In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.

Nongynecologic

The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but the phenomenon is common (Fig. 35.21). In autopsy data of women who died of metastatic breast cancer, the ovaries were involved in 24% of cases, and 80% of the involvement was bilateral (499,500,501,502,503,504).

Similarly, when ovaries are removed to palliate advanced breast cancer, about 20% to 30% of the cases reveal ovarian involvement, 60% of those bilaterally. The involvement of ovaries in early-stage breast cancer seems to be considerably lower, but precise figures are not available. In almost all cases, either ovarian involvement is occult or a pelvic mass is discovered after other metastatic disease becomes apparent.

Krukenberg Tumor

The Krukenberg tumor, which can account for 30% to 40% of metastatic cancers to the ovaries, arises in the ovarian stroma and has characteristic mucin-filled, signet-ring cells (505,506,507) (Fig. 35.22). The primary tumor is most frequently located in the stomach and less commonly in the colon, breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for about 2% of ovarian cancers at some institutions, and they are usually bilateral. The lesions are usually not discovered until the primary disease is advanced and, therefore, most

P.1526

P.1527

patients die of their disease within 1 year. In some cases, a primary tumor is never found.

Figure 35.21 Metastatic carcinoma in the ovary. Note the "Indian file" pattern found in this metastatic breast carcinoma.

Figure 35.22 Krukenberg tumor of the ovary metastatic from a gastric carcinoma. Malignant cells have discrete vacuoles that push nuclei eccentrically, giving a signet-ring appearance. Mucicarmine stain demonstrates the cytoplasmic vacuoles to be mucin.

Other Gastrointestinal Tumors

In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the small intestine. As many as 1% to 2% of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease (501). Before exploration for an adnexal tumor in a woman older than 40 years, a barium enema is indicated to exclude a primary gastrointestinal carcinoma with metastases to the ovaries, particularly if there are any gastrointestinal symptoms. Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically (500,501), and the histological distinction between the two can be difficult (508,509,510,511,512). Lesions that arise in the appendix may be associated with

ovarian metastasis and have frequently been confused with primary ovarian malignancies, especially when associated with pseudomyxoma peritonei (508,512). Therefore, it is reasonable to consider the performance of prophylactic bilateral salpingo-oophorectomy at the time of surgery for women with colon cancer (513).

Melanoma

Rare cases of malignant melanoma metastatic to the ovaries have been reported (515). In these circumstances, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion. Malignant melanoma can arise rarely in a mature cystic teratoma (516).

Carcinoid Tumors

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries (517). Conversely, only about 2% of patients with primary carcinoids have evidence of ovarian metastasis, and only 40% of them have the carcinoid syndrome at the time of discovery of the metastatic carcinoid. However, in perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. Furthermore, the discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion (518).

Lymphoma and Leukemia

Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral (519,520,521). About 5% of patients with Hodgkin disease will have lymphomatous involvement of the ovaries, but this involvement occurs typically with advanced-stage disease. **With Burkitt's lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries much less frequently, and leukemic infiltration of the ovaries is uncommon** (521). Sometimes the ovaries can be the only apparent site of involvement of the abdominal or pelvic viscera with a lymphoma; if this circumstance is found, a careful surgical exploration may be necessary. Intraoperatively, a hematologist-oncologist should be consulted to determine the need for these procedures if frozen section of a solid ovarian mass reveals a lymphoma. In general, most lymphomas no longer require extensive surgical staging, although biopsy of enlarged lymph nodes should generally be performed. In some cases of Hodgkin disease, a more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia in general. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.

Fallopian Tube Cancer

Carcinoma of the fallopian tube accounts for 0.3% of all cancers of the female genital tract (2,3,522,523,524,525,526,527 528). In histologic features and behavior, fallopian tube carcinoma is

P.1528

similar to ovarian cancer; thus, the evaluation and treatment are also essentially the same (Fig. 35.23). The fallopian tubes are frequently involved secondarily from other primary sites, most often the ovaries, endometrium, gastrointestinal tract, or breast. They may also be involved in primary peritoneal carcinomatosis. Almost all cancers are of epithelial origin, most frequently of serous histology. Rarely, sarcomas have also been reported.

Figure 35.23 Carcinoma of the fallopian tube. This is the mixed papillary and the papillary-alveolar pattern.

Clinical Features

Tubal cancers are seen most frequently in the fifth and sixth decades, with a mean age

of 55 to 60 years (522). Women who have germline mutations in BRCA1 and BRCA2 are at substantially higher risk for developing fallopian tube carcinoma; therefore, prophylactic surgery in these women should include a complete removal of both tubes along with the ovaries (66,529).

Symptoms and Signs

The classic triad of symptoms and signs associated with fallopian tube cancer is (i) a prominent watery vaginal discharge (i.e., hydrops tubae profluens), (ii) pelvic pain, and (iii) a pelvic mass. However, this triad is noted in fewer than 15% of patients (3).

Vaginal discharge or bleeding is the most common symptom reported by patients with tubal carcinoma and is documented in more than 50% of patients (3,523).

Lower abdominal or pelvic pressure and pain also are noted in many patients. However, the symptoms may be rather vague and nonspecific. For perimenopausal and postmenopausal women with unusual, unexplained, or persistent vaginal discharge, even in the absence of bleeding, the clinician should be concerned about the possibility of occult tubal cancer.

Fallopian tube cancer is often found incidentally in asymptomatic women at the time of abdominal hysterectomy and bilateral salpingo-oophorectomy.

On examination, a pelvic mass is present in about 60% of patients, and ascites may be present if advanced disease exists. For patients with tubal carcinoma, the results of dilation and curettage will be negative (525), although abnormal or adenocarcinomatous cells may be seen in cytologic specimens obtained from the cervix in 10% of patients.

Spread Pattern

Tubal cancers spread in much the same manner as epithelial ovarian malignancies, principally by the transcoelomic exfoliation of cells that implant throughout the peritoneal cavity. In about 80% of the patients with advanced disease, metastases are confined to the peritoneal cavity at the time of diagnosis (524).

The fallopian tube is richly permeated with lymphatic channels, and spread to the para-aortic and pelvic lymph nodes is common. Metastases to the para-aortic lymph nodes have been documented in at least 33% of the patients with all stages of disease (528).

Staging

Fallopian tube cancer is staged according to FIGO (522,527). The staging is based on the surgical findings at laparotomy (Table 35.9). According to this system, about 20% to 25% of patients have stage I disease, 20% to 25% have stage II disease, 40% to 50% have stage

III disease, and 5% to 10% have stage IV disease (522). A somewhat lower incidence of advanced disease is seen in these patients than in patients with epithelial ovarian carcinomas, presumably because of the earlier occurrence of symptoms, particularly vaginal bleeding or unusual vaginal discharge. Findings on transvaginal ultrasonography and CT scan may be suspicious for tubal carcinomas (530).

Treatment

The treatment of this disease is the same as that of epithelial ovarian cancer (522,525,531,532,533,534,535,536,537). Exploratory laparotomy is necessary to remove the primary tumor, to stage the disease, and to resect metastases. After surgery, the most frequently employed treatment is *carboplatin* and *paclitaxel* chemotherapy

Surgery

Patients with tubal carcinoma should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy (3). If there is no evidence of gross tumor spread, a staging operation is performed. The retroperitoneal lymph nodes should be adequately evaluated, and peritoneal cytologic studies and biopsies should be performed, along with an infracolic omentectomy.

In patients with metastatic disease, an effort should be made to remove as much tumor bulk as possible. The role of cytoreductive surgery in this disease is unclear, but extrapolation from the experience with epithelial ovarian cancer indicates that significant benefit might be expected, particularly if all macroscopic disease can be resected (532).

Chemotherapy

As with epithelial ovarian cancer, the most active agents are platinum and the taxanes. Experience with *cisplatin* and paclitaxel indicates that complete responses can be obtained (531,532). **Therefore, the recommended treatment for fallopian tube cancer is the same as that for epithelial ovarian cancer, i.e., platinum and taxane-based chemotherapy.** A variety of other chemotherapeutic agents that are effective against recurrent ovarian cancer appear to be active in recurrent or persistent fallopian tube carcinomas. These agents include *docetaxel*, *etoposide*, *topotecan*, *gemcitabine* and *liposomally encapsulated doxorubicin* (533,534,535,536,537). As data on well-staged lesions are scarce, it is unclear whether patients with disease confined to the fallopian tube (i.e., a stage Ia, grade 1 or 2 carcinoma) benefit from additional therapy.

Table 35.9 Modified FIGO Staging of Fallopian Tube Cancer (Based on Operative Findings before Debulking and Pathologic Findings)

Stage 0	Carcinoma <i>in situ</i>^a(limited to tubal mucosa).^b
Stage I	Growth is limited to the fallopian tubes.
Ia	Growth is limited to one tube with extension into the submucosa^c and/or muscularis but not penetrating the serosal surface; no ascites.
Ib	Growth is limited to both tubes with extension into the submucosa ^c and/or muscularis but not penetrating the serosal surface; no ascites.
Ic	Tumor either stage Ia or Ib but with tumor extension through or onto the tubal serosa; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage II	Growth involving one or both fallopian tubes with pelvic extension.
IIa	Extension and/or metastasis to the uterus and/or ovaries.
IIb	Extension to other pelvic tissues.
IIc	Tumor either stage IIa or IIb but with tumor extension through or onto the tubal serosa; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage III	Tumor involves one or both fallopian tubes with peritoneal implants outside of the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastases equals stage III. Tumor appears limited to the true pelvis but with histologically proven malignant extension to the small bowel or omentum.
IIIa	Tumor is grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces.
IIIb	Tumor involving one or both tubes with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter. Lymph nodes are negative.
IIIc	Abdominal implants greater than 2 cm in diameter and/or positive retroperitoneal or inguinal nodes.
Stage IV	Growth involving one or both fallopian tubes with distant metastases. If pleural effusion is present, there must be positive cytology to be stage IV. Parenchymal liver metastases equals stage IV.

International Federation of Gynecology and Obstetrics.

^aThe staging system does not distinguish between microscopic foci or replacement of tubal epithelium by malignant epithelium and grossly evident masses in the tubal lumen that do not penetrate the wall beyond the epithelium. The former have not been reported to spread beyond the tube, whereas the latter can extend beyond the tube, recur, and be fatal.

^bThe *mucosa* presumably refers to the epithelium because involvement of the lamina propria component of the mucosa requires staging of the tumor as Ia.

^cBecause the fallopian tube has no *submucosa*, this designation presumably refers to the lamina propria.

Radiation Therapy

Although most patients with tubal cancers have been treated with radiation therapy in the past, its role in the management of the disease is limited because of the more recent data with chemotherapy (532,533,534,535,536,537). An alternative is whole-abdominal irradiation, which has been used in patients with no evidence of gross disease in the abdomen (i.e., completely resected disease or microscopic metastases only) (3,522). Pelvic irradiation alone was once popular, but this approach should be abandoned because this disease tends to spread to the upper abdomen (523).

Prognosis

The overall 5-year survival for patients with epithelial tubal carcinomas is about 40%. This number is higher than for patients with ovarian cancer and reflects the

P.1531

somewhat higher proportion of patients diagnosed with early-stage disease. The outlook is clearly related to the stage of disease, but the available data relate to patients who have not been surgically staged. Thus, the reported 5-year survival rate for patients with stage I disease is only about 65%. The 5-year survival rate for patients with stage II disease is 50% to 60%, but it is only 10% to 20% for patients with stages III and IV disease (522,527).

Tubal Sarcomas

Tubal sarcomas, particularly malignant mixed mesodermal tumors, have been described but are rare. They occur mainly in the sixth decade and are typically advanced at the time of diagnosis. If all gross disease can be resected, platinum-based combination chemotherapy should be tried. However, survival is generally poor, and most patients die of their disease within 2 years (2,492).

Vulvar Cancer

Christine H. Holschneider

Jonathan S. Berek

- **Vulvar lesions require biopsy to avoid delay in diagnosis.**
- **The modern approach to patients with vulvar cancer is individualized.**
- **Management of the primary lesion and groin nodes is determined separately.**
- **Most T₁, T₂, and early T₃ lesions can be managed with radical local excision.**
- **Large T₃ and T₄ primary tumors are best treated with chemoradiation followed by more limited surgical resection.**
- **If groin dissection is indicated, it should be a thorough inguinofemoral lymphadenectomy.**
- **The single most important prognostic factor is lymph node status: 5-year survival with no groin node metastases is greater than 90%; with groin**

node metastases, it is 50%.

- **Recurrence in the groin is almost universally fatal.**

With 3,740 new cases and 880 deaths annually in the United States (1), vulvar cancer is uncommon, representing 3% to 5% of malignancies of the female genital tract. Squamous cell carcinomas account for about 90% of all primary vulvar malignancies, whereas melanomas, adenocarcinomas, basal cell carcinomas, and sarcomas are much less common. **The incidence of *in situ* vulvar cancer nearly doubled between the mid-1970s and the mid-1990s, whereas the overall rate of invasive squamous cell carcinoma has remained relatively stable** (2,3). However, in women younger than 50 years, there has been a striking increase in the incidence of not only *in situ* but also invasive squamous cell carcinoma of the vulva (4).

Following the reports of Taussig (5) in the United States and Way (6) in Great Britain, radical vulvectomy and *en bloc* groin dissection, with or without pelvic lymphadenectomy, has been considered standard treatment for all patients who have operable disease.

Postoperative morbidity was high and prolonged hospitalization common. **During the**

P.1550

past 20 years, a number of significant advances have been made in the management of vulvar cancer, reflecting a paradigm shift toward a more conservative surgical approach without compromised survival and with markedly decreased physical and psychological morbidity:

- **Individualization of treatment for all patients with invasive disease (7,8)**
- **Vulvar conservation for patients with unifocal tumors and an otherwise normal vulva (7,8,9,10,11)**
- **Omission of the groin dissection for patients with T₁ tumors and, 1 mm of stromal invasion (7,8)**
- **Elimination of routine pelvic lymphadenectomy (12,13,14,15,16)**
- **The use of separate incisions for the groin dissection to improve wound healing (17,18)**
- **Omission of the contralateral groin dissection in patients with lateral T₁ lesions and negative ipsilateral nodes (8,19)**
- **The use of preoperative radiation therapy to obviate the need for exenteration in patients with advanced disease (20,21)**
- **The use of postoperative radiation therapy to decrease the incidence of groin recurrence in patients with multiple positive groin nodes (16)**

Etiology

The etiology of vulvar cancer has been only partially elucidated and is likely to be multifactorial. **Based on histopathologic and environmental factors, there appear to be at least two distinct etiologic entities of squamous cell carcinoma of the vulva.**

- **Basaloid or warty types, which tend to be multifocal, occur generally in younger patients and are related to human papillomavirus (HPV) infection, vulvar intraepithelial neoplasia (VIN), and cigarette smoking.**
- **Keratinizing types, which tend to be unifocal, occur predominantly in older patients, are not related to HPV, and often are found in areas adjacent to lichen sclerosus and squamous hyperplasia.**

High-grade vulvar intraepithelial neoplasia (VIN 3) has been most closely studied as a potential precancerous lesion. The direct progression of VIN to cancer is difficult to document, but a recent review of 3,322 published patients with VIN 3, reports a 9% progression rate to cancer for untreated cases (22). Ten percent to 20% of vulvar carcinoma *in situ* lesions harbor an occult invasive component (23,24), and VIN is found adjacent to basaloid or warty vulvar squamous cell carcinomas in more than 80% of cases. DNA of HPV has been documented in 89% of patients with VIN 3 and in up to 86% of warty or basaloid type carcinomas of the vulva, but it occurs in less than 10% of the keratinizing type of carcinomas of the vulva (25).

Epidemiologic risk factors for the basaloid or warty type squamous cell carcinoma of the vulva are similar to those for cervical cancer and include a history of multiple lower genital tract neoplasias, immunosuppression, and smoking (25,26). Frequently implied as an etiologic variable for the keratinizing carcinoma is the itch–scratch cycle associated with lichen sclerosus and squamous hyperplasia,

P.1551

P.1552

with atypical changes occurring in the repaired epithelium. **In keratinizing carcinoma, associated lichen sclerosus or squamous hyperplasia is found in more than 80% of patients (27,28), yet their causative role remains controversial.** Supportive evidence that some of these lesions could be precancerous comes from molecular studies that demonstrate aneuploid DNA content, *p53* overexpression, and monoclonal expansion of keratinocytes in lichen sclerosus and associated squamous hyperplasia (29,30). In the past, some studies have reported vulvar cancer to be more common in patients who are obese, have hypertension and diabetes mellitus, or are nulliparous (31,32), but a more recent case-control study of vulvar cancer was unable to confirm any of these as risk factors (26).

Types of Invasive Vulvar Cancer

The varieties of invasive vulvar cancer are shown in Table 36.1.

Table 36.1 Types of Vulvar Cancer

Type	Percent
Squamous	92
Melanoma	2-4
Basal cell	2-3
Bartholin gland (adenocarcinoma, squamous cell, transitional cell, adenoid cystic)	1
Metastatic	1
Verrucous	<1
Sarcoma	<1
Appendage (e.g., hidradenocarcinoma)	Rare

Squamous Cell Carcinoma

Approximately 90% to 92% of all invasive vulvar cancers are of the squamous cell type. As discussed previously, squamous carcinomas of the vulva can be divided into distinct histologic subtypes designated as *basaloid carcinoma*, *warty carcinoma*, and *keratinizing squamous carcinoma* (27). Mitoses are noted in these malignancies, but atypical keratinization is the histologic hallmark of invasive vulvar cancer (33). Most vulvar squamous carcinomas reveal keratinization (Fig. 36.1). Histologic features that correlate with the occurrence of inguinal lymph node metastasis are lymph-vascular space invasion, tumor thickness, depth of stromal invasion, histologic pattern of invasion (spray and stellate versus broad and pushing), and increased amount of keratin (34,35,36,37).

Microinvasive Squamous Carcinoma

Microinvasive carcinoma of the vulva has been defined as a lesion ≤ 2 cm in diameter with ≤ 1 mm stromal invasion (38). Depth of stromal invasion is measured vertically from the epithelial-stromal junction (basement membrane) of the most superficial dermal papilla to the deepest point of tumor invasion (Fig. 36.2). **When the tumor invades ≤ 1 mm, metastasis to the inguinal lymph nodes is extremely rare among reported series. However, when invasion is >1 mm, there is a significant risk of inguinal lymph node metastasis.**

Clinical Features

Squamous cell carcinoma of the vulva is predominantly a disease of postmenopausal women; the mean age at diagnosis is about 65 years. However, 15% of patients who

P.1553

develop vulvar cancer do so before age 40. There may be a long-standing history of an associated vulvar intraepithelial disorder, such as lichen sclerosus, squamous hyperplasia, or VIN. As many as 27% of patients with vulvar cancer are reported to have a second primary malignancy (39,40,41). Based on data from the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) program, patients with invasive vulvar cancer have an increased risk of 1.3 for developing a subsequent cancer. **Most of the excess second cancers were smoking related** (eg, cancers of the lung, buccal cavity and pharynx, esophagus, nasal cavity, and larynx) **or related to infection with human papillomavirus** (e.g., cervix, vulva, vagina, and anus) (42).

Figure 36.1 Squamous cell carcinoma of the vulva, keratinizing type. The multiple pearl formations consist of laminated keratin.

Figure 36.2 Early invasive carcinoma of vulva originating from vulvar intraepithelial neoplasia. An irregular nest of malignant cells extend from the base of rete pegs. Desmoplastic stromal reaction and chronic inflammation are useful diagnostic signs of stromal invasion. The depth of stromal invasion is measured from the base of the most superficial dermal papilla vertically to the deepest tumor cells.

Most patients are asymptomatic at the time of diagnosis. If symptoms exist, vulvar pruritus, a lump, or a mass are the most common findings. Less frequent symptoms include a bleeding or ulcerative lesion, discharge, pain, or dysuria. Occasionally, a large metastatic mass in the groin may be the initial symptom.

A careful inspection of the vulva should be part of every gynecologic examination.

On physical examination, vulvar carcinoma is usually raised and may be fleshy, ulcerated, leukoplakic, or warty in appearance. It may be pigmented, red or white, and tender or painless. The lesion may be clinically indistinct, especially in the presence of VIN or vulvar dystrophies (24). Thus, any lesion of the vulva warrants a biopsy.

Most squamous carcinomas of the vulva occur on the labia majora and minora (60%), but the clitoris (15%) and perineum (10%) also may be primary sites. Approximately 10% of the cases are too extensive to determine a site of origin, and about 5% of the cases are multifocal.

As part of the clinical evaluation, a careful assessment of the extent of the lesion, including whether it is unifocal or multifocal, should be performed. The groin lymph nodes should be evaluated carefully, and a complete pelvic examination should be performed. A cytologic sample should be taken from the cervix, and **colposcopy of the cervix and vagina should be performed because of the common association with other squamous intraepithelial or invasive neoplasms of the lower genital tract.**

Diagnosis

Diagnosis requires a wedge biopsy specimen, which usually can be obtained in the office using local anesthesia. If the lesion is only about 1 cm in diameter, excisional biopsy is preferable. The biopsy should include sufficient underlying dermis to assess for microinvasion.

Physician delay is a common problem in the diagnosis of vulvar cancer, particularly if the lesion has a warty appearance. Any confluent warty lesion requires biopsy before medical or ablative therapy is initiated.

Routes of Spread

Vulvar cancer spreads by the following routes:

- **Direct extension**, to involve adjacent structures such as the vagina, urethra, and anus
- **Lymphatic embolization** to the regional inguinal and femoral lymph nodes
- **Hematogenous spread** to distant sites, including the lungs, liver, and bone

Lymphatic metastases may occur early in the disease. Twelve percent of T₁ tumors have regional metastases (39,2). Initially, spread is usually to the inguinal lymph nodes, which are located between Camper's fascia and the fascia lata (9). From these superficial groin nodes, the disease will spread to the deep femoral nodes, which are located medially

P.1554

along the femoral vessels (Fig. 36.3). *Cloquet's* or *Rosenmüller's node*, situated beneath the inguinal ligament, is the most cephalad of the femoral node group. **Metastases to the femoral nodes without involvement of the inguinal nodes have been reported (44,45,46,47).** A recent study from the MD Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer who at initial surgery had negative nodes on superficial inguinal lymphadenectomy (48), and intraoperative lymphatic mapping studies have found the sentinel node to be deep to the cribriform fascia in 5% of cases (49).

Figure 36.3 Inguinal-femoral lymph nodes. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005: 548, with permission.)

From the inguinal-femoral nodes, the cancer spreads to the pelvic nodes, particularly the external iliac group. Although direct lymphatic pathways from the clitoris and Bartholin gland to the pelvic nodes have been described, these channels seem to be of minimal clinical significance (12,50,51). The lymphatics of the vulva from either side form a rich network of anastomoses along the midline. Lymphatic drainage from the clitoris, anterior labia minora, and perineum is bilateral. For lateral vulvar tumors, metastases to contralateral lymph nodes in the absence of ipsilateral nodal involvement is rare (0.4% for T₁ tumors) (43).

The overall incidence of inguinal-femoral lymph node metastases is reported to be about 30% (10,11,47,49,50,51,52,53,54) (Table 36.2). Metastases to pelvic nodes occur in about 12% of cases. Pelvic nodal metastases are rare (0.6 %) in the absence of groin

node involvement, but they occur on average in about 16% of cases with positive groin nodes (see Table 36.2). The risk increases to 33% in the presence of clinically suspicious groin nodes (13) and to about 50% if there are three or more pathologically positive inguinal-femoral nodes (13,16,40). The incidence of lymph node metastases in relation to depth of invasion is shown in Table 36.3. Hematogenous spread usually occurs late in the course of vulvar cancer and is rare in the absence of lymph node metastases.

Staging

Previously, vulvar carcinoma was staged clinically based on tumor size and location, palpable regional lymph node status, and a limited search for distant metastases. The prognostic

P.1555

importance of the lymph node status is significant, yet the accuracy of the clinical assessment of the lymph nodes is limited. Microscopic metastases may be present in nodes that are not clinically suspicious, and suspicious nodes may be enlarged because of inflammation only.

When compared with surgical staging, the percentage of error in clinical staging increases from 18% for stage I disease to 44% for stage IV disease (40).

These factors led the Cancer Committee of the International Federation of Gynecology and Obstetrics (FIGO) in 1988 to introduce a surgical staging system for vulvar cancer, which was revised in 1995 to separate T₁ lesions invasive to 1 mm or less as stage Ia (Table 36.4).

This surgical staging system offers much improvement over the previous clinical staging system, but there remains need for further refinements. One major problem is that stage III represents a very heterogeneous group of patients. It includes patients ranging from those

P.1556

with a small tumor involving the distal urethra or vagina and negative nodes and those with

one microscopically involved groin node, who should have a good prognosis, to those with multiple positive groin nodes, who have a very poor prognosis.

Prognosis and Survival

Survival of patients with vulvar cancer correlates with FIGO stage. The prognosis for patients with early-stage disease is generally very good (Table 36.5). **The single most important prognostic factor is lymph node status** (55,56,57,58,59,60). A recent report from the Mayo Clinic on 330 patients with primary squamous cell carcinoma of the vulva demonstrated a significant correlation between lymph node status and risk of treatment failure, especially in the first 2 years after initial therapy: 44.2% overall recurrence rate with positive versus 17.5% with negative lymph nodes. Interestingly, more than one third of relapses presented 5 years or more after initial therapy (61). **Patients with negative lymph nodes have a 5-year survival rate of approximately 90%, which falls to approximately 50% for patients with positive nodes** (62). The number of positive nodes is of critical importance: **Patients with one microscopically positive lymph node have a prognosis similar to those with negative lymph nodes, whereas patients with three or more positive nodes have a poor prognosis with a two-year survival rate of 20%** (63). The survival

P.1557

rate for patients with positive pelvic nodes is about 11% (64). Histologic grade, tumor thickness, depth of stromal invasion, and lymph–vascular space involvement contribute to the risk of lymph node involvement but are not independent predictors of survival (63). Tumor ploidy is another important prognostic factor. Data from the Norwegian Radium Hospital (65) demonstrate a 5-year crude survival rate of 62% for diploid and 23% for the aneuploid tumors ($p < 0.001$). In a multivariate Cox regression analysis, tumor ploidy was the second most important prognostic factor after lymph node status.

Table 36.5 Five-year Survival for Patients with Vulvar Carcinoma

FIGO Stage	No. of Patients	Corrected 5-Year Survival (%)
I	148 (26%)	98%
II	191 (33%)	85%
III	176 (31%)	74%
IV	62 (11%)	31%
All stages	577	79%

Treatment

After the pioneering work of Taussig (5) in the United States and Way (6) in Great Britain, *en bloc* radical vulvectomy and bilateral dissection of the groin and pelvic nodes became the standard treatment for most patients with operable vulvar cancer. If the disease involved the anus, rectovaginal septum, or proximal urethra, some type of pelvic exenteration was combined with the dissection.

Although the survival rate improved markedly with this aggressive surgical approach, several factors have led to modifications of this treatment plan during the past 30 years. These factors are summarized as follows:

- An increasing proportion of patients with early-stage disease—up to 50% of patients in many centers—have T₁ tumors.
- There were concerns about the postoperative morbidity and associated long-term hospitalization common with the *en bloc* radical dissection.
- Increasing awareness has emerged of the psychosexual consequences of radical vulvectomy.

To individualize the patient's care and determine the appropriate therapy, it is necessary to determine independently the primary lesion as well as groin lymph nodes. Before initiation of therapy, all patients should undergo colposcopy of the cervix, vagina, and vulva. Preinvasive (and rarely invasive) lesions may be present at other sites along the lower genital tract.

Management of the Primary Lesion

Early Vulvar Cancer (T₁)

The modern approach to the management of patients with T₁ carcinoma of the vulva should be individualized (7,2). There is no standard approach applicable to every

patient, and emphasis is on performing the most conservative operation that is consistent with cure of the disease. Radical vulvectomy has in

the past been considered the standard treatment for primary vulvar lesions, but this operation is associated with significant surgical morbidity and disturbances of sexual function and body image. Psychosexual sequelae are a major long-term morbidity associated with the treatment of vulvar cancer (9). One study reported that sexual arousal was reduced to the eighth percentile and body image was reduced to the fourth percentile for women who had undergone vulvectomy when compared with healthy adult women (66).

Traditionally, there has been concern that without an *en bloc* resection, intervening tissue left between the primary tumor and the regional lymph nodes may contain microscopic tumor foci in draining lymphatics. However, **experience with a separate incision technique for node dissection has confirmed that metastases rarely occur in the skin bridge in patients without clinically suspicious nodes in the groin** (18).

During the past 20 years, several investigators have advocated a radical local excision rather than a radical vulvectomy for the primary lesion for patients with T₁ tumors (7,8,9,10). Regardless of whether a radical vulvectomy or a radical local excision is performed, the surgical margins adjacent to the tumor will be the same. An analysis of the available literature indicates that the incidence of local invasive recurrence after radical local excision is not higher than that after radical vulvectomy (10,43,64,67). This finding suggests that in the presence of an otherwise normal-appearing vulva, **radical local excision is a safe surgical option, regardless of the depth of invasion**. A review of 135 patients with all stages of disease assessed the surgical margin that must be obtained to prevent local disease recurrence. In this study, a 1-cm tumor-free surgical margin on the vulvar specimen (0.8-cm on pathologic specimen) resulted in a very high rate of local control (68). Neither clinical tumor size nor the presence of coexisting benign vulvar pathology correlated with local recurrence. It is important to bear in mind that paraffin-embedded tissue shrinks by about 25%. Thus, **at the time of radical local excision, at least a 1-cm grossly negative margin, which should extend down to the level of the inferior fascia of the urogenital diaphragm, should be obtained. For stage Ia lesions, lesser forms of vulvar excision, such as wide local excision, are as effective as radical surgery for the prevention of vulvar recurrences** (69).

When vulvar cancer arises in the presence of VIN or some nonneoplastic epithelial disorder, treatment will be influenced by the patient's age. Elderly patients who often have had many years of chronic itching may not be disturbed by the prospect of a vulvectomy. In younger women, it will be desirable to conserve as much of the vulva as possible. Thus, radical local excision should be performed for the invasive disease, and the associated intraepithelial disease should be treated in the manner most appropriate to the patient. For example, topical steroids may be required for lichen sclerosus or squamous hyperplasia, whereas VIN may require superficial local excision and primary closure.

Radical local excision is most appropriate for lesions on the lateral or posterior aspects of the vulva (Fig. 36.4). Midline lesions pose special challenges because of their proximity to clitoris, urethra, or anus. For anterior lesions, conservative clitoris-sparing surgery allows for excellent local control as long as pathological margins are at least 8 mm (70). For tumors that involve the clitoris or that are in close proximity to it, any type of surgical excision will have psychosexual consequences. In addition, marked edema of the posterior vulva may occur. For young patients with periclitoral lesions, the primary lesion can be treated with a small field of radiation therapy, possibly with concomitant sensitizing chemotherapy. Small vulvar lesions should respond very well to about 5,000 cGy external radiation, and biopsy can be

performed after therapy to confirm the absence of any residual disease (62).

Figure 36.4 Small (T_1) vulvar carcinoma at the posterior fourchette. (From Berek JS, Hacker NF. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins 2005:554, with permission.)

T₂ and T₃ Vulvar Cancer

In recent years, the indications for vulvar conservation have been extended to selected patients with T_2 and early T_3 tumors. Although the reported experience is limited (10,11,71), **a recent study suggests that the local recurrence rate for patients with conservatively treated T_2 tumors is identical to that for patients with T_1 tumors (72) as long as surgical margins of at least 1 cm are obtained.** The tumor-free margin should be the same, whether or not a radical vulvectomy or a radical local excision is performed, so it would be seem to be

both feasible and desirable to extend the indications for vulvar conservation, particularly for younger patients. **Tumors that are most suitable to a more conservative resection are those involving the posterior half of the vulva, where preservation of the clitoris and mons pubis is feasible.**

For patients with more advanced T₂ and T₃ lesions, management consists of radical vulvectomy and bilateral inguinal-femoral lymphadenectomy or chemoradiation therapy, as discussed below. If the disease involves the distal urethra, vagina, or anus, partial resection

P.1560

of these organs would be required. Alternatively, it is often preferable to give preoperative radiation therapy with chemosensitization to allow for a less radical resection (see below).

Closure of Large Defects

After radical local excision, primary closure without tension often can be accomplished for smaller defects. However, if a more extensive dissection has been required to treat a large primary lesion, a number of options are available to repair the defect.

- An area may be left open to granulate, which it will usually do over a period of 6 to 8 weeks (73).
- Full-thickness skin flaps may be devised (74,75,76,77). The rhomboid flap is best suited to covering large defects of the posterior vulva (77), whereas for lateral defects, a mons pubis pedicle flap has been advocated (74).
- Myocutaneous flaps may be developed to cover the defect. Unilateral or bilateral gracilis myocutaneous grafts are most useful when an extensive area from the mons pubis to the perianal area has been resected. Because the graft brings a new blood supply to the area, it is particularly applicable if the vulva is poorly vascularized from prior surgical resection or radiation (78).
- If extensive defects exist in the groin and vulva, the tensor fascia lata myocutaneous graft may be the most applicable (79).

Advanced Disease: Large T₃ and T₄ Primary Tumors

To achieve primary surgical clearance for tumors involving the upper urethra, anus, rectum, or rectovaginal septum, pelvic exenteration would be needed in addition to radical vulvectomy and inguinal-femoral lymphadenectomy, which carries an extremely high physical and psychological morbidity (66,2). Reported 5-year survival rates are about 50% (81,82,83,84). For many of these patients, a combined approach of surgery and radiation therapy offers improved survival and reduced morbidity and thus becomes the preferred treatment approach. Numerous small prospective and retrospective series report on the use of external beam radiation, often with concomitant chemotherapy to shrink the primary tumor. Reported initial response rates to chemoradiation approximate 90% (85,86,87,88). **It is important that this chemoradiation is followed by a more limited resection of the tumor bed and lymphadenectomy on an individualized basis.** About one half of the specimens will contain residual tumor (21,2), and local relapse rates are as high as 50% to 79% with

external radiation alone (with or without concomitant chemotherapy) (90,2), emphasizing the need for a combined approach that involves radiation and surgery.

As experience with this combination therapy has evolved, it appears that **external beam therapy is generally appropriate for most cases, with more selective use of brachytherapy. The extensiveness of the surgery has also been significantly modified. A more limited vulvar resection is now advocated, and bulky N₂ and N₃ nodes are resected without full groin lymphadenectomy to avoid the leg edema associated with groin lymphadenectomy and radiation. With this combined radiation-surgical approach, 5-year survival rates as high as 76% have been reported (89).** With the experience now accrued, preoperative radiation, with or without concurrent chemotherapy, should be regarded as the treatment of first choice for patients with advanced vulvar cancer who would otherwise require some type of pelvic exenteration.

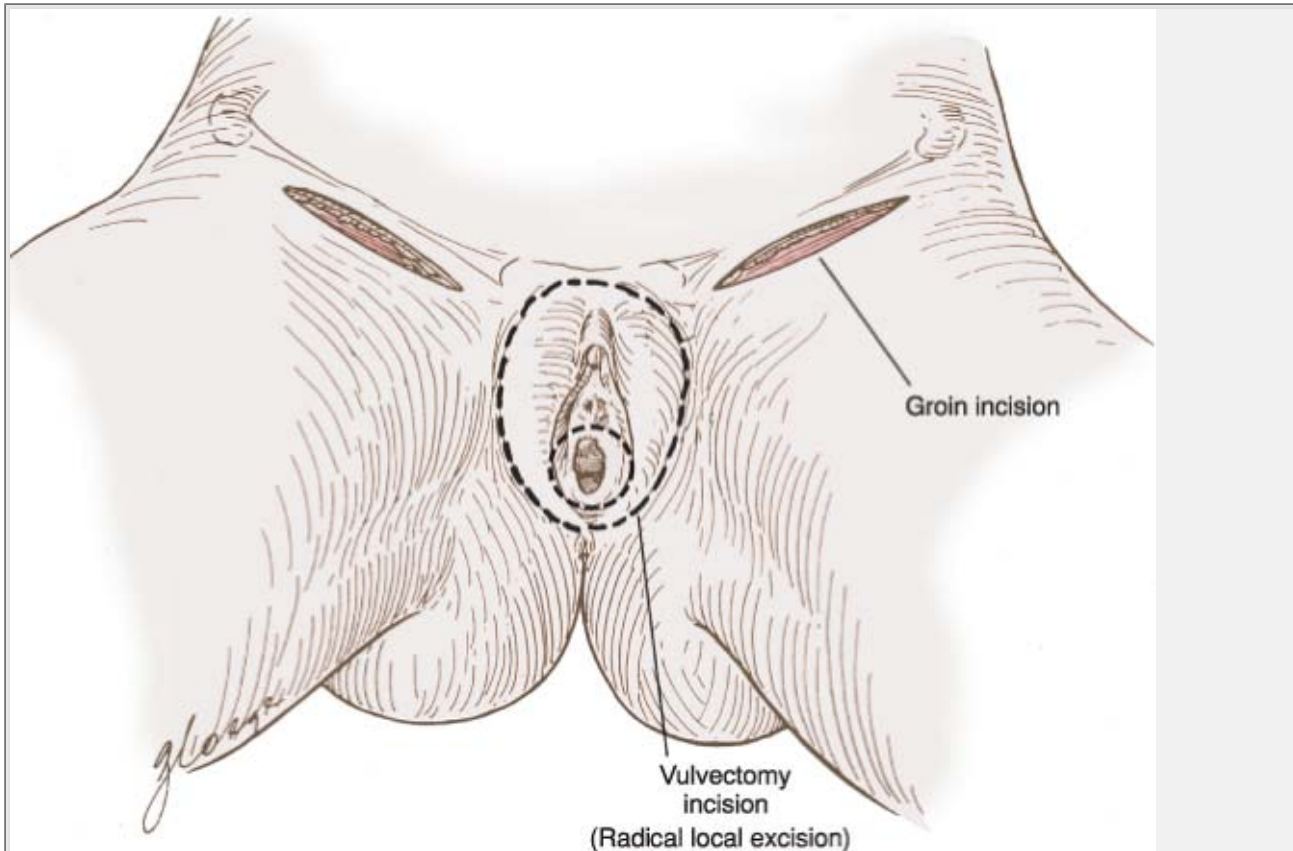

Figure 36.5 Skin incision for groin dissection through a separate incision. A line is drawn 1 cm below and parallel to the groin crease, and a narrow ellipse of skin is removed. Radical local excision which would be appropriate for patient in Figure 36.4. (Revised from **Berek JS, Hacker NF. Practical gynecologic oncology**, 2nd ed. Baltimore, MD: Williams & Wilkins, 1994, p. 418. with permission.)

Management of the Lymph Nodes

Groin dissection is associated with postoperative wound infection and breakdown, as well as chronic leg edema. Although the incidence of wound breakdown is reduced significantly

P.1561

when separate incisions are used for the groin dissection (Fig. 36.5) (18), chronic leg edema remains a major problem. When assessing a patient for groin dissection, the following three facts should be kept in mind:

- The only patients with virtually no risk of lymph node metastases are those whose tumor invades the stroma to <1 mm.
- Patients who develop recurrent disease in an undissected groin have a >90% mortality (92).
- Based on the laterality of the vulvar lesions, an ipsilateral or bilateral lymphadenectomy becomes necessary.

Appropriate groin dissection is the single most important factor in decreasing the mortality for early vulvar cancer.

Microinvasive Carcinoma

All patients whose tumors demonstrate more than 1 mm of stromal invasion require inguinal-femoral lymphadenectomy. A wedge biopsy specimen of the primary tumor should be obtained, and the depth of invasion should be determined. If it is smaller than 1 mm on the wedge biopsy specimen, the entire lesion should be locally excised and analyzed histologically to determine the depth of invasion. If there is still no invasive focus larger than 1 mm, groin dissection may be omitted provided there is no lymph-vascular space invasion and there are no clinically suspicious groin lymph nodes. Although an occasional patient with less than 1 mm of stromal invasion has had documented groin node metastases (93), the incidence is so low that it is of no practical significance.

P.1562

Inguinal-femoral Lymphadenectomy

If groin dissection is indicated in patients with early vulvar cancer, it should be a thorough inguinal-femoral lymphadenectomy. The GOG reported six groin recurrences among 121 patients with T₁ N₀ tumors after a superficial (inguinal) dissection, even though the removed inguinal nodes were negative (47), and a recent study from the MD Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer and negative nodes on superficial inguinal lymphadenectomy (48). Whether all of these recurrences were in the femoral nodes is unclear, but both studies indicate that an incomplete groin dissection will increase the number of groin recurrences and, therefore, mortality. Furthermore, GOG data indicate that radiation therapy cannot substitute for groin dissection followed by selective radiation as indicated, even in patients with clinically nonsuspicious lymph nodes (94). This GOG study was closed early because a significantly higher incidence of recurrences occurred in women who were receiving groin radiation therapy only (19% versus 0%). The dose of radiation was 5,000 cGy given in daily 200-cGy fractions to a depth of 3 cm below the anterior skin surface. Although the radiation regimen prescribed has been criticized extensively, the therapeutic effects of an alternative radiation regimen remain to be determined.

Unilateral Versus Bilateral Groin Dissection

It is clear that it is not necessary to perform a bilateral groin dissection if the primary lesion is unilateral and the ipsilateral lymph nodes are negative. In a patient with unilateral T₁ lesion and negative ipsilateral groin nodes, the risk of contralateral lymph node metastasis is 0.4% (43). However, there is an increase in the risk of contralateral

nodal involvement proportional to the number of positive ipsilateral inguinal nodes (16). Thus, **it is recommended that patients with any bulky or multiple microscopically positive ipsilateral groin lymph nodes undergo contralateral inguinal-femoral lymphadenectomy as well. Bilateral inguinal-femoral lymphadenectomy should be performed for midline lesions (clitoris, anterior labia minora, posterior fourchette) or those within 2 cm of the midline because of the more frequent contralateral lymph flow from these regions (95).**

Management of Pelvic Lymph Nodes

In the past, pelvic lymphadenectomy has been considered part of the routine surgery for invasive vulvar cancer. However, the incidence of pelvic lymph node metastasis is rare in the absence of groin node involvement (see Table 36.2), thus a more selective approach is preferred. Patients most prone to pelvic lymph node metastasis are those with clinically suspicious or three or more pathologically positive groin nodes (12,13,15,40). In these patients, the pelvis requires treatment by pelvic lymphadenectomy or radiation. **If a preoperative pelvic imaging study reveals enlarged pelvic lymph nodes, resection of these nodes should be performed via an extraperitoneal approach because of the inability of external beam radiation therapy to sterilize bulky positive pelvic nodes.**

Sentinel Lymph Node Studies

A number of investigators have explored the use of intraoperative lymphatic mapping using lymphoscintigraphy with technetium-99m-labeled nanocolloid or isosulfan blue dye to identify a sentinel node that would predict the presence or absence of regional nodal metastases (49,96,97,98). A recent systematic review of 29 mostly small studies published to date of 961 groins found lymphoscintigraphy to be the most accurate technique with a pooled sensitivity and negative likelihood ratio of 97% and 0.12, respectively (99). **These preliminary studies suggest that a sentinel node can be identified in most patients (100).** The sensitivity of the sentinel node assessment may be further enhanced by ultrastaging using serial sectioning or immunohistochemistry to detect micrometastases (101,102,103). Reliable identification of the sentinel node and foregoing a full lymphadenectomy in patients with clinically nonsuspicious groin lymph nodes and a negative sentinel node may significantly reduce the number of patients who undergo unnecessary, extensive lymphadenectomy in the absence of disease. Intraoperative lymphatic mapping and sentinel node identification is currently being evaluated by the Gynecologic Oncology Group in a large multi-institutional

P.1563

study (GOG 173), and the European Organization for Research and Treatment of Cancer is performing an intergroup randomized controlled trial of sentinel node versus full inguinofemoral lymphadenectomy (EORTC 55001). **Until these trials document the accuracy of the negative predictive value of an uninvolved sentinel node, complete inguinal-femoral lymphadenectomy remains indicated in all but stage Ia disease, given the high mortality of recurrence in an undissected groin.**

Postoperative Management

Despite the age and general medical condition of many elderly patients with vulvar cancer, surgery is usually remarkably well tolerated. Patients should be able to commence eating a low-residue diet on the first postoperative day. In the past, bed rest had been advised for 3 to 5 days postoperatively to allow for immobilization of the wounds and foster healing.

Because radical local excisions are being performed with increasing frequency and

groin lymphadenectomy are done through separate incisions, patients generally begin ambulation on postoperative day 1 or 2. Pneumatic calf compression or subcutaneous heparin should be given to help prevent deep venous thrombosis, and active leg movements are to be encouraged. Frequent dressing changes are performed to keep the vulvar wound dry. Meticulous perineal hygiene is maintained. Suction drainage of each side of the groin is continued until output is minimal to help decrease the incidence of groin seromas. It is not uncommon for suction drainage to continue for 10 or more days. The Foley catheter is removed once the patient is ambulatory. If there is significant periurethral swelling, prolonged bladder drainage may be advisable. If there is breakdown of the vulvar wound, sitz baths or whirlpool therapy is helpful, followed by drying of the perineum with a hair dryer.

Early Postoperative Complications

The major immediate morbidity is related to groin wound infection, necrosis, and breakdown. This complication has been reported in as many as 53% to 85% of patients having an *en bloc* operation (39,2). **With the separate-incision approach**, the incidence of wound breakdown can be reduced to about 44%; **major breakdown occurs in about 14% of patients** (18,41,104). With appropriate antibiotics, debridement, and wound dressings, the area will granulate and re-epithelialize over the next several weeks and may be managed with home nursing. Whirlpool therapy is effective for areas of extensive breakdown.

Other early postoperative complications include urinary tract infection, seromas in the femoral triangle, deep venous thrombosis, pulmonary embolism, myocardial infarction, hemorrhage, and, rarely, osteitis pubis. Lymphocysts or groin seromas occur in about 10% to 15% of cases and should be managed by periodic sterile aspiration. Anesthesia of the anterior thigh resulting from femoral nerve injury is common and usually resolves slowly.

Late Complications

One major late complication is chronic lymphedema, which occurs on average in about 30% of patients (39,40,41,104,105). Recurrent lymphangitis or cellulitis of the leg develops in about 10% of patients and usually responds to oral antibiotics. Urinary stress incontinence, with or without genital prolapse, occurs in about 10% of patients after radical vulvectomy and may require corrective surgery. Introital stenosis can lead to dyspareunia and may require a vertical relaxing incision, which is sutured transversely. An uncommon late complication is femoral hernia, which usually can be prevented intraoperatively by closure of the femoral canal with a suture from the inguinal ligament to Cooper's ligament. Pubic osteomyelitis and rectovaginal or rectoperineal fistulas are rare late complications.

P.1564

Other major long-term treatment complications associated with the extent of vulvar surgery include depression, altered body image, and sexual dysfunction (66,2). Modifications in the radical extent of the surgical approach and appropriate preoperative and postoperative counseling may help lessen some of the psychological trauma.

Role of Radiation Therapy

Radiation therapy traditionally has been considered to have a limited role in the management of patients with vulvar cancer. In the orthovoltage era, local tissue tolerance was poor and vulvar necrosis was common, but with megavoltage therapy, tolerance has improved significantly. Thus, radiation therapy, frequently with concurrent chemotherapy, is gaining

an increasingly important role in the management of patients with vulvar cancer. It is important to remember, though, that with a rare exception, radiation therapy alone has little place in the primary management of vulvar cancer. It is generally indicated in conjunction with surgery.

The indications for radiation therapy for patients with primary vulvar cancer are still evolving.

At present, radiation seems to be clearly indicated in the following situations:

- **Preoperatively, in patients with advanced disease who would otherwise require pelvic exenteration (20,2) or suffer loss of anal or urethral sphincteric function**
- **Postoperatively, to treat the pelvic lymph nodes and groin of patients with two or more microscopically positive or one grossly positive groin node (16)**

Possible roles for radiation therapy include the following:

- Postoperatively, to help prevent local recurrences in patients with involved or close surgical margins (106,107,108)
- As primary therapy for patients with small primary tumors, particularly clitoral or periclitoral lesions in young and middle-aged women, for whom surgical resection would have significant psychological consequences (62)

No additional treatment is recommended if one microscopically positive groin node is found. The prognosis for this group of patients is excellent (13), and only careful observation is required. Even if an unilateral groin dissection has been performed for a lateral lesion, there seems to be no indication for dissection of the other side, because contralateral lymph node involvement is likely only if there are multiple microscopic or any gross ipsilateral inguinal node metastases (13,2).

If clinically evident groin metastases or two or more microscopically positive groin nodes are found, which is unusual in patients with T₁ vulvar cancer, the patient is at increased risk of groin and pelvic recurrence and should receive postoperative groin and pelvic irradiation. In 1977, the GOG initiated a prospective trial in which patients with positive groin nodes were randomized to either ipsilateral pelvic node dissection or bilateral pelvic node dissection plus groin irradiation (16). Radiation therapy consisted of 4,500 to 5,000 cGy to the midplane of the pelvis at a rate of 180 to 200 cGy per day. The survival rate for the radiation group (68% at 2 years) was significantly better than the survival rate for the pelvic lymphadenectomy group (54% at 2 years) ($p = 0.03$). The survival advantage was limited to patients with clinically evident groin nodes or more than one microscopically positive groin node. Groin recurrence occurred in 3 of 59 patients (5%) treated with radiation, compared with 13 of 55 (23.6%) patients treated with lymphadenectomy ($p = 0.02$). Four patients who received radiation had a pelvic recurrence, compared with one who had lymphadenectomy. These data indicate no benefit from

P.1565

pelvic irradiation compared with pelvic lymphadenectomy for the prevention of pelvic recurrence, but they do highlight the value of prophylactic groin irradiation in preventing groin recurrence in patients with multiple positive groin nodes.

Recurrent Vulvar Cancer

Approximately two thirds of recurrences of vulvar cancer occur within the first 2 years from initial therapy (109), with groin recurrences occurring sooner (median time to recurrence 6 months) than vulvar recurrences (median time to recurrence 3 years) (110).

Recurrence of vulvar cancer correlates most closely with the number of positive groin nodes (13). Patients with fewer than three positive nodes, particularly if the nodes are only microscopically involved, have a low incidence of recurrence at any site, whereas patients with three or more positive nodes have a high incidence of local, regional, and systemic recurrences (13,2).

Local Recurrence

Margin status at the time of radical resection of the vulvar cancer is the most powerful predictor of local vulvar recurrence, with an almost 50% recurrence risk with margins closer than 0.8 cm (68). Margin status does not, however, predict survival (60). Local vulvar recurrences are likely in patients with primary lesions larger than 4 cm in diameter, especially if lymph-vascular space invasion is present (106,2) and in patients with deeply invasive tumors (112). When detected early, isolated local failure is usually salvageable by additional surgical therapy (10,18,41,47,113), often with a gracilis myocutaneous graft to cover the defect. Radiation therapy, particularly a combination of external beam therapy plus interstitial needles, at times combined with chemotherapy, has also been used to treat vulvar recurrences (114). One study reported on 10 patients treated in this manner, nine of whom were still alive with a mean follow-up of 28 months (115). However, 6 of the 10 patients developed severe radionecrosis at a median of 8.5 months after radiation, and the authors concluded that although this treatment was highly effective, it also had a high degree of morbidity.

Regional and Distant Recurrence

Regional and distant recurrences are difficult to manage and are associated with a poor prognosis (106,109,110). Radiation therapy may be used in conjunction with surgery for groin recurrence, whereas chemotherapeutic agents that have activity against squamous carcinomas may be offered for distant metastases. The literature on the use of chemotherapy for recurrent vulvar cancer consists of mainly small series. The most extensively studied regimens contain *bleomycin* and *methotrexate*, with or without *cisplatin* or *CCNU* (a nitrosourea) and *bleomycin* and *mitomycin C* (116,2), but response rates are low and the duration of response is usually disappointing. Long-term survival is very uncommon with regional or distant recurrence.

Figure 36.6 Melanoma of the vulva involving the right labium minus. (From Hacker NF, Moore JG, Gambone JC. Essentials of obstetrics and gynecology. In: Berek JS, Hacker NF. Practical gynecologic oncology, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005:473, with permission.)

Melanoma

Vulvar melanomas are rare, with an incidence of 0.1 to 0.19 per 100,000 women (118,2). They account for 4% to 10% of all cases and are the second most common form of vulvar malignancy (38). Most melanomas arise *de novo* (120), but they may arise from a pre-existing junctional nevus. Vulvar melanomas occur predominantly in postmenopausal white women. The incidence of cutaneous melanomas worldwide is increasing significantly. Vulvar melanomas appear to behave in a manner similar to that of other cutaneous melanomas (121,122,123).

Most patients with vulvar melanoma have no symptoms except for a pigmented lesion that may be enlarging. Some patients have itching or bleeding, and a few have a groin mass. Vulvar melanomas occur most frequently on the labia minora or the clitoris (Fig. 36.6),

P.1566

and extension into the urethra or vagina at discovery is not uncommon. Any pigmented lesion on the vulva should be excised or, if the lesion is large, sampled for biopsy unless it is known to have been present and unchanged for some years. Most vulvar nevi are junctional and may be precursor lesions to melanoma; thus, any nevus of the vulva should be removed.

Histopathology

There are three basic histologic types of vulvar melanoma (Fig. 36.7).

The *mucosal lentiginous melanoma* is a flat freckle that may become quite extensive but tends

to remain superficial.

- The *superficial spreading melanoma* tends to remain relatively superficial early in its development.
- The *nodular melanoma*, which is the most aggressive, is characterized by a raised lesion that penetrates deeply and may metastasize widely.

In the largest series reported to date, more than one fourth of the cases of melanomas were macroscopically amelanotic (118). Vulvar melanoma tends to spread early, not only lymphatically but also hematogenously.

Figure 36.7 Vulvar melanoma. Spindle-shaped melanoma cells form interlacing bundles, and some contain melanin pigment (right upper corner). Epidermal invasion is evident in the form of Pagetoid migration (left upper corner).

Staging

The FIGO staging used for squamous lesions is not applicable to melanomas because the lesions are usually much smaller and the prognosis is related to the depth of tumor invasion rather than to the diameter of the lesion (121,124,125). The leveling system established by Clark et al. (125) for cutaneous melanomas is less readily applicable to vulvar lesions because of the different skin morphology. The vulvar skin

lacks a well-defined papillary dermis. Breslow (126) measured the thickest portion of the melanoma from the surface of intact epithelium to the deepest point of invasion. This system is more adequate for the vulva. Chung et al. (124) proposed a modified system that retained

Clark's definitions for levels I and V but arbitrarily defined levels II, III, and IV, using measurements in millimeters. A comparison of these systems is shown in Table 36.6.

	Clark Level (125)	Chung Depth of Invasion (124)	Breslow Tumor Thickness (126)
I	Intraepithelial	Intraepithelial	<0.76 mm
II	Into papillary dermis	<1 mm from granular layer	0.76–1.5 mm Superficial invasion
III	Filling dermal papillae	1.1–2.0 mm from granular layer	1.51–2.25 mm Intermediate invasion
IV	Into reticular dermis	>2 mm from granular layer	2.26–3.0 Intermediate invasion
V	Into subcutaneous fat	Into subcutaneous fat	>3 mm Deep invasion

The revised 2002 American Joint Committee on Cancer (AJCC) staging for cutaneous melanoma replaced the Clark level of invasion by tumor thickness and included other important prognostic factors, such as primary tumor ulceration, number of metastatic lymph nodes, micrometastatic disease based on sentinel lymph node biopsy or elective node dissection, the site(s) of distant metastatic disease, and serum LDH levels (127).

P.1568

Treatment

With better understanding of the prognostic significance of the microstage, some individualization of treatment has developed. However, treatment of vulvar melanoma continues to be controversial, in part because of the lack of large retrospective studies, which makes it difficult to draw conclusions regarding its behavior and best treatment. Currently used treatments are guided by experience from cutaneous melanoma in general and squamous cell carcinomas of the vulva. Paralleling the trend toward more conservative surgical management of cutaneous melanoma, there is a shift toward more conservative management of vulvar melanoma (122,123,128,129).

It is generally accepted that lesions with less than 1 mm of invasion may be treated with radical local excision alone (124,2). With more invasive lesions, *en bloc* resection of the primary tumor and regional groin nodes has traditionally been recommended. In the last 15 years, however, **radical vulvectomy has been performed less frequently, and survival does not seem to be compromised** (131). One study reported on 32 patients with vulvar melanoma who underwent local excision ($n = 14$), simple vulvectomy ($n = 7$), or radical resection ($n = 11$) (132). No group had a superior survival rate, although the overall survival rate at 5 years was only 25%. More recently, another study reported on 59 patients who underwent radical vulvectomy and 19 who underwent more conservative resections (122). Survival was not improved by the more radical approach, and they recommended radical local excision for the primary tumor, with groin dissection for tumors with a thickness of more than 1 mm. Current literature on cutaneous melanoma suggests that a 1-cm margin of skin and subcutaneous tissue is sufficient for the treatment of superficial localized melanoma (Breslow tumor thickness <0.76 mm), whereas a 2-cm margin suffices for intermediate-thickness lesions (1 to 4 mm) (133,2). Because melanomas commonly involve the clitoris and labia minora, the vaginourethral margin of resection is a common site of failure, and care should

be taken to obtain an adequate "inner" resection margin (135). A 10-year survival rate of 61% has been shown for lateral lesions, compared with 37% for medial lesions ($p = 0.027$) (111).

Controversy exists as to which patients may benefit from inguinal-

femoral lymphadenectomy. A prospective study by the GOG demonstrated that the risk of inguinal-femoral lymph node metastasis correlated with the Breslow microstage (123). As with cutaneous melanoma, it appears that for superficial lesions (Breslow tumor thickness <0.76 mm), the risk for nodal spread is so low that routine lymphadenectomy is not indicated as long as the nodes appear clinically to be free of disease. **For intermediate-thickness (1 to 4 mm) cutaneous melanoma, a randomized controlled trial of elective lymph node dissection versus observation showed a 5-year survival advantage for patients who underwent elective lymph node dissection, who were younger than 60 years, and whose tumors were characterized by 1- to 2-mm thickness and no ulcerations (136). Patients with deeply invasive cutaneous melanomas (>4-mm tumor thickness) have a high risk of regional and systemic metastases and are unlikely to benefit from regional lymphadenectomy (137).** Given some of the epidemiologic, histologic, and prognostic differences between vulvar and cutaneous melanoma (138), extrapolation of these data to the vulva should be done with caution. Specific to patients with vulvar melanoma, there is a small body of literature to suggest that there may be a clinical benefit in elective groin lymphadenectomy and the resection of clinically positive nodes (121,2).

Table 36.7 Prognosis for Patients with Vulvar Melanoma Stratified by Breslow Microstaging

<i>Breslow Tumor Thickness</i>	<i>No. of Patients</i>	<i>% DOD</i>
< 0.76 mm	31 [19]	7 (23%) [1 (5%)] ^a
0.76–1.5 mm	35	6 (17%)
1.51–3.0 mm	42	23 (55%)
> 3.0 mm	195	131 (67%)

DOD, died of disease.

^aAll but one of these seven deaths were reported in one study with an unusually low 5-year survival of 48% for 12 patients with superficial melanomas of Breslow thickness <0.76 mm. If these 12 cases were excluded, 5% of patients with superficial melanoma of the vulva died of disease.

From references 118, 122, 130, 139, 140, 148–151.

Pelvic node metastases do not occur in the absence of groin node

metastases (135,139,140). In addition, the prognosis for patients with positive pelvic nodes is so poor that there seems to be no value in performing pelvic lymphadenectomy for this disease. Immunotherapy and chemotherapy have demonstrated modest results in cutaneous melanoma. Several randomized cooperative and intergroup trials of high-risk melanoma patients have demonstrated a small but significant improvement in disease-free and overall

P.1569

survival with adjuvant interferon alpha (141,142,143). Dacarbazine (DTIC) is considered the most active single-agent chemotherapy with a response rate of 16%, and randomized controlled trials have failed to date to demonstrate superiority of any multiagent regimen (144). Targeted therapy is an area of promising development as single agents, in combination, and combined with chemotherapy. Vaccines stimulating both antibody and T-cell responses against melanoma are a promising but still considered experimental treatment that is under investigation (145). Radiation has a role in the palliative management of brain metastasis and symptomatic bony metastases. Estrogen receptors have been demonstrated in

human melanomas, and an occasional response to *tamoxifen* has been reported (146,2).

Prognosis

The behavior of melanomas can be quite unpredictable, but the overall prognosis is poor. The reported 5-year survival rate for vulvar melanoma ranges from 25% (132) to 50% (118,2). Because vulvar melanoma has a propensity for late recurrences, 5-year survival may not reflect cure. Prognosis is best predicted by microstaging. Patients with lesions invading to 1 mm or less have a good prognosis, but as depth of invasion increases, the prognosis worsens (Table 36.7). Tumor volume has been reported to correlate with prognosis; patients whose lesions have a volume less than 100 mm³ have an excellent prognosis (140). Additional prognostic factors are the patient's age, AJCC stage, presence of multifocal or satellite lesions, tumor ulceration, central tumor location, histologic growth pattern, lymph-vascular space involvement, and aneuploidy (118,121,122,123,149).

Bartholin Gland Carcinoma

Epidemiology

Primary carcinoma of the Bartholin gland is a rare form of vulvar cancer, which accounts for about 2% to 7% of vulvar malignancies (152). Because of its rarity, individual experience with the tumor is limited, and recommendations for management must be based on the review of small published series. To date, only about 300 cases have been reported (50,152,153). Bartholin gland carcinoma is 5 times more common in postmenopausal than in premenopausal women (154).

Histopathology

The bilateral Bartholin glands are greater vestibular glands situated posterolaterally in the vulva. Their main duct is lined with stratified squamous epithelium, which changes to transitional epithelium as the terminal ducts are reached. Because tumors may arise from the

P.1570

gland or the duct, a variety of histologic types occur, including adenocarcinomas, squamous carcinomas, and, rarely, transitional cell, adenosquamous, and adenoid cystic carcinomas.

Classification of a vulvar tumor as a Bartholin gland carcinoma has typically required that it fulfill Honan's criteria, which are as follows:

- **The tumor is in the correct anatomic position.**
- **The tumor is located deep in the labium majus.**
- **The overlying skin is intact.**
- **There is some recognizable normal gland present.**

Strict adherence to these criteria will result in underdiagnosis of some cases. Large tumors may ulcerate through the overlying skin and obliterate the residual normal gland. Although transition between normal and malignant tissue is the best criterion, some cases will be

diagnosed on the basis of their histologic characteristics and anatomic location.

Signs and Symptoms

The most common initial symptom of Bartholin gland carcinoma is a vulvar mass or perineal pain. About 10% of patients have a history of inflammation of the Bartholin gland, and malignancies may be mistaken for benign cysts or abscesses. Therefore, delay of diagnosis is common, particularly for premenopausal patients. The differential diagnosis of any pararectovaginal neoplasm should include cloacogenic carcinoma and secondary neoplasm (153).

Treatment

Traditionally, treatment has been radical vulvectomy with bilateral groin and pelvic node dissection (155). However, there seems to be **no indication for dissection of the pelvic nodes in the absence of positive groin nodes, and good results have been reported with hemivulvectomy or radical local excision for the primary tumor** (153). Because these lesions are deep in the vulva, extensive dissection is required in the ischiorectal fossa; even then, surgical margins are often close. Postoperative radiation to the vulva decreased the likelihood of local recurrence from 27% (6 of 22 patients) to 7% (1 of 14 patients) (153). If the ipsilateral groin nodes are positive, bilateral groin and pelvic irradiation may decrease regional recurrence. If the tumor is fixed to the inferior pubic ramus or involves adjacent structures, such as the anal sphincter or rectum, preoperative radiation and chemotherapy is preferable to avoid ultraradical surgery.

Table 36.8 Survival of Patients with Bartholin Gland Carcinoma

<i>FIGO Stage</i>	<i>No. of Patients</i>	<i>No. of Patients with Recurrent Disease</i>	<i>No. of Patients NED at last F/U^a</i>
I	15 (21%)	3 (20%)	14 (93%)
II	16 (23%)	2 (13%)	15 (94%)
III	30 (42%)	11 (37%)	22 (73%)
IV	10 (14%)	5 (50%)	5 (50%)
Total	71 (14%)	21	56 (79%)

FIGO, International Federation of Gynecology and Obstetrics; NED, no evidence of disease; F/U, follow-up.

^aMedian follow-up in each study was at least 5 years.

From references 50, 152, 153, 156

Prognosis

Because of the deep location of the gland, disease tends to be more advanced than squamous carcinomas at the time of diagnosis but, stage for stage, the prognosis is similar. Five-year disease-free survival rates by stage are summarized in Table 36.8.

Adenoid Cystic Carcinoma of the Bartholin Gland

The adenoid cystic variety accounts for 15% of Bartholin gland carcinomas. It is less likely to metastasize to lymph nodes and carries a somewhat better prognosis (50,2) (Fig. 36.8). Local recurrences are common, however, and metastases may occur, particularly to the lungs. The slowly progressive nature of these tumors and the tendency for late

recurrences is reflected in the disparity between progression-free interval and survival curves (157).

Figure 36.8 Adenoid cystic tumor of the Bartholin gland. Basaloid cells form cribriform, sievelike spaces containing mucinous material. The hyaline stroma is another distinct feature of this tumor.

Other Adenocarcinomas

Adenocarcinomas of the vulva usually arise in a Bartholin gland or occur in association with Paget disease. They may rarely arise from the skin appendages, paraurethral glands, minor vestibular glands, aberrant breast tissue, endometriosis, or a misplaced cloacal remnant (158).

P.1572

Adenosquamous Carcinoma

A particularly aggressive type of carcinoma is the adenosquamous carcinoma. This tumor has a number of synonyms, including cylindroma, pseudoglandular squamous cell carcinoma, adenoid squamous cell carcinoma, and adenoacanthoma of the sweat gland of Lever. The tumor has a propensity for perineural invasion, early lymph node metastasis, and local recurrence. One study noted a crude 5-year survival rate of 5.5% (1 of 18) for adenosquamous carcinoma of the vulva, compared with 62.3% (48 of 77) for patients with squamous cell carcinoma (159). Treatment should be radical vulvectomy and bilateral groin dissection. Postoperative radiation therapy may be appropriate.

Basal Cell Carcinoma

Basal cell carcinomas represent about 2% of vulvar cancers. As with other basal cell carcinomas, vulvar lesions commonly appear as a "rodent ulcer" with rolled edges, although nodules and macules are other morphologic varieties that occur. Most lesions are smaller than 2 cm in diameter and are usually situated on the anterior labia majora. Giant lesions occasionally occur (160). Basal cell carcinoma usually affects postmenopausal white women and is locally aggressive. Symptoms are frequently present for a prolonged period and most frequently include pruritus, soreness, and irritation (161). It is diagnosed by biopsy, and **radical local excision is generally adequate treatment** (162). **Metastasis to regional lymph nodes has been reported but is rare** (163,164,165). The local recurrence rate is about 10% to 20% (161,2). Basal cell carcinoma of the vulva is associated with a high incidence of antecedent or concomitant malignancies elsewhere (161). In a series of 28 women with vulvar basal cell carcinoma, 10 patients had other basal cell carcinomas, and 10 patients suffered from other primary malignancies (161).

About 3% to 5% of basal cell carcinomas contain a malignant squamous component, the so-called *basosquamous carcinoma*. These lesions are more aggressive and should be treated as squamous carcinomas (165). Another subtype of basal cell carcinoma is the adenoid basal cell carcinoma, which must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or the skin (165).

Verrucous Carcinoma

Verrucous carcinoma is a variant of squamous cell carcinoma and has distinctive clinical and pathologic characteristics (167). Although most commonly found in the oral cavity, verrucous lesions may be found on any moist membrane composed of squamous epithelium (168). In the female genital tract, these lesions may develop on the cervix, vulva, and vagina. The cause of the lesion in the female genital tract is not fully understood, but associated HPV-6 and HPV-11 have been found in some studies (169), whereas others find it to have no association with HPV infection (170). Some studies have found as many as one third of the cases to have coexisting squamous carcinoma of the vulva (171), underscoring the importance of careful histopathologic assessment of these tumors.

Figure 36.9 Verrucous carcinoma of the vulva. Note the exophytic hyperkeratotic papillary fronds and endophytic bulky rete pegs with smooth borders.

Grossly, the tumors have a cauliflowerlike appearance; microscopically, they contain multiple papillary fronds that lack the central connective tissue core that characterizes condylomata acuminata (Fig. 36.9). The gross and microscopic features of a verrucous carcinoma are very similar to those of the **giant condyloma of Buschke-Loewenstein**, and they probably represent the same disease entity (158). Adequate biopsy from the base of the lesion is required to differentiate a verrucous carcinoma from a benign condyloma acuminatum or a squamous cell carcinoma with a verrucous growth pattern.

Verrucous carcinomas usually occur in postmenopausal women, and they are slow-growing but locally destructive lesions. Even bone may be invaded.

P.1573

Metastasis to regional lymph nodes is rare but has been reported (172). Radical local excision is the basic treatment, although any palpably suspicious groin nodes should be evaluated with fine-needle aspiration cytology or excisional biopsy. Usually, enlarged nodes will be caused by inflammatory hypertrophy (173). If the nodes contain metastases, radical vulvectomy and bilateral inguinal-femoral lymphadenectomy are indicated.

Several small studies failed to document any therapeutic advantage with radiation therapy (173,2). In addition, there is concern that radiation may induce anaplastic transformation with subsequent regional and distant metastasis (175). One study reported a corrected 5-

year survival rate of 94% for 17 patients treated with surgery alone, compared with 42% for 7 patients treated with surgery and radiation (173). The latter patients had, however, more advanced disease. If there is a recurrence, further surgical excision is the treatment of choice, which occasionally may necessitate some type of exenteration.

Vulvar Sarcoma

Sarcomas represent 1.5% of vulvar malignancies and constitute a heterogenous group of tumors (176). Leiomyosarcomas are the most common, and other histologic

P.1574

types include fibrosarcomas, neurofibrosarcomas, liposarcomas, rhabdomyosarcomas, angiosarcomas, epithelioid sarcomas, and malignant schwannomas.

Leiomyosarcomas usually appear as enlarging, often painful masses, usually in the labium majus. Smooth muscle tumors of the vulva that show at least three of the following four criteria should be regarded as sarcomas: (i) diameter >5 cm, (ii) infiltrating margins, (iii) 5 or more mitotic figures per 10 high-power fields, (iv) moderate-to-severe cytological atypia (177). The absence of one, or even all, of these features does not guarantee against recurrence (178). Lymphatic metastases are uncommon, and radical local excision is the usual treatment.

Epithelioid sarcomas characteristically develop in the soft tissues of the extremities of young adults but rarely may occur on the vulva. In a description of two cases and review of three other reports, the authors concluded that these tumors may mimic a Bartholin cyst, thus leading to inadequate initial treatment (179). They also believed that vulvar epithelioid sarcomas behave more aggressively than their extragenital counterparts, with four of the five patients dying of metastatic disease. They suggested that early recognition and wide excision should improve the prognosis.

Rhabdomyosarcomas are the most common soft tissue sarcomas in childhood, and 20% involve the pelvis or genitourinary tract (180). Dramatic gains have been made in the treatment of these tumors during the past 20 years. Previously, radical pelvic surgery was the standard approach, but results were poor. More recently, a multimodal approach has evolved, and survival rates have improved significantly, with a corresponding decrease in morbidity. In a report of the experience of the Intergroup Rhabdomyosarcoma Study I and II (1972 to 1984) with primary tumors of the female genital tract, nine patients aged 1 to 19 years had primary vulvar tumors, and these tumors were often regarded as a form of Bartholin gland infection before biopsy (181). They were all managed with chemotherapy (*vincristine*, or *actinomycin D* and *cyclophosphamide* and *doxorubicin*), with or without radiotherapy. Wide local excision of the tumor, with or without inguinal-femoral lymphadenectomy, was carried out before or after the chemotherapy. Seven of the nine patients were free of disease 4 or more years from diagnosis, one patient was free of disease when lost to follow-up at 5 years, and one patient was alive with disease.

Rare Vulvar Malignancies

In addition to the previously mentioned tumors, a number of malignancies more commonly seen in other areas of the body may rarely occur as isolated vulvar tumors.

Lymphomas

The genital tract may be involved primarily by malignant lymphomas but, more commonly, involvement is a manifestation of systemic disease. In the lower genital tract, the cervix is most often involved, followed by the vulva and the vagina (182). Most patients are

in their third to sixth decade of life, and about three fourths of the cases involve diffuse large cell or histiocytic non-Hodgkin's lymphomas. The remainder are nodular or Burkitt's lymphomas. Treatment is by surgical excision followed by chemotherapy and radiation or both, and the overall 5-year survival rate is about 70% (182).

Endodermal Sinus Tumor

There have been four case reports of endodermal sinus tumor of the vulva, and three of the four patients died of distant metastases (183). All patients were in their third decade of life, but none was treated with modern chemotherapy.

P.1575

Merkel Cell Carcinoma

Merkel cell carcinomas are primary small cell carcinomas of the skin that resemble oat cell carcinomas of the lung. They metastasize widely and have a very poor prognosis (184,2). They should be locally excised and treated with *cisplatin*-based chemotherapy.

Dermatofibrosarcoma Protuberans

This rare, low-grade cutaneous malignancy occasionally involves the vulva. It has a marked tendency for local recurrence but a low risk of systemic spread (186). Radical local excision should be sufficient treatment.

Metastatic Tumors of the Vulva

Eight percent of vulvar tumors are metastatic. The most common primary site is the cervix, followed by the endometrium, kidney, and urethra. Most patients in whom vulvar metastases develop have advanced primary tumors when diagnosed, and in about one fourth of the patients, the primary lesion and the vulvar metastasis are diagnosed simultaneously (187).

Gestational Trophoblastic Disease

Ross S. Berkowitz

Donald P. Goldstein

- **Complete molar pregnancies are generally diploid, and all chromosomes are of paternal origin.**
- **Partial molar pregnancies are triploid, and the extra set of chromosomes is paternal.**
- **Complete moles are being diagnosed earlier in pregnancy and less frequently present with the classic signs and symptoms.**
- **Single-agent chemotherapy achieves a high remission rate in nonmetastatic and low-risk metastatic gestational trophoblastic tumors.**
- **After achieving remission with chemotherapy, patients with gestational trophoblastic tumors can generally anticipate normal reproduction in the future.**

Gestational trophoblastic disease (GTD) is among the rare human tumors that can be cured even in the presence of widespread dissemination (1,2). It encompasses

a spectrum of interrelated tumors, including complete and partial hydatidiform mole, placental-site trophoblastic tumor, and choriocarcinoma, which have varying propensities for local invasion and metastasis. Although persistent gestational trophoblastic tumors (GTTs) most commonly follow a molar pregnancy, they can occur after any gestational event, including induced or spontaneous abortion, ectopic pregnancy, or term pregnancy.

Hydatidiform Mole

Epidemiology

Estimates of the incidence of GTD vary dramatically in different regions of the world.

For example, the incidence of molar pregnancy in Japan (2 per 1,000 pregnancies)

P.1582

P.1583

has been reported to be about threefold higher than the incidence in Europe or North America (about 0.6 to 1.1 per 1,000 pregnancies) (3). The variation in the incidence rates of molar pregnancy may in part result from differences between reporting population-based versus hospital-based data. The incidences of both complete and partial mole have been investigated in Ireland by reviewing all products of conception from first- and second-trimester abortions (4). **Based on a thorough pathologic review, the incidence of complete and partial mole was found to be 1 per 1,945 and 1 per 695 pregnancies, respectively.**

Case-control studies have been undertaken to identify risk factors for complete and partial molar pregnancy. The high incidence of molar pregnancy in some populations has been attributed to nutritional and socioeconomic factors. **Case-control studies from Italy and the United States have shown that low dietary intake of carotene may be associated with an increased risk of complete molar pregnancy (5,6). Areas with a high incidence of molar pregnancy also have a high frequency of vitamin A deficiency. Dietary factors, therefore, may partly explain regional variations in the incidence of complete mole.**

Maternal age older than 35 years has consistently been shown to be a risk factor for complete mole. Ova from older women may be more susceptible to abnormal fertilization. In one study, the risk for complete mole was increased 2.0-fold for women older than 35 years and 7.5-fold for women older than 40 years (7).

Limited information is available concerning risk factors for partial molar pregnancy. However, the epidemiologic characteristics of complete and partial mole may differ. The risk for partial mole has been associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors (8). There is no association between maternal age and the risk for partial mole (7).

Complete versus Partial Hydatidiform Mole

Hydatidiform moles may be categorized as either complete or partial moles on the basis of gross morphology, histopathology, and karyotype (Table 37.1).

Complete Hydatidiform Mole

Complete hydatidiform moles exhibit characteristic swelling and trophoblastic

hyperplasia (Fig. 37.1).

They usually have a 46, XX karyotype, although about 10% have a 46, XY karyotype (9). The molar chromosomes are entirely of paternal origin, although mitochondrial DNA is of maternal origin (10,11) (Fig. 37.2). It appears that complete moles usually

P.1584

arise from an ovum that has been fertilized by a haploid sperm, which then duplicates its own chromosomes. The ovum nucleus may be either absent or inactivated (12).

<i>Features</i>	<i>Complete Mole</i>	<i>Partial Mole</i>
Fetal or embryonic tissue	Absent	Present
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Scalloping of chorionic villi	Absent	Present
Trophoblastic stromal inclusions	Absent	Present
Karyotype	46, XX (90%); 46, XY	Triploid

Figure 37.1 Photomicrograph of complete mole demonstrating enlarged villous with central cavitation and surrounding trophoblastic hyperplasia.

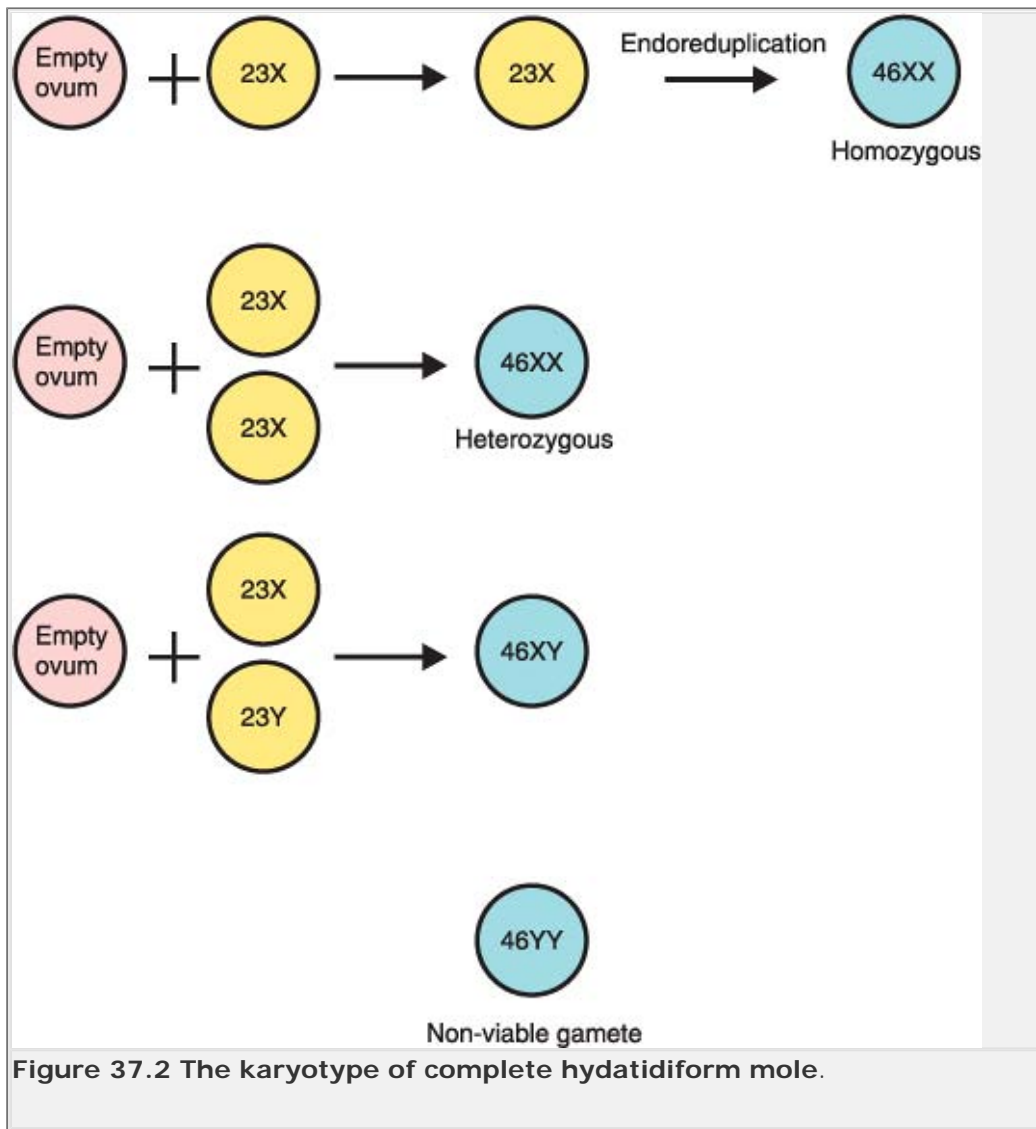

Figure 37.2 The karyotype of complete hydatidiform mole.

Figure 37.3 Photomicrograph of partial mole showing marked disparity in villous size, trophoblastic inclusions (center), and mild trophoblastic hyperplasia. (From Berkowitz RS, Goldstein OP. Gestational trophoblastic diseases. In: Ryan KJ, Berkowitz R, Barbieri R, eds. *Kistner's gynecology principles and practice*, 5th ed. Chicago, IL: Year Book Medical Publishers, 1990:433, with permission.)

Partial Hydatidiform Mole

Partial hydatidiform moles are characterized by the following pathologic features (13) (Fig. 37.3):

- Chorionic villi of varying size with focal hydatidiform swelling, cavitation, and trophoblastic hyperplasia
- Marked villous scalloping
- Prominent stromal trophoblastic inclusions
- Identifiable embryonic or fetal tissues

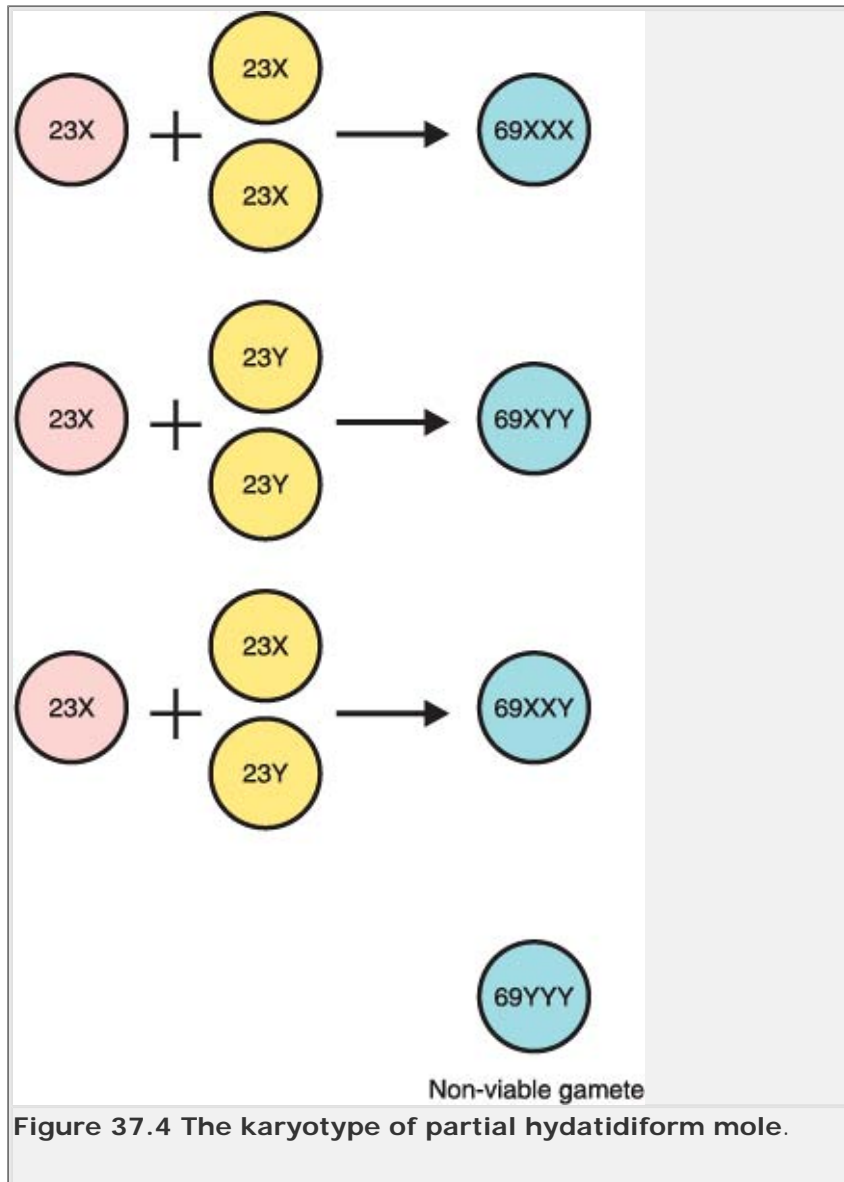

Partial moles generally have a triploid karyotype (69 chromosomes); the extra haploid set of chromosomes usually is derived from the father (Fig. 37.4) (14). It is possible that nontriploid partial moles do not exist (15). When a fetus is present in conjunction with a partial mole, it generally exhibits the stigmata of triploidy, including growth retardation and multiple congenital malformations such as syndactyly and hydrocephaly (Fig. 37.5).

Clinical Features

Patients with complete molar pregnancy are increasingly being diagnosed earlier in pregnancy and treated before they develop the classic clinical signs and symptoms. This may

P.1585

be because of changes in clinical practice, such as the frequent use of human chorionic gonadotropin (hCG) measurement and vaginal probe ultrasonography in early pregnancy in women with vaginal staining and even asymptomatic women. Following is a description of the classic and current clinical features of complete molar pregnancy (16).

Complete Hydatidiform Mole

Vaginal Bleeding

Vaginal bleeding is the most common symptom causing patients to seek treatment for complete molar pregnancy. Previously it was reported to occur in 97% of cases, whereas currently it is reported to occur in 84% of patients (17). Molar tissues may separate from the decidua and disrupt maternal vessels, and large volumes of retained blood may distend

the endometrial cavity. Because vaginal bleeding may be considerable and prolonged, one half of these patients had anemia (hemoglobin <10 g/100 mL). Currently anemia is present in only 5% of patients.

Excessive Uterine Size

Excessive uterine enlargement relative to gestational age is one of the classic signs of a complete mole, although it was present in only about one half of patients.

Currently, excessive uterine size occurs in only 28% of patients.

The endometrial cavity may be expanded by both chorionic tissue and retained blood. Excessive uterine size is generally associated with markedly elevated levels of hCG, because uterine enlargement results in part from trophoblastic overgrowth.

Figure 37.5 Photomicrograph of a fetal hand demonstrating syndactyly. The fetus had a triploid karyotype, and the chorionic tissues were a partial mole.

Preeclampsia

Preeclampsia was once observed in 27% of patients with a complete hydatidiform mole. Preeclampsia is now reported in only 1 of 74 patients with complete mole at the initial visit (17). Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia, eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform mole should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum

Hyperemesis requiring antiemetic or intravenous replacement therapy once occurred in one fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels. Severe electrolyte disturbances may develop and require treatment with parenteral fluids. Currently, only 8% of patients have hyperemesis.

P.1587

Hyperthyroidism

Clinically evident hyperthyroidism was once observed in 7% of patients with a complete molar gestation. These women may have tachycardia, warm skin, and tremor, and the diagnosis can be confirmed by detection of elevated serum levels of free thyroxine (T_4) and tri-iodothyronine (T_3). Currently, clinical evidence of hyperthyroidism with complete mole is rare.

Anesthesia or surgery may precipitate thyroid storm. Thus, if hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, β -adrenergic blocking agents should be administered. Thyroid storm may be manifested by hyperthermia, delirium, convulsions, tachyarrhythmia, high-output heart failure, or cardiovascular collapse. Administration of β -adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results return rapidly to normal.

Hyperthyroidism develops almost exclusively in patients with very high hCG levels. Some investigators have suggested that hCG is the thyroid stimulator in women with GTD, because positive correlations between serum hCG levels and total T_4 or T_3 concentrations have been observed. However, in one study in which thyroid function was measured in 47 patients with a complete mole, no significant correlation was found between serum hCG levels and serum values of free T_4 index or free T_3 index (18). Although some investigators have speculated about a separate chorionic thyrotropin, this substance has not yet been isolated.

Trophoblastic Embolization

Respiratory distress developed in 2% of patients with a complete mole in the past, but currently rarely occurs. Respiratory distress is usually diagnosed in patients with excessive uterine size and markedly elevated hCG levels. These patients may have chest pain, dyspnea, tachypnea, and tachycardia and may experience severe respiratory distress

during and after molar evacuation. Auscultation of the chest usually reveals diffuse rales, and chest radiographic evaluation may show bilateral pulmonary infiltrates. Respiratory distress usually resolves within 72 hours with cardiopulmonary support. In some circumstances, patients may require mechanical ventilation. Respiratory insufficiency may result from trophoblastic embolization and the cardiopulmonary complications of thyroid storm, preeclampsia, and massive fluid replacement.

Theca Lutein Ovarian Cysts

Prominent theca lutein ovarian cysts (6 cm in diameter) develop in about one half of patients with a complete mole (19). Theca lutein ovarian cysts result from high serum hCG levels, which cause ovarian hyperstimulation (20). Because the uterus also may be excessively enlarged, theca lutein cysts may be difficult to palpate during physical examination; however, ultrasonography can accurately document their presence and size. **After molar evacuation, theca lutein cysts normally regress spontaneously within 2 to 4 months.**

Prominent theca lutein cysts may cause symptoms of marked pelvic pressure, and they can be decompressed by laparoscopic or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture. Early diagnosis of complete mole not only alters the clinical presentation but also changes the pathologic characteristics. First trimester complete moles have smaller chorionic villi and less extensive trophoblastic hyperplasia and may, therefore, be difficult to distinguish from partial mole or hydropic abortion (21).

Partial Hydatidiform Mole

Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. **In general, these patients have the signs and symptoms of incomplete or missed abortion, and partial mole can be diagnosed after histologic review of the tissue obtained by curettage (22).**

P.1588

In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (23). Excessive uterine enlargement and preeclampsia were present in only three patients (3.7%) and two (2.5%) patients, respectively. No patient had theca lutein ovarian cysts, hyperemesis, or hyperthyroidism. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in only five patients (6.2%). Pre-evacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/mL in only two patients (6.6%).

Natural History

Complete Hydatidiform Mole

Complete moles have a potential for local invasion and dissemination. **After molar evacuation, local uterine invasion occurs in 15% of patients, and metastasis occurs in 4% (19).**

A review of 858 patients with complete hydatidiform mole revealed that two fifths of the patients had the following signs of marked trophoblastic proliferation at the time they sought treatment (19):

- **hCG level > .100,000 mIU/mL**
- **Excessive uterine enlargement**
- **Theca lutein cysts 6 cm in diameter**

In this review, patients with any one of these signs were considered at high risk for developing postmolar tumor. After molar evacuation, local uterine invasion occurred in 31%, and metastases developed in 8.8% of the 352 high-risk patients. For the 506 low-risk patients, local invasion was found in only 3.4%, and metastases developed in 0.6%.

Older patients are also at increased risk of developing postmolar GTT. One study reported that persistent tumor developed after a complete molar pregnancy in 37% of women older than 40 years (24), whereas in another study this finding occurred in 56% of women older than 50 years (25).

Partial Hydatidiform Mole

Persistent tumor, usually nonmetastatic, develops in approximately 2% to 4% of patients with a partial mole, and chemotherapy is required to achieve remission (26). Patients who develop persistent disease have no distinguishing clinical or pathologic characteristics (27).

Diagnosis

Ultrasonography is a reliable and sensitive technique for the diagnosis of complete molar pregnancy. Because the chorionic villi exhibit diffuse hydropic swelling, complete moles produce a characteristic vesicular ultrasonographic pattern even in the first trimester (Fig 37.6).

Ultrasonography also may contribute to the diagnosis of partial molar pregnancy by demonstrating focal cystic spaces in the placental tissues and an increase in the transverse diameter of the gestational sac (28). When both of these criteria are present, the positive predictive value for partial mole is 90%.

Figure 37.6 Ultrasonogram of a uterus showing a typical pattern of a complete hydatidiform mole. Note the characteristic vesicular ultrasonographic pattern.

P.1589

Treatment

After molar pregnancy is diagnosed, the patient should be evaluated carefully for the presence of associated medical complications, including preeclampsia, hyperthyroidism, electrolyte imbalance, and anemia. After the patient's condition has been stabilized, a decision must be made concerning the most appropriate method of evacuation.

Hysterectomy

If the patient desires surgical sterilization, a hysterectomy may be performed with the mole *in situ*. *The ovaries may be preserved at the time of surgery, even in the presence of prominent theca lutein cysts. Large ovarian cysts may be decompressed by aspiration. Hysterectomy does not prevent metastasis; therefore, patients still require follow-up with assessment of hCG levels.*

Suction Curettage

Suction curettage is the preferred method of evacuation, regardless of uterine size, for patients who desire to preserve fertility. It involves the following steps:

- **Oxytocin infusion**—This procedure is begun before the induction of anesthesia.
 - **Cervical dilation**—As the cervix is being dilated, uterine bleeding often increases. Retained blood in the endometrial cavity may be expelled during cervical dilation. However, active uterine bleeding should not deter the prompt completion of cervical dilation.
-
- **Suction curettage**—Within a few minutes of commencing suction curettage, the uterus may decrease dramatically in size, and the bleeding is generally well controlled. The use of a 12-mm cannula is strongly advised to facilitate evacuation. If the uterus is larger than 14 weeks of gestation, one hand should be placed on top of the fundus, and the uterus should be massaged to stimulate uterine contraction and reduce the risk of perforation.
 - **Sharp curettage**—When suction evacuation is believed to be complete, gentle sharp curettage is performed to remove any residual molar tissue.

P.1590

Because trophoblast cells express RhD factor, patients who are Rh negative should receive Rh immune globulin at the time of evacuation.

Prophylactic Chemotherapy

The use of prophylactic chemotherapy at the time of molar evacuation is controversial (29). The debate concerns the wisdom of exposing all patients to potentially toxic treatment when only about 20% are at risk of developing persistent tumor.

In a study of 247 patients with complete molar pregnancy who received prophylactically a single course of *actinomycin D* at the time of evacuation, local uterine invasion subsequently developed in only 10 patients (4%), and no patients experienced metastasis (29). Furthermore, all 10 patients with local invasion achieved remission after only one additional course of chemotherapy. **Prophylactic chemotherapy, therefore, not only prevented metastasis but also reduced the incidence and morbidity of local uterine invasion.**

In two prospective randomized studies of prophylactic chemotherapy in patients with a complete mole, a significant decrease in persistent tumor was detected in patients with high-risk mole who received prophylactic chemotherapy (47% and 50% versus 14%) (30,31). **Prophylaxis may be particularly useful in the management of high-risk complete molar pregnancy, especially when hCG assessments for follow-up are unavailable or unreliable.**

Follow-up

Human Chorionic Gonadotropin

After molar evacuation, patients should be monitored with weekly determinations of β -subunit hCG levels until these levels are normal for 3 consecutive weeks, followed

by monthly determinations until the levels are normal for 6 consecutive months. The average time to achieve the first normal hCG level after evacuation is about 9 weeks (32). At the completion of follow-up, pregnancy may be undertaken. After a patient achieves a nondetectable hCG level, the risk of developing tumor relapse is very low and may approach zero (33).

Contraception

Patients are encouraged to use effective contraception during the entire interval of hCG follow-up. Because of the potential risk of uterine perforation, intrauterine devices should not be inserted until the patient achieves a normal hCG level. If the patient does not desire surgical sterilization, either oral contraceptives or barrier methods should be used.

P.1591

The incidence of postmolar persistent tumor has been reported to be increased among patients who used oral contraceptives before gonadotropin remission (34). However, more recent data indicate that oral contraceptive use does not increase the risk of postmolar trophoblastic disease (35,36). **It appears that oral contraceptives may be used safely after molar evacuation during the entire interval of hormonal follow-up.**

Persistent Gestational Trophoblastic Tumor

Nonmetastatic Disease

Locally invasive GTT develops in about 15% of patients after evacuation of a complete mole and infrequently after other gestations (1). These patients usually present with the following symptoms:

- Irregular vaginal bleeding
- Theca lutein cysts
- Uterine subinvolution or asymmetric enlargement
- Persistently elevated serum hCG levels.

The trophoblastic tumor may perforate the myometrium, causing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage. Bulky, necrotic tumor may involve the uterine wall and serve as a nidus for infection. Patients with uterine sepsis may have a purulent vaginal discharge and acute pelvic pain.

After molar evacuation, persistent GTT may exhibit the histologic features of either hydatidiform mole or choriocarcinoma. After a nonmolar pregnancy, however, persistent GTT always has the histologic pattern of choriocarcinoma. Histologically, choriocarcinoma is characterized by sheets of anaplastic syncytiotrophoblast and cytotrophoblast without chorionic villi.

Placental-site Trophoblastic Tumor

Placental-site trophoblastic tumor is an uncommon but important variant of choriocarcinoma that consists predominantly of intermediate trophoblast (37). Relative to their mass, these tumors produce small amounts of hCG and human placental lactogen (hPL), and they tend to remain confined to the uterus, metastasizing late in their course. In contrast to other trophoblastic tumors, placental-site tumors are relatively insensitive to chemotherapy.

Metastatic Disease

Metastatic GTT occurs in about 4% of patients after evacuation of a complete mole, but it is seen more often when GTT develops after nonmolar pregnancies (1). Metastasis is usually associated with choriocarcinoma, which has a tendency toward early vascular invasion with widespread dissemination. Because trophoblastic tumors often are perfused by fragile vessels, they are frequently hemorrhagic. Symptoms of metastases may result from spontaneous bleeding at metastatic foci. The most common sites of metastases are lung (80%), vagina (30%), pelvis (20%), liver (10%), and brain (10%).

Pulmonary

At the time of diagnosis, lung involvement is visible by chest radiography in 80% of patients with metastatic GTT. Patients with pulmonary metastasis may have chest pain, cough, hemoptysis, dyspnea, or an asymptomatic lesion visible by chest radiography. Respiratory symptoms may be acute or chronic, persisting over many months.

P.1592

GTT may produce four principal pulmonary patterns:

- An alveolar or "snowstorm" pattern
- Discrete rounded densities
- Pleural effusion
- An embolic pattern caused by pulmonary arterial occlusion

Because respiratory symptoms and radiographic findings may be dramatic, the patient may be thought to have a primary pulmonary disease. Some patients with extensive pulmonary involvement have minimal, if any, gynecologic symptoms because the reproductive organs may be free of trophoblastic tumor. Unfortunately, the diagnosis of GTT may be confirmed only after thoracotomy has been performed, particularly in patients with a nonmolar antecedent pregnancy.

Pulmonary hypertension may develop in patients with GTT secondary to pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a poor clinical outcome (38).

Vaginal

Vaginal metastases occurs in 30% of the patients with metastatic tumor. These lesions are usually highly vascular and may bleed vigorously when biopsied. Metastases

to the vagina may occur in the fornices or suburethrally and may produce irregular bleeding or a purulent discharge.

Hepatic

Liver metastases occur in 10% of patients with disseminated trophoblastic tumor.

Hepatic involvement is encountered almost exclusively when there is a protracted delay in diagnosis and the patient has an extensive tumor burden. Epigastric or right upper quadrant pain may develop if metastases stretch the hepatic capsule. Hepatic lesions may be hemorrhagic, causing hepatic rupture and exsanguinating intraperitoneal bleeding.

Central Nervous System

Metastatic trophoblastic disease involves the brain in 10% of patients. Cerebral involvement is generally seen in patients with advanced disease; virtually all patients with brain metastasis have concurrent pulmonary or vaginal involvement or both. Because cerebral lesions may hemorrhage spontaneously, patients may develop acute focal neurologic deficits.

Staging

An anatomic staging system for GTT has been adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 37.2). It is hoped that this staging system will encourage the objective comparison of data from various centers (39).

Stage I: Patients have persistently elevated hCG levels and tumor confined to the uterine corpus.

Stage II: Patients have metastases to the vagina and pelvis or both.

Stage III: Patients have pulmonary metastases with or without uterine, vaginal, or pelvic involvement. The diagnosis is based on a rising hCG level in the presence of pulmonary lesions viewed by chest radiography.

P.1593

Stage IV: Patients have advanced disease and involvement of the brain, liver, kidneys, or gastrointestinal tract. These patients are in the highest risk category because they are most likely to be resistant to chemotherapy. Choriocarcinoma is usually present, and the disease commonly follows a nonmolar pregnancy.

Table 37.2 Staging of Gestational Trophoblastic Tumors^{a,b}

Stage I	Disease confined to uterus
Ia	Disease confined to uterus with no risk factors
Ib	Disease confined to uterus with one risk factor
Ic	Disease confined to uterus with two risk factors
Stage II	Gestational trophoblastic tumor extending outside uterus but limited to genital structures (adnexa, vagina, broad ligament)
IIa	Gestational trophoblastic tumor involving genital structures without risk factors
IIb	Gestational trophoblastic tumor extending outside uterus but limited to genital structures with one risk factor
IIc	Gestational trophoblastic tumor extending outside uterus but limited to genital structures with two risk factors

Stage III	<i>Gestational trophoblastic disease extending to lungs with or without known genital tract involvement</i>
IIIa	Gestational trophoblastic tumor extending to lungs with or without genital tract involvement and with no risk factors
IIIb	Gestational trophoblastic tumor extending to lungs with or without genital tract involvement and with one risk factor
IIIc	Gestational trophoblastic tumor extending to lungs with or without genital tract involvement and with two risk factors
Stage IV	<i>All other metastatic sites</i>
IVa	All other metastatic sites without risk factors
IVb	All other metastatic sites with one risk factor
IVc	All other metastatic sites with two risk factors

^aRisk factors affecting staging include the following: (i) human chorionic gonadotropin > .100,000 mIU/mL and (ii) duration of disease longer than 6 months from termination of antecedent pregnancy.

^bThe following factors should be considered and noted in reporting: (i) prior chemotherapy has been given for known gestational trophoblastic tumor, (ii) placental site tumors should be reported separately, and (iii) histologic verification of disease is not required.

Prognostic Scoring

In addition to anatomic staging, it is important to consider other variables to predict the likelihood of drug resistance and to assist in selecting appropriate chemotherapy (40). **A prognostic scoring system proposed by the World Health Organization reliably predicts the potential for resistance to chemotherapy** (Table 37.3).

	0	1	2	4
Age (years)	≤ 39	> 39		
Antecedent pregnancy	Hydatidiform mole	Abortion	Term	
Interval between end of antecedent pregnancy and start of chemotherapy (months)	<4	4–6	7–12	>12
Human chorionic gonadotropin (IU/L)	<10 ³	10 ³ –10 ⁴	10 ⁴ –10 ⁵	>10 ⁵
ABO groups		O or A	B or AB	
Largest tumor, including uterine (cm)	<3	3–5	>5	
Site of metastases		Spleen kidney	Gastrointestinal tract, liver	Brain
Number of metastases		1–3	4–8	8
Prior chemotherapy			1 drug	2 drugs

^aThe total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: <4, low risk; 5–7, middle risk; ≥8, high risk.

When the prognostic score is higher than 7, the patient is categorized as high risk and requires intensive combination chemotherapy to achieve remission. Patients with stage I disease usually have a low-risk score, and those with stage IV disease have a high-risk score. The distinction between low and high risk applies mainly to patients with stage II or III disease.

P.1594

Diagnostic Evaluation

Optimal management of persistent GTT requires a thorough assessment of the extent of the disease before the initiation of treatment. **All patients with persistent GTT should undergo a careful pretreatment evaluation, including the following:**

- Complete history and physical examination
- Measurement of the serum hCG value
- Hepatic, thyroid, and renal function tests
- Determination of baseline peripheral white blood cell and platelet counts

The metastatic workup should include the following:

- Chest radiograph or computed tomography (CT) scan
- Ultrasonography or CT scan of the abdomen and pelvis
- CT or magnetic resonance imaging (MRI) scan of the head

When the pelvic examination and chest radiographic findings are negative, metastatic involvement of other sites is uncommon.

Liver ultrasonography and CT or MRI scanning will disclose most hepatic metastases in patients with abnormal liver function tests. CT or MRI scan of the head has facilitated the early diagnosis of asymptomatic cerebral lesions. Chest CT scans may detect micrometastases not visible on chest radiography. Chest CT will demonstrate pulmonary micrometastases in about 40% of patients with presumed nonmetastatic disease (41).

P.1595

In patients with choriocarcinoma or metastatic disease, hCG levels may be measured in the cerebrospinal fluid (CSF) to exclude cerebral involvement if the results of CT scanning of the brain are normal. The ratio of plasma-to-CSF hCG tends to be lower than 60 in the presence of cerebral metastases (42). However, a single plasma-to-CSF hCG ratio may be misleading, because rapid changes in plasma hCG levels may not be reflected promptly in the CSF (43).

Pelvic ultrasonography appears to be useful in detecting extensive trophoblastic uterine involvement and may also aid in identifying sites of resistant uterine tumor

(44). Because ultrasonography can accurately and noninvasively detect extensive uterine tumor, it may help identify patients who would benefit from hysterectomy.

Table 37.4 Protocol for Treatment of Gestational Trophoblastic Tumor

Stage I	
Initial	Single-agent chemotherapy or hysterectomy with adjunctive chemotherapy
Resistant	Combination chemotherapy
	Hysterectomy with adjunctive chemotherapy
	Local resection
	Pelvic infusion
Stage II and III	
Low risk^a	
Initial	Single-agent chemotherapy
Resistant	Combination chemotherapy
High risk^a	
Initial	Combination chemotherapy
Resistant	Second-line combination chemotherapy
Stage IV	
Initial	Combination chemotherapy
Brain	Whole-head irradiation (3,000 cGy)
	Craniotomy to manage complications
Liver	Resection to manage complications
Resistant^a	Second-line combination chemotherapy
	Hepatic arterial infusion

^aLocal resection optional.

Management of Persistent GTT

A protocol for the management of GTT is presented in Table 37.4.

Stage I

In patients with stage I disease, the selection of treatment is based primarily on whether the patient desires to retain fertility.

P.1596

Hysterectomy plus Chemotherapy

If the patient does not wish to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons:

- To reduce the likelihood of disseminating viable tumor cells at surgery

To maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery

To treat any occult metastases that may already be present at the time of surgery

Chemotherapy can be administered safely at the time of hysterectomy without increasing the risk of bleeding or sepsis. In a series of 31 patients treated with primary hysterectomy and a single course of adjuvant chemotherapy, all achieved complete remission with no additional therapy.

Hysterectomy also is performed in all patients with stage I placental-site trophoblastic tumor. Because placental-site tumors are resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the only curative treatment. Patients with metastatic placental site trophoblastic tumor may still achieve remission but their tumors are less responsive to chemotherapy (45).

Chemotherapy Alone

Single-agent chemotherapy is the preferred treatment in patients with stage I disease who desire to retain fertility. When primary single-agent chemotherapy was administered to 495 patients with stage I GTT, 452 patients (91.3%) attained complete remission. The remaining 43 resistant patients subsequently achieved remission after combination chemotherapy or surgical intervention.

When patients are resistant to single-agent chemotherapy and desire to preserve fertility, combination chemotherapy should be administered. If the patient is resistant to both single-agent and combination chemotherapy and wants to retain fertility, local uterine resection may be considered. When local resection is planned, a preoperative ultrasonography, MRI, or arteriography may help to define the site of the resistant tumor.

Stages II and III

Vaginal and Pelvic Metastasis

Low-risk patients treated with primary single-agent chemotherapy have a high (approximately 80%) rate of remission. High-risk patients often do not achieve remission with single-agent treatment and are treated with primary intensive combination chemotherapy.

Vaginal metastases may bleed profusely because they are highly vascular and friable. When bleeding is substantial, it may be controlled by packing the vagina or by wide local excision. Infrequently, arteriographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases.

Pulmonary Metastasis

Of 153 patients treated with stage III disease, 152 (99%) attained complete remission. Gonadotropin remission was induced with single-agent chemotherapy in 85 of 104

(81.7%) patients with low-risk disease. All patients who were resistant to single-agent treatment subsequently achieved remission with combination chemotherapy.

Thoracotomy

Thoracotomy has a limited role in the management of stage III disease. **If a patient has persistent viable pulmonary metastasis following intensive chemotherapy, however, thoracotomy may be attempted to excise the resistant focus.** A thorough metastatic workup should be performed before surgery to exclude other sites of persistent disease. Fibrotic pulmonary nodules may persist indefinitely on chest radiography, even after complete gonadotropin remission has been attained. In patients undergoing thoracotomy for resistant disease, chemotherapy should be administered postoperatively to treat potential occult sites of micrometastasis.

Hysterectomy

Hysterectomy may be required in patients with metastatic disease to control uterine hemorrhage or sepsis. Furthermore, in patients with extensive uterine tumor, hysterectomy may substantially reduce the trophoblastic tumor burden and thereby limit the need for multiple courses of chemotherapy.

Follow-up

All patients with stage I through stage III disease should receive follow-up with:

- **Weekly measurement of hCG levels until they are normal for 3 consecutive weeks**
- **Monthly measurement of hCG values until levels are normal for 12 consecutive months**
- **Effective contraception during the entire interval of hormonal follow-up**

Stage IV

All patients with stage IV disease should be treated with primary intensive combination chemotherapy and the selective use of radiation therapy and surgery.

Before 1975, only 6 of 20 patients (30%) treated with stage IV disease attained complete remission, whereas after that time, 15 of 19 patients (78.9%) achieved remission. This improvement in survival has resulted from the use of primary combination chemotherapy in conjunction with radiation and surgical treatment. Patients with stage IV disease are at greatest risk of developing rapidly progressive and unresponsive tumors despite intensive multimodal therapy. They should preferably be referred to centers with special expertise in the management of trophoblastic disease.

Hepatic Metastasis

The management of hepatic metastasis is particularly difficult. If a patient is resistant to systemic chemotherapy, hepatic arterial infusion of chemotherapy may induce complete remission in selected cases. Hepatic resection may also be required to control acute bleeding or to excise a focus of resistant tumor. New techniques of arterial embolization may reduce the need for surgical intervention.

Cerebral Metastasis

If cerebral metastases are diagnosed, whole-brain irradiation (3,000 cGy in 10 fractions) can be instituted promptly. Because irradiation may be both hemostatic and tumoricidal, the risk of spontaneous cerebral hemorrhage may be lessened by the concurrent use of combination chemotherapy and brain irradiation. However, excellent remission rates

P.1598

(86%) have been reported in patients with cranial metastases treated with intensive intravenous combination chemotherapy and intrathecal *methotrexate* (MTX) (46).

Craniotomy

Craniotomy may be required to provide acute decompression or to control bleeding.

It should be performed to manage life-threatening complications in the hope that the patient ultimately will be cured with chemotherapy. In one study (47), the use of craniotomy to control bleeding in six patients resulted in complete remission in three patients.

Infrequently, cerebral metastases that are resistant to chemotherapy may be amenable to local resection. Fortunately, patients with cerebral metastases who achieve sustained remission generally have no residual neurologic deficits.

Follow-up

Patients with stage IV disease should receive follow-up with:

- Weekly determination of hCG levels until they are normal for 3 consecutive weeks
- Monthly determination of hCG levels until they are normal for 24 consecutive months

These patients require prolonged gonadotropin follow-up because they are at increased risk of late recurrence.

An algorithm for the management of persistent GTT is presented in Figure 37.7.

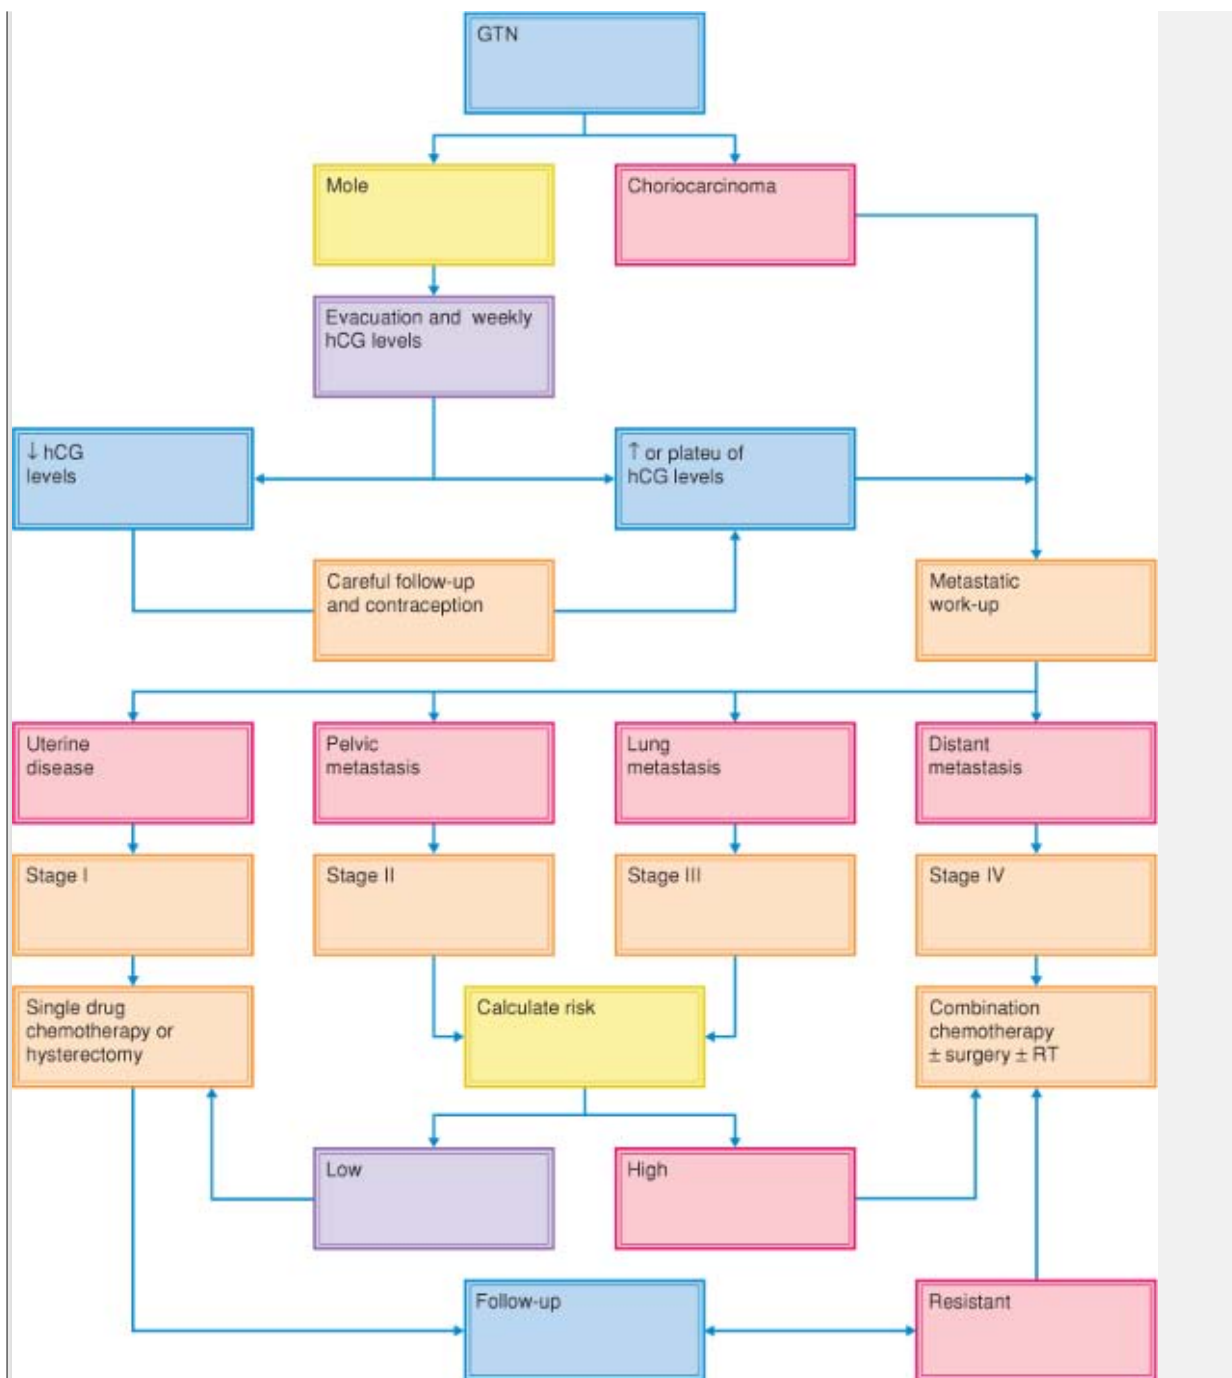

Figure 37.7 Algorithm for the management of persistent gestational trophoblastic tumor. GTN, gestational trophoblastic neoplasia; hCG, human chorionic gonadotropin; RT, radiotherapy. (From **Berkowitz RS, Goldstein DP.** Gestational trophoblastic neoplasia. In: **Berek JS, Hacker NF,** eds. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005;618, with permission.)

Chemotherapy

Single-Agent Treatment

Single-agent chemotherapy with either actinomycin D (Act-D) or MTX has achieved comparable and excellent remission rates in both nonmetastatic and low-risk metastatic GTT (48). Several protocols using these agents are available. *Act-D* can be given every other week as a 5-day regimen or in a pulsatile fashion; similarly, *MTX* can be given either in a 5-day regimen

or pulsatile weekly. No study has compared all of these protocols with regard to success. An optimal regimen should maximize the response rate while minimizing morbidity and cost.

The administration of *methotrexate* with *folinic acid* (*MTX-FA*) in GTT to limit systemic toxicity was first reported in 1964 (49). Subsequently, it has been confirmed that *MTX-FA* is both effective and safe in the management of GTT (50).

An evaluation of 185 patients treated with *MTX-FA* revealed that complete remission was achieved in 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of *MTX-FA* to attain remission (50). *MTX-FA* induced remission in 147 of 163 patients (90.2%) with stage I GTT and in 15 of 22 patients (68.2%) with low-risk stages II and III GTT. Resistance to therapy was more common in patients with choriocarcinoma, metastasis, and pretreatment serum hCG levels higher than 50,000 mIU/mL. After treatment with *MTX-FA*, thrombocytopenia, granulocytopenia, and hepatotoxicity developed in only 3 (1.6%), 11 (5.9%), and 26 (14.1%) patients, respectively. **Thus**, *MTX-FA* achieved an excellent therapeutic outcome with minimal toxicity and attained this goal with limited exposure to chemotherapy.

Technique of Single-agent Treatment

The serum hCG level is measured weekly after each course of chemotherapy.

The Treatment hCG regression curve serves as the primary basis for determining the need for additional treatment.

P.1599

P.1600

After the first treatment:

- **Further chemotherapy is withheld as long as the hCG level is falling progressively.**
- **Additional single-agent chemotherapy is not administered at any predetermined or fixed interval.**

A second course of chemotherapy is administered under the following conditions:

- **If the hCG level plateaus for more than 3 consecutive weeks or begins to rise again**
- **If the hCG level does not decline by 1 log within 18 days after completion of the first treatment**

If the patient's response to the first treatment was adequate and a second course of *MTX-FA* is required, the dosage of *MTX* is unaltered. An adequate response is defined as a fall in the hCG level by 1 log after a course of chemotherapy.

If the response to the first treatment is inadequate, the dosage of *MTX* is increased from 1.0 mg/kg per day to 1.5 mg/kg per day for each of the 4 treatment days. If the response to two consecutive courses of *MTX-FA* is inadequate, the patient is considered to be resistant to *MTX*, and *Act-D* is promptly substituted. If the hCG levels do not decline by 1

log after treatment with *Act-D*, the patient also is considered resistant to *Act-D* as a single agent. She must then be treated intensively with combination chemotherapy to achieve remission.

Combination Chemotherapy

Triple Therapy

Triple therapy with *MTX*, *Act-D*, and *cyclophosphamide* is inadequate as an initial treatment in patients with metastasis and a high-risk prognostic score.

Collectively, data from three centers indicate that triple therapy induced remission in only 21 (49%) of 43 patients with metastasis and a high-risk score (score >7) (51,52,53).

EMA-CO

Etoposide has been reported to induce complete remission in 56 (95%) of 60 patients with nonmetastatic and low-risk metastatic GTT (54). A new combination regimen described in 1984 included *etoposide*, *MTX*, *Act-D*, *cyclophosphamide*, and *vincristine* (*EMA-CO*) and had an 83% remission in patients with metastasis and a high-risk score (55). Another study confirmed that primary *EMA-CO* induced complete remission in 76% of the patients with metastatic GTT and a high-risk score (56). Still another study reported that *EMA-CO* induced complete sustained remission in 87 (90.6%) of 96 patients with high-risk (score >7) GTT (57). Furthermore, remission occurred with *EMA-CO* in 30 (86%) of 35 patients with brain metastasis (46).

The *EMA-CO* regimen is generally well tolerated, and treatment seldom has to be suspended because of toxicity. The *EMA-CO* regimen is the preferred primary treatment in patients with metastasis and a high-risk prognostic score. However, the optimal combination drug protocol for management of GTT has not yet been clearly defined. If patients experience resistance to

 P.1601

EMA-CO, they may then be treated successfully by substituting *etoposide* and *cisplatin* on day 8 (*EMA-EP*). *EMA-EP* has induced remission alone or with surgery in 16 (76%) of 21 patients who were resistant to *EMA-CO* (58). The optimal combination drug protocol will most likely include *etoposide*, *MTX*, and *Act-D* and perhaps other agents administered in the most dose-intensive manner.

Duration of Therapy

Patients who require combination chemotherapy must be treated intensively to attain remission. Combination chemotherapy should be given as often as toxicity permits until the patient achieves three consecutive normal hCG levels. After normal hCG levels are attained, at least two additional courses of chemotherapy are administered to reduce the risk of relapse.

Subsequent Pregnancies

Pregnancies after Hydatidiform Mole

Patients with hydatidiform moles can anticipate normal reproduction in the future (59). From 1965 until 2001, patients who were treated for complete mole had 1,278 subsequent pregnancies that resulted in 877 term live births (68.6%), 95 premature deliveries (7.4%), 11 ectopic pregnancies (0.9%), 7 stillbirths (0.5%), and 18 repeat

molar pregnancies (1.4%). First- and second-trimester spontaneous abortions occurred in 229 (17.9%) pregnancies. Major and minor congenital malformations were detected in 40 infants (4.1%), and primary cesarean delivery was performed in 70 of 373 (18.8%) term or preterm births from 1979 to 2001.

Although data regarding pregnancies after partial mole are limited (251 subsequent pregnancies), the information is reassuring (59). **Patients with both complete and partial mole should be reassured that they are at no increased risk of complications in later gestations.**

When a patient has had a molar pregnancy, she is at an increased risk of having a molar gestation in subsequent conceptions. **After one molar pregnancy, the risk of having molar disease in a future gestation is about 1%.** Of 34 patients with at least two documented molar pregnancies, every possible combination of repeat molar pregnancy was observed. After two molar gestations, these 34 patients had 35 later conceptions resulting in 20 (57.1%) term deliveries, 7 (20.0%) moles (6 complete, 1 partial), 3 spontaneous abortions, 3 therapeutic abortions, 1 intrauterine fetal death, and 1 ectopic pregnancy. In six patients, the medical records indicated that the patient had a different partner at the time of different molar pregnancies (60).

Therefore, for any subsequent pregnancy, it seems prudent to undertake the following approach:

- **Perform pelvic ultrasonographic examination during the first trimester to confirm normal gestational development.**
- **Obtain an hCG measurement 6 weeks after completion of the pregnancy to exclude occult trophoblastic neoplasia.**

Pregnancies after Persistent Gestational Trophoblastic Tumor

Patients with GTT who are treated successfully with chemotherapy can expect normal reproduction in the future. Patients who were treated with chemotherapy at the authors' institution from 1965 to 2001 had 581 subsequent pregnancies that resulted in 393 term live births (67.6%), 35 preterm deliveries (6.0%), 7 ectopic pregnancies (1.2%), 9 stillbirths (1.5%), and 8 repeat molar pregnancies (1.4%) (59). First- and second-trimester

P.1602

spontaneous abortions occurred in 99 (17.0%) pregnancies. Major and minor congenital malformations were detected in 10 infants (2.3%). Primary cesarean delivery was performed in 68 (20.3%) of 335 subsequent term and preterm births from 1979 to 2001. It is particularly reassuring that the frequency of congenital anomalies is not increased, although chemotherapeutic agents are known to have teratogenic and mutagenic potential.

Breast Cancer

Kristine E. Calhoun

Armando E. Giuliano

- **Breast cancer accounts for one third of cancers in women. The risk of breast cancer increases with a positive family history and the use of hormone therapy. Breast cancer may be either *in situ* (ductal carcinoma *in situ* or lobular carcinoma *in situ*) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma).**
- **The standard screening modalities for detection of breast cancer include yearly mammography and physical examination.**
- **Tissue diagnosis is achieved using fine-needle aspiration cytology (FNAC) or core needle biopsy (CNB). Open biopsy is performed if FNAC or CNB has not been performed or if these results are negative, equivocal, or discordant with the clinical findings.**
- **The combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy is equivalent to modified radical mastectomy for the management of**

certain patients with stages I and II breast cancer.

- **Axillary lymph node status and the number of involved nodes is the most important prognostic indicator in primary breast cancer.**
- **Adjuvant systemic therapy prolongs survival in selected breast cancer patients and is recommended for women with a greater than 10% chance of relapse within 10 years.**

Breast cancer accounts for approximately one third of all cancers in women and is second only to lung cancer as the leading cause of cancer deaths among women.

Breast cancer, however, has the highest incidence rate of all cancers. According to statistics from the American Cancer Society, 213,000 new cases of invasive breast cancer, as well as nearly 62,000 cases of *in situ* cancers, will be diagnosed during 2006 in the United States, with 41,000 women succumbing to the disease during the same period (1). Over the past 50 years, the incidence of breast cancer in the United States has increased significantly; currently one in every seven women will develop the disease during her lifetime. Fortunately, the mortality rate has declined since 1990.

P.1606

Predisposing Factors

Fewer than 1% of breast cancers occur in women younger than 25 years of age. After age 30, however, there is a sharp increase in the incidence of breast cancer. Except for a short plateau between the ages of 45 and 50 years, the incidence increases steadily with age (2).

Family History

Of women who develop breast cancer, 20% to 30% have a family history of the disease. Although any family history of breast cancer increases the overall relative risk (3), this risk is not significantly increased if the disease was diagnosed postmenopausally in a first degree or more distant relative. If a woman's mother or sister had unilateral breast cancer premenopausally, her lifetime risk of developing the disease approaches 30%, whereas a woman whose mother or sister had bilateral breast cancers premenopausally has at least a 40% to 50% lifetime risk. The increased incidence in these women is probably due to inherited oncogenes.

Approximately 5% to 10% of breast cancers have an inherited basis. All inherited genes are autosomal dominant but have variable penetrance. Men carry the gene 50% of the time. The most common mutations are the ***BRCA1*** (chromosome 17q21) and ***BRCA2*** (chromosome 13q12–13) gene deletions. **Carriers of these germline mutations have up to a 4%-per-year risk of developing breast cancer and a lifetime risk that ranges from 35% to 85% (4).** In addition, these individuals have up to a 65% risk of developing a contralateral breast cancer. The ***BRCA1*** mutation also is associated with an increased risk of ovarian and prostate cancer, whereas ***BRCA2*** carriers, although less common, demonstrate increased risks of male breast and prostate cancers. Both mutations are rare in the general public (0.1%) but are more commonly identified in Jews of Ashkenazi descent (1%–2.3%) (5). **Genetic testing is available and should be considered if there is a high likelihood that results will be positive and will be used to influence decisions regarding the clinical management of the care of the patient and her family.**

Diet, Obesity, and Alcohol

There are marked geographic differences in the incidence of breast cancer that may be related to diet. A recent meta-analysis demonstrated an association between higher intakes of total fat and an increased risk of breast cancer (6). Although a definitive relationship between total alcohol consumption and an increased risk of breast cancer has yet to be determined, high wine intake has been shown to be associated with elevated risk (7).

Reproductive and Hormonal Factors

The risk of breast cancer increases with the length of a woman's reproductive phase (8). Although early menarche has been reported among breast cancer patients, early menopause appears to protect against the development of the disease, with artificial menopause from oophorectomy lowering the risk more than early natural menopause (9). There is no clear association between the risk of breast cancer and menstrual irregularity and the duration of menses. Although lactation does not affect the incidence of breast cancer, women who have never been pregnant have a higher risk of breast cancer than those who are multiparous. Also, women who give birth to their first child later in life have a higher incidence of breast cancer than do younger primigravida women (10).

An historic well-controlled study from the Centers for Disease Control and Prevention showed that oral contraceptive use does not increase the risk of breast cancer, regardless of duration of use, family history, or coexistence of benign breast

P.1607

disease (11). However, a more recent pooled analysis from 54 epidemiologic studies showed current users of oral contraceptives had a small but significant increased risk when compared with nonusers. Ten years after discontinuation, the risk of past users declined to that of the normal population (12).

Although it was previously reported that short-term estrogen treatment for menopausal symptoms did not increase the risk of breast cancer, this belief was refuted by publication of the results of the Women's Health Initiative randomized trial. This prospective trial, involving 16,000 postmenopausal women randomly assigned to receive estrogen plus progesterone or placebo, revealed an association between hormone therapy use and the development of breast cancer. In addition, when invasive breast cancer did develop, it was diagnosed at a more advanced stage compared with tumors that developed among placebo users. Based on interim analysis, the trial was stopped early and the investigators concluded that even relatively short-term use of combined estrogen-progesterone therapy increases the development of invasive breast cancer (13). The risk demonstrated by this study must be considered when postmenopausal hormone therapy is used to treat conditions such as hot flashes and osteoporosis.

History of Cancer

Women with a history of breast cancer have a 50% risk of developing microscopic cancer and a 20% to 25% risk of developing clinically apparent cancer in the contralateral breast, which occurs at a rate of 1% to 2% per year (14). Lobular carcinoma has a higher incidence of bilaterality than does ductal carcinoma. A history of endometrial, ovarian, or colon cancer also is associated with an increased risk of subsequent breast cancer, as is a history of radiation therapy for Hodgkin's lymphoma.

Diagnosis

Breast cancer most commonly arises in the upper outer quadrant, where there is proportionally more breast tissue. Masses are most often discovered by the patient and less frequently by the physician during routine breast examination. The increasing use of screening mammography has enhanced the ability to detect nonpalpable breast abnormalities. Metastatic breast cancer is found as an axillary mass without obvious malignancy in less than 1% of cases.

The standard screening modalities of mammography and physical examination are complementary. Approximately **10% to 50% of cancers detected mammographically are not palpable, whereas physical examination detects 10% to 20% of cancers not seen radiographically** (15). The purpose of screening is to detect tumors when they are small (less than 1 cm) and have the highest potential for surgical cure. Most trials have shown a 20% to 30% reduction in breast cancer mortality for women age 50 and older who undergo annual screening mammography. Data on screening women younger than 40 years have been more controversial. **Results from the Gothenburg screening trial showed a 45% reduction in mortality for women screened between the ages of 40 and 49** (16). **Because of these findings, it is recommended that all women undergo yearly screening mammography starting at age 40, along with clinical breast examination and breast self-examination.** No other tests, including ultrasonography, computed tomography (CT) scans, sestamibi scans, positron emission tomography (PET) scans, or serum blood markers, have been shown to be effective screening modalities. Screening guidelines recommended by the American College of Radiology and the American Cancer Society are presented in Table 38.1. Recently, MRI was identified as a valuable adjunct to screening mammography for women with either a familial or genetic predisposition to breast cancer, although exact guidelines for its implementation have yet to be defined (17).

Table 38.1 Screening Recommendations

Bilateral mammograms

Beginning at age 40 yearly mammogram

Women at increased risk (positive family history, gene positive, personal history of breast cancer) should talk to their physicians about the potential benefits of starting mammography earlier than age 40, having additional imaging studies such as MRI, or having more frequent clinical exams.

Self-examination

Premenopausal 5–7 days after menstrual period monthly

Postmenopausal same day every month

Clinical breast examination

Age 20–40 exam by physician every 3 years, annually if positive history
(May do annually if there is a positive family history)

Age ≥ 40 exam by physician every year

Tumor markers CA27–29, CA15–3, not recommended as screening tests

From American Cancer Society, *Screening guides for the early detection of breast cancer*, 2003.

Unfortunately, although breast MRI is exceptionally sensitive in the detection of breast abnormalities, the technology is currently not specific enough for this imaging modality to be used for routine screening.

Masses are easier to palpate in older women with fatty breasts than in younger women with dense, nodular breasts. An area of thickening amid normal nodularity may be the only clue to an underlying malignancy. Skin dimpling, nipple retraction, or skin erosion, while obvious, are later-stage disease signs. Algorithms for the evaluation of breast masses in premenopausal and postmenopausal women are presented in Chapter 19.

When a dominant breast mass is identified, the presence of a carcinoma must be considered, and biopsy should be performed to establish a tissue diagnosis. About 30% to 40% of lesions believed clinically to be malignant will be benign on histologic examination (18). Conversely, 25% of clinically benign-appearing lesions will be malignant when biopsied (19).

Biopsy Techniques

In rare cases, it may be reasonable to perform frozen section analysis on a biopsy specimen immediately before mastectomy or other definitive surgical treatment. It is preferable, however, for the patient to be involved in the planning of her therapy. In most instances, initial biopsy is better followed by definitive treatment at a later date. This approach allows the physician to discuss alternative forms of surgical therapy with the patient who has a malignancy. It also gives the patient an opportunity to obtain a second opinion before undergoing definitive treatment.

Fine-needle Aspiration Cytology

Fine-needle aspiration cytology (FNAC) is usually performed on palpable lesions or under ultrasound guidance using a 20- or 22-gauge needle. The technique has a high level of diagnostic accuracy, with low false-negative rates and rare, but persistent, false-positive results (20). In most reported series, **false-negative rates range from 10% to 15%, and false-positive rates are generally less than 1%, whereas insufficient specimens account for about 15% of samples** (21). If a mass appears to be malignant on physical

P.1609

examination, mammography, or both, FNAC cytology results can be used for definitive diagnosis. Negative FNAC results do not exclude malignancy and should be evaluated by either a core needle or traditional excisional biopsy for suspicious lesions. In younger women, it is prudent to monitor a benign-appearing mass for one or two menstrual cycles. Confirmation of a clinically apparent fibroadenoma with FNAC can serve as the basis for observational follow-up without excision.

Core Needle Biopsy

Core needle biopsy can be performed on both palpable and nonpalpable breast masses. **Performing a core biopsy instead of FNAC on a palpable lesion has the advantage of obtaining more tissue for diagnostic purposes, including tests for estrogen and progesterone receptors and Her2/*neu*.** Core biopsy of nonpalpable breast lesions usually is performed using mammographic or ultrasonographic guidance. Mammographic units with computerized stereotactic modifications can be used to localize abnormalities and perform CNB without surgery. **Under mammographic guidance, a biopsy needle is inserted into the lesion and a core of tissue is removed for histologic examination.** Devices with suction assistance are often used to increase the volume of tissue removed for evaluation. A titanium clip often is used to mark the biopsy site and serve as a guide should further excision be required. Ultrasonography may also be used to perform core biopsy on a nonpalpable lesion. Because it is less invasive and less expensive than

open mammographic localization biopsy, CNB is preferred for accessible lesions. If a definitive diagnosis is not established, these procedures must also be followed by open biopsy.

Open Biopsy

Open biopsy may be performed if FNAC or CNB has not been performed or if needle biopsy results are negative, equivocal, or discordant with the clinical findings. **An unequivocal histologic diagnosis of cancer should be obtained before treatment of breast cancer is undertaken.** Cytologic diagnosis may be relied on if the mass clinically or mammographically appears to be malignant.

Open biopsy can be performed in the outpatient setting with local anesthesia in the following manner:

- The patient is positioned and the location of the mass confirmed.
- Local anesthesia is used to infiltrate the skin and subcutaneous tissue surrounding the palpable mass.
- The skin is incised directly over the mass. Placement of this incision is critical. It should be situated in such a way that it can be excised with an ellipse of skin should the patient require a subsequent mastectomy or placed cosmetically so that partial mastectomy can be performed through it successfully. Para-areolar incisions are appropriate only for lesions in proximity to the nipple-areolar complex.
- The mass is gently grasped with Allis forceps or with a stay suture and moved into the operative field.
- The mass should be excised completely whenever possible. Larger lesions that are difficult to totally excise can be incised for diagnostic purposes only. When an incisional biopsy is performed, a frozen section should be obtained to confirm that appropriate tissue for diagnosis is present. Such masses, however, are preferably sampled with FNAC or CNB, with incisional biopsy rarely indicated.
- Once the mass is removed, hemostasis is achieved and the incision is closed. A cosmetically superior result will be achieved if the deep breast parenchyma is not

P.1610

reapproximated. The most superficial subcutaneous fat can be reapproximated with fine absorbable sutures, and the skin can be closed with a subcuticular suture and adhesive strips.

Image-Guided Localization Biopsy

Biopsy of nonpalpable lesions is a potentially difficult procedure that requires close cooperation between the surgeon and radiologist. Using ultrasonographic or mammographic guidance, a needle or specialized wire is placed into the breast parenchyma at or near the site of the suspected abnormality. Some mammographers will also inject a biologic dye into the breast parenchyma to assist localization further. The surgeon reviews the films and localizes the abnormality with respect to

the tip of the wire or needle. Alternatively, the surgeon will perform ultrasonography intraoperatively to directly localize the lesion. An incision is made directly over the abnormality, and a small portion of the breast tissue suspected of containing the abnormality is excised. For mammographically detected lesions, a specimen radiograph is obtained to ensure that the abnormality has been recovered. Often, the radiologist can place a needle in the specimen at the site of the abnormality to facilitate histologic evaluation and ensure that the pathologist examines the site of the abnormality.

Pathology and Natural History

Breast cancer may arise in the intermediate-sized ducts, terminal ducts, or lobules. In most cases, the diagnosis of lobular and intraductal carcinoma is based more on histologic appearance than site of origin. The cancer may be either *in situ* (ductal carcinoma *in situ* or lobular carcinoma *in situ*) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma). Morphologic subtypes of infiltrating ductal carcinoma include scirrhous, tubular, medullary, and mucinous carcinoma.

True invasive ductal carcinoma accounts for 80% of all invasive tumors, with the final 20% split evenly between lobular carcinoma and special variants of infiltrating ductal carcinoma (22). Mammographically, invasive ductal cancers are characterized by a stellate density or microcalcifications. Macroscopically, gritty, chalky streaks are present within the tumor that most likely represent a desmoplastic response. Finally, invasion of the surrounding stroma and fat, with a fibrotic, desmoplastic reaction surrounding the invasive carcinoma, generally are present.

Special types of infiltrating ductal carcinoma are uncommon and typically account for nearly 10% of all invasive cancers. Medullary carcinoma, which accounts for 5% to 8% of breast carcinomas, arises from larger ducts within the breast and has a dense lymphocytic infiltrate. The tumor appears to be a slower growing and less-aggressive malignancy than other forms of carcinoma. Even when axillary disease is present, the prognosis with medullary carcinoma is better than that of other variants of invasive ductal carcinoma. **Mucinous (colloid) carcinoma accounts for 5% of all breast cancers.**

Grossly, areas of the tumor may appear mucinous or gelatinous, whereas microscopically they are relatively acellular. Infiltrating comedo carcinoma accounts for less than 1% of all breast malignancies and is an invasive cancer characterized by foci of necrosis that exude a comedonecrosislike substance when biopsied. Usually, comedocarcinomas are *in situ* malignancies. Papillary carcinoma is predominantly a noninvasive ductal carcinoma; when invasive components are present, it should be specified as invasive papillary carcinoma.

Tubular carcinoma, a well-differentiated breast cancer that accounts for 1% to 2% of all malignant breast neoplasms, tends to have a better prognosis than infiltrating ductal carcinoma and rarely metastasizes to axillary lymph nodes. Finally, **adenoid cystic carcinomas are extremely rare breast tumors that histologically are similar to those seen in the salivary glands.** They generally are well differentiated cancers that are slow to metastasize.

P.1611

P.1612

Growth Patterns

The growth potential of breast cancer and the patient's resistance to malignancy vary widely with the individual and the stage of disease. **The doubling time of breast cancer ranges from several weeks for rapidly growing tumors to months or years for slowly**

growing lesions. If the doubling time of a breast tumor was constant and a tumor originated from one cell, a doubling time of 100 days would result in a 1-cm tumor in about 8 years (Fig. 38.1) (23). During the preclinical phase, tumor cells may be circulating throughout the body. Because of the long preclinical tumor growth phase and the tendency of infiltrating lesions to metastasize early, many clinicians view breast cancer as a systemic disease at the time of diagnosis. Although cancer cells may be released from the tumor before diagnosis, variations in the tumor's ability to grow in other organs and the host's response to tumor cells may inhibit dissemination of the disease. Many women with breast cancer can be treated successfully with surgery alone, and some patients have been cured even in the presence of palpable axillary disease. Thus, a pessimistic attitude that breast cancer is systemic and incurable at diagnosis is unwarranted.

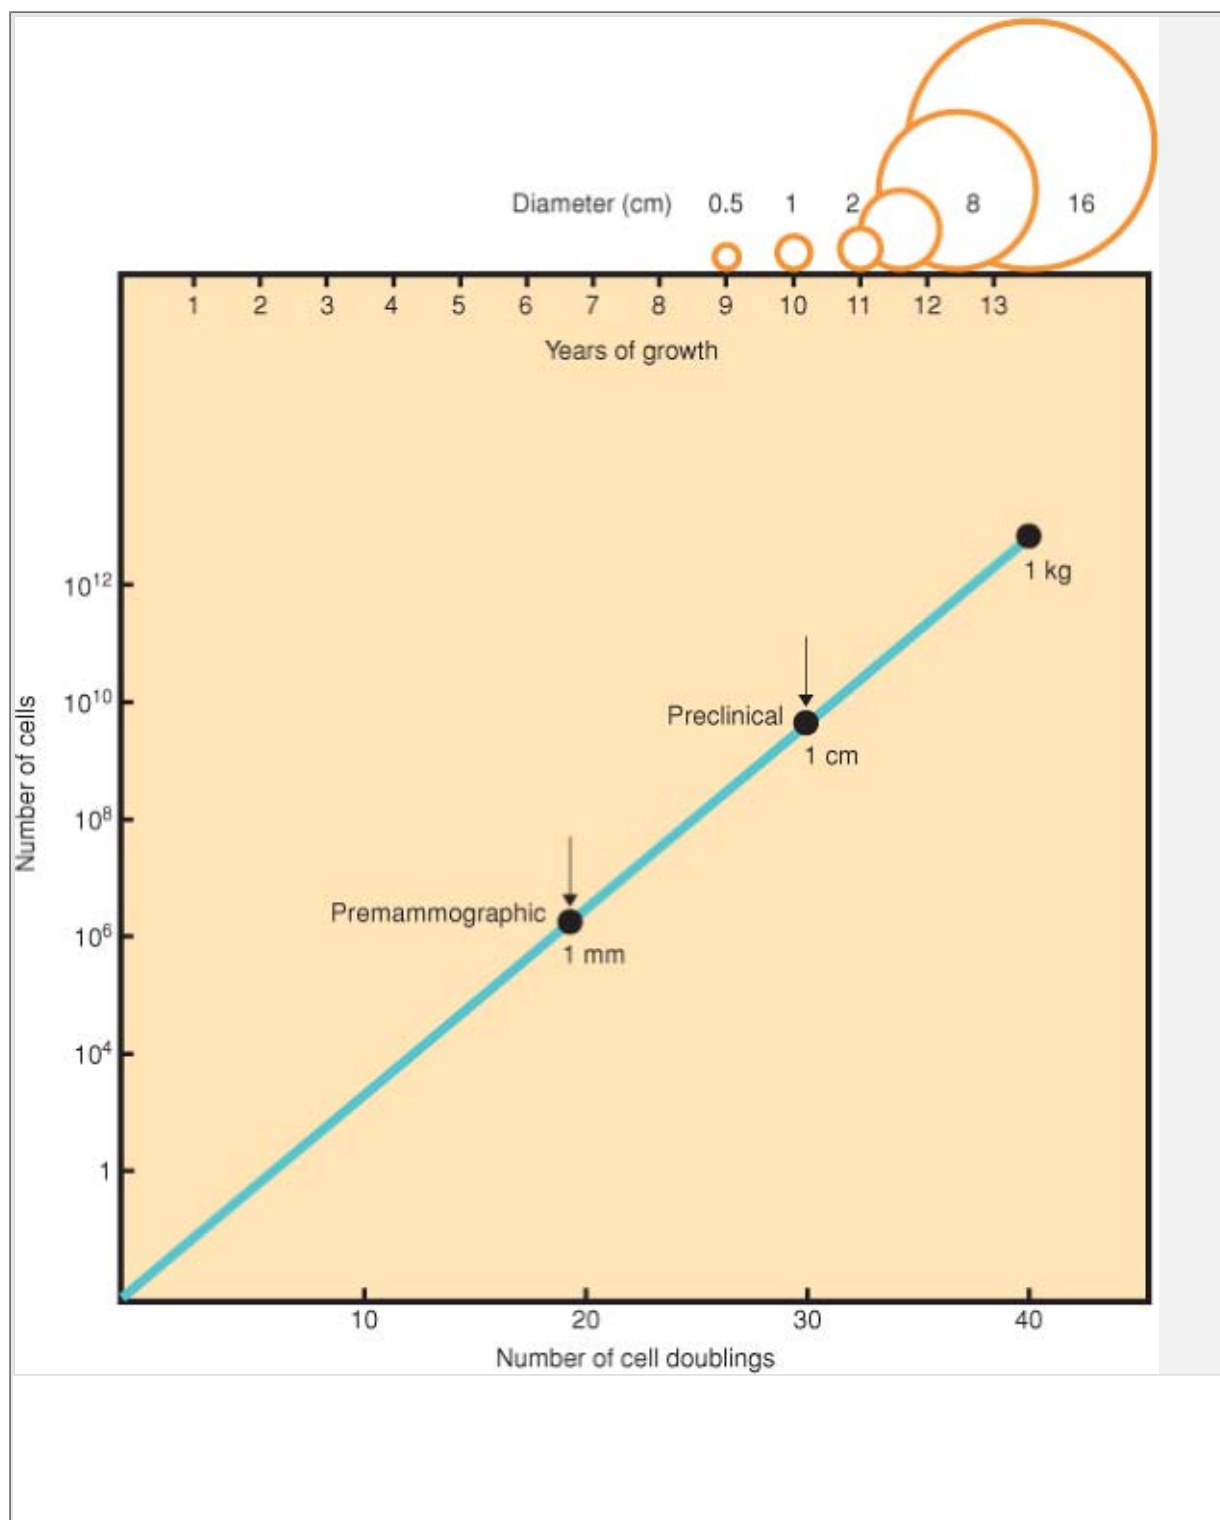

Figure 38.1 Growth rate of breast cancer indicating long preclinical phase. (From Gullino PM. Natural history of breast cancer: progression from hyperplasia to neoplasia as predicted by angiogenesis. *Cancer* 1977;39:2699. with permission.)

Table 38.2 Tumor–Nodes–Metastasis (TNM) System for Staging of Breast Cancer

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T₀	No evidence of primary tumor
T_{is}	Carcinoma <i>in situ</i>
T_{is} (DCIS)	Ductal carcinoma <i>in situ</i>
T_{is} (LCIS)	Lobular carcinoma <i>in situ</i>
T_{is} (Paget)	Paget disease of the nipple with no tumor
T₁	Tumor 2 cm or less in greatest dimension
T_{1mic}	Microinvasion 0.1 cm or less in greatest dimension
T_{1a}	Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension
T_{1b}	More than 0.5 cm but not more than 1 cm in greatest dimension
T_{1c}	More than 1 cm but not more than 2 cm in greatest dimension
T₂	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T₃	Tumor more than 5 cm in greatest dimension
T₄	Tumor of any size with direct extension to chest wall or skin
T_{4A}	Extension to chest wall, not including pectoralis muscle
T_{4B}	Edema (including <i>peau d'orange</i>) or ulceration of the skin of breast or satellite skin nodules confined to same breast
T_{4C}	Both T _{4A} and T _{4B}
T_{4D}	Inflammatory carcinoma
Lymph node (N)	
Clinical	
N X	Regional lymph nodes cannot be assessed (e.g., previously removed)
N₀	No regional lymph node metastasis
N₁	Metastasis to movable ipsilateral axillary lymph node(s)
N₂	Metastases to ipsilateral axillary lymph node(s) fixed or matted, or in clinically apparent ipsilateral mammary nodes in the absence of clinically evident axillary node metastasis
N_{2a}	Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N_{2b}	Metastasis only in clinically apparent ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
N₃	Metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent ipsilateral internal mammary lymph nodes and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph nodes with or without axillary or internal mammary lymph node involvement

N_{3a}	Metastasis in ipsilateral infraclavicular lymph nodes
N_{3b}	Metastasis in ipsilateral internal mammary lymph nodes and axillary lymph nodes
N_{3c}	Metastasis in ipsilateral supraclavicular lymph node(s)
Pathologic classification (pN)	
pN X	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)
pN₀	No regional lymph node metastasis histologically, no additional examination for isolated tumor cells (single tumor cells or small cell clusters not greater than 0.2 mm, usually detected only by immunohistochemical [IHC] or molecular methods but which may be verified on H&E stains)
pN₀₍₋₎	No regional lymph node metastasis histologically, negative IHC
pN_{0(i+)}	No regional lymph node metastasis histologically, positive IHC, no IHC cluster greater than 0.2 mm
pN_{0(mol-)}	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)
pN_{0(mol+)}	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR)
pN₁	Metastasis in 1 to 3 axillary lymph node(s), and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
pN_{1mic}	Micrometastasis (>0.2 mm, none >2.0 mm)
pN_{1A}	Metastasis in 1 to 3 axillary lymph node(s)
pN_{1B}	Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
pN_{1c}	Metastasis in 1 to 3 axillary lymph node(s), and in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
PN₂	Metastasis in 4 to 9 axillary lymph nodes, or in clinically apparent internal mammary lymph nodes in the absence of axillary lymph node metastasis
PN_{2a}	Metastasis in 4 to 9 axillary lymph nodes (at least 1 tumor deposit >2.0 mm)
PN_{2b}	Metastasis in clinically apparent internal mammary lymph nodes in the absence of axillary lymph node metastasis
PN₃	Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent ipsilateral internal mammary nodes in the presence of 1 or more positive axillary nodes; or in more than 3 axillary nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes
PN_{3a}	Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit greater than 2.0 mm), or metastasis in infraclavicular lymph nodes
PN_{3b}	Metastasis in clinically apparent ipsilateral internal mammary nodes in the presence of 1 or more positive axillary nodes; or in more than 3 axillary nodes and in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
PN_{3c}	Metastasis in ipsilateral supraclavicular nodes
Distant metastasis (M)	
MX	Presence of distant metastasis cannot be assessed

M₀	No distant metastasis
M₁	Distant metastasis

P.1613

A more realistic approach may be to view breast cancer as a two-component disease involving the breast and the body as a whole. Although the primary breast tumor and issues of local control must be managed, the possibility of systemic metastases with their life-threatening consequences should not be overlooked.

Although breast cancer can metastasize to any organ, involvement of bone, lungs, or liver occurs in up to 85% of women who develop distant disease (24,25). In addition to these sites, invasive lobular carcinoma is known to disseminate to the abdominal viscera, uterus, ovaries, and peritoneal surfaces.

Staging

After the diagnosis of breast cancer has been definitively established, the clinical stage of the disease should be determined. The Columbia Clinical Staging System was used historically (26) but has been replaced by the tumor–nodes–metastases (TNM)

P.1614

system of the American Joint Committee on Cancer (27). The TNM system allows both preoperative clinical staging and postoperative pathologic staging to be determined (Tables 38.2 and 38.3).

	<i>TNM Classification^a</i>		
	<i>Tumor</i>	<i>Node</i>	<i>Metastasis</i>
Stage 0	Tis	N ₀	M ₀
Stage I	T ₁	N ₀	M ₀
Stage IIa	T ₀	N ₁	M ₀
	T ₁	N ₁	M ₀
	T ₂	N ₀	M ₀
IIb	T ₂	N ₁	M ₀
	T ₃	N ₀	M ₀

Treatment

Preoperative Evaluation

The extent of the preoperative workup varies with the initial stage of the disease (28).

For most patients with small tumors, clinically negative lymph nodes, and no evidence of metastasis (TNM stage I), the preoperative evaluation should consist of bilateral mammography, chest radiography, complete blood count, and screening blood chemistry tests. Bone, CT, and MRI scanning are unnecessary unless there are symptoms or abnormal blood chemistry levels to suggest the existence of bone or intra-abdominal involvement. For patients with clinical stage II, node-positive disease, a bone scan is recommended, but CT scan of the abdomen is not necessary unless symptoms or laboratories suggest liver disease. Patients with clinical stage III or stage IV disease should undergo both bone and liver scanning.

Radical Mastectomy

Traditionally, the treatment of breast cancer has been surgical, but the type of procedure has remained a controversial and highly emotional issue. During the nineteenth century, surgical treatment of breast cancer was haphazard, varying from local excision alone to total mastectomy. The radical mastectomy was based on the principle that breast

P.1615

carcinoma was a locally infiltrative process that spread in a stepwise fashion from breast, to nodes, to distant sites (29). Thus, **radical mastectomy removes the entire breast, the underlying pectoral muscles, and the contiguous axillary lymph nodes in continuity (30)** (Fig. 38.2A). A report of 51 years of experience with radical mastectomy, which included 1,036 patients with a follow-up of 47 years, is thus far unequaled in evaluating any single method of treating breast cancer (31).

P.1616

Figure 38.2 Appearance of breast after radical mastectomy (A) versus modified mastectomy (B). (From **Chang SS, Haigh PI, Giuliano AE**. Breast disease. In: **Berek JS, Hacker NF**, eds. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005:648, with permission.)

During the twentieth century, extensions and modifications of the radical mastectomy were devised that involved removal of more local and regional tissue. At one time, supraclavicular

lymph node dissections were considered a routine component of surgical treatment (32). In addition, supraclavicular, mediastinal, and internal mammary lymph node dissections were performed (33).

An *en bloc* internal mammary lymph node dissection was added to the standard radical mastectomy in the 1960s (34). This technique became popular and is the operation commonly referred to as the *extended radical mastectomy*. Unfortunately, extended radical mastectomy did not enhance overall survival rates (35), because only 3% to 5% of patients with negative axillary nodes will have involvement of internal mammary nodes. Locally destructive surgery is not justified, however, based on current understanding of the biologic behavior of breast cancer.

Modified Radical Mastectomy

In contrast to radical mastectomy, modified radical mastectomy preserves the pectoralis major muscle (36,37) (Fig. 38.2B). The breast is removed in a manner similar to that of radical mastectomy, but neither the axillary lymph node dissection nor the skin excision is as extensive. Consequently, there is no need for skin grafting. Although there are no differences in survival rates between radical and modified radical mastectomy, the latter procedure has a better functional outcome and a superior cosmetic result (38). Modified radical mastectomy has therefore replaced radical mastectomy in the United States.

Total Mastectomy

Total mastectomy involves removal of the entire breast, nipple, and areolar complex without resection of the underlying muscles or intentional excision of axillary lymph nodes. Low-lying lymph nodes, however, in the upper outer portion of the breast and low axilla often are excised. Total mastectomy has local control rates comparable with those of radical or modified radical mastectomy but has a higher risk of axillary recurrence. Regional recurrence will occur in at least 15% to 20% of patients treated with total mastectomy alone.

Postmastectomy Radiation Therapy

McWhirther developed the combination of total mastectomy followed by radiation (39). Many have advocated adjuvant radiation therapy used in combination with various operative procedures. Unfortunately, studies claiming improvements in overall survival usually are flawed by the use of historical controls and inaccurate preoperative staging. Classic trials, both prospective randomized and historical control studies, have showed that adjuvant radiation therapy improves local control but not overall survival rates (40,41,42,43). In a prospective randomized trial performed by the National Surgical Adjuvant Breast Project (NSABP), the roles of postoperative radiation therapy and axillary treatment were examined. Patients were randomly assigned to either total mastectomy, radical mastectomy, or total mastectomy with radiation therapy. This trial showed no difference in survival among the three treatment arms, whereas radiation therapy and axillary treatment improved local and regional control. Twenty-five-year follow-up data continue to support these conclusions (44).

Three randomized control studies from the 1990s showed that postmastectomy radiation therapy reduced the risk of local-regional failure by 20% and produced an absolute survival benefit of 10% at 10 years among women with stage II to III breast cancer, regardless of menopausal status (45,46,47). More recently, additional trials challenged the need for postmastectomy radiation among women with only one to three involved axillary nodes and T₁ or T₂ primary tumors. These studies showed adequate

local-regional control rates with mastectomy and chemotherapy alone (48,49,50).

Current guidelines from the American Society of Clinical Oncology recommend postmastectomy

P.1617

radiation therapy for women with T₃ (>5 cm) primary tumors and four or more positive axillary lymph nodes (51).

Breast Conservation Therapy with or without Radiation Therapy

Radiation therapy alone, without excision of the tumor, is associated with a high local failure rate (52,53,54,55), as is local excision without radiation. Throughout the last quarter of the twentieth century, a paradigm shift occurred in the surgical management of breast cancer. Data from the NSABP B-04 trial, for which 25-year follow-up exists, established the equivalency of radical versus total mastectomy with regards to overall survival (56). Shortly after initiation of the B-04 trial, a number of studies were designed to evaluate the efficacy of breast preservation among women with early-stage breast cancers. **The Milan trial, a major prospective randomized trial that began accruing patients in 1973, compared treatment with either radical mastectomy or a combination of quadrantectomy, axillary lymph node dissection, and postoperative radiation therapy.** In total, 701 clinically node-negative patients with noncentrally located, small tumors (<2 cm) (T₁ N₀ M₀) were enrolled. **After 20 years of follow-up, there continues to be no statistically significant difference between the two groups in either local control or overall survival rates (57).**

At nearly the same time, **in the NSABP B-06 trial, patients with early breast cancer (stage I or stage II, T₁ or T₂, and N₀ or N₁) were randomized to modified radical mastectomy, segmental mastectomy (lumpectomy), and axillary lymph node dissection, or segmental mastectomy, axillary lymph node dissection, and postoperative radiation therapy.** Unlike the quadrantectomy performed in the Milan study, segmental mastectomy consists of removing only the tumor and a small rim of normal surrounding tissue, yielding cosmetically superior results (Fig. 38.3). A total of 1,843 women were enrolled, with the lowest local recurrence rate seen among patients treated with segmental mastectomy and postoperative radiation therapy. Although the addition of radiation clearly

P.1618

improved the local control rate, no significant differences in overall survival or disease-free survival rates were detected among the three treatment arms; there was a trend, however, in favor of patients who received radiation. **This NSABP study established, now with 25-year follow-up, that the combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy is as effective as modified radical mastectomy for the management of patients with stage I and II breast cancer (58).** A number of additional studies also demonstrated no decrease in overall survival among women being treated with breast preservation therapy (59,60,61).

Figure 38.3 Appearance of breast after lumpectomy, axillary dissection, and radiation therapy. (From **Chang SS, Haigh PI, Giuliano AE.** Breast disease. In: **Berek JS, Hacker NF,** eds. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Williams & Wilkins, 2005:650, with permission.)

Axillary lymph node status and the number of involved nodes is the most important prognostic indicator for patients with primary breast cancer (62). For these reasons, axillary lymphadenectomy traditionally was used to detect and quantify the extent of nodal metastasis (63). Before the introduction of sentinel lymph node dissection in the 1990s, axillary lymph node dissection was performed routinely on all patients with early breast cancer. Although axillary dissection is associated with a very low risk of regional recurrence (1%–3%), the rate of acute complications is as high as 30% (64). Similarly, the risk of chronic lymphedema ranges from 6% to as high 30% (65). Limiting the dissection to level I nodes or random sampling is associated with unacceptably high false-negative rates and should not be done (66). Only one third of patients with a clinically negative axilla will be found to have nodal metastasis after histopathologic examination of all harvested lymph nodes (67). This means that two thirds of patients will be exposed to the morbidity of axillary lymph node dissection without proven benefit when performed routinely in the presence of invasive breast cancer.

In 1991, intraoperative lymphatic mapping and sentinel lymph node dissection were introduced to address these problems (68). The concept behind sentinel lymph node dissection is best described by the definition of a sentinel node. The sentinel node is the lymph node that has the greatest potential to harbor metastasis if axillary disease is present. The sentinel lymph node dissection thus accurately predicts the status of the entire nodal basin. Removing only one or two lymph nodes can accurately stage the axilla with minimal morbidity. Numerous investigators have demonstrated that, with proper training, sentinel lymph node dissection identification rates range from 90% to 99%, with false-negative rates of less than 5% found in most large studies (69). **In one study of 107 patients with T₁ and T₂ breast cancer who underwent sentinel lymph node dissection followed by axillary**

lymph node dissection, the sentinel node was successfully identified in 100 patients (93.5%). There were no false-negative results, and the sentinel node accurately predicted axillary status in all 100 patients.

The technique of sentinel lymph node dissection has been validated by a number of authors using a variety of techniques (70,71). The information obtained from sentinel lymph node dissection appears to be equivalent to that of axillary lymph node dissection in the trials conducted to date. One prospective study demonstrated that in node-negative patients undergoing sentinel lymph node dissection, only the recurrence rate in the axilla was zero at a median follow-up of 39 months (72). An additional randomized trial demonstrated sentinel node biopsy to be both safe and accurate when compared with axillary dissection, with fewer complications and no axillary recurrences among the sentinel node trial arm (73). **This degree of accuracy in predicting axillary metastasis, combined with its very low morbidity rate, makes sentinel lymph node dissection the preferred procedure for staging the axilla in breast cancer today.**

Adjuvant Systemic Therapy

For many patients, local and regional control of breast cancer is achieved with surgery and radiation therapy alone. About 90% of patients will never experience an in-breast recurrence; these patients, however, may still develop metastatic disease. The goal of adjuvant

P.1619

systemic therapy is to eliminate occult metastases during the early postoperative period and thus reduce the risk of local and distant recurrence (74).

Adjuvant systemic therapy will prolong survival in selected breast cancer patients.

In patients with favorable tumors and a low risk of recurrence and subsequent death, however, such as those with node-negative cancers smaller than 1 cm or node-negative cancers smaller than 2 cm with grade 1 histology, this benefit is small and may not justify the risks of systemic therapy. **Adjuvant systemic therapy reduces the odds of death by 25% per year in both node-negative and node-positive patients** (75). Because this risk reduction is relatively constant, patients with favorable, node-negative disease have a much smaller absolute benefit compared with patients who have higher-risk, node-positive disease. For patients with node-negative disease, the absolute benefit may be minimal versus 10% to 20% for those with nodal involvement.

Cytotoxic chemotherapy and hormonal therapy have inherent risks that must be considered when treatment decisions are made. Although there are many known acute side effects with current standard regimens, there is growing evidence that patients who undergo chemotherapy report more frequent chronic neurocognitive deficits than do untreated controls (76). The impact of these deficits remains undefined. Similarly, systemic therapy with *tamoxifen* has been associated with an increased incidence of uterine cancer, vaginal dryness, and hot flashes, whereas aromatase inhibitors have been linked to osteoporosis and musculoskeletal symptoms. Choosing those patients who should receive adjuvant therapy can be a difficult decision that often entails analyzing a variety of prognostic and predictive factors, identifying patients at risk for recurrence, and quantifying that risk. **Based on available data, adjuvant chemotherapy is currently recommended for women with greater than a 10% chance of relapse within 10 years.** The choice of therapy generally depends on an evaluation of specific risk factors. Recently, gene assays such as the Oncotype DX have been introduced to help identify those estrogen receptor-positive, lymph node-negative patients who will benefit most from systemic chemotherapy. This test, which calculates a recurrence risk score for each individual, allows the treating physician to determine the average rate of distant disease at 10 years and make treatment

recommendations based on this risk (77).

Prognostic Indicators

Factors that determine each patient's risk of recurrence include nodal involvement, tumor size, estrogen and progesterone receptor status, nuclear grade, histologic type, proliferative rate, and biologic markers such as Her2/*neu* status. These prognostic factors and their effects on recurrence are summarized in Table 38.4. Patients with high-risk prognostic factors are more likely to benefit from adjuvant cytotoxic or hormonal therapy and usually are offered such treatment.

Patients with lymph node metastasis have a higher risk of recurrence than patients with node-negative disease. The 10-year survival rate for women with palpable metastatic axillary lymph nodes who fail to receive systemic therapy is only about 50% to 60%. The number of lymph nodes involved and the presence of extracapsular invasion are important indicators of poor prognosis.

Another prognostic indicator of relapse is primary tumor size. In an evaluation of 767 patients with node-negative disease who underwent radical or modified radical mastectomy without adjuvant chemotherapy, the relapse rate in patients with tumors larger than 1 cm or special tumor types larger than 3 cm (tubular, mucinous, or papillary) was 27% at 10 years, compared with 9% for tumors smaller than 1 cm (78).

Hormone receptor status is an important predictor not only of long-term prognosis but also of response to endocrine therapy. Several studies demonstrated that patients with positive estrogen and progesterone receptor status have improved overall

P.1620

survival (79,80). Receptor status should be known when determining the need for and choice of adjuvant therapy. Histologic grade also appears to predict overall survival. Patients with well-differentiated tumors tend to have more favorable outcomes than those with poorly differentiated ones (Table 38.5). In a British study of 1,168 women, histologic grade, along with tumor size and lymph node status, was an independent predictor of overall survival at 10 years (81).

Table 38.4 Prognostic Factors in Node-negative Breast Carcinoma

<i>Factor</i>	<i>Increased Risk of Recurrence</i>
Size	Larger tumors
Histologic grade	High-grade tumors
DNA ploidy	Aneuploid tumors
Labeling index	High index (>3%)
S phase fraction	High fraction (>5%)
Lymphatic-vascular invasion	Present
Cathepsin D	High levels
HER-2/<i>neu</i> oncogene expression	High expression
Epidermal growth factor	High levels

From **Giulino AE**. Breast. In: **Tierney LM, McPhee SJ, Papadakis MA**, eds. 1995 current medical diagnosis and treatment. Norwalk, CT: Appleton & Large, 1995;607.

Finally, the possible roles of specific tumor markers in predicting which patients will respond to chemotherapy regimens have been investigated. The most thoroughly researched of these markers is HER-2/*neu*. In an NSABP study, patients with HER-2/*neu* overexpression who were not treated with *anthracycline*-based regimens fared worse (82). Another study showed that the addition of *trastuzumab* (*Herceptin*), an antibody directed against the HER-2/*neu*

receptor, significantly increased the response rate to therapy over standard chemotherapy alone in the presence of metastatic disease (83). At the 2005 meeting of the American Society of Clinical Oncology, **data were reported from trials investigating the adjuvant use of Herceptin for women with early-stage Her2/neu breast cancers. Significant improvements in disease-free survival were reported for those women receiving Herceptin** (84), suggesting that its routine use as an adjuvant therapy is inevitable.

Table 38.5 Year Survival According to Stage of Breast Cancer

P.1621

Systemic Regimens

Based on the results of more than 100 prospective, randomized trials examining the role of adjuvant chemotherapy in breast cancer, a variety of systemic regimens have emerged. Systemic therapy includes cytotoxic agents and hormonal agents, used alone or in combination. Following is a brief description of the more commonly used regimens. Initially, trials involved a single perioperative course of chemotherapy aimed at eradicating circulating tumor cells. The Nissen-Meyer study from Norway showed that a single course of *cyclophosphamide* improved overall survival rates (85). Subsequently, numerous trials demonstrated the benefit of adjuvant chemotherapy for certain subgroups of patients (86). In the initial NSABP adjuvant trial, a 2-year course of *melfhalan* was shown to be superior to no treatment (87), and further trials demonstrated enhanced beneficial effect with the use of multiple drugs as well as with the combination of hormonal manipulation with chemotherapy (88).

Historically, the most frequently used adjuvant combination chemotherapy has been CMF: *cyclophosphamide* (C), *methotrexate* (M), and *5-fluorouracil* (5-FU). In the original study by Bonadonna et al., patients with positive axillary lymph nodes were randomized to receive either 12 monthly cycles of CMF or no therapy after radical mastectomy (89). A statistically significant benefit was found with CMF treatment for premenopausal patients, especially those with one to three positive nodes. A subsequent study showed six cycles of CMF to be as effective as 12 cycles (90). Interestingly, no significant effect was seen for postmenopausal women, which was probably related in part to the fact that these women were less likely to tolerate the full course of therapy (91). **After 20 years of follow-up, this trial demonstrated a persistent survival advantage for premenopausal women receiving CMF adjuvant therapy (92). In a later study involving node-negative, estrogen receptor-negative breast cancer patients, after 12 years of follow-up, 71% of patients treated with adjuvant CMF remained disease free compared with 48% in**

the control group, regardless of menopausal status (93).

Currently, *anthracyclines* (A) are more commonly used in the adjuvant and metastatic treatment of breast cancer than any other agents. A large randomized NSABP study compared CMF with AC regimens in node-positive patients and found similar treatment outcomes among both groups. The AC regimen, however, was preferred because of its shorter duration (four cycles for 3 months versus six cycles for 6 months) and better tolerance (94).

Taxanes are also being used in a variety of multiple-agent chemotherapy regimens because of their demonstrated activity in metastatic breast cancer patients (95). **In a randomized trial of 3,170 node-positive patients who received four cycles of AC followed by four cycles of paclitaxel for 4 weeks or no additional therapy, survival rates improved from 84% to 87% in the treated group after 36 months of follow-up.** Benefits were similar in both premenopausal and postmenopausal women (96). Although the role of taxanes in the adjuvant setting for women with node-negative disease has yet to be definitively defined, early results suggest an improvement in overall survival when taxanes are used in the treatment of women with early-stage breast cancer (97).

Neoadjuvant Systemic Therapy

The use of neoadjuvant chemotherapy traditionally was limited to those individuals with either inoperable locally advanced or inflammatory breast cancers. The goal of preoperative systemic therapy was to convert inoperable patients into resectable candidates on the basis of pathologic and clinical responses (98). More recently, indications for neoadjuvant chemotherapy have been broadened to include individuals presenting with large operable tumors who desire to attempt breast preservation instead of mastectomy. Recent reports indicate that breast conservation therapy is possible and that low rates of in-breast or local-regional recurrences occur when neoadjuvant chemotherapy results in clinical and pathological tumor downstaging (99). In addition to large, operable tumors, neoadjuvant therapy continues to have a role in the treatment of inflammatory breast cancers and those presenting in a locally advanced state.

P.1622

Hormonal Therapy

Hormonal manipulation with *tamoxifen* or an aromatase inhibitor, used alone or in combination with a cytotoxic regimen, is beneficial in select groups of women. *Tamoxifen*, an estrogen analogue, offers substantial benefits in both premenopausal and postmenopausal women. Taken at a dose of 20 mg per day for 5 years, *tamoxifen* reduces the annual risk of recurrence by about 50% and the annual risk of death by about 25%. These benefits were seen in women with estrogen receptor–positive disease regardless of chemotherapy treatment (100).

***Tamoxifen*, when used in combination with cytotoxic chemotherapy, improves survival in women with positive axillary lymph nodes and positive estrogen receptor expression (101).** In patients with node-negative, estrogen receptor–positive disease, the addition of *tamoxifen* to chemotherapy improved disease-free survival rates after 5 years of follow-up (102). In NSABP study B-14, 2,644 patients with estrogen receptor–positive tumors and no axillary metastases were randomized to either *tamoxifen* (10 mg orally twice daily for 5 years) or a placebo control. After a 4-year median follow-up, the disease-free survival rate for the 1,318 patients treated with *tamoxifen* was 82% compared with 77% for the 1,326 patients treated with placebo ($P = 0.00001$), again regardless of menopausal status.

The Early Breast Cancer Trialists' Collaborative Group performed a meta-analysis

of adjuvant systemic therapy for breast cancer. They analyzed randomized trials involving adjuvant systemic hormonal, cytotoxic, or immune therapy administered to more than 75,000 women with stage I or II carcinoma. **The investigators concluded that for postmenopausal women with estrogen receptor–positive tumors, *tamoxifen* daily for at least 2 years had a significant beneficial effect on disease-free survival rates, with these effects lasting up to 10 years. The incidence of both carcinoma in the contralateral breast and death rate from heart disease decreased.**

In addition to *tamoxifen*, aromatase inhibitors have been approved for use in the adjuvant treatment of patients with estrogen-receptor positive cancers.

Aromatase inhibitors act by inhibiting the aromatase enzyme, thus blocking the conversion of androgens into estrogens. These drugs should be used only in postmenopausal patients or premenopausal women who have undergone chemical ovarian suppression or oophorectomy. Although aromatase inhibitors cause fewer episodes of thrombotic events, hot flashes, and endometrial cancers, musculoskeletal symptoms and osteoporosis are more commonly encountered among aromatase inhibitor users than those taking *tamoxifen*. Results from the Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial showed overall lower recurrence rates, as well as fewer contralateral tumors, among women treated with *Arimidex* alone after 68 months of follow up (103). Based on these results, **aromatase inhibitors are now often offered as a first-line treatment option for adjuvant therapy.** In addition, **recent research suggests that conversion of patients from *tamoxifen* to an aromatase inhibitor, such as *Femara*, after 2.5 or 5 years may improve survival, although concurrent use of the two agents offers no benefit (103,104).**

General Recommendations

Adjuvant systemic therapy lowers the incidence of recurrence by 25% to 30%. It is important to understand that the proportional reduction in risk of relapse is relatively constant regardless of absolute risk (105) (Table 38.6). As mentioned earlier, adjuvant cytotoxic chemotherapy appears to affect the natural history of patients with either axillary node-negative or node-positive breast cancer. All high-risk patients with node-negative disease are now considered candidates for adjuvant cytotoxic therapy.

In postmenopausal, estrogen receptor–positive women, chemotherapy is about one half as effective as *tamoxifen* in the adjuvant setting (106). For most postmenopausal women with hormone-responsive disease (estrogen- and progesterone-responsive positivity),

P.1623

including node-positive patients, hormonal therapy alone may be adequate treatment. High-risk patients with hormone-resistant disease benefit from cytotoxic systemic therapy. Caution should be exercised when using chemotherapeutic agents. Patients in whom the risk of recurrence is low are likely to derive little overall benefit from the use of adjuvant systemic therapy, whereas those with a high risk of recurrence are likely to receive the greatest benefit. Regardless, comorbidities must always be considered on an individual basis.

Table 38.6 Effect of Systemic Therapy on Recurrence and Survival from Breast Cancer

Age	Therapy	Reduction in Annual Odds of Recurrence	Reduction in Annual Odds of Death
<50	Tamoxifen × 5 yrs	45 ± 8	32 ± 10
50–59	Tamoxifen × 5 yrs	37 ± 6	11 ± 8
60–69	Tamoxifen × 5 yrs	54 ± 5	33 ± 6
<40	Polychemotherapy	37 ± 7	27 ± 8
40–49	Polychemotherapy	35 ± 5	27 ± 5
50–59	Polychemotherapy	22 ± 4	14 ± 4
60–69	Polychemotherapy	18 ± 4	8 ± 4

From **Early Breast Cancer Trialists' Collaborative Group**. Polychemotherapy for early breast cancer: an overview of the randomized trials. *Lancet* 1998; 352: 930, with permission.

The current recommendations for adjuvant systemic therapy in breast cancer are summarized as follows:

- Premenopausal women with lymph node involvement should be treated with adjuvant combination chemotherapy. *Tamoxifen* should be added for patients with estrogen receptor–positive tumors following cytotoxic therapy.
- Premenopausal women without evidence of axillary lymph node involvement but with large (>1 cm) size, aneuploid, or estrogen receptor–negative tumors should be treated with combination chemotherapy. *Tamoxifen* should be given to patients with estrogen receptor–positive tumors.
- Postmenopausal patients with negative lymph nodes who are hormone receptor positive should receive adjuvant *tamoxifen* or aromatase inhibitor therapy. Those with positive lymph nodes may receive *tamoxifen* or an aromatase inhibitor alone, multidrug cytotoxic therapy, or a combination thereof.
- Postmenopausal women with lymph node metastases who are hormone receptor negative may be treated with adjuvant chemotherapy.
- Adjuvant systemic therapy is not recommended for patients with favorable tumors smaller than 1 cm. Hormonal therapy may be considered if the patient is estrogen receptor positive.

Prognosis

The treatment of advanced, metastatic breast cancer is largely palliative. For most physicians, quality-of-life issues are paramount when choosing which type of therapy is

P.1624

offered. In patients with locally advanced disease in conjunction with distant metastasis, palliative radiotherapy may be advised to control pain or avoid pathologic fractures. This approach is best exemplified in the treatment of isolated bone metastases, chest wall recurrences, brain metastases, and spinal cord compression.

Systemic disease may be controlled by hormonal or cytotoxic therapy. Because the quality of life during an endocrine-induced remission is usually superior to one following cytotoxic chemotherapy, it is preferable to try endocrine manipulation first. As many as one third of patients with disseminated disease respond favorably to either functional end-organ ablation (ovary, pituitary, adrenal glands) or administration of drugs that block hormonal function. For patients with estrogen receptor–positive tumors, this response rate may be as high as 60%. Because only 5% to 10% of women with estrogen receptor–negative cancers respond to endocrine treatment, they should not routinely receive hormonal therapy except in unusual cases, such as elderly women who are intolerant of cytotoxic therapy (107).

Cytotoxic chemotherapy should be considered for the treatment of metastatic breast cancer if organ involvement is potentially life-threatening (brain, lung, or liver), if hormonal treatment is unsuccessful, if the disease has progressed after an initial response to endocrine manipulation, or if the tumor is estrogen receptor negative. The most useful single chemotherapeutic agent is an anthracycline such as *doxorubicin*, which has an estimated response rate of 40% to 50%. Combination therapy using multiple agents has response rates as high as 60% to 80% (108). Clinical trials, including those investigating the use of *Herceptin* for Her-2/*neu*-positive women with metastases, are under way to examine a variety of combinations for stage IV disease. The historically prominent side effects of debilitating nausea and vomiting are now well controlled with central-acting antiemetics. The importance of controlling these potentially devastating symptoms cannot be overemphasized.

Special Breast Cancers

Paget Disease

In the 1870s, Sir James Paget first described a nipple lesion similar to eczema and recognized that this nipple change was associated with an underlying breast malignancy (109). The erosion results from invasion of the nipple and surrounding areola by characteristic large cells with irregular nuclei, now called Paget cells. Although the origin of these cells has been much debated by pathologists, they are probably extensions of an underlying carcinoma into the major ducts of the nipple–areolar complex. There may be no visible changes associated with the initial invasion of the nipple. Often, the patient's presenting symptom will be nipple discharge, which is actually a combination of serum and blood from the involved ducts.

The overall prognosis for patients with this rare form of breast cancer depends on the stage of the underlying malignancy. When an intraductal carcinoma alone is identified, the prognosis remains favorable, whereas patients with infiltrating ductal carcinoma metastatic to the regional lymph nodes have worse outcomes. Traditionally, treatment has almost always been total mastectomy and lymph node dissection, although breast conservation therapy with resection of the tumor and nipple–areolar complex, followed by whole breast radiation, is being performed in appropriately identified patients (110).

Inflammatory Carcinoma

Patients presenting with inflammatory carcinoma initially appear to have acute inflammation of the breast with corresponding redness and edema. Additional clinical findings are variable and range from complete absence of a dominant mass to the presence of either satellite skin nodules or a large palpable abnormality.

Inflammatory cancer, rather than infiltrating ductal carcinoma, should be diagnosed when more than one third of the breast is involved with erythema and edema and when biopsy of the involved area, including the skin, demonstrates metastatic cancer in the subdermal lymphatics. Most of these tumors are poorly differentiated. Mammographically, the breast shows skin thickening with an infiltrative process and may or may not identify a mass or calcifications.

Except for biopsy of the lesion to establish the diagnosis, surgery is not part of the initial management of inflammatory carcinoma. Mastectomy usually fails locally within 2 years of the initial diagnosis and does not improve overall or disease-free survival rates. **Better results are achieved with a combination of chemotherapy and radiation therapy.** Mastectomy may be indicated for patients who remain free of distant metastatic disease after initial chemotherapy and radiation (111).

In Situ Carcinomas

Both lobular and ductal carcinoma may be confined by the basement membrane of the ducts. These carcinomas do not invade the surrounding tissue and, theoretically, lack the ability to spread.

Lobular Carcinoma In Situ

***Lobular carcinoma in situ* should not be considered a true malignancy but rather a risk factor for the subsequent development of invasive ductal or lobular carcinoma in either breast (112).** A more appropriate nomenclature for lobular carcinoma *in situ* may be lobular neoplasia. Most women with lobular carcinoma *in situ* are premenopausal and have neither clinical nor mammographic signs of an abnormality. The lesion typically is not a discrete mass, but rather a multifocal entity within one or both breasts incidentally discovered by the pathologist during the evaluation of a completely unrelated issue. Lobular carcinoma *in situ* usually is managed with an excisional biopsy followed by careful surveillance with clinical breast examinations and mammography. Occasionally, a patient may request either bilateral prophylactic mastectomy or *tamoxifen* for chemoprevention. **Women with lobular carcinoma *in situ* have a 1% per year and up to a 30% lifetime risk of developing an invasive cancer.**

Ductal Carcinoma In Situ

Ductal carcinoma *in situ* is more common in postmenopausal women. It may manifest as a palpable mass but usually is detected mammographically as a cluster of branched or Y-shaped pleomorphic microcalcifications. By definition, intraductal disease does not invade beyond the basement membrane. **Unlike patients with lobular carcinoma *in situ*, 30% to 50% of patients with ductal carcinoma *in situ* will develop an invasive ductal cancer within the same breast if treated by excisional biopsy alone (113).**

Although modified radical mastectomy was previously the standard treatment for intraductal carcinoma, more conservative surgery, with or without radiation therapy, has been shown to yield good results. In NSABP trial B17, 818 patients were randomly assigned to excision alone or excision followed by radiation therapy. The mean extent of ductal carcinoma *in situ* lesions was 13 mm, and 88% were larger than 20 mm. All lesions were completely resected with negative margins. After a median follow-up of 43 months, the actuarial 5-year local recurrence rate was 10.4% without radiation versus 7.5% with radiation ($P = 0.055$) for noninvasive cancers, and 10.5% without radiation versus 2.9% with radiation ($P > 0.001$) for invasive cancers. Of 83 recurrences, only 9 (11%) were not in the index quadrant. A recent reanalysis with a mean follow up of 90 months confirmed these results (114). **These data suggest that segmental mastectomy offers excellent local control.**

Axillary metastases occur in fewer than 5% of patients diagnosed with ductal carcinoma *in situ*, making routine axillary dissection unnecessary. When axillary disease is

P.1626

identified, further evaluation of the breast or surgical specimen or both is warranted because nodal metastases indicate that an invasive ductal component was missed. Sentinel node biopsy may be offered to certain individuals with ductal carcinoma *in situ*, especially if the lesion is high grade, contains comedonecrosis, or was diagnosed on core biopsy and has clinical or radiographic features suggesting invasive disease. About 5% of patients whose initial biopsy results show intraductal carcinoma will be found to have infiltrating ductal carcinoma when treated with mastectomy, whereas core biopsy may underestimate the invasiveness of the disease in up to 20% of patients. The incidence of contralateral breast cancer in women with intraductal carcinoma is the same as in those with invasive ductal carcinoma (5%–8%) (115).

Breast Cancer in Pregnancy

Breast cancer complicates 1 in 3,000 pregnancies (116,117). It is the second most common malignancy seen in association with pregnancy, surpassed only by cervical cancer (118). Initial studies suggested a significantly worse prognosis for patients first diagnosed during pregnancy, but recent data indicate that the hormonal changes associated with pregnancy seem to have little, if any, influence on prognosis. **When pregnant patients are matched stage for stage with nonpregnant patients, survival rates seem equivalent** (119). Patients typically present with a painless mass. Up to 60% will have concurrent lymph node involvement. The evaluation includes imaging with ultrasonography and mammography, which, although controversial, expose the fetus to less than 0.02 cGy of radiation and may be obtained with proper abdominal shielding (120). If biopsy is warranted, the procedure can be performed safely and should not be delayed until after delivery. Needle biopsy is safe and easily accomplished in the office setting.

The treatment of breast cancer in pregnant women must be highly individualized. Considerations include the patient's age and desire to continue the pregnancy. The overall prognosis should be considered, especially when axillary lymph nodes are involved, because adjuvant chemotherapy can be teratogenic or lethal to the fetus during the first trimester, but may be given later in the pregnancy. It is believed that interruption of pregnancy does not alter the prognosis for patients with potentially curable breast cancer.

Following are generalized recommendations for treatment of pregnant women with breast cancer:

- **Traditionally, cancers diagnosed during the first or second trimester of pregnancy have been treated with modified radical mastectomy. Sentinel node biopsy remains a controversial procedure in pregnancy;** the use of blue dye is contraindicated, and the safety of radiocolloid has not been documented. In addition, most centers do not offer breast conservation therapy based on the theory that radiation therapy should not be given to the gravid patient. In a patient diagnosed before the third trimester, waiting until after delivery may result in an unacceptable delay in the initiation of therapy and should not be encouraged. Adjuvant chemotherapy can be given after the first trimester, although many oncologists prefer not to give it to pregnant women outside of clinical trials. A classic study reported the risk of fetal malformations to be 20% during the first trimester, a rate which dropped to 1.5% during the second and third trimesters (121). *Tamoxifen*, however, is a class D drug and should not be given to pregnant or lactating patients with breast cancer.

- **Localized tumors found during the third trimester of pregnancy can be managed**

with breast conservation therapy, with radiation delayed until after delivery, or with modified radical mastectomy. Initially, tumors should

P.1627

be excised early in the third trimester using local anesthesia. If delivery is imminent, standard therapy can be performed immediately postpartum. In the patient with a viable fetus, it may be preferable to induce early labor to avoid delaying definitive cancer therapy.

- **If the breast cancer is diagnosed during lactation, lactation should be suppressed and the cancer should be treated definitively.**

- **Advanced, incurable cancer should be treated with palliative therapy.** Decisions regarding continuation of the pregnancy should be based on the therapy necessary and the desires of the mother.

Counseling regarding future childbearing is important for women who have had carcinoma of the breast. Although it generally has been assumed that subsequent pregnancies are detrimental because of the high levels of circulating estrogens, **there is no clear difference in survival for women who become pregnant after the diagnosis of breast cancer.** One study evaluated the effect of subsequent pregnancy on overall survival after the diagnosis of early-stage breast cancer. Although approximately 40% of the women in the study had node-positive disease, 5- and 10-year survival rates were better in women who became pregnant than in matched pair controls who did not. This study suggests that subsequent pregnancy does not adversely affect the prognosis of early-stage breast cancer (122). A subsequent investigation demonstrated no increase in the relative risk of death for patients who gave birth more than 10 months after their initial diagnosis of cancer (123). Theoretically, it may be that only women with estrogen receptor-positive or progesterone-positive tumors would be affected deleteriously by subsequent pregnancy, but this possibility has not been studied. Because recurrences are most frequent within the first 2 to 3 years after diagnosis, patients with receptor-positive tumors and advanced-stage disease probably should wait until after that time before becoming pregnant again.
