Benign Breast Disease

Baiba J. Grube

Armando E. Giuliano

- **Early detection of breast cancer is improved by risk assessment, clinical breast examination, and screening mammography.**
- **Triple-test concordance requires agreement between results of clinical breast examination, breast imaging, and tissue diagnosis. In the absence of concordance, further diagnostic intervention is required.**
- **The most common benign breast problems include fibrocystic changes and mastalgia. These problems are usually best treated by reassurance. Pharmaceutical agents are available but have side effects that usually are not well tolerated.**
- **Histologic differences exist between fibroadenomas and phyllodes tumors; phyllodes tumors require excision, whereas small asymptomatic fibroadenomas can be observed if the diagnosis is confirmed by histologic or cytologic assessment and there is no evidence of growth.**
-

Spontaneous, unilateral, bloody discharge requires histologic evaluation to exclude malignancy, but symptoms usually are caused by a benign process such as intraductal papilloma or duct ectasia.

- **Breast abscesses are managed with fine needle aspiration and antibiotics, with use of incision and drainage reserved for recurrence.**

Practicing gynecologists should be familiar with techniques for the diagnosis and management of common benign breast conditions, particularly those that mimic malignancy, as well as options for their treatment (1). Benign breast disease is a complex entity of its own with a range of physiologic changes and clinical manifestations that have an impact on a woman's health independent of breast cancer risk (2).

P.638

Detection

History

Evaluation of a new breast symptom begins with assessment of symptoms based on a thorough clinical history (3). The history should include questions regarding current symptoms, duration of the condition, fluctuation of the signs and symptoms, and factors that aggravate or relieve the symptom. **Assessment of breast problems should focus on the following points:**

- Nipple discharge
- Characteristics of discharge (spontaneous or nonspontaneous, appearance, unilateral or bilateral, single or multiple duct involvement)
- Breast mass (size and change in size, density, or texture)
- Breast pain (cyclic versus continuous)
- Association of symptoms with menstrual cycle
- Change in breast shape, size, or texture
- Previous breast biopsies

The patient should be questioned about the following risk factors for breast cancer (see Chapter 38 for more details).

- Sex

- Increasing age (approximately 50% of breast cancers occur *after* age 65)
- Age of menarche less than 12 years
- Nulliparity or first pregnancy at greater than 30 years of age
- Late menopause (older than 55 years of age)
- Family history of breast cancer (especially premenopausal or bilateral disease)
- Number of first-degree relatives with breast cancer and their ages when diagnosed
- Family history of male breast cancer
- Inherited conditions associated with a high risk for breast cancer, including *BRCA1* and *BRCA2* genes, Li-Fraumeni syndrome, Cowden's disease, ataxia telangiectasia syndrome, and Peutz-Jeghers syndrome
- Other malignancies (ovary, colon, and prostate)
- Pathology of previous breast biopsy showing atypia or lobular or ductal carcinoma in situ
- Hormone therapy
- Alcohol consumption
- Postmenopausal weight gain
- Personal history of breast cancer

Breast cancer risk can be determined by the **Gail Risk assessment model**, which is available electronically (4). **The Gail Risk assessment model calculates risk based on patient race, age, age of menarche, age of first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsies, and presence of atypia on the biopsy.**

P.639

It also is important to obtain a current list of medications used, including hormone therapy and herbal medications such as phytoestrogens. The gestational history should take into consideration the possibility that the patient may be pregnant. A personal history of exposure to radiation, especially in the treatment of childhood malignancies, is associated with a higher incidence of developing breast cancer (5). The goal of breast evaluation is to determine clearly if the symptom represents a benign breast condition or may be indicative of a neoplastic process.

Physical Examination

Breast tumors, particularly cancerous ones, usually are asymptomatic and are discovered only by physical examination or screening mammography. Typically, the breast changes slightly during the menstrual cycle. During the premenstrual phase, most women have increased innocuous nodularity and mild engorgement of the breast. Rarely, these characteristics can obscure an underlying lesion and make examination difficult. Findings should be carefully documented in the medical record to serve as a baseline for future reference.

Inspection

Inspection is performed initially while the patient is seated comfortably with her arms relaxed at her sides. The breasts are compared for symmetry, contour, and skin appearance. Edema or erythema is identified easily, and skin dimpling or nipple retraction is shown by having the patient raise her arms above her head and then press her hands on her hips, thereby contracting the pectoralis muscles (Fig. 19.1). Palpable and even nonpalpable tumors that distort Cooper's ligaments may lead to skin dimpling with these maneuvers.

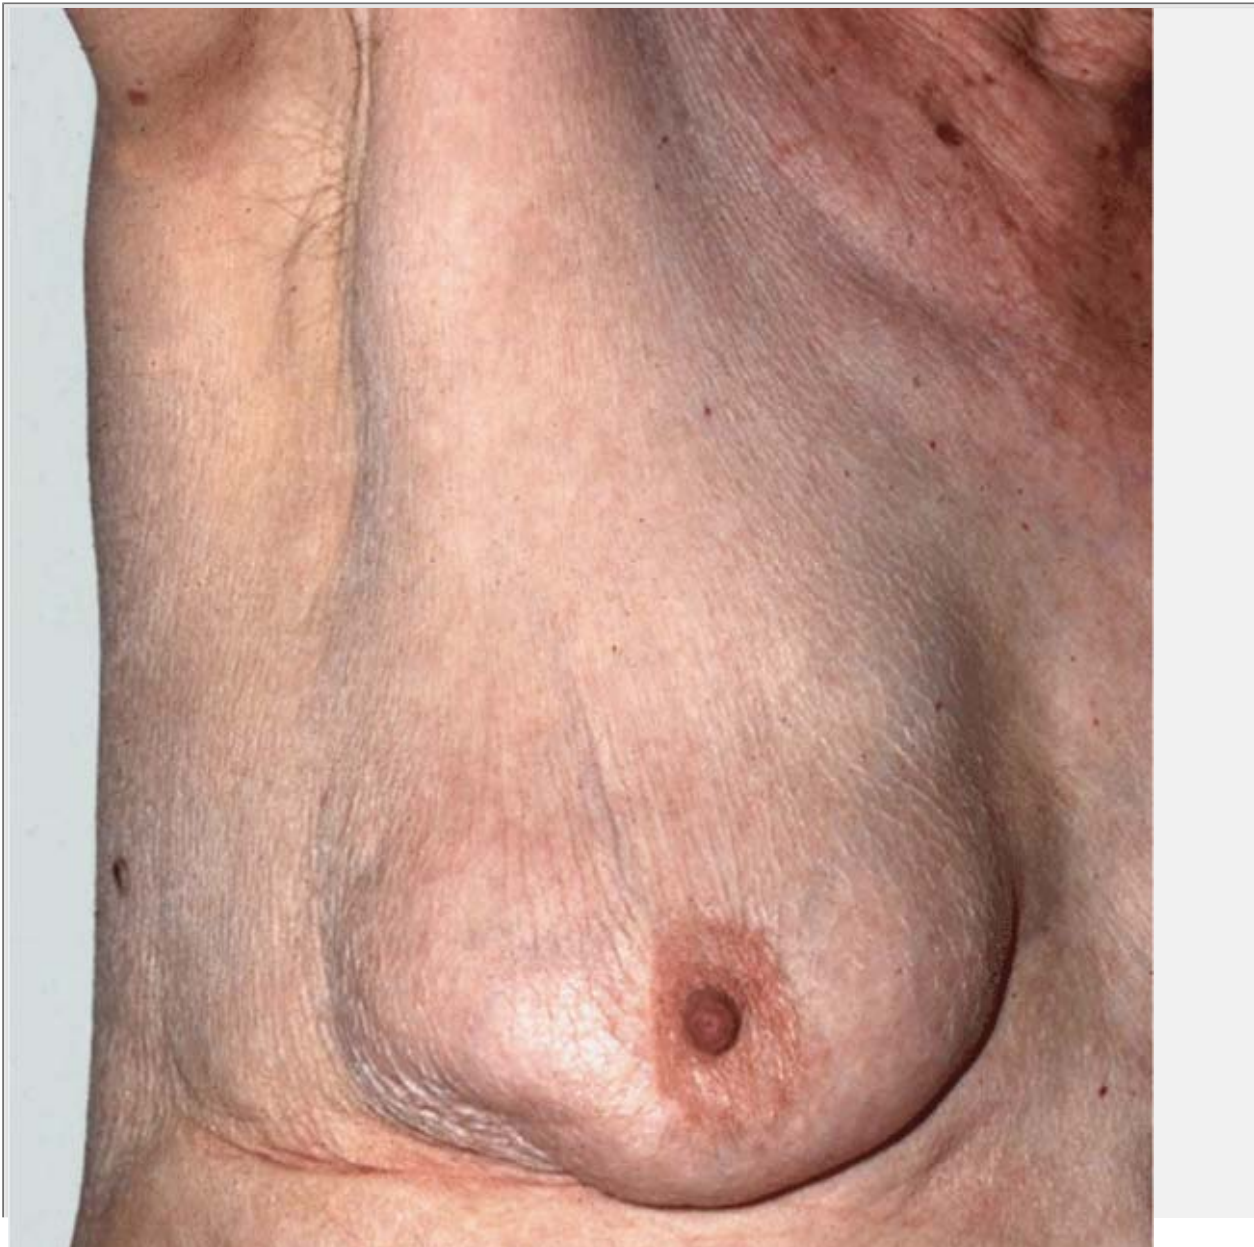

Figure 19.1 Raising the arm reveals retraction of the skin of the lower outer quadrant caused by a small palpable carcinoma. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:628, with permission.)

Palpation

While the patient is seated, each breast should be palpated methodically. Some physicians recommend palpating the breast in long strips, but the exact palpation technique used is probably not as important as the thoroughness of its application over the entire breast. One very effective method is to palpate the breast in enlarging concentric circles until the entire breast has been covered. A pendulous breast can be palpated by placing one hand between the breast and the chest wall and gently palpating the breast between both examining hands. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses.

While the patient is supine with one arm over her head, the ipsilateral breast is again methodically palpated from the clavicle to the costal margin. If the breast is large, a pillow or towel should be placed beneath the scapula to elevate the side being examined; otherwise, the breast tends to fall to the side, making palpation of the lateral hemisphere more difficult. The major features to be identified on palpation of the breast are temperature, texture and thickness of skin, generalized or focal tenderness, nodularity, density, asymmetry, dominant masses, and nipple discharge. Most premenopausal patients have normally nodular breast parenchyma. The nodularity is diffuse but predominantly in the upper outer quadrants, where there is more breast tissue. These benign parenchymal nodules are small, similar in size, and indistinct. By comparison, breast cancer usually occurs in the form of a nontender, firm mass with irregular margins. A cancerous mass feels distinctly different from the surrounding nodularity. A malignant mass may be fixed to the skin or to the underlying fascia. A suspicious mass is usually unilateral. Similar findings in both breasts are unlikely to represent malignant disease (6).

Breast Self-examination

Breast self examination (BSE) increases breast health awareness (7,8). It helps promote early detection of cancer and may improve the survival rates for patients with breast carcinoma (9,10,11). Most breast cancers are detected by women themselves (48%), followed by breast imaging (41%), and by physician clinical examination in only 11%

P.640

(12). Although young women have a low incidence of breast cancer, it is important to teach self-examination early so that it becomes habitual. Organizations such as the American Cancer Society sponsor courses in BSE. Reassurance, support, and patient education may encourage women to overcome psychologic barriers to routine BSE (13). Such instruction also available is through electronic resources (14).

The following seven "P's represent essential components of breast examination:

.

Positions

- Palpation
- Pads of fingers for palpation

Pressure

P.641

- Perimeter
- Pattern of search
- Patient education

The woman should inspect her breasts while standing or sitting before a mirror, looking for any asymmetry, skin dimpling, or nipple retraction. Elevating her arms over her head or pressing her hands against her hips to contract the pectoralis muscles will highlight any skin dimpling. Finally, the woman should examine her breasts while bending over and leaning forward. While standing or sitting, she should carefully palpate her breasts with the fingers of the opposite hand. She should then lie down and again palpate each quadrant of the breast as well as the axilla using the pads of the three middle fingers with three pressures—light, medium, and deep—covering the entire breast from the clavicle to the inframammary fold, from sternum to latissimus dorsi laterally. The area within the perimeter of the breast should be palpated, preferably using an up-and-down method called vertical stripe, rather than the concentric circular or radial methods, in which the edges of the breast tissue often are omitted. Many women feel anxious about performing breast examination. The examination may be performed while showering; soap and water may increase the sensitivity of palpation, and the privacy of the shower may provide a less anxiety-provoking environment.

It is helpful for all women to examine their breasts at the same time each month to develop a routine. Premenopausal women should examine their breasts monthly 7 to 10 days after the onset of the menstrual cycle. For postmenopausal women, selection of a specific calendar date is a helpful way to remember to perform a monthly BSE.

Women should be instructed to report any abnormalities or changes to their physicians. If the physician cannot confirm the patient's findings, the examination should be repeated in 1 month or after her next menstrual period.

Breast Imaging

Mammography

The best method for imaging of the breast is screen-film mammography (15). Full-field digital mammography, which records mammographic images on a computer, is a modification of screen-film mammography (16). Some advantages of digital mammography include lower radiation exposure, ability to manipulate a computerized image for optimal viewing, and access to distance consultations through telemammography (17). Studies comparing the sensitivity of full-field digital mammography with screen-film mammography

in detecting cancer have had mixed results. Full-field digital mammography had lower detection rates than screen-film mammography in community-based programs, but a randomized trial showed full-field digital mammography to have higher detection rates and lower recall rates than screen-film mammography (16,18).

Slow-growing breast cancers can be identified by mammography at least 2 years before the mass reaches a size detectable by palpation. These tumors have a less aggressive biologic behavior than interval breast cancers (19,20,21). In fact, mammography is the only reproducible method of detecting nonpalpable breast cancer, but its use depends on the availability of state-of-the-art equipment and a dedicated breast radiologist.

Compression of the breast is necessary to obtain good images, and patients should be forewarned that breast compression is uncomfortable. With good technique and well-maintained modern equipment, exposure to radiation can be limited. For all facilities in the United States inspected under the Mammography Quality Standards Act in the first

P.642

one half of 1997, the average mean glandular radiation dose per mammographic image was 1.6 mGy (160 mrad) (22).

Indications for Mammography

The indications for mammography are as follows:

- **To screen, at regular intervals, women who are at high risk for developing breast cancer.** About one third of the abnormalities detected on screening mammography prove malignant when biopsy is performed (23).
- **To evaluate a questionable or ill-defined breast mass or other suspicious change in the breast that is detected by clinical breast examination.**
- **To establish a baseline breast mammogram and reevaluate patients at yearly intervals to diagnose a potentially curable breast cancer before it has been diagnosed clinically.**
- **To search for occult breast cancer in a patient with metastatic disease in axillary nodes or elsewhere from an unknown primary origin.**
- **To screen for unsuspected cancer before cosmetic operations or biopsy of a mass.**
- **To monitor breast cancer patients who have been treated with a breast-conserving surgery and radiation.**

Screening

Screening programs to evaluate asymptomatic, healthy women combine physical examination with mammographic screening to identify breast abnormalities. During the past 30 years, there has been an increase in the use of mammography, mammographic screening, and public awareness of breast health care. The cancer detection rate for screening mammography is 5 per 1,000 screening examinations (24). The cancer detection rate is 11-fold higher, at 55 per

1,000 examinations, when breast imaging is performed for a specific finding (i.e., diagnostic imaging) (24). Of seven randomized mammographic screening trials performed, five have demonstrated a reduction in overall mortality from breast cancer screening programs (25,26,27,28,29,30,31,32). A study from the Rhode Island Cancer Registry indicates that the institution of population-based breast cancer screening programs can result in the reduction in the median tumor size at initial detection from 2.0 to 1.5 cm, which is associated with a 25% reduction in mortality (33). Detecting breast cancer before it has spread to the axillary nodes greatly increases the chance of survival; about 85% of women with such cancer will survive at least 5 years (31,34). Because breast cancer presents first as local disease, screening mammography for breast cancer in asymptomatic women can detect small tumors that have a better prognosis. These tumors have not had the opportunity to metastasize regionally or systemically; thus women have more options for treatment with reduced toxicity.

The American Cancer Society has published an extensive review of the benefits, limitations, and potential harms of screening mammography (35). In addition, it addresses the role of physical examination, discusses screening in older and high-risk women, and reviews the role of newer technologies. **A summary of the guidelines recommends that women of average risk for breast cancer begin mammographic screening at age 40. The rationale for beginning mammographic screening at age 40 is a 24% reduction in mortality in screened populations** (28). For women in their 20s and 30s, a clinical breast examination is suggested at least every 3 years, and preferably annually, as part of a well-woman examination. For women older than age 40 years, annual clinical breast

P.643

examination and mammography are recommended. For older women, recommendations for mammographic screening may be individualized based on the presence of any comorbidities. Chronologic age alone should not be considered a contraindication to mammographic screening as long as a woman is in reasonable health and has a life expectancy of 3 to 5 years (35). **The American Geriatrics Society recommends annual or at least biennial mammography for women up to age 75 years, and after that age, every 2 to 3 years if the woman has a life expectancy of more than 4 years** (36). The reasons for liberalization of the screening interval recommendations for older women include improved biology profile, slower growth rate, and lower risk for recurrence (37,38,39,40,41). The natural history of the disease in older women must be balanced against life expectancy as a function of overall health (42). **For high-risk women, consideration can be given to earlier initiation of screening (5–10 years earlier than the age of the index case) and shorter intervals between screening**, as well as the use of additional imaging modalities such as breast ultrasonography and magnetic resonance imaging (MRI) with dedicated breast coils. No screening test is perfect, however, and false-negative imaging studies or benign clinical examinations may lead the patient to an erroneous sense of well-being only to be confronted later with a subsequent interval cancer. Likewise, a false-positive result can lead to significant anxiety and unnecessary biopsy.

Mammographic Abnormalities

A mammographic abnormality includes a mass (solid versus cystic), microcalcifications (benign, indeterminate, suspicious), asymmetric density, architectural distortion, and appearance of a new density. There are eight morphologic categories of mammographic abnormalities (43,44):

- Calcification distribution

•

Number of calcifications

- Description of calcifications
- Mass margin
- Shape of mass
- Density of mass
- Associated findings
- Special cases

Mammographic abnormalities should be visible on two views, usually craniocaudal (CC) and mediolateral oblique (MLO). The lesion should triangulate to the same location on those two views. Calcifications can be macrocalcifications, which are coarse and usually represent benign degenerative breast conditions. Calcifications associated with breast cancer are clustered pleomorphic microcalcifications; typically, five to eight or more calcifications are aggregated in one part of the breast (45). These calcifications may be associated with a mammographic mass density. A mass density may appear without evidence of calcifications. It can represent a cyst, benign tumor, or a malignancy. A malignant density usually has irregular or ill-defined borders and may lead to architectural distortion, which may be subtle and difficult to detect in a dense breast. Other mammographic findings suggesting breast cancer are architectural distortion, asymmetric density, skin thickening or retraction, or nipple retraction. Examples of mammographic abnormalities can be found in several electronic sources (46).

P.644

Mammographic Reports

The American College of Radiology has recommended the **Breast Imaging Reporting and Data System (BI-RADS)** as a standardized scheme for describing mammographic lesions (47). In the BI-RADS system, there are six categories for mammographic findings (other than incomplete) (43,44).

- Incomplete, needs further imaging
- Negative
- Benign finding
- Probably benign, short-interval follow-up recommended
- Suspicious finding and biopsy should be considered

Highly suggestive of malignancy and appropriate action should be undertaken

- Known malignancy (a category that is often used for follow-up of a lesion that is undergoing neoadjuvant treatment)

The patient should be referred to a surgeon if the report identifies a lesion as a category 4 or 5 (47). A category 0 indicates incomplete evaluation, and further diagnostic studies are required. Category 3 connotes a finding that is most likely benign; a short-interval follow-up is recommended, and breast examination by an expert should be considered.

Correlation of Findings

Biopsy must be performed on patients with a dominant or suspicious mass despite absence of mammographic findings (48). Mammography should be performed before biopsy so other suspicious areas can be noted and the contralateral breast can be checked (Fig. 19.2). **Mammography is never a substitute for biopsy because it may not reveal clinical cancer**, especially when it occurs in the dense breast tissue of young women with fibrocystic changes. In fact, the sensitivity of mammography is 75%, with a specificity of 92.3% depending on the patient's age; breast density; use of hormone therapy; and the size, location, and mammographic appearance of the tumor (49). Mammography is less sensitive in young women with dense breast tissue than in older women, who tend to have fatty breasts, in which mammography can detect at least 90% of malignancies (50). Small tumors, particularly those without calcifications, are more difficult to detect, especially in women with dense breasts.

Figure 19.2 Bilateral mammography shows the extent of breast carcinoma, illustrating the importance of bilateral mammography in the workup of a clinically apparent mass. (From Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:630, with permission.)

Ultrasonography

Breast ultrasonography is generally used for focused scanning of a questionable finding or for evaluation of a mammographic finding (51). Reliable, portable, computer-enhanced ultrasonography with high-frequency transducers and improved imaging is now available to evaluate and treat problems of the breast (52). It is a sensitive, minimally invasive technique that is being used more frequently in evaluating some breast symptoms, especially in younger women with dense breast tissue, but is dependent on the availability of a skilled ultrasonographer (53). The reporting of findings is not standardized as with the BI-RADS system for mammography. Some lesions can be detected only with ultrasonography (54). It is the preferred modality to distinguish a solid from a cystic mass (52). Breast ultrasonography is not recommended for routine screening, but it has been used to supplement

P.645

mammographic screening in high-risk women (55). Ultrasonography has a higher false-positive rate than mammography (51,53,54).

Following are indications for breast ultrasonography:

- Characterization:
 - Palpable abnormality
 - Ambiguous mammographic findings
 - Silicone leak
 - Mass in woman younger than 30 years, lactating, or pregnant
- Guidance for interventional procedures
- Possible role for additional imaging in high-risk individuals

Ultrasonography is useful in distinguishing benign from malignant lesions if identified by mammography (56). Ultrasonography may be especially useful if the patient feels a mass, but the physician cannot detect an abnormality and the mammogram does not disclose one. It may identify cancers in the dense breast tissue of premenopausal women, but it is usually used to distinguish a benign cyst from a solid tumor. Ultrasonography cannot reliably detect microcalcifications, and it is not as useful as mammography in assessing women with fatty breasts.

Handheld or real-time ultrasonography is 95% to 100% accurate in differentiating solid masses from cysts (57). However, this finding is of limited clinical value because a dominant mass should be evaluated by biopsy, and a cystic mass can be studied by needle aspiration, which is far less expensive than ultrasonography. If such a lesion proves to be a

simple cyst, no further evaluation is necessary. Rarely, ultrasonography may identify a small cancer within a cyst, an intracystic carcinoma. These complex cysts warrant surgical biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging may be of value in assessing breast lesions of an indeterminate nature detected by clinical and mammographic examination or occurring in patients who have implants (58). Both MRI and positron emission tomography (PET) have been used to identify occult lesions (59,60), and MRI is increasing in popularity as a means of imaging the breast (58,61). It tends to be highly sensitive but not very specific, leading to biopsies of many benign lesions. Image enhancement with gadolinium can discriminate between benign and malignant lesions with varying degrees of accuracy.

Several roles have been proposed for breast MRI. The lack of radiation exposure makes MRI theoretically an ideal method for screening of healthy women, but currently such widespread use is not cost-effective. Focal asymmetry is usually benign but can represent a malignancy. Magnetic resonance imaging may help identify those patients with focal asymmetric areas who should undergo biopsy. Usually, a scar can easily be distinguished from recurrent tumor based on the evaluation and diminution of the scar over time. Some scars, however, do not resolve rapidly and are confused with cancer or, more commonly, with recurrent cancer after breast-conserving surgery and whole breast irradiation. Ideally, such cases are evaluated with MRI, sometimes obviating the need for biopsy. Magnetic resonance imaging is extremely useful in identifying silicone released by ruptured breast implants in patients with augmented breasts (Fig. 19.3). In patients with implants, MRI with gadolinium may be performed to detect breast cancer even if silicone release is not suspected. There may be a role for **MRI in evaluation of specific conditions. It has been used for the following indications:**

- Stage tumor to rule out multicentric disease
- Differentiate postoperative scar from recurrence after breast-conserving surgery
- Find a lesion seen in only one view of mammogram
- Evaluate positive axillary nodes in the presence of negative mammogram and clinical breast examination results
- Rule out silicone implant rupture
- Assess focal asymmetry

Figure 19.3 Mammography shows implant and extracapsular free silicone (arrow).

Potential future considerations for MRI include assessment of *BRCA1* and *2* mutation-carriers, women with personal history of breast cancer, biopsy results showing atypia or local carcinoma *in situ*, young patients, or dense breasts.

A study from the Netherlands in high-risk women reported a 71% sensitivity for MRI compared with 17.9% for clinical breast examination and 40% for mammography (62). The International Cooperative Magnetic Resonance Mammography Study that is currently under way will help identify the advantages and limitations of MRI. At present, MRI should be considered only after conventional imaging is performed; it should not be used as a screening tool or a substitute for mammography or biopsy.

Positive Emission Tomography Scan

Positive emission tomography scanning is a diagnostic modality that assesses the metabolic activity of tumors. Radioactive fluorodeoxyglucose (FDG) is an analog of glucose that is

metabolized by tissues of high metabolic rates. In two prospective trials comparing PET with mammography, primary breast lesions were correctly identified and lymph nodes

P.647

status was determined with a high degree of sensitivity using PET (59,63). This technique has been used to identify occult breast lesions with positive axillary lymph nodes (59).

Breast Tissue Evaluation: Histology and Cytology

The safest course is tissue or cytologic biopsy evaluation of all dominant masses found on physical examination and, in the absence of a mass, of suspicious lesions shown by mammography or ultrasonography. The diagnosis of a benign breast lesion versus breast cancer is often difficult to determine based on clinical examination and ultimately requires evaluation of tissue by fine needle aspiration cytology (FNAC), core needle biopsy (CNB), or excisional biopsy (EB). Both FNAC and CNB are accurate methods of diagnosis when compared with EB and are valuable tools in the assessment of breast lesions (64). The false-positive and false-negative rate for FNAC is 1.7% and 7.1%, and for CNB 0% and 5.7%, respectively (64). Confirmation of the accuracy of a negative FNAC result requires triple-test concordance between breast imaging studies, clinical breast examination, and cytologic assessment. Accuracy can be 100% when all three evaluations have negative results (65). Compared with CNB, FNAC is faster, simpler, and does not require anesthesia. The superiority of FNAC versus CNB has not been established, and the techniques are comparable for

P.648

most lesions. One study reported that FNAC was more sensitive than CNB (97.5% versus 90%, respectively) (66). In recent series comparing CNB with FNAC, the sensitivity was 88% versus 92%, positive predictive value for malignancy was 99% versus 100%, and inadequacy rate 7% versus 7%, respectively (67). The specificity of CNB was found to be higher than that of FNAC (90% versus 82%). Both FNAC and CNB are reasonable techniques for the evaluation of a palpable or image-identified lesion, although FNAC is more accurate when an experienced physician is performing the technique, and it allows immediate assessment of the adequacy of material and additional sampling if there is a paucity of cells (64). Collagenous lesions are more difficult to diagnose by FNAC. Distinguishing invasive from noninvasive carcinoma cannot be done reliably with FNAC. Another technique, imprint cytology from core biopsies, has been used increasingly as an alternative to FNAC.

About 30% of lesions suspected to be cancer prove on biopsy to be benign, and about 15% of lesions believed to be benign prove to be malignant (23). Dominant masses or suspicious nonpalpable mammographic findings must be evaluated by biopsy (48,68). Histologic or cytologic diagnosis should be obtained before the decision is made to monitor a breast mass (69). An exception may be a premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease. However, **an apparently fibrocystic lesion that does not completely resolve within several menstrual cycles should be sampled for biopsy. Any mass in a postmenopausal woman who is not taking estrogen therapy should be presumed to be malignant.** Some clinicians will monitor a mass when results of the clinical diagnosis, breast imaging studies, and cytologic studies are all in agreement, such as with fibroadenoma. Many clinicians will not leave a dominant mass in the breast even when FNAC results are negative, unless perhaps if the fine-needle aspiration shows fibroadenoma. Such cases require periodic follow-up. Some surgeons excise lesions when the aspiration shows only fibrocystic disease. Presented in Figures 19.4 and 19.5 are algorithms for management of breast masses in premenopausal and postmenopausal patients. Simultaneous evaluation of a breast mass using clinical breast examination, radiography, and FNAC can lower the risk of missing cancer to only 1%, effectively reducing the rate of

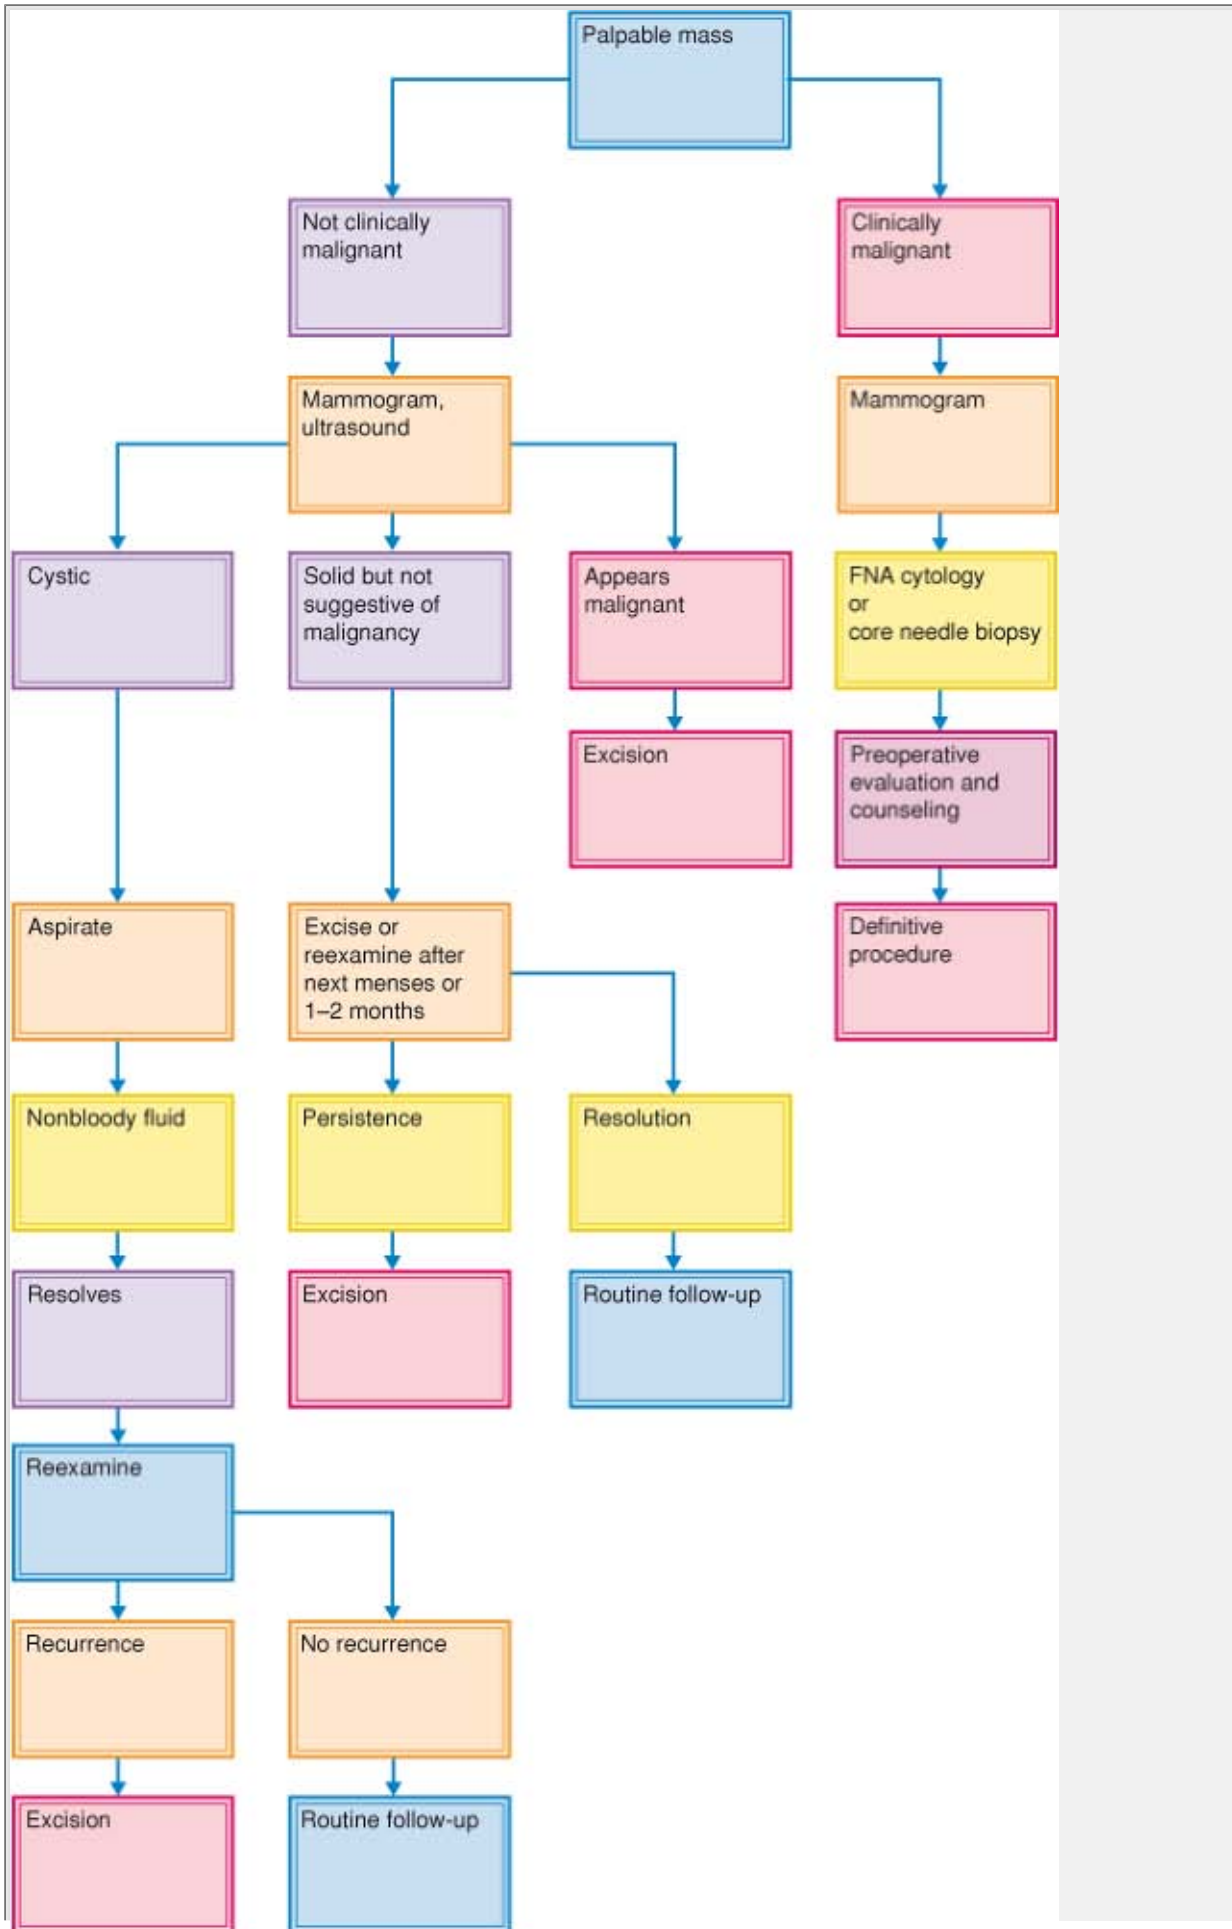

Figure 19.4 Algorithm for management of breast masses in premenopausal women.

If the presence of breast cancer is strongly suggested by physical examination, the diagnosis can be confirmed by FNAC or CNB, and the patient may be counseled regarding treatment. Treatment should not be determined based on results of physical examination and mammography alone, in the absence of biopsy results.

The most reasonable approach to the diagnosis and treatment of breast cancer is outpatient biopsy (either FNAC, CNB, or EB), followed by definitive surgery at a later date if needed. **This two-step approach allows patients to adjust to the diagnosis of cancer, carefully consider alternative forms of therapy, and seek a second opinion. Studies have shown no adverse effect from the 1- to 2-week delay associated with the two-step procedure (71). Because cancer is found in the minority of patients who require biopsy for diagnosis of a breast mass, definitive treatment should not be undertaken without an unequivocal histologic diagnosis of cancer.**

Fine-needle Aspiration

With FNAC, cells from a breast tumor are aspirated with a small (usually 22-gauge) needle and examined by a pathologist. Precise guidelines for this technique are available (72). It can be performed easily, with no morbidity, and is much less expensive than excisional or open biopsy. However, it requires the availability of a pathologist skilled in the cytologic diagnosis of breast cancer to interpret the results, and it is subject to sampling problems, particularly when lesions are deep. Cytologic diagnoses must be correlated with clinical and imaging findings to achieve triple-test concordance and to decrease the false-negative rate (73). **The triple-test concordance (ie, concordance between fine-needle aspiration, physical examination, and mammography) is the foundation of breast evaluation. The triple-test results are more powerful than each modality alone (74).** The incidence of false-positive diagnoses was 0% to 0.3%, and the rate of false-negative diagnoses was 1.4% to 2.3% in several recent studies (74,75).

P.649

P.650

Core Needle Biopsy

A core of tissue can be obtained from palpable lesions using a large cutting needle (76). Image-guided large-core needle biopsy is a reliable diagnostic alternative to surgical excision of suspicious nonpalpable breast lesions (77). As in the case of any needle biopsy, the main drawback is false-negative findings caused by improper positioning of the needle. False-negative findings may be reduced if core biopsy is performed with ultrasonographic guidance. **The interpretation of results from CNB is classified by categories B1–B5 (78).**

- B1: Normal tissue
- B2: Benign lesions: fibroadenomas, fibrocystic change, sclerosing adenosis, duct ectasia, fat necrosis, abscess

P.651

- B3: Uncertain malignant potential: atypical epithelial hyperplasia, lobular neoplasia, phyllodes tumor, papillary lesions, radial scar, complex sclerosing lesions

- B4: Suspicious
- B5: Malignant

Open Excisional Biopsy

Open biopsy with local anesthesia as a separate procedure before deciding on definitive treatment is the most reliable means of diagnosis. It is required when the results of needle biopsy are nondiagnostic or equivocal.

Histologic Analysis

Histologic evaluation with hematoxylin and eosin (H&E) staining confirms benign or malignant disease. Images of benign and malignant breast lesions can be viewed through the Internet Pathology Laboratory for Medical Education (79). **Assessment of prognostic factors, tumor grade, estrogen, progesterone, her-2/*neu* receptor status, and proliferative indices is performed on paraffin-fixed tissue by immunohistochemistry (78). Her-2/*neu* assessment in breast cancer by immunohistochemistry (IHC) is appropriate for patients with tumors that score 3+. Fluorescence *in situ* hybridization (FISH) is recommended for 2+ IHC to more accurately assess her-2/*neu* amplification and provide better prognostic information (80).**

Ductal Lavage Cytology

Ductal lavage using a microcatheter is a new modality that has been investigated in high-risk women (81). Patients undergo gentle nipple suction to elicit nipple fluid. A duct that yields fluid is then cannulated with a microcatheter, and 10 to 20 mL of saline are introduced in 2- to 4-mL increments. **The cytologic assessment of a sample obtained by ductal lavage is more sensitive than that of nipple aspiration.** Ductal lavage is a better modality to obtain a large number of cells for cytological evaluation. It is safe and well tolerated (81).

Benign Breast Conditions

Benign breast disorders account for most breast problems. These conditions are frequently considered in the context of excluding breast cancer and often are not recognized for their own associated morbidity (82). To provide appropriate management, it is important to consider benign breast disorders from four aspects: (i) clinical picture, (ii) medical significance, (iii) treatment intervention, (iv) and pathologic etiology (83). A framework to understand benign breast problems is called Aberrations of Normal Development and Involution (ANDI) (2,82,83). It includes symptoms, histology, endocrine state, and pathogenesis in a progression from a normal to a disease state. Most benign breast conditions arise from normal changes in breast development, hormone cycling, and reproductive evolution (82).

Three life cycles reflect different reproductive phases in a woman's life and are associated with unique breast manifestations.

- **During the early reproductive period (15–25 years), lobule and stromal formation occurs.** The ANDI conditions associated with this period are fibroadenoma (mass) and juvenile hypertrophy (excessive breast development). In this first stage, the progression from

ANDI to a disease state results in the formation of giant fibroadenomas and multiple fibroadenomas.

During the mature reproductive period (25–40 years), cyclic hormonal changes affect glandular tissue and stroma. In this second period, the ANDI is an exaggeration of these cyclic effects, such as cyclic mastalgia and generalized nodularity.

P.652

The third phase is involution of lobules and ducts or turnover of epithelia, which occurs during ages 35 to 55 years. The ANDI associated with lobular involution are macrocysts (lumps) and sclerosing lesions (mammographic abnormalities). Those associated with ductal involution are duct dilation (nipple discharge) and periductal fibrosis (nipple retraction), and those with epithelial turnover are mild hyperplasia (pathologic description).

Disease conditions with increased epithelial turnover are epithelial hyperplasias with atypia. Hughes feels that this framework allows the clinician to understand the pathogenesis of these conditions and to understand that these disorders are aberrations of a normal process that does not usually require any specific treatment (82).

Fibrocystic Change

Fibrocystic change, the most common lesion of the breast, is an imprecise term that covers a spectrum of clinical signs and symptoms and histologic changes (76).

The term refers to a histologic picture of fibrosis, cyst formation, and epithelial hyperplasia (83). Cysts arise from the breast lobules and are an aberration of normal breast involution (82). Macroscopic cysts occur in approximately 7% of women, and microscopic, nonpalpable cysts occur in close to 40% of women (84). It is common in women 35 to 55 years of age but rare in postmenopausal women not taking hormone therapy. The presence of estrogen seems necessary for the clinical symptoms to occur. This finding is supported by the observation that it is present bilaterally, increased in the perimenopausal age group, and responsive to endocrine therapy (85). In essence, a diagnosis of fibrocystic change is of little clinical significance as long as malignancy is excluded but can lead to significant patient anxiety (86). These lesions are associated with benign changes in the breast epithelium.

Cyst Fluid Analysis

Investigators have examined the electrolyte and protein content of cyst fluid, but this has been of little significance in the clinical management of fibrocystic disease. The potassium-to-sodium ratio is a marker that may be used to distinguish cyst subtypes (87). Cysts are either lined by apocrine epithelium with a high potassium-to-sodium ratio and a higher hormone or steroid concentration (type I); or by flattened lobule epithelium with a low potassium-to-sodium ratio and a higher concentration of albumin, CEA, CA125, and steroid hormone-binding globulin (type II) (85,87). Apocrine cysts produce and secrete large amounts of prostate-specific antigen (PSA) (88). The role of this serine protease in proliferative breast disease is not fully understood.

Clinical Findings in Fibrocystic Disease

Fibrocystic changes may produce an asymptomatic mass that is smooth and mobile that may be compressible. Fibrocystic change is more often accompanied by pain or tenderness and sometimes nipple discharge. In many cases, discomfort coincides

with the premenstrual phase of the cycle, when the cysts tend to enlarge. Fluctuation in size and rapid appearance or disappearance of a breast mass are common. Multiple or bilateral masses appear frequently, and many patients have a history of a transient mass in the breast or cyclic breast pain. Cyclic breast pain is the most common associated symptom of fibrocystic changes.

Differential Diagnosis

Pain, fluctuation in size, multiplicity of lesions, and bilaterality are the features most helpful to differentiate fibrocystic disease from carcinoma. If a dominant mass is present, however, the diagnosis of cancer should be suspected until it is disproved by complete aspiration of a cyst, or histopathologic analysis if a mass is present after aspiration, or by breast imaging. Microscopic findings associated with fibrocystic disease include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia (89).

P.653

Diagnostic Tests

Patients with cystic disease may have a discrete fibrocystic mass that is frequently indistinguishable from carcinoma based on clinical findings. Mammography may be helpful, but there are no mammographic signs diagnostic of fibrocystic change. Ultrasonography is useful in differentiating a cystic from a solid mass.

Characteristic findings on ultrasonography that confirm a simple cyst include the following:

- Mass with thin walls
- Smooth round shape
- Absence of internal echoes
- Posterior acoustic enhancement

If these imaging criteria are not met, a tissue diagnosis of the mass usually requires a FNA, FNAC, or EB. The finding of a simple cyst by ultrasonography rules out carcinoma. **Any lesion that is suspicious by mammography or ultrasonography should be biopsied.**

When the diagnosis of fibrocystic change has been established by ultrasonography or is practically certain because the history is classic, aspiration of a discrete mass suggestive of a cyst is indicated if the patient is symptomatic, the cyst obscures visualization of breast tissue on mammography and prevents adequate imaging, or if the ultrasonographic criteria are not met. In one study of a screened population, 1% of individuals developed a new cyst that resolved in more than 50% of cases (90). Aspiration may be performed with ultrasonographic guidance, but image guidance is usually not necessary if the cyst is palpable (91). Fine needle aspiration of a cyst is a minimally invasive procedure performed with a 21- or 22-gauge needle without local anesthesia and is not associated with significant risks or complications. There is minimal pain and little risk for infection or bleeding. Benign cyst fluid is straw colored to dark green to brownish and does not need to be submitted for cytologic evaluation (6). Injection of air into the cyst cavity has been reported to reduce the likelihood of cyst recurrence but is generally

not performed (86). The patient should be reexamined at a short interval thereafter for cyst recurrence. Further cysts will occur in 30% of patients, cause anxiety, and require repeated evaluations (84). **Tissue biopsy should be performed in the presence of the following findings:**

- No cyst fluid is obtained
- The fluid is bloody
- The fluid is thick
- The cyst is complex
- There is an intracystic mass
- A mass persists after aspiration
- A persistent mass is noted at any time during follow-up

Even if a needle biopsy is performed and results are negative for malignancy, a suspicious mass that does not resolve over several months should be excised. Surgery should be conservative, because the primary objective is to exclude cancer. Simple mastectomy or extensive removal of breast tissue is not indicated for fibrocystic disease. Most patients do not require treatment for fibrocystic changes, just reassurance that fibrocystic change is a transient phenomenon of aging that is associated with hormonal effects on the breast glandular tissue that eventually subside.

Fibrocystic Change and Risk for Breast Cancer

Fibrocystic change is not associated with an increased risk of breast cancer unless there is histologic evidence of epithelial proliferative changes, with or without atypia

P.654

(92,93,94,95,96,97). The common coincidence of fibrocystic disease and malignancy in the same breast reflects the fact that both processes are common events. Approximately 80% of biopsies show fibrocystic changes. In an evaluation of the relationship between fibrocystic change and breast cancer in 10,366 women who underwent biopsy from 1950 until 1968 and were followed for a median of 17 years, approximately 70% of the biopsies showed nonproliferative breast disease, whereas 30% showed proliferative breast disease (95). Cytologic atypia were present in 3.6% of cases. Women with nonproliferative disease had no increased risk of breast cancer, whereas women with proliferative breast disease and no atypical hyperplasia had a twofold higher risk of breast cancer. **Patients whose biopsy results showed atypical ductal or lobular hyperplasia had an approximately fivefold higher risk than women with nonproliferative disease to develop invasive breast cancer in either breast.** Patients with carcinoma *in situ* have an eight- to tenfold risk of developing breast cancer. This risk is bilateral for lobular lesions and ipsilateral for ductal lesions. A family history of breast cancer added little risk for women with nonproliferative disease, but

family history plus atypia increased breast cancer risk 11-fold. The presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk about threefold (76,92,93,94,95,96,97). Women with these risk factors (family history of breast cancer and proliferative breast disease) should be followed carefully with physical examination and mammography. For such women, age-specific probability of developing invasive breast carcinoma in the next 10 years is 1 in 2,000 (age 20), 1 in 256 (age 30), 1 in 67 (age 40), 1 in 39 (age 50), and 1 in 29 (age 60) (93). The relative risk for developing breast cancer depends on the type of proliferative lesion diagnosed.

Management of Fibrocystic Change

Fibrocystic change is a normal evolutionary change in breast development and involution and does not require a specific treatment other than a good clinical breast examination and age-appropriate mammographic screening or imaging studies directed to signs and symptoms. A number of nutritional and dietary supplements have been investigated to relieve symptoms. The role of caffeine consumption in the aggravation of fibrocystic change is controversial (98,99,100,101). Results of some studies suggest that eliminating caffeine from the diet is associated with improvement of symptoms (100,101). Many patients are aware of these studies and report relief of symptoms after discontinuing intake of coffee, tea, and chocolate. Similarly, many women find vitamin E (150–600 IU daily) or B₆ (200–800 mg/day) helpful (102,103). However, observations about these effects have been difficult to confirm and are anecdotal (104,105,106). A recent review of nutritional interventions for fibrocystic breast conditions that evaluated evening primrose oil, vitamin E, or pyridoxine suggested that there are insufficient data to draw clear conclusions about their effectiveness (107). Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside unless patients are taking estrogen. **A patient with fibrocystic changes should be advised to examine her own breasts each month just after menstruation and to inform her physician if a mass appears.**

Mastalgia

Mastalgia is a recognized organic condition that has not been studied as thoroughly as other breast problems (108,109). Inflammatory cytokines have been implicated in the etiology of breast pain. A study evaluating expression of interleukin-6 and tumor necrosis factor- α in painful and nonpainful breast tissue showed lower levels of these cytokines in painful breast tissue during the luteal phase; however, these levels did not reach statistical significance (110). Elevated estrogen, low progesterone, or an imbalance in the ratio of estrogen and progesterone have been suggested as a possible cause for the symptoms (111).

Natural History of Mastalgia

Approximately 70% to 80% of women experience severe breast pain at some time in their lives (112,113). Mastalgia accounts for 30% to 47% of breast clinical evaluations (111,114). In 15% of the patients, the mastalgia is so severe that it alters lifestyle and

P.655

requires repeated investigations and treatment (112). Mastalgia interferes with sexual (48%), physical (37%), social (12%), and work or school activities (8%) (115).

Types of Mastalgia

Breast pain is a distressing constellation of symptoms that is classified as cyclic, non-cyclic, or extramammary (116). **Cyclic mastalgia** is related to exaggerated

premenstrual symptoms beginning in the luteal phase of the menstrual cycle associated with breast engorgement, pain, ache, heaviness, and tenderness that is bilateral and can last for more than 7 days in 11% of women (116,117,118). Cyclical mastalgia is more prevalent in women in their third and fourth decades of life and accounts for two thirds of all breast pain symptoms (119). **Noncyclic mastalgia** is independent of menstrual cycles and is described as achy, burning soreness. It may be intermittent or constant, is usually unilateral, occurs in the fourth and fifth decades, and is more difficult to treat than cyclic mastalgia (116). **Extramammary pain** is perceived to be located in the breast but is related to an extramammary site. Chest wall muscular pain, costal cartilage symptoms, herpes zoster, radiculopathies, and rib fractures are among some of the more common causes of extramammary pain. Costochondritis (Tietze's syndrome) is a manifestation of chest wall pain that is frequently interpreted as breast pain.

Management of Mastalgia

Breast pain is an unlikely symptom of malignancy, and once malignancy has been excluded by a clinical breast examination and age-appropriate breast imaging for focal breast pain, the most important treatment is reassurance. Treatments used have included medications, such as anesthetics, diuretics, *bromocriptine*, and *tamoxifen*; vitamins and supplements, such as evening primrose oil; mechanical support with a well-fitting bra; local excision; and decreased fat intake and reduction in methylxanthines from caffeine, tea, and chocolate (108,116). **Discontinuation of hormone therapy may be effective in some women. Maintenance of a pain score diary is important to understand the relationship of pain to factors such as the menstrual cycle, activities of daily living, and stress.** External support may be effective for breast pain associated with generalized fibrocystic changes and is best treated by avoiding trauma and by wearing (night and day) a brassiere that gives good support and protection (120). One study evaluated resolution of symptoms in 200 women randomized either to a regimen of *danazol* (200 mg/day) or to mechanical support with a sports brassiere worn for regular activities for 12 weeks. The group using mechanical support had 85% relief of symptoms compared with 58% improvement in the *danazol* group. Symptoms recurred after discontinuance of treatment with *danazol* (113). The *danazol* group experienced drug-related side effects in 42%, which led to discontinuance of the medication in 15%. The breast has minimal structural support and is at significant risk for motion-related displacement resulting in mastalgia. The use of external support to minimize breast motion appears to be effective in reducing breast pain. The application of heat packs or cold packs and light breast massage may reduce symptoms in some individuals (116).

Hormone-modulating drugs, including *danazol*, *bromocriptine*, *tamoxifen*, and *Depo-provera*, are recognized drug treatments for mastalgia, although *tamoxifen* is not approved for this use in the United States (116,121,122,123,124). These drugs are associated with significant side effects that limit their general use (116). **Withdrawal of birth control pills or hormone therapy may be all that is required to alleviate symptoms** (116).

Danazol is a synthetic androgen that suppresses release of pituitary gonadotropin, prevents luteinizing hormone surge, and inhibits ovarian steroid formation. It is the only medication approved by the Food and Drug Administration for mastalgia (116). The androgenic effects—acne, edema, change in voice, weight gain, headaches, depression, and hirsutism—often are intolerable, and many patients stop taking *danazol* even when symptoms are improved (122). It can be initiated at doses of 100 to 200 mg twice daily orally for patients with severe pain and then tapered to a lower dose of 100 mg per day (122). A survey of surgeons in Great Britain revealed that 75% prescribed *danazol* as first-line

therapy (108). A recent study was conducted to evaluate the response to administration of

danazol (200 mg daily) just during the luteal phase (125). This approach reduced the premenstrual mastalgia and resulted in virtually no side effects.

The use of oral progesterone agents has been shown to reduce cyclical breast pain by 50% (111). Further studies may be warranted to see whether *medroxyprogesterone acetate* suppresses cyclic mastalgia in reproductive-age women.

Breast pain is increased in some individuals who have elevated prolactin (PRL) levels induced by thyrotropin-releasing hormone (TRH) (116). *Bromocriptine* is a dopamine antagonist that inhibits the release of PRL. *Bromocriptine* (2.5 mg twice daily) given for 3 to 6 months is effective in reducing mastalgia in women who have TRH-induced elevation of PRL (123). Patients who have normal TRH levels, or are resistant to *bromocriptine*, or do not tolerate the side effects of nausea, vomiting, and headache, respond favorably to progesterone and systemic nonsteroidal anti-inflammatory drugs (NSAIDs).

Prolactin induces active transport of iodine in breast tissue (126,127). Iodine deficiency in rats causes hyperplasia and atypia (128). Iodine replacement is associated with improvement in subjective pain (129). A randomized, double-blind study with supraphysiologic levels of iodine in women with documented cyclic mastalgia demonstrated dose-dependent reduction in physician-assessed and self-reported pain at 3 and 6 months of treatment (130).

Goserelin is a potent synthetic analog of luteinizing-hormone releasing-hormone (LHRH) that causes reversible reduction in serum estrogen level and decrease in breast pain (131). Side effects of *goserelin* include vaginal dryness, hot flushes, decreased libido, oily skin and hair, and decreased breast size. A recent clinical trial randomized 147 women into *goserelin* versus placebo groups. The study had a 49% dropout rate. The mean breast pain score decreased by 67% in the *goserelin* arm and 35% in the placebo arm. The authors concluded that *goserelin* is an effective treatment for mastalgia with significant side effects and should be kept as second-line therapy. Hormonal blockade of the estrogen receptor is another approach to minimizing the effects of circulating estrogen on breast pain. Treatment with the selective estrogen receptor modulator *tamoxifen* has demonstrated reduction in breast pain at 10 and 20 mg per day, with equivalent effects compared with *danazol* and *bromocriptine* in most studies (124,132,133,134). Topical nonsteroidal therapy is another option for women with mastalgia (135). Gel forms of NSAIDs often are used for relief of pain. Patients were stratified by cyclic versus noncyclic pain and then randomized to treatment with NSAIDs versus placebo. There was a significant reduction in cyclic and noncyclic pain in all groups, but the magnitude of change was greater in the treatment arms and similar for cyclic and noncyclic pain. Use of NSAIDs appears to be a less toxic treatment and may be considered as an option for both cyclic and noncyclic breast pain.

Nonhormonal therapies such as dietary restrictions, vitamins and supplements, and restriction of methylxantines have been investigated as possible treatments for mastalgia because they are less likely to be associated with adverse drug-related side effects (116). Because mastalgia is one of the symptoms associated with fibrocystic disease, the treatments described for fibrocystic disease are also relevant to mastalgia. A low-fat diet was effective in one randomized trial (136). Ninety percent of patients taking in 15% dietary fat experienced resolution of pain symptoms after 6 months compared with only 22% of those on a diet containing 36% fat ($P = 0.0023$). Evening primrose oil containing essential fatty acids (γ -linolenic acid, GLA) has been studied because of its affect on prostaglandin synthesis (137). It has been used as first-line therapy, reserving *danazol* and *bromocriptine* for treatment of more severe symptoms (112). In a small prospective mastalgia trial, women were given eight capsules of evening primrose oil daily for 4 months (320 mg GLA) (138). Those who responded had a lower level of essential fatty acids at the time of initiation when compared with poor responders, suggesting that evening primrose oil increases essential fatty acids and that this increase may be associated with the improvement in

symptoms in the responders. Two more recent trials have failed to demonstrate efficacy of evening primrose oil capsules over placebo (139,140). In a Dutch trial, 124 women with cyclic or noncyclic pain lasting on average 7 or more days (minimum 5 days) were randomized to receive the following regimens: (i) fish oil and control oil, (ii) evening primrose oil and control oil, (iii) fish and evening primrose oil, or (iv) both control oils for 6 months (139). There was a statistically significant reduction in the number of days per month with pain but not in the pain score in the entire study population. There was a greater reduction in cyclic than noncyclic pain symptoms, and this finding was true for both the test oils and for the control oils. The authors concluded that neither fish oil nor evening primrose oil had a better effect than the less expensive wheat germ and corn oils. A second large double-blind randomized prospective trial was conducted in 555 women with cyclic mastalgia of moderate to severe degree present for at least 7 days of a menstrual cycle (140). The four groups were (i) GLA and placebo antioxidants, (ii) placebo fatty acids and antioxidants, (iii) GLA and placebo antioxidants, and (iv) placebo fatty acids and placebo antioxidants. The treatments were given in a blinded fashion for 4 months. All groups had a similar 35% reduction in symptoms. This treatment was followed by open treatment with GLA in all groups and blinded treatment with antioxidants. There was continued improvement of symptoms in all groups with a reduction in mastalgia by 50% over the next 12 months. This is the largest and best-controlled study to date evaluating GLA for relief of mastalgia, and GLA was not found to be superior to placebo. The results of this study were not consistent with those from previous smaller studies. The authors cannot exclude a significant psychologic impact that may confound the effect of GLA. GLA use was found to be safe, without any significant side effects, and has been prescribed as therapy for mastalgia because of its lack of side effects. The recent randomized trials, however, bring into serious question the efficacy of these options.

Fibroepithelial Lesions

Fibroadenoma

Fibroadenomas are the most common benign tumors of the breast. In one series, they accounted for 50% of all breast biopsies (141). They usually occur in young women (age 20–35 years) and may occur in teenagers (142). In women younger than 25 years, fibroadenomas are more common than cysts. They rarely occur after menopause, although occasionally they are found, often calcified, in postmenopausal women. For this reason, it is postulated that fibroadenomas are responsive to estrogen stimulation. A recent study reports the *de novo* occurrence of fibroadenoma in 51 women older than age 35 years who had no evidence of a palpable or mammographic visualized lesion in well-documented prior visits (143). Fibroadenomas may appear as single masses or as multiple lesions.

Clinically, a young woman usually notices a mass while showering or dressing. Most masses are 2 to 3 cm in diameter when detected, but they can become extremely large (i.e., the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery. They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of the skin or nipple retraction. They are often bilobed, and a groove can be palpated on examination. On mammographic and ultrasonographic imaging, the typical features are of a well-defined, smooth, solid mass with clearly defined margins and dimensions that are longer than wide and craniocaudad dimensions that are less than the length.

Fibroadenoma is not associated with an increased risk for breast cancer (144). The natural history of fibroadenoma can be regression, growth, or no change in size. In one study, a 50% regression was reported (145). Because transformation of a fibroadenoma into cancer is

rare and regression is frequent, current management recommendations are conservative unless there is evidence of growth (141). A suspected fibroadenoma should be confirmed by FNAC or CNB and observed for increase in size or excised based on patient preference. Rarely will the fibroadenoma increase to more than 2 to 3 cm in size. Large or

growing fibroadenomas must be excised. Complete excision of a fibroadenoma with local anesthesia can be performed to treat the lesion and confirm the absence of malignancy. Less invasive local treatment of a fibroadenoma is advocated by some and can be performed with either ultrasonographically guided percutaneous vacuum-assisted biopsy devices (146) or percutaneous cryoablation (147). However, a young woman with a clinical fibroadenoma can undergo needle cytology and observation of the mass (148). Acceptance of observation varies, and many women choose to have the fibroadenoma excised (149).

On gross examination of an excised mass, the fibroadenoma appears encapsulated and sharply delineated from the surrounding breast parenchyma. Microscopically, there is proliferation of both the epithelial and a stromal component. In long-standing lesions and in postmenopausal patients, calcifications may be observed within the stroma.

Multiple Fibroadenomas

Multiple fibroadenomas occur in some women and have been reported to occur more frequently in premenopausal women undergoing immunosuppression for transplant (150,151,152). Excision of all lesions through separate incisions could leave significant scarring and deformity. Excision of these mobile lesions through a single periareolar incision has been suggested, but this approach can lead to significant ductal disruption (153). Another approach that has been used is through an incision in the inframammary crease. Alternatively, these lesions can be treated with observation based on triple-test concordance of results of a classic clinical examination with histologic corroboration with FNAC and ultrasonographic diagnostic criteria consistent with a fibroadenoma (151).

Phyllodes Tumor

Phyllodes tumors are rare fibroepithelial tumors that display a spectrum of clinical and pathologic behaviors that are benign, borderline, and malignant (154,155).

The distribution of phyllodes tumors demonstrates that **most tumors are benign (70%) compared with malignant (23%) and borderline lesions (7%)** (156). This distribution is similar to a larger, older study that reported an incidence of 64% benign, 21% malignant, and 14% borderline phyllodes tumors (157). The incidence in some studies should be viewed with caution because of variation in histologic interpretation (156).

Phyllodes tumors may occur at any age but tend to be more common in women who are in their late 30s, 40s, and 50s (156,158,159,160,161,162). **These lesions are rarely bilateral and usually appear as isolated masses that are difficult to distinguish clinically from a fibroadenoma.** Patients often relate a long history of a previously stable nodule that suddenly increases in size. Reported sizes range from 1.0 to 50 cm (154,163,164). Size is not a dependable diagnostic criterion, although phyllodes tumors tend to be larger than fibroadenomas, probably because of their rapid growth. There are no good clinical criteria by which to distinguish a phyllodes tumor from a fibroadenoma. Whereas observation of a fibroadenoma is acceptable, excision of a phyllodes tumor is necessary for local control and for determination of benign or malignant features. To avoid unnecessary excision of benign fibroadenomas that are indistinguishable from phyllodes tumors on clinical examination, imaging criteria have been sought to aid in identifying patients who require EB for complete histopathologic evaluation and local control. Mammography may show a halo around

a phyllodes tumor mass but cannot reliably distinguish a fibroadenoma from a phyllodes tumor (165,166,167). Ultrasonography evaluation also has limitations even when color and pulse Doppler ultrasonography are used in conjunction with it (163).

Microscopic evaluation of a lesion is important to determine the diagnosis. The histologic distinction between fibroadenoma, benign, borderline, and malignant phyllodes tumor can, however, be very difficult on minimal tissue sampling with FNAC or CNB (168,169). It may be easier to distinguish benign phyllodes from malignant phyllodes tumors than benign phyllodes tumors from fibroadenomas (170). Histologic features that stratify lesions include number of mitoses per high power field, stromal cellularity, pushing or infiltrating tumor margin, cellular atypia, tumor necrosis, and stromal overgrowth (171).

P.659

If a lesion cannot clearly be characterized as a fibroadenoma, excision may be necessary. Factors that are considered in recommending excision include older age, new mass in a well-screened individual, rapid growth, size greater than 2.5 to 3 cm, suspicious FNAC or CB, and mammographic or ultrasonographic features that demonstrate lobulation and intramural cysts. If observation is elected, repeat clinical examination and imaging in a short interval is essential to evaluate change in size.

Treatment of biopsy-proven phyllodes tumor is wide local excision, attempting to obtain a 1- to 2-cm margin (156,157,158,159,160,161). Massive tumors, or large tumors in relatively small breasts, may require mastectomy; otherwise, mastectomy should be avoided, and axillary lymph node dissection is not indicated. Often, however, a patient will undergo excisional biopsy of a mass believed to be fibroadenoma, and final histologic examination reveals a phyllodes tumor. Re-excision with normal breast margins is recommended for borderline and malignant phyllodes tumors (159). An expectant approach is an option for unanticipated diagnosis of benign phyllodes tumors (157).

The prognosis of benign and malignant phyllodes tumors is variable (154,155,157,162,172). **Tumors judged to be benign phyllodes tumors can recur locally in up to 10% of patients** (159,160,161). Recurrence is associated with margin involvement, whereas mortality correlates with size and grade (173). In a series reviewing only high-grade malignant phyllodes tumors, size and excision margins were associated with local recurrence and metastatic spread, and mastectomy may be required to achieve complete surgical excision (174). **Malignant phyllodes tumors tend to recur locally and occasionally may metastasize to the lung, although brain, pelvic, and bone metastases also may occur** (160,161,162). The stromal component of the tumor is malignant and metastasizes, behaving like a sarcoma. Axillary involvement is extremely unusual. Often, the appearance of metastasis is the first sign that a phyllodes tumor is malignant. Chemotherapy for metastatic phyllodes tumors should be based on regimens for sarcoma, not adenocarcinoma (159). Radiation therapy has generally not been used in the treatment of phyllodes tumors. In the presence of a bulky tumor, positive margins, recurrence, or malignant histology, radiation therapy may be of some benefit (175).

Breast Conditions Requiring Evaluation

Nipple Discharge

Nipple discharge is a presenting breast symptom in 4.5% of patients seeking evaluation of a breast symptom, with 48% spontaneous and 52% provoked (176). Nipple discharge that does not occur spontaneously has no pathologic significance. Provoked or self-induced nipple discharge should be managed by reassurance and instruction to discontinue

manipulation. Spontaneous nipple discharge is more likely to be associated with an underlying pathologic problem than provoked discharge. **Although it is a distressing finding, spontaneous nipple discharge is infrequently found to be associated with carcinoma, ranging from 4% to 10% (176,177,178).** Nipple discharge can be caused by neoplastic or nonneoplastic processes (179). Nonneoplastic processes include galactorrhea, physiologic changes resulting from mechanical manipulation, parous condition, periductal mastitis, subareolar abscess, fibrocystic change, and mammary duct ectasia. Neoplastic causes of nipple discharge in nonlactating women are solitary intraductal papilloma, carcinoma, papillomatosis, squamous metaplasia, and adenosis (176,179,180). Extramammary causes are related to hormones and drugs (179). **Following are the important characteristics of the discharge and other factors to be evaluated by history and physical examination (180):**

- Nature of discharge (serous, bloody, or milky)
- Association with a mass

- Unilateral or bilateral
- Single or multiple ducts
- Discharge that is spontaneous (persistent or intermittent) or expressed by pressure at a single site or on entire breast
- Relation to menses
- Premenopausal or postmenopausal
- Hormonal medication (contraceptive pills or estrogen)

P.660

Unilateral, spontaneous, bloody, or serosanguinous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. In either case, a mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple and at the margin of the areola. Bloody discharge is more suggestive of cancer but usually is caused by a benign papilloma in the duct. In premenopausal women, spontaneous multiple-duct discharge, unilateral or bilateral, is most marked just before menstruation. It often is caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed. Milky discharge from multiple ducts in nonlactating women presumably reflects increased secretion of pituitary prolactin; serum prolactin and thyroid-stimulating hormone levels should be evaluated to detect a pituitary tumor or hypothyroidism. Hypothyroidism may cause galactorrhea. Alternatively, *phenothiazines* may cause milky discharge that disappears when the medication is discontinued. Oral contraceptive agents may cause clear, serous, or milky discharge from multiple ducts or, less often, from a single duct. The discharge is more evident just before menstruation and

disappears when the medication is stopped.

Chronic unilateral nipple discharge, especially if it is bloody, is an indication for resection of the involved ducts. Mammography and ultrasonography are performed to rule out an associated mass. On occasion, ductography may be performed to identify a filling defect before excision of the duct system, but usually this technique is of little value (178). Ductography, however, is not a substitute for excision because it misses multiple lesions and cannot visualize the periphery (181).

A new technology, fiberoptic ductoscopy, is emerging to evaluate patients with nipple discharge (182). In 259 patients with nipple discharge, fiberoptic ductoscopy successfully detected intraductal papillary lesions in 92 patients (36%). Office-based minimally invasive breast ductoscopy with intraductal biopsy is available in some centers (183,184). It was performed for diagnosis in 83 patients with nipple discharge (183). A diagnosis of severe or malignant atypia was established in 21% of patients.

Cytologic examination of nipple discharge or cyst fluid rarely is performed. **Cytologic examination usually is of no value but may identify malignant cells** (178). Negative findings do not rule out cancer, which is more likely in women older than 50 years of age. In any case, the involved duct—and a mass, if present—should be excised (177,178,180,185). Complete histopathologic evaluation of the involved ductal system is the preferred method of diagnosis, and cytologic assessment should not be relied on for diagnosis.

The usual approach for nipple discharge is surgical excision through a periareolar incision adjacent to the trigger point, the pressure point that elicits nipple discharge (179). A microdochetomy of a single duct or a central duct excision of the major subareolar ducts can be performed under local or general anesthesia. The putative duct can be cannulated,

P.661

methylene blue can be injected, or a lacrimal probe can be inserted into the duct for localization. A resection of breast tissue for 3 to 5 cm, or until no bloody fluid can be identified in the ductal system, is performed. The patient must be warned of possible skin and nipple loss as a result of compromised vascularity, change in nipple sensation, deformity, inability to breastfeed, and recurrence if only a single duct is removed.

When there is a history of unilateral nipple discharge, localization is not possible, and no mass is palpable, the patient should be reexamined every week for 1 month. When unilateral discharge persists, even without definite localization or tumor, surgical exploration should be considered. The alternative is careful follow-up at intervals of 1 to 3 months.

Mammography should be performed. Purulent discharge may originate in a subareolar abscess and requires excision of the related lactiferous sinus (186).

Erosive Adenomatosis of the Nipple

Erosive adenomatosis is a rare benign condition of the nipple that mimics Paget's disease (187). Patients seek treatment for pruritus, burning, and pain. On clinical examination, the nipple can appear ulcerated, crusting, scaling, indurated, and erythematous. The nipple can be enlarged and more prominent during menstrual cycles (188). The differential diagnosis includes squamous cell carcinoma, psoriasis, contact dermatitis, seborrheic keratosis, adenocarcinoma metastatic to the skin, and unusual primary tumors of the nipple (187). Biopsy should be performed to diagnose the lesion. Local excision is curative (187).

Fat Necrosis

Fat necrosis of the breast is rare but clinically important because it produces a mass,

often accompanied by skin or nipple retraction, which is indistinguishable from carcinoma. Fat necrosis often presents as a confusing clinical finding. Trauma is presumed to be the cause, although only about one half of patients have a history of injury to the breast. Ecchymosis is occasionally seen near the tumor. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Diagnostic imaging studies are usually insufficient (189). As a rule, the safest course is needle-core or excisional biopsy of the entire mass to rule out carcinoma (189). Fat necrosis is also common after segmental resection and radiation therapy or transverse rectus abdominis musculocutaneous (TRAM) flap (190).

Breast Abscess

Lactational Abscesses

Infection in the breast is rare unless the patient is lactating. Lactational mastitis must be distinguished from lactational abscess (191). During lactation, an area of redness, tenderness, and induration frequently develops in the breast. **Lactational mastitis is caused by transmission of bacteria during nursing and poor hygiene. The organism most commonly found in lactational mastitis and abscesses is *Staphylococcus aureus*** (192). If mastitis is diagnosed, manual pressure, antibiotics, and continued breastfeeding are recommended. In its early stages, the infection often can be treated while breastfeeding is continued by administering an antibiotic such as *dicloxacillin* 250 mg four times daily, or *oxacillin*, 500 mg four times daily for 7 to 10 days. **If the lesion progresses to a localized mass with local and systemic signs of infection, an abscess is present. It should be drained, and breastfeeding should be discontinued.**

Nonlactational Abscess

Rarely, infections or abscesses may develop in young or middle-aged women who are not lactating (193). The current approach to nonlactational abscess is conservative (194,195). A suspected abscess should be evaluated with preliminary ultrasonography to detect the

P.662

presence of an inflammatory mass, frank pus, solitary cavity, or a multiloculated abscess (196). Aspiration of pus, if present, and antibiotic therapy is instituted with reaspiration, if necessary (196). When the fluid collection is greater than 3 mL, percutaneous drain placement is an option (194). A single aspiration is sufficient in about one half of patients (194). Recurrent abscess formation is low (10%) (194). Bacteriologic analysis of 22 abscesses in nonlactating women shows a preponderance of gram-positive cocci, including *Staphylococcus epidermidis* (11 women), *Staphylococcus aureus* (3 women), *Proteus mirabilis* (3 women), *Pseudomonas aeruginosa* (1 woman), and sterile abscess (4 women) (196). **If these infections recur after multiple aspirations, incision and drainage followed by excision of the involved lactiferous duct or ducts at the base of the nipple may be necessary during a quiescent interval.** In virtually all cases, mammillary sinus (lactiferous duct fistula) can be confirmed as the cause of reinfection or persistent infection (197). Inflammatory carcinoma is a consideration when erythema of the breast is present. Patients should not undergo prolonged treatment for an apparent infection unless biopsy has eliminated the possibility of inflammatory carcinoma.

Subareolar Abscess and Lactiferous Duct Fistula

Subareolar abscess and fistula of the lactiferous ducts secondary to squamous metaplasia can

occur (198). The distal duct can be occluded with inspissated debris. Two large recent reviews report a high association of lactiferous duct fistulae in women who smoke (199,200). The definitive treatment for lactiferous duct sinus is excision of the lactiferous duct and drainage of the abscess cavity. In both studies, **the recurrence rate was greater when only incision and drainage were performed**. The most common organism occurring in primary subareolar abscess was *Staphylococcus aureus*, but anaerobic organisms occurred more frequently in chronic recurring abscesses (200).

Disorders of Breast Augmentation

Estimates indicate that nearly 4 million women in the United States have undergone augmentation mammoplasty. Breast implants are usually placed under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel or saline.

The complications of breast implantation are significant. About 15% to 25% of patients develop capsule contraction or scarring around the implant, leading to a firmness and distortion of the breast that can be painful and sometimes requires removal of the implant and capsule. Implant rupture may occur in as many as 5% to 10% of women, and bleeding of gel through the capsule is even more common (201).

In April 1992, the U.S. Food and Drug Administration concluded that the safety and effectiveness of silicone gel breast implants had not been established and called for additional preclinical and clinical studies (202). The agency advised symptomatic women with ruptured implants to discuss the need for surgical removal with their physicians. When there is no evidence of associated symptoms or rupture, implant removal is generally not indicated because the risks of removal are probably greater than the risk of retention. If screening ultrasonography shows no rupture, the probability of rupture is 2.2% (203). If ultrasonography shows rupture, true rupture is present in 37.8%. In this setting, a large number of women would have normal implants removed. When MRI is used in addition to ultrasonography, the probability of rupture increases to 86%.

The suggested association between silicone gel and autoimmune disease has been poorly documented (204,205). A retrospective cohort study from the Mayo Clinic showed no increased incidence of autoimmune disorders among women with silicone implants (206). Subsequent studies have demonstrated no clinical data proving an increased incidence of connective tissue disorders in patients with silicone gel breast implants (207,208,209). The data continue to reaffirm previous observations that there is no evidence of an association between breast implants and connective tissue diseases (210). In a study of Danish

P.663

women undergoing reduction mammoplasty compared with silicone implant augmentation, there was no increased incidence of antinuclear antibodies or other autoantibodies between the groups (211). The augmentation group experienced capsular contraction and more pain than the group undergoing reduction mammoplasty. Any association between implants and an increased incidence of breast cancer is unlikely (212). However, breast cancer may develop in any patient with a silicone gel prosthesis.

Preoperative Evaluation and Postoperative Management

Daniel L. Clarke-Pearson

Paula S. Lee

Monique A. Spillman

Christopher V. Lutman

- **The preoperative evaluation should be complete and thorough, taking into account the essential aspects of the patient's general medical condition and prior surgical history. The risks and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure.**
- **The calculated body mass index (BMI) can be used as a surrogate marker for nutritional status.**
- **Careful and meticulous fluid and electrolyte management is essential for all patients undergoing major surgical procedures.**
- **Although satisfactory analgesia is easily achievable with currently available methods, patients continue to suffer unnecessarily from**

postoperative pain.

- **Prophylactic antibiotics should be employed judiciously. Prompt identification of perioperative infections and their specific treatments are critical to minimize the impact of this common morbidity.**
 - **Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.**
 - **Because pulmonary embolism is the leading cause of deaths following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens is an essential part of management. Calf compression during and after gynecologic surgery significantly reduces the incidence of deep venous thrombosis on a level similar to that of low-dose *heparin*.**
-
- **Patients who are predisposed to cardiovascular, respiratory, and endocrine illnesses must be thoroughly screened preoperatively. Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. Patients with hypertension should receive medication to control their disease before surgery. Chronic obstructive pulmonary disease is the greatest risk factor for the development of postoperative pulmonary complications. Perioperative management of medical complications must be prompt and meticulous.**

P.672

The successful outcome of gynecologic surgery is based on thorough evaluation, careful preoperative preparation, and attentive postoperative care. Discussed in this chapter are

approaches to the general perioperative management of patients undergoing major gynecologic surgery with specific medical problems that could complicate the surgical outcome.

Medical History and Physical Examination

Gynecologic surgery should only be undertaken after gaining a thorough understanding of a patient's medical history and performing a complete physical examination.

- **The medical history should include detailed questions to identify any medical illnesses that might be aggravated by surgery or anesthesia.** Coronary artery disease and pulmonary diseases are the most common sources of postoperative complications.
- **Medications currently being taken (including nonprescription drugs) as well as those discontinued within the previous month before surgery should be recorded.** In addition, information about the use of "alternative therapies," herbs, and vitamins should be elicited. Specific instructions must be given to the patient regarding the need to discontinue any medications before surgery (e.g., aspirin, antiplatelet agents, or oral contraceptives), as well as those medications that should be continued (e.g., cardiac or antihypertensive medications).
- **The patient should be questioned regarding known allergies to medications (e.g., sulfa and penicillin), foods, or environmental agents.** A history of sensitivity to shellfish may be the only clue of iodine sensitivity, which could be fatal if intravenous contrast materials are used without corticosteroid preparation.
- **Previous surgical procedures, and the patient's course following those surgical procedures, should be reviewed to identify potential complications that might be avoided.** The patient should be asked about specific complications, such as excessive bleeding, wound infection, deep venous thrombosis, peritonitis, or bowel obstruction. A history of pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy and pre-existing injury to adjacent organ systems such as small bowel adhesions or ureteral stenosis from previous periureteral scarring. In such cases, it may be prudent to identify any

pre-existing abnormality by performing intravenous pyelography (IVP) or computed tomography (CT). Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Therefore, operative notes from previous procedures should be obtained and reviewed.

- **Family history may identify familial traits that might complicate planned surgery.** A family history of excessive intraoperative or postoperative bleeding,

P.673

venous thromboembolism, malignant hyperthermia, and other potentially inherited conditions should be sought.

- **A review of systems should also be detailed to identify any coexisting medical or surgical conditions.** Inquiry about gastrointestinal and urologic function is particularly important before undertaking pelvic surgery because many gynecologic diseases also involve adjacent nongynecologic viscera.
- **Although many women undergoing gynecologic surgical procedures are otherwise healthy, with pathology identified only on pelvic examination, other major organ systems should not be neglected in the physical examination.** Identification of abnormalities, such as a heart murmur or pulmonary compromise, should lead the surgeon to obtain additional testing and consultation to minimize intraoperative and postoperative complications.

Laboratory Evaluation

The selection of appropriate preoperative laboratory studies depends on the extent of the anticipated surgical procedure and the patient's medical status.

- For patients undergoing general anesthesia, a blood count including hematocrit, white cell

count, and platelet count should be obtained routinely.

- Serum chemistry and liver function test results rarely are abnormal in asymptomatic patients who have no significant medical history and who are not taking medications.
- Coagulation studies are of little value unless the patient has a significant medical history (1).
- In women younger than 50 years of age, a chest x-ray and electrocardiography are of very low yield in identifying asymptomatic cardiopulmonary disease and thus are not necessary (2,3).

Detailed evaluation of adjacent organ systems should be undertaken in individual cases as follows:

- CT urography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. However, a CT urogram is not of value in the evaluation of most patients undergoing pelvic surgery (4).
- Upper endoscopy, colonoscopy, barium enema, or upper gastrointestinal studies with small bowel assessment may be of value in evaluating some patients before undergoing pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or pelvic inflammatory disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or a mass of inflamed small intestines (Crohn's disease) or, rarely, a gastric or pancreatic carcinoma. Clearly, any patient with gastrointestinal symptoms should be further evaluated.
- Other imaging studies, including ultrasonography, CT scanning, or MRI, may be useful in selected patients.

Preoperative Discussion and Informed Consent

The preoperative discussion should include a description of the surgical procedure, its expected outcome, and risks; it is the basis for obtaining signed informed consent

(5). Informed consent is an educational process for the patient and her family and fulfills the physician's need to convey information in understandable terms. The items listed in Table 20.1 should be discussed, and, after each item, the patient and family should be invited to ask questions.

Table 20.1 Outline of Key Points of the Preoperative Informed Consent Discussion

- | |
|---|
| 1. The nature and extent of the disease process |
| 2. The extent of the actual operation proposed and the potential modifications of the operation, depending on intraoperative findings |
| 3. The anticipated benefits of the operation, with a conservative estimate of successful outcome |
| 4. The risks and potential complications of the surgery |
| 5. Alternative methods of therapy and the risks and results of those alternative methods of therapy |
| 6. The results likely if the patient is not treated |

Following are components of the informed consent process:

- **A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease or condition.** Printed materials, computer-based learning programs, and videotapes may assist in this process.
- **The goals of surgery should be discussed in detail.** Some gynecologic surgical procedures

are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, diagnostic laparoscopy), whereas most are aimed at correcting a specific problem. The extent of the surgery should be outlined, including which organs will be removed. Most patients like to be informed regarding the type of surgical incision and the estimated duration of anesthesia.

- **The expected outcome of the surgical procedure should be explained.** If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating an anatomic deformity or disease, the expected success of the operation should be discussed, as well as the potential for failure of the operation (e.g., failure of tubal sterilization or the possibility that stress urinary incontinence may not be alleviated). When treating cancer, the possibility of finding more advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include discussion of loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these emotionally charged issues. Unanticipated findings at the time of surgery should also be mentioned. For example, if the ovaries are unexpectedly found to be diseased, the best surgical judgment may be that they should be removed.

P.675

- **The risks and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure.** For most major gynecologic surgery, the risks include intraoperative and postoperative hemorrhage, postoperative infection, venous thromboembolism, injury to adjacent viscera, and wound complications. If the patient has a preexisting medical problem (e.g., diabetes, obesity, chronic obstructive pulmonary disease [COPD], coronary artery disease) additional risks should be reviewed.

- **The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery.** Information

regarding the need for a suprapubic catheter or prolonged central venous monitoring helps the patient accept her postoperative course and avoids surprises to the patient that may be disconcerting. The expected duration of the recovery period, both in and out of the hospital, should be outlined.

- **Alternative methods of therapy should be discussed, including medical management or other surgical approaches.** The patient should also have an understanding of the outcome of the disease if nothing is done.

General Considerations

Nutrition

In general, young patients undergoing elective gynecologic surgery have adequate nutritional stores and, for the most part, do not require nutritional support. However, **all patients should have a nutritional assessment, especially elderly patients and those undergoing gynecologic cancer surgery or other major gynecologic procedures in which a prolonged postoperative recovery is expected.** Nutritional status should be reassessed at regular intervals postoperatively until the patient has successfully returned to a regular diet.

A nutritional assessment includes a careful history and physical examination, which are the most useful, reliable, and cost-effective methods of determining a patient's nutritional status. In particular, information about recent weight loss, dietary history, fad diets, extreme exercise, or anorexia or bulimia should be elucidated. Physical evidence of malnutrition includes temporal wasting, muscle wasting, ascites, and edema. Accurate height and weight measurements should be obtained and an ideal body weight, percent ideal body weight, and percent usual body weight may be calculated. Many Internet-based body weight calculators are available. A variety of techniques have been developed to determine a patient's nutritional state; however, many methods lack clinical utility outside of a research setting.

Anthropometric measurements of skinfold thickness and arm-muscle circumference provide an estimate of total body fat and lean muscle mass.

The calculated body mass index (BMI) can be used as a surrogate marker for nutritional status.

The BMI is calculated as body weight in kilograms divided by the height in square centimeters. A BMI less than 22 increases the risk of malnutrition, and a BMI less than 19 gives clear evidence of malnutrition (6).

Patients who have lost less than 6% of their ideal body weight do not need preoperative nutritional intervention. However, **patients who have lost more than 10% of their ideal body weight in 6 months meet the definition of severely malnourished and should be considered for preoperative intervention (7).** Patients who have lost between 6% and 12% should undergo further studies to determine if preoperative intervention is needed. Laboratory assessments of albumin, transferrin, zinc, lipids, and liver function may be obtained in addition to the routine preoperative tests. The degree of malnutrition can in

P.676

part be determined by serum concentrations of albumin, transferrin, and prealbumin. The levels of these serum proteins are greatly influenced by the patient's level of hydration. Prealbumin has the shortest half-life, at 2 to 3 days, and levels of this protein are depressed very early in comparison with serum transferrin and albumin, which have half-lives of 8 and 20 days, respectively (8). Serum albumin was determined to be a substitute for the Prognostic Nutritional Index, which is a time-consuming calculation, in assessing malnutrition in women with gynecologic malignancies (9). **A serum albumin level of 3.5 to 5.0 is in the normal range, 2.8 to 3.4 is considered to indicate mild malnutrition, 2.1 to 2.7 moderate malnutrition, and less than 2.1 severe malnutrition (10).**

Hypoalbuminemia is correlated with morbidity, mortality, and increased postoperative complication rates in data from the National Surgical Quality Improvement Program (11). Decisions regarding the need for nutritional support should be based on several individualized factors. These factors include the patient's prior nutritional state, the anticipated length of time in which the patient will not be able to eat, the severity of surgery, and the likelihood of complications. The nutritional assessment should also determine whether the cause of the malnutrition is increased enteral loss (malabsorption, intestinal fistula), decreased oral intake, increased nutritional requirements as a result of hypermetabolism (sepsis, malignancy), or a combination of these factors. Severe malnutrition, if not corrected, can further complicate the postoperative problem by causing altered immune function, chronic anemia, impaired wound healing, and eventually multiple organ system failure and death.

The patient's nutritional requirements are increased by surgery for several reasons. First, there is a period following surgery during which oral intake is not allowed or is very limited. In addition, the operation itself causes increased protein catabolism, increased energy requirements, and a negative nitrogen balance. If the surgery is uncomplicated and the patient is without food for less than 7 days, this response is limited and patients usually recover without the need for nutritional support. An adequate diet is defined as providing 75% of estimated caloric and protein needs. Therefore, **if an adequate oral diet is not expected for 7 to 10 days, perioperative nutritional support may be required to avoid progressive malnutrition and associated complications** (10). Perioperative nutritional support reduces operative morbidity and decreases the length of hospitalization when commenced early in the postoperative course. Therefore, patients with either normal nutritional indices or mild or moderate malnutrition, who will be undergoing surgical procedures likely to require a prolonged catabolic period of more than 7 to 10 days, should have enteral or parenteral nutrition instituted in the early postoperative period as soon as the patient is hemodynamically stable. This type of management should be strongly considered in patients undergoing pelvic exenterations, urinary diversions, or multiple enterectomies (12). Preoperative nutritional support is indicated for patients who have significant preexisting malnutrition or require major elective surgery. **According to the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, evidence-based medicine supports the use of preoperative nutritional support for 7 to 14 days in moderately to severely malnourished patients undergoing major nonemergent, gastrointestinal surgery** (8). A Veterans Affairs Total Parenteral Nutrition Cooperative Study found that severely malnourished patients preconditioned with total parenteral nutrition (TPN) had fewer complications than did control patients, excluding infectious complications (13). In a meta-analysis review of 22 studies of preoperative TPN use, a 10% decrease in postoperative complications occurred in TPN-supported patients (14). Although encouraging, these findings are controversial and not supported by all studies or meta-analyses (15). If preoperative TPN is prescribed, it should be tapered and stopped at midnight before surgery, restarted 24 to 72 hours after the procedure, and continued until the patient is able to meet nutritional requirements.

ASPEN guidelines do not support the routine use of nutritional support in the immediate postoperative period for patients undergoing major gastrointestinal surgery; however, the guidelines do indicate a role for nutritional support postoperatively in patients in whom

oral intake will be inadequate for 7 to 10 days (8). In summary, clinical trials have demonstrated that TPN can improve nutritional status as measured by biochemical assays, immune function, and nitrogen balance. The effect of TPN on clinical outcome, however, is less well established. **Despite what would seem reasonable based on common sense as well as preoperative nutritional parameters, the data do not support TPN for mild to moderately malnourished patients. With severe malnutrition, preoperative TPN would seem to be beneficial and should be instituted.**

Route of Administration

After the decision has been made that nutritional support is required, the appropriate route of administration must be determined. **Enteral nutrition should be considered primarily because it is easy to deliver, associated with the fewest complications, linked to enhanced wound healing, and relatively inexpensive** (16). Contraindications to this route of delivery include intestinal obstruction, gastrointestinal bleeding, and diarrhea. Many different types of preparations are commercially available and can be chosen based on their caloric content, fat content, protein content, osmolality, viscosity, and price. Depending on the patient's problem, the route of delivery may be through a Dobhoff feeding tube, a gastrostomy tube, or a feeding jejunostomy tube (17). If the gastrointestinal tract is unusable for more than 7 days postoperatively, TPN should be implemented.

Total parenteral nutrition must be delivered through a central vein and has gained wide acceptance as a means of providing nutritional support for surgically ill patients. It must be delivered through a subclavian or internal jugular vein, and the catheter must be placed using meticulous sterile surgical technique. Only intravenous access lines in the right atrium, superior vena cava, or inferior vena cava can be truly deemed central lines (18). Proper daily care is required to avoid infectious complications. When managed by an experienced team, the most frequent complication, infection, can be reduced to a very reasonable level (19).

Composition of Total Parenteral Nutrition Solutions

Calories. The daily caloric requirements can be met by providing **1,000 calories more than the patient's basal energy expenditure.** Caloric requirements can be calculated based on **Long's modification of the Harrison-Benedict formula** for actual energy expenditure (AEE) (20). This is the most accurate available method to calculate an individual's AEE:

$$\text{AEE (women)} = [655.10 + 9.56 \text{ Weight (kg)} + 1.85 \text{ Height (cm)} - 4.68 \text{ Age (yrs)}] \times (\text{activity factor}) \times (\text{injury factor})$$

Activity factor: confined to bed (1.2), out of bed (1.3).

Injury factor: minor surgery (1.2), skeletal trauma (1.3), major sepsis (1.6), severe burn (2.1).

Alternatively, daily caloric requirements can be met by giving the patient 35 kcal/kg/day for maintenance and 45 kcal/kg/day for anabolic states.

- **Protein.** Daily nitrogen requirements may be met by providing **1 g of nitrogen (6.25 g of protein) for every 130 to 150 calories.** Protein is provided by synthetic amino acids. **The amino acids provide 15% to 20% of total calories** (19).

- **Carbohydrates.** The carbohydrate base of TPN is dextrose (glucose) in approximately 25% solution. Adults need approximately 100 g of dextrose per day at baseline. However, the maximal rate of glucose oxygenation in adults is approximately 7 g/kg/day, and glucose administration in excess of the caloric requirements can lead to fatty infiltration of the liver and other metabolic complications.

P.678

When given by TPN infusion, the dextrose tolerance in critically ill patients is 5 mg/kg/minute (19). Insulin should be used to maintain serum glucose concentration between 150 and 250 mg/dL, and it may be added directly to the TPN solution.

- **Fats.** Lipids in a 10% to 20% emulsion can be given as further caloric supplement and supply the essential fatty acids, linoleic acid, and alpha-linoleic acids. More calories can be given in the form of free fatty acids, which are the major source of energy for most peripheral tissues. When lipids are used as a major source of calories, a minimum of 50 to 150 g/day of glucose should also be given to provide a substrate for the central nervous system. Most patients

can tolerate up to 2 g of fat/kg/day, and daily dosages should not exceed 4 g of fat/kg/day. In critically ill patients, the lipid content should not exceed 1g/kg/day. These lipid emulsions are isotonic and can be delivered simultaneously with the protein and carbohydrate mixture in a 3-liter bag over a 24-hour infusion. **In general, 30% to 50% of nonprotein calories should be supplied in lipid form.** Serum triglyceride levels should be monitored to ensure that the patient can metabolize the fat.

- **Electrolytes, vitamins, and minerals.** In addition to calories and protein, nutritional support should be maintained in terms of electrolytes, vitamins, and trace elements. Daily maintenance requirements for electrolytes are as follows: sodium, 40 to 50 mEq; potassium, 30 to 40 mEq; magnesium, 8 to 10 mEq; calcium, 2 to 5 mEq; and phosphate, 13 to 25 mmol (19). A number of vitamins and trace elements must also be supplied to ensure that the patient is eumetabolic.

Fluid and Electrolytes

Water constitutes approximately 50% to 55% of the body weight of the average woman. Two thirds of this water is contained in the intracellular compartment. One third is contained in the extracellular compartment, of which one fourth is contained in plasma, and the remaining three fourths is in the interstitium.

Osmolarity, or tonicity, is a property derived from the number of particles in a solution. Sodium and chloride are the primary electrolytes contributing to the osmolarity of the extracellular compartment. Potassium and, to a lesser extent, magnesium and phosphate are the major intracellular electrolytes. Water flows freely between the intracellular and the extracellular spaces to maintain osmotic neutrality throughout the body. Any shifts in osmolarity in any fluid spaces within the body are accompanied by corresponding shifts in free water from spaces of lower to higher osmolarity, thus maintaining equilibrium.

The average adult daily fluid maintenance requirement is approximately 30 mL/kg per day, or 2,000 to 3,000 mL/day (21). This level is offset partially by insensible losses of 1,200 mL/day, which include losses from the lungs (600 mL), skin (400 mL), and gastrointestinal tract (200 mL). Urinary output from the kidney accounts for the

remainder of the fluid loss, and this output will vary depending on total body intake of water and sodium. Approximately 600 to 800 mOsm of solute are excreted by the kidney daily. Healthy kidneys can concentrate urine up to approximately 1,200 mOsm and, therefore, the minimum output can range between 500 and 700 mL/day. The maximal urine output of the kidney can be as high as 20 L/day, as seen in patients with diabetes insipidus. In healthy individuals, the kidney adjusts output commensurate with daily fluid intake.

The major extracellular buffer used in the acid-base balance is the bicarbonate-carbonic acid system: $\text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{CO}_3 \leftrightarrow \text{H}^+ + \text{HCO}_3^-$ (22). Typically, the body will maintain a bicarbonate-to-carbonic acid ratio of 20:1 to maintain an extracellular pH

P.679

of 7.4. Both the lung and the kidney play integral roles in the maintenance of normal extracellular pH via retention or excretion of carbon dioxide and bicarbonate. Under conditions of alkalosis, minute ventilation decreases and renal excretion of bicarbonate increases to restore the normal ratio of bicarbonate to carbonic acid; the opposite occurs with acidosis.

Ultimately, the kidney plays the most important role in fluid and electrolyte balance through excretion and retention of water and solute. Circulating antidiuretic hormone and aldosterone help modulate the process. Serum osmolarity affects hypothalamic release of antidiuretic hormone and aldosterone secretion in response to renal perfusion. Under states of dehydration or hypovolemia, serum antidiuretic hormone levels increase, leading to increased resorption of water in the distal tubule of the kidney. In addition, increased aldosterone release promotes increased sodium and water retention. The opposite occurs in states of fluid excess. As a result, individuals with normal renal function and circulating antidiuretic hormone and aldosterone levels maintain normal serum osmolarity and electrolyte composition, despite daily fluctuations of fluid and electrolyte intake.

Various disease states can alter the normal fluid and electrolyte homeostatic mechanisms, making perioperative fluid and electrolyte management more difficult. Patients with intrinsic renal disease are unable to excrete solute and to maintain acid-base balance. In patients undergoing the stress of chronic starvation or severe illness, there may be an inappropriately high level of circulating antidiuretic hormone and aldosterone, resulting in fluid and sodium retention. With severe cardiac disease, secondary renal hypoperfusion can lead to increased aldosterone synthesis and, therefore, increased sodium and water retention by the

kidney. Finally, patients with severe diabetes can have significant osmotic diuresis as well as acid-base dysfunction secondary to circulating keto acids. Treatment of renal, cardiac, or endocrine disorders preoperatively is imperative and often will rectify fluid and electrolyte abnormalities.

Special attention is warranted in the elderly patient undergoing surgery.

Normal physiological changes associated with aging can increase the likelihood of fluid and electrolyte disorders. These changes include decreased glomerular filtration rate, decreased urinary concentrating ability, and narrowed limits for excretion of water and electrolytes (23). Fluid and electrolyte management in the preoperative and perioperative periods requires knowledge of the daily fluid and electrolyte requirements for maintenance, replacement of ongoing fluid and electrolyte losses, as well as correction of any existing abnormalities.

Fluid and Electrolyte Maintenance Requirements

The body adjusts to higher and lower volumes of intake by changes in plasma tonicity. Alterations in plasma tonicity induce adjustments in circulating antidiuretic hormone levels, which ultimately regulate the amount of water retained in the distal tubule of the kidney. In the preoperative and the early postoperative periods, it is usually only necessary to replace sodium and potassium. Chloride is automatically replaced, concomitant with sodium and potassium, because chloride is the usual anion used to balance sodium and potassium in electrolyte solutions. There are various commercially available solutions containing 40 mmol of sodium chloride, with smaller amounts of potassium, calcium, and magnesium, designed to meet the requirements of a patient who is receiving 3 L of intravenous fluids per day. **The daily requirement, however, can be met by any combination of intravenous fluids. For example, 2 L of D5 (5% dextrose)/0.45 normal saline (7 mEq sodium chloride each), supplemented with 20 mEq of potassium chloride, followed by 1 liter of D5W (5% dextrose in water) with 20 mEq of potassium chloride, would suffice.**

Fluid and Electrolyte Replacement

Fluid and electrolyte losses beyond the daily average must be replaced by appropriate solutions. The choice of solutions for replacement depends on the composition of the fluids lost. Often, it

is difficult to measure free water loss, particularly in patients who

have high losses from the lungs, skin, or the gastrointestinal tract. Weighing these patients daily can be very useful. Up to 300 g of weight loss daily can be attributable to weight loss from catabolism of protein and fat in the patient who is taking nothing by mouth (21). Any loss beyond this level, however, represents fluid loss, which should be replaced accordingly.

Patients with a high fever can have increased pulmonary and skin loss of free water, sometimes in excess of 2 to 3 L/day. These losses should be replaced with free water in the form of D5W. Perspiration typically has one third the osmolarity of plasma and can be replaced with D5W or, if the loss is excessive, with D5/0.25 normal saline.

Patients with acute blood loss need replacement with appropriate isotonic fluid or blood or both. There is a wide range of plasma volume expanders, including albumin, dextran, and hetastarch solutions, that contains large-molecular-weight particles (< 50 kilodaltons (kDa) molecular weight). These particles are slow to exit the intravascular space, and about one half of the particles remain after 24 hours. Controversy exists over the ideal strategy for intravascular volume replacement (24). Meta-analyses on the use of human albumin and crystalloids versus colloids in fluid resuscitation have not shown a benefit in mortality rates (25,26). However, caution is required in interpreting results from these pooled controlled trials because mortality outcome was not the end point of most of the studies, and publication bias is a limitation. Possible side effects with synthetic colloid solutions include adverse effects on hemostasis, severe anaphylactic reactions, and impairment of renal function (24). These solutions are expensive, however, and **for most cases, simple replacement with 0.9 normal saline or lactated Ringer's solution will suffice.** One third of the volume of lactated Ringer's solution or normal saline typically will remain in the intravascular space, and the remainder goes to the interstitium.

Appropriate replacement of gastrointestinal fluid loss depends on the source of fluid loss in the gastrointestinal tract. Gastrointestinal secretions beyond the stomach and up to the colon are typically isotonic with plasma, with similar amounts of sodium, slightly lower amounts of chloride, slightly alkaline pH, and more potassium (in the range of 10–20 mEq/L). Under normal conditions, stool is hypotonic. However, under conditions of increased flow (i. e., severe diarrhea), stool contents are isotonic with a composition similar to that of the small bowel contents. Gastric contents are typically hypotonic, with one third the sodium of

plasma, increased amounts of hydrogen ion, and low pH.

In patients who have gastric outlet obstruction, nausea, and vomiting, or who undergo nasogastric suction, appropriate replacement of gastric secretions can be provided with a solution such as D5/0.45 normal saline with 20 mEq/L of potassium. Potassium supplementation is particularly important to prevent hypokalemia in these patients, whose kidneys attempt to conserve hydrogen ions in the distal tubule of the kidney in exchange for potassium ions.

In patients with bowel obstruction, 1 to 3 L of fluid can be sequestered daily in the gastrointestinal tract. This fluid should be replaced with isotonic saline or lactated Ringer's solution. Similarly, patients with enterocutaneous fistulas or new ileostomies should receive replacement with isotonic fluids.

Correction of Existing Fluid and Electrolyte Abnormalities

Patients who have fluid or electrolyte abnormalities preoperatively can pose a diagnostic challenge. The correct diagnosis and therapy is contingent on a correct assessment of total body fluid and electrolyte status. The management of hyponatremia, for example, may be either fluid restriction or fluid replacement. The choice of treatment depends on whether there is overall extracellular fluid excess and normal body sodium stores or decreased overall total body sodium stores and extracellular fluid. A detailed history is necessary to disclose any underlying medical illness and to assess the amount and duration of any

P.681

abnormal fluid losses or intake. Initial evaluation should include an assessment of hemodynamic, clinical, and urinary parameters to determine the overall level of hydration as well as the fluid status of the extracellular fluid compartment. The patient who has good skin turgor, moist mucosa, stable vital signs, and good urinary output is well hydrated. Nonpitting edema is indicative of extracellular fluid excess, whereas patients with orthostasis, sunken eyes, parched mouth, and decreased skin turgor clearly have extracellular volume contraction. A patient's overall extracellular fluid status does not always reflect the hydration status of the intravascular compartment, however. A patient can have increased interstitial fluid and yet be intravascularly dry, requiring replacement with isotonic fluid.

The laboratory workup for patients who may have pre-existing fluid problems should include assessment of blood hematocrit, serum chemistry, glucose, blood urea nitrogen (BUN) and creatinine, urine osmolarity, and urine electrolyte levels.

Serum osmolarity is mainly a function of the concentration of sodium and is given by the following equation:

$$2 \times \text{Na}^+ + \text{glucose (mg/dL)}/18 + \text{BUN (mg/dL)}/2.8$$

Normal serum osmolarity is typically 290 to 300 mOsm. Blood hematocrit will rise or fall inversely at a rate of 1% per 500-mL alteration of extracellular fluid volume. The BUN:creatinine ratio is typically 10:1 but will rise to a ratio of greater than 20:1 under conditions of extracellular fluid contraction. Under conditions of extracellular fluid deficit, urine osmolarity will typically be high (>400 mOsm), whereas urine sodium concentration is low (<15 mEq/L), indicative of an attempt by the kidney to conserve sodium. Under conditions of extracellular fluid excess or in cases of renal disease in which the kidney has impaired ability to retain sodium and water, urine osmolarity will be low and urine sodium will be high (>30 mEq/L). Finally, changes in sodium can give insight into the degree of extracellular fluid excess or deficit. In the average person, the serum sodium rises by 3 mmol/L for every liter of water deficit and falls by 3 mmol/L for each liter of water excess. One must be careful in making these estimates, however, because patients with prolonged water and electrolyte loss can have low serum sodium levels and marked water deficits.

Specific Electrolyte Disorders

Hyponatremia

Because sodium is the major extracellular cation, shifts in serum sodium levels are usually inversely correlated with the hydration state of the extracellular fluid compartment. The pathophysiology of hyponatremia, then, is usually expansion of body fluids leading to excess total body water (22,27). Symptomatic hyponatremia usually does not occur until the serum sodium is below 120 to 125 mEq/L. The severity of the symptoms (nausea, vomiting, lethargy, seizures) is related more to the rate of change of serum sodium than to the actual serum sodium level.

Hyponatremia in the form of extracellular fluid excess can be seen in patients with renal or

cardiac failure as well as in conditions such as nephrotic syndrome, in which total body salt and water are increased, with a relatively greater increase in the latter. Administration of hypertonic saline to correct the hyponatremia would be inappropriate in this setting. The treatment should include, in addition to correcting the underlying disease process, water restriction with diuretic therapy. Inappropriate secretion of antidiuretic hormone (ADH) can occur with head trauma, pulmonary or cerebral tumors, and states of stress. The abnormally elevated ADH results in excess water retention. Treatment includes water restriction

P.682

and, if possible, correction of the underlying cause. *Demeclocycline* has been shown to be effective in this disorder via its action in the kidney.

Inappropriate replacement of body salt losses with water alone will result in hyponatremia. This situation will typically occur in patients who lose large amounts of electrolytes secondary to vomiting, nasogastric suction, diarrhea, or gastrointestinal fistulas, and who received replacement with hypotonic solutions. Simple replacement with isotonic fluids and potassium will usually correct the abnormality. Rarely, rapid correction of the hyponatremia is necessary, in which case hypertonic saline (3%) can be administered. Hypertonic saline should be administered very cautiously to avoid a rapid shift in serum sodium, which will induce central nervous system dysfunction.

Hypernatremia

Hypernatremia is an uncommon condition that can be life-threatening if severe (serum sodium greater than 160 mEq/L). The pathophysiology is extracellular fluid deficit. The resultant hyperosmolar state leads to decreased water volume in cells in the central nervous system, which, if severe, can cause disorientation, seizures, intracranial bleeding, and death. The causes include excessive extrarenal water loss, which can occur in patients who have a high fever, have undergone tracheostomy in a dry environment, or have extensive thermal injuries; who have diabetes insipidus, either central or nephrogenic; and who have iatrogenic salt loading. The treatment involves correction of the underlying cause (correction of fever, humidification of the tracheostomy, administration of pitressin for control of central diabetes insipidus) and replacement with free water either by the oral route or intravenously with D5W. As with severe hyponatremia, marked hypernatremia should be

corrected slowly.

Hypokalemia

Hypokalemia may be encountered preoperatively in patients with significant gastro-intestinal fluid loss (prolonged emesis, diarrhea, nasogastric suction, intestinal fistulas) and marked urinary potassium loss secondary to renal tubular disorders (renal tubular acidosis, acute tubular necrosis, hyperaldosteronism, prolonged diuretic use). It can also arise from prolonged administration of potassium-free parenteral fluids in patients who are restricted from ingesting anything by mouth. The symptoms associated with hypokalemia include neuromuscular disturbances, ranging from muscle weakness to flaccid paralysis, and cardiovascular abnormalities, including hypotension, bradycardia, arrhythmias, and enhancement of digitalis toxicity. These symptoms rarely occur unless the serum potassium level is less than 3 mEq/L. The treatment is potassium replacement. Oral therapy is preferable in patients who are on an oral diet. If necessary, potassium replacement can be given intravenously in doses that should not exceed 10 mEq/hour.

Hyperkalemia

Hyperkalemia is encountered infrequently in preoperative patients. It is usually associated with renal impairment but can also be seen in patients who have adrenal insufficiency, are taking potassium-sparing diuretics, and have marked tissue breakdown such as that occurring with crush injuries, massive gastrointestinal bleeding, or hemolysis. The clinical manifestations are mainly cardiovascular. Marked hyperkalemia (potassium greater than 7 mEq/L) can result in bradycardia, ventricular fibrillation, and cardiac arrest. The treatment chosen depends on the severity of the hyperkalemia and whether there are associated cardiac abnormalities detected with electrocardiography. *Calcium gluconate* (10 mL of a 10% solution), given intravenously, can offset the toxic effects of hyperkalemia on the heart. One ampule each of sodium bicarbonate and D50, with or without insulin, will cause a rapid shift of potassium into cells. Over the longer term, cation exchange resins such as *sodium polystyrene sulfate* (*Kayexalate*), taken orally

or by enema, will bind and decrease total body potassium. Hemodialysis is reserved for emergent conditions in which other measures are not sufficient or have failed.

Postoperative Fluid and Electrolyte Management

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH. Circulating aldosterone levels also are increased, especially if sustained episodes of hypotension have occurred either intraoperatively or postoperatively. The elevated levels of circulating ADH and aldosterone make patients prone to sodium and water retention postoperatively.

Total body fluid volume may be altered significantly postoperatively. First, 1 mL of free water is released for each gram of fat or tissue that is catabolized and, in the postoperative period, several hundred milliliters of free water is released daily from tissue breakdown, particularly in the patient who has undergone extensive intra-abdominal dissection and who is restricted from ingesting food and fluids by mouth. This free water is often retained in response to the altered levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing, or sequestration of fluid in the surgical field. **The development of an ileus may result in an additional 1 to 3 L of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.**

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. **In the postoperative period, the kidneys will continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores (22).** If this potassium loss is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. However, beyond the first postoperative day, potassium supplementation is necessary.

Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters before surgery. Postoperatively, close monitoring of daily weight, urine output, serum hematocrit, serum electrolytes, and hemodynamic parameters will yield the necessary information to make correct adjustments in crystalloid replacement. The

normal daily fluid and electrolyte requirements must be met and any unusual fluid and electrolyte losses, such as from the gastrointestinal tract, lungs, or skin, must be replaced. After the first few postoperative days, third-space fluid begins to mobilize back into the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid retained perioperatively is thus mobilized and excreted through the kidneys, and exogenous fluid requirements decrease. Patients with inadequate cardiovascular or renal reserve are prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.

The most common fluid and electrolyte disorder in the postoperative period is fluid overload. The fluid excess can occur concomitantly with normal or decreased serum sodium. Large amounts of isotonic fluids are usually infused intraoperatively and postoperatively to maintain blood pressure and urine output. Because the infused fluid is often isotonic with plasma, it will remain in the extracellular space. Under such conditions, serum sodium will remain within normal levels. Fluid excess with hypotonicity (decreased serum sodium) can occur if large amounts of isotonic fluid losses (e.g., blood and gastrointestinal tract) are inappropriately replaced with hypotonic fluids. Again, the predisposition toward retention of free water in the immediate postoperative period compounds the problem. An increase in body weight occurs concomitantly with the fluid expansion. In the patient who is not allowed anything by mouth, catabolism should induce a daily weight loss as great as 300 g/day. Clearly, the patient who is gaining weight in excess of 150 g/day

P.684

is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. When necessary, diuretics can be used to increase urinary water excretion.

States of fluid dehydration are uncommon but will occur in patients who have large daily fluid losses that are not replaced. **Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L/day of free water can be lost through perspiration and hyperventilation.** Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Postoperative Acid-Base Disorders

A variety of metabolic, respiratory, and electrolyte abnormalities in the postoperative period can result in an imbalance in normal acid-base homeostasis, leading to alkalosis or acidosis. Changes in the respiratory rate will directly affect the amount of carbon dioxide that is exhaled. **Respiratory acidosis will result from carbon dioxide retention in patients who have hypoventilation from central nervous system depression.** This condition can result from oversedation with narcotics, particularly in the presence of concurrent severe chronic obstructive pulmonary disease. **Respiratory alkalosis can result from hyperventilation caused by excitation of the central nervous system by drugs, pain, or excess ventilator support.** Numerous metabolic derangements can result in *alkalosis* or *acidosis*. Proper fluid and electrolyte replacement as well as maintenance of adequate tissue perfusion will help prevent most acid-base disorders that occur during the postoperative period.

Alkalosis

The most common acid-base disorder encountered in the postoperative period is alkalosis (22). Alkalosis is usually of no clinical significance and resolves spontaneously. Several etiologic factors may include hyperventilation associated with pain; posttraumatic transient hyperaldosteronism, which results in decreased renal bicarbonate excretion; nasogastric suction, which removes hydrogen ions; infusion of bicarbonate during blood transfusions in the form of citrate, which is converted to bicarbonates; administration of exogenous alkali; and use of diuretics. Alkalosis can usually be corrected easily with removal of the inciting cause, as well as with correction of extracellular fluid and potassium deficits (Table 20.2). Full correction can usually be safely achieved over 1 to 2 days.

Table 20.2 Causes of Metabolic Acidosis

<i>Disorder</i>	<i>Source of Alkali</i>	<i>Cause of Renal HCO Retention</i>
<i>Gastric alkalosis</i>	Gastric mucosa	↓↓ECF, ↓K
Nasogastric suction		
Vomiting		
<i>Renal alkalosis</i>		
Diuretics	Renal epithelium	↓ECF, ↓K
Respiratory acidosis and diuretics		↓ECF, ↓K, ↑PCO ₂
<i>Exogenous base</i>	NaHCO ₃ , Na citrate, Na lactate	Coexisting disorder of ECF, K, PaCO ₂
↓ECF, extracellular fluid depletion; ↓K, potassium depletion; ↑↑PCO ₂ , carbon dioxide retention; NaHCO ₃ , sodium bicarbonate; PaCO ₂ , partial pressure of carbon dioxide, arterial.		

Marked alkalosis, with serum pH higher than 7.55, can result in serious cardiac arrhythmias or central nervous system seizures. Myocardial excitability is particularly

P.685

pronounced with concurrent hypokalemia. Under such conditions, fluid and electrolyte replacement may not be sufficient to correct the alkalosis rapidly. *Acetazolamide* (250–500 mg), can be given orally or intravenously 2 to 4 times daily to induce renal bicarbonate diuresis. Treatment with an acidifying agent is rarely necessary and should be reserved for acutely symptomatic patients (i.e., those with cardiac or central nervous system dysfunction) or for patients with advanced renal disease. Under such conditions, *hydrogen chloride* (5–10 mEq/hour of a 100-mmol solution) can be given via a central intravenous line. *Ammonium chloride* can also be given orally or intravenously but should not be given to patients with hepatic disease.

Acidosis

Metabolic acidosis is less common than alkalosis during the postoperative period, but acidosis can potentially be serious because of its effect on the cardiovascular system. Under conditions of acidosis, there are decreased myocardial contractility, a propensity for vasodilation of the peripheral vasculature leading to hypotension, and refractoriness of

the fibrillating heart to defibrillation (22). These effects promote decompensation of the cardiovascular system and can hinder attempts at resuscitation.

Metabolic acidosis results from a decrease in serum bicarbonate levels caused by the consumption and replacement of bicarbonate by circulating acids or the replacement by other anions such as chloride. The proper workup includes a measurement of the anion gap:

$$\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-) = 10 \text{ to } 14 \text{ mEq/L (normal)}$$

The anion gap is also composed of circulating protein, sulfate, phosphate, citrate, and lactate (28).

With metabolic acidosis, the anion gap can be increased or normal. An increase in circulating acids will consume and replace bicarbonate ion, thus increasing the anion gap. The causes include an increase in circulating lactic acid secondary to anaerobic glycolysis, such as that seen under conditions of poor tissue perfusion; increased ketoacids, as with cases of severe diabetes or starvation; exogenous toxins; and renal dysfunction, which leads to increased circulating sulfates and phosphates (29). The diagnosis can be established via a thorough history and measurement of serum lactate (normal <2 mmol/L), serum glucose, and renal function parameters. Metabolic acidosis in the face of a normal anion gap is usually the result of an imbalance of the ions chloride and bicarbonate, which occurs under conditions leading to excess chloride and decreased bicarbonate. Hyperchloremic acidosis can be seen in patients who have undergone saline loading. Bicarbonate loss will be seen in patients with small bowel fistulas, new ileostomies, severe diarrhea, or renal tubular acidosis. Finally, in patients with marked extracellular volume expansion, which often occurs postoperatively, the relative decrease in serum sodium and bicarbonate will result in a mild acidosis. A summary of the various causes of metabolic acidosis is shown in Table 20.3.

Table 20.3 Causes of Metabolic Acidosis

High Anion Gap	Normal Anion Gap	
	Hyperkalemic	Hypokalemic
Uremia	Hyporeninism	Diarrhea
Ketoacidosis	Primary adrenal failure	Renal tubular acidosis
Lactic acidosis	NH ₂ Cl	Ileal and sigmoid bladders
<i>Aspirin</i>	Sulfur poisoning	Hyperalimentation
Paraldehyde	Early chronic renal failure	
Methanol	Obstructive uropathy	
Ethylene glycol		
Methyl malonic aciduria		
NH ₂ Cl (chloramine)		

Adapted from **Narins RG, Lazarus MJ**. Renal system. In: **Vandam LD**, ed. *To make the patient ready for anesthesia: medical care of the surgical patient*, 2nd ed. Menlo Park, CA: Addison Wesley, 1984:67–114.

The treatment of metabolic acidosis depends on the cause. In patients with lactic acidosis, restoration of tissue perfusion is imperative. This state can be accomplished through cardiovascular and pulmonary support as needed, oxygen therapy, and aggressive treatment of systemic infection wherever appropriate. Ketosis from diabetes can be corrected gradually with *insulin* therapy. Ketosis resulting from chronic starvation or from lack of caloric support postoperatively can be corrected with nutrition. In patients with normal anion gap acidosis, bicarbonate losses from the gastrointestinal tract should be replaced, excess chloride administration can be curtailed and, where necessary, a loop diuretic can be used to induce renal clearance of chloride. Dilutional acidosis can be corrected with mild fluid restriction.

Bicarbonates should not be given unless serum pH is lower than 7.2 or severe cardiac complications secondary to acidosis are present. Furthermore, close monitoring of serum potassium levels is mandatory. Under states of acidosis, potassium will exit the cell and enter the circulation. The patient with a normal potassium concentration and metabolic acidosis is actually depleted of intracellular potassium. Treatment of the acidosis without potassium replacement will result in severe hypokalemia with its associated risks. A summary of

the various acid-base abnormalities and associated therapies is shown in Table 20.4.

Table 20.4 Acid-Base Disorders and Their Treatment				
Primary Disorder	Defect	Common Causes	Compensation	Treatment
<i>Respiratory acidosis</i>	Carbon dioxide (hypoventilation)	Central nervous system depression Airway and lung impairment	Renal excretion of acid salts Bicarbonate retention dioxide production Chloride shift into red blood cells	Restoration ventilation Control of excess
<i>Respiratory alkalosis</i>	Hyperventilation	Central nervous system excitation Excess ventilator support	Renal excretion of sodium, potassium bicarbonate Absorption of hydrogen and chloride ions Lactate release from red blood cells	Correction hyperventilation
<i>Metabolic acidosis</i>	Excess loss of base Increased nonvolatile acids	Excess chloride versus sodium Increased bicarbonate loss Lactic, ketoacidosis Uremia Dilution acidosis	Respiratory alkalosis Renal excretion of hydrogen and chloride ions Resorption of potassium bicarbonate	Increase sodium load give bicarbonate for pH < 7.2 Restore buffers, protein, hemoglobin

<i>Metabolic acidosis</i>	Excess loss of chloride and potassium Increased bicarbonate	Gastrointestinal losses of chloride Excess intake of bicarbonate Diuretics Hypokalemia Extracellular fluid volume contraction	Respiratory acidosis May be hypoxia Renal excretion of bicarbonate and potassium Absorption of hydrogen and chloride ions	Increased chloride content Potassium replacement Acetazolamide (Diamox) to waste bicarbonate Vigorous volume replacement Occasional 0.1 NaHCl as needed
---------------------------	--	---	--	---

NaHCl, sodium hydrochloride.

Perioperative Pain Management

Although satisfactory analgesia is easily achievable with currently available methods, patients continue to suffer unnecessarily from postoperative pain. Studies have consistently shown that 30% to 40% of patients suffer moderate to severe pain in the postoperative period (30,31). There are several reasons for the existing inadequacies in pain management. First, patient expectations of pain relief are low and they are not aware of the extent of analgesia that they should expect. In a study of the perception of pain relief after surgery, 86% of patients had moderate to severe pain after surgery, but 70% felt that the pain was as severe as they had expected (32). Second, there is a lack of formal physician training in pain management. This lack is epitomized by the commonly written order prescribing a range of narcotic to be given intramuscularly every 3 to 4 hours as needed, leaving pain management decisions to the nursing staff, with no attempt made to titrate the dose of the prescribed narcotic commensurate with individual patient requirements. Third, attitudes continue to be influenced by the common misconception that the use of narcotics in the postoperative period can result in opioid dependence. In one review, 20% of nurses responding to a staff questionnaire expressed concern that the use of opioid analgesics during the postoperative period could cause addiction (32). Studies have confirmed that nurses will administer less than one fourth of the total dose of narcotic that is prescribed on an as-needed basis. To facilitate acute pain management and reduce the number of adverse outcomes, the American Society of Anesthesiologists has established practice guidelines for acute

pain management in the perioperative setting (33).

The *minimal effective analgesic concentration (MEAC)* refers to the serum concentration of a drug below which very little analgesia is achieved. At the MEAC, receptor and plasma concentrations of a drug are in equilibrium. Steady-state drug concentrations above the MEAC are difficult to achieve with intramuscular depot injection (34). In one study, patients receiving intramuscular injections with *meperidine hydrochloride (Demerol)* every 4 hours experienced marked inpatient and interpatient variations in

P.687

narcotic drug peak concentrations as well as in the time required to reach these peaks. As a result, serum concentrations of drug were above the MEAC an average of only 35% of each 4-hour dosing interval (35). Variable pain control following intermittent intramuscular injections is the result of inadequate, highly variable, and unpredictable blood concentrations (36).

Adequate analgesia can be achieved through intramuscular or subcutaneous modes of administration, but unpredictable absorption can make titration difficult. Small intravenous boluses can be more easily titrated but may be shorter acting, requiring more frequent injections and thus intensive nursing care, whereas larger intravenous boluses may be associated with a higher incidence of central nervous system and respiratory depression.

The *patient-controlled analgesia (PCA) technique*, which allows patients to self-administer small doses of narcotic on demand, allows titration of measured boluses of narcotic as needed to relieve pain. This technique can provide a more thorough analgesia with maintenance of steady-state drug concentrations above the MEAC.

Irrespective of the route of administration, analgesics must be front loaded to provide prompt analgesia from the start. Without front loading, attainment of the MEAC will not occur for at least three elimination half-lives of the narcotic agent that is used. After front loading, additional small boluses of narcotic can be administered until analgesia is achieved. From the total dose of drug required to achieve analgesia, maintenance drug dosages can then be determined and administered either as a continuous infusion or on a

P.688

scheduled basis, so that the dose of drug administered offsets the amount that is cleared. Thereafter, prescribed doses of narcotic can be adjusted as needed.

Patient-controlled Analgesia

Devices for administering PCA are electronically controlled infusion pumps that deliver a preset dose of narcotic into a patient's indwelling intravenous catheter upon patient request. The devices all contain delay intervals or lockout times during which patient demands for more narcotic are not met. **These devices eliminate the delay between the onset of pain and the administration of analgesic agents, a common problem inherent with on-demand analgesic orders in busy hospital wards.** Patient-controlled analgesia has enjoyed excellent patient acceptance. Compared with conventional intramuscular injections, serum narcotic levels have significantly lower variability in patients using PCA (34). Patients using PCA have been shown to have improved analgesia, a lower incidence of postoperative pulmonary complications, and less confusion than those given intramuscular narcotics (37). Furthermore, the total dose of narcotic used has been lower with PCA than with conventional intramuscular depot injection.

The use of PCA does not by any means eliminate the adverse side effects of narcotics. Potentially life-threatening respiratory depression is seen in as many as 0.5% of patients using PCA. The use of a continuous narcotic infusion in addition to demand dosing has been associated with a fourfold increase in respiratory depression. Elderly patients and those with pre-existing respiratory compromise also are at risk for respiratory depression (34).

Carefully supervised regimens using continuous infusions, on-demand intramuscular therapy, or fixed dosage schedules (every-4-hour dosing) with on-demand supplementation can have analgesic efficacy comparable with PCA. Nonetheless, the type of close supervision required to achieve adequate on-demand analgesia without PCA is difficult to maintain. **Use of PCA shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and allows for an overall steadier state of pain control.**

Epidural and Spinal Analgesia

Anesthetics and narcotics administered either in the epidural space or intrathecally are among the most potent analgesic agents available; the efficacy of these agents is greater than that provided by intravenous PCA techniques. These drugs can be administered in one of several ways, including a single-shot dose given by epidural or intrathecal injection,

intermittent injection given either on schedule or on demand, and continuous infusion.

Because of the risk of central nervous system infections and headaches, intrathecal administration is usually limited to a single dose of narcotic, local anesthetic, or both. In comparison with epidural administration, duration of action for a single dose is increased via the intrathecal route as a result of the high concentrations of drug attained in the cerebrospinal fluid. However, the risk of central nervous system and respiratory depression, as well as systemic hypotension, also is increased. Even the low doses of opioids required for intrathecal analgesia have been associated with an increased risk of respiratory depression (38). Therefore, some investigators have warned against the use of intrathecal spinal analgesia outside the intensive care setting.

Epidural administration is the preferred approach and provides extended (greater than 24 hours) pain control during the postoperative period. Relative contraindications are the presence of coagulopathy, sepsis, and hypotension. Both anesthetic and narcotic agents have been used with excellent efficacy. Among the anesthetic agents, *bupivacaine* has been the most popular, providing excellent analgesia with minimal toxicity. Epidural analgesia is most suited for pain control in the lower abdomen and extremities. Potential adverse effects of epidural anesthetic agents include urinary retention, motor weakness,

P.689

hypotension, and central nervous system and cardiac depression. In contrast to anesthetic agents, opioids offer excellent analgesia without accompanying sympathetic blockade. Epidural opioids tend to have a much longer duration of action, and hypotension is a rare complication. Compared with epidural anesthetics, however, there is a higher incidence of nausea and vomiting, respiratory depression, and pruritus (39).

Compared with analgesics administered intramuscularly or intravenously, epidural analgesia has been shown to be associated with improved pulmonary function postoperatively, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic complications (most likely secondary to earlier ambulation), fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence (39). **A recent systematic review concluded that continuous epidural anesthesia is more effective than intravenous opioid PCA in reducing postoperative pain for up to 72 hours after abdominal surgery** (40).

Severe respiratory depression, which occurs in less than 1% of patients, is the most serious potential complication. A lower incidence of respiratory depression occurs with the

more lipophilic drugs such as *fentanyl*, which is quickly absorbed within the spinal cord and is, therefore, less likely to diffuse to the central nervous system respiratory control centers. Pruritus, nausea, and urinary retention are common but can be managed easily and usually are of little clinical significance. Cost is perhaps the main and most limiting drawback of epidural analgesia.

Close monitoring by nursing staff is required for safe administration of epidural analgesia. However, an intensive care setting is not necessary. Epidural analgesics can be administered safely in a hospital ward setting under close nursing supervision, using respiratory monitoring with hourly ventilatory checks during the first 8 hours of epidural analgesia.

Nonsteroidal Anti-inflammatory Drugs

Current therapeutic strategies for perioperative pain control are largely dependent on multimodal therapy with opioid analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs). The nonselective NSAID *ketorolac* is a potent drug that can be given orally or parenterally. ***Ketorolac has a slightly slower onset of activity than fentanyl but has an analgesic potency comparable to morphine.*** The theoretical advantages of NSAIDs over opioids include absence of respiratory depression, lack of abuse potential, decreased sedative effects, decreased nausea, early return of bowel function, and faster recovery. In clinical studies, *ketorolac* has been found to have analgesic effects similar to those of morphine in postoperative orthopedic patients and, when used in conjunction with PCA, significantly reduced opioid requirements (41,42). Depending on the type of surgery, *ketorolac* has an opioid dose-sparing effect of a mean of 36% and improves analgesic control of moderate to severe pain 24 hours postoperatively (43). In the obstetric population, intravenous *ketorolac* is effective in reducing postoperative narcotic use after cesarean delivery (44). Although the U. S. Food and Drug Administrative has not approved *ketorolac* for use during lactation, it has been quantified in breast milk and has lower levels than *ibuprofen* (45).

Potential adverse effects associated with the use of NSAIDs include an increased risk of renal compromise (particularly in patients suffering from acute hypovolemia), gastrointestinal side effects, hypersensitivity reactions, and bleeding. The effects of *ketorolac* on bleeding have been inconsistent. Studies of *ketorolac* on healthy volunteers showed transient increases in bleeding time and decreases in platelet aggregation, but these changes were not clinically significant (46). A retrospective cohort study showed increased risk of gastrointestinal and

operative site bleeding in elderly patients receiving high doses of *ketorolac*, between 105 mg/day and 120 mg/day (47). In addition, increased risk for all gastrointestinal bleeding was associated with use of *ketorolac* for more than 5 days (47). Controlled prospective studies have not shown a significant increase in blood loss in patients who receive NSAIDs perioperatively. *Ketorolac* may be associated with elevated

rates of acute renal failure when therapy exceeds 5 days (48). A meta-analysis of the use of postoperative NSAIDs in patients with normal preoperative renal function showed a clinically insignificant reduction in renal function (49). Finally, these agents should be used with extreme care, if at all, in patients with asthma, because 5% to 10% of adult patients with asthma are sensitive to *aspirin* and other NSAID preparations.

With the potential advantage of less gastrointestinal toxicity, interest increased in the use of selective cyclooxygenase-2 (COX-2) inhibitors in perioperative pain management. However, in light of subsequent evidence showing increased incidence of serious cardiovascular events associated with COX-2 inhibitors, the use of these agents in the perioperative setting should be carefully assessed, especially in patients who have cardiovascular disease or who are at risk for it (50,51,52,53,54).

Antimicrobial Prophylaxis in Gynecologic Surgery

Gynecologic procedures often involve breaching of the reproductive and gastrointestinal tracts, which harbor endogenous flora capable of causing polymicrobial infections in the postoperative period. **Despite great advances in aseptic technique and drug development, bacterial contamination of the operative site and postoperative infections are an inevitable part of the practice of gynecologic surgery.** Prevention of these surgical complications includes using proper aseptic technique, minimizing tissue trauma, minimizing the amount foreign material in the surgical site, controlling diabetes, avoiding immunologic suppression, maximizing tissue oxygenation, draining blood and serum from the surgical site, and using prophylactic antibiotics. Antibiotic prophylaxis is given with the belief that antibiotics can enhance the immune mechanisms in the host tissues that would resist such infections by killing bacteria that inoculate the surgical site at the time of surgery (55).

Infections in the skin or pelvis that result from gynecologic surgery (e.g., parametritis, cuff cellulitis, pelvic abscess) typically are polymicrobial in nature. These infections are complex and often involve gram-negative rods, gram-positive cocci, and anaerobes (Table 20.5). Antibiotic prophylaxis should be sufficiently broad to cover these potential pathogens (56).

<i>Lactobacillus</i>	<i>Enterobacter agglomerans</i>
Diphtheroids	<i>Klebsiella pneumoniae</i>
<i>Staphylococcus aureus</i>	<i>Proteus mirabilis</i>
<i>Staphylococcus epidermidis</i>	<i>Proteus vulgaris</i>
<i>Streptococcus agalactiae</i>	<i>Morganella morganii</i>
<i>Streptococcus faecalis</i>	<i>Citrobacter diversus</i>
α -Hemolytic streptococci	<i>Bacteroides</i> species
Group D streptococci	<i>B. disiens</i>
Peptostreptococci	<i>B. fragilis</i>
<i>Peptococcus</i>	<i>B. melaninogenicus</i>
<i>Clostridium</i>	
<i>Gaffky anaerobia</i>	
<i>Escherichia coli</i>	
<i>Fusobacterium</i>	
<i>Enterobacter cloacae</i>	

The timing of antimicrobial prophylaxis is important. There is a relatively narrow window of opportunity for affecting outcomes (57). In the United States, it is customary to give antimicrobial prophylaxis shortly before or during the induction of anesthesia. **Data have revealed that a delay of 3 hours or more between the time of bacterial inoculation (i.e., skin incision) and administration of antibiotics may result in ineffective**

prophylaxis. Evidence indicates that for prophylaxis, one dose of antibiotic is appropriate. When the surgical procedure proceeds longer than 1 to 2 times the half-life of the drug or blood loss is greater than 1.5 liters, additional intraoperative doses of antibiotics should be administered to maintain adequate levels of medication in

serum and tissues. There are no data to support the continuation of prophylactic antimicrobial agents into the postoperative period for routine gynecologic procedures.

The cephalosporins have emerged as the most important class of antimicrobial agents for prophylaxis. These drugs have a broad spectrum and relatively low incidence of adverse reactions. *Cefazolin* (1 g) appears to be most widely used in the United States by gynecologic surgeons because of its relatively low cost and long half-life. Other cephalosporins such as *cefoxitin*, *cefotaxime*, and *cefotetan* also commonly are used for prophylaxis. These agents appear to have a broader spectrum of activity against anaerobic bacteria; however, there is little evidence to indicate that there is a clinically relevant distinction between *cefazolin* and the other agents.

Antimicrobial prophylaxis, although usually beneficial, is not without risk. Anaphylaxis is the most life-threatening complication from antibiotic use. Anaphylactic reactions to penicillins are reported to occur in 0.2% courses of treatment. The fatality rate is 0.0001%. Data indicate that it generally is safe to administer cephalosporins to women who report a history of adverse reactions to penicillins. The incidence of adverse reactions (e.g., skin flushing, itching) in women with a history of penicillin allergy who are given cephalosporins is 1% to 10%. The incidence of anaphylaxis in this setting is less than 0.02% (58).

A single dose of broad-spectrum antibiotics can result in pseudomembranous colitis, caused by *Clostridium difficile*. Diarrhea may develop in as many as 15% of hospitalized patients treated with beta-lactam antibiotics. In patients receiving *clindamycin*, the rate of diarrhea is nearly 30%. These gastrointestinal complications from antibiotics may cause serious morbidity in the surgical patient, and the surgeon should be familiar with recognizing and managing these problems (59).

Not all gynecologic surgery patients need to receive prophylactic antibiotics. The surgeon should choose agents to cover procedures based on available data, thereby avoiding the potential for adverse reactions and minimizing the unnecessary use of antibiotics, which may contribute to increased rates of antimicrobial resistance. In patients reporting adverse reactions to the aforementioned agents, other drugs or combinations should be chosen that will provide adequate prophylactic coverage. For example, *metronidazole* and *levofloxacin* or *clindamycin* and *gentamycin* are two alternative broad-spectrum prophylactic regimens that can be used patients undergoing hysterectomy to cover anaerobes, gram-positive cocci, and gram-negative rods (60). Some commonly used recommendations are listed in Table 20.6.

Table 20.6 Antibiotic Prophylaxis Regimens

Hysterectomy (vaginal/abdominal)	1 to 2 g IV <i>cefazolin</i> 2 g IV <i>cefoxitin</i> 1 to 2 g IV <i>cefotetan</i> 1 g IV <i>cefotaxime</i>
Hysterosalpingogram	100 mg <i>doxycycline</i> PO bid for 5 days
Abortion/dilation & curettage	100 mg <i>doxycycline</i> PO 1 hour before procedure, then 200 mg po after the procedure
Cervical conization	No clear recommendations; <i>doxycycline</i> suggested by some authors
Colporrhaphy	No clear recommendations, cephalosporins suggested by some authors
Laparoscopy (clean)	None
Laparotomy (clean)	None
Hysteroscopy	None
IV, intravenous; PO, by mouth; bid, twice daily.	

Subacute Bacterial Endocarditis Prophylaxis

Often, the gynecologic surgeon encounters the issue of endocarditis prophylaxis. Most commonly, a woman will report a history of a murmur or mitral valve prolapse to the surgeon during the preoperative interview. Data clearly indicate that surgeons and dentists in the United States overtreat these women with prophylactic antibiotics meant to prevent endocarditis.

It appears that most patients who report these cardiac conditions are at no increased risk for endocarditis. For example, most patients with mitral valve prolapse or benign murmurs do not require endocarditis prophylaxis at the time of gynecologic surgery.

A thorough history and physical examination, coupled with a preoperative echocardiography and consultation with a cardiologist, will provide a detailed assessment of the risk of endocarditis in these patients. The American Heart Association (AHA) has published guidelines for physicians and dentists to use in selecting patients and procedures for endocarditis prophylaxis. If the surgeon is uncertain, consultation with a cardiologist is appropriate. If it appears that the patient would benefit from endocarditis

prophylaxis, based on the cardiac lesion and the procedure she will undergo, the risk is stratified as high or moderate. **High-risk patients should receive *ampicillin* or *vancomycin* plus *gentamycin* in a multidose regimen. Moderate-risk patients receive *amoxicillin* or *ampicillin* or *vancomycin* as prophylaxis in a single-dose regimen. Of note, low-risk patients require no subacute bacterial endocarditis (SBE) prophylaxis regardless of the procedure.**

Antibiotics administered to prevent surgical site infection are not sufficient for endocarditis prophylaxis; however, some experts feel that antibiotics given for endocarditis prophylaxis may provide adequate coverage against postoperative infections. This claim may be suspect, however, in patients undergoing gynecologic surgery. Some of the regimens (e.g., single-dose oral *amoxicillin*) prescribed for endocarditis prophylaxis in some patients may not provide adequate coverage for flora (gram-negative rods and anaerobes) found in the reproductive or gastrointestinal tracts. The AHA guidelines provide detailed dosing and schedule information for endocarditis prophylaxis (Table 20.7) (61).

Table 20.7 Recommendations for Prophylaxis of Bacterial Endocarditis for Genitourinary and Gastrointestinal Procedures

<i>High-Risk Patients</i>	<i>Agents</i>	<i>Regimen</i>
Standard regimen	<i>Ampicillin</i> and	2.0 g IM or IV within 30 min of starting procedure; 1.0 g IM or IV 6 hr later
	<i>Gentamicin</i>	1.5 mg/kg (not to exceed 120 mg) within 30 min of starting procedure
Penicillin-allergic	<i>Vancomycin</i> and	1.0 g IV over 1–2 h completed within 30 min of starting procedure
	<i>Gentamicin</i>	1.5 mg/kg (not to exceed 120 mg) within 30 min of starting procedure
<i>Moderate-Risk Patients</i>	<i>Agents</i>	<i>Regimen</i>
Standard regimen	<i>Ampicillin</i> or	2.0 g IM or IV within 30 min of starting procedure
	<i>Amoxicillin</i>	2.0 g orally 1 h before procedure
Penicillin-allergic	<i>Vancomycin</i>	1.0 g IV over 1–2 h completed within 30 min of starting procedure

IM, intramuscularly; IV, intravenously.

Postoperative Infections

Infections are a major source of morbidity in the postoperative period. Risk factors for infectious morbidity include the absence of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, poor nutrition, chronic and debilitating severe illness, poor surgical technique, and pre-existing focal or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic side wall, vaginal cuff, abdominal wound, and sites of indwelling intravenous catheters. Early identification and treatment of infection will result in the best outcome for these potentially serious complications.

Although infectious morbidity is an inevitable complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures.

In cases that involve transection of the large bowel, spillage of fecal contents inevitably occurs. A thorough preoperative mechanical and antibiotic bowel preparation in combination with systemic antibiotic prophylaxis will help decrease the incidence of postoperative

P.693

pelvic and abdominal infections in these patients. The surgeon can further decrease the risk of postoperative infections by using meticulous surgical technique. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. In cases in which there is higher-than-usual potential for serum and blood to collect in spaces that have been contaminated by bacterial spill, closed-suction drainage may reduce the risk of infection. Antibiotic therapy, rather than prophylaxis, should be initiated during surgery in patients who have frank intra-abdominal infection or pus. Elective surgical procedures should be postponed in patients who have infections preoperatively. In an epidemiologic study conducted by the Centers for Disease Control and Prevention, the incidence of nosocomial surgical infections ranged from 4.3% in community hospitals to 7% in municipal hospitals (62). Urinary tract infections accounted for approximately 40% of these nosocomial infections. Infections of the

skin and wound accounted for approximately one third of the infections, and respiratory tract infections accounted for approximately 16%. In patients who had any type of infection before surgery, the risk of infection at the surgical wound site was increased fourfold. Rates of infection were higher in older patients, in patients with increased length of surgery, and in those with increased length of hospital stay before surgery. The relative risk was 3 times higher in patients with a community-acquired infection before surgery. These community-acquired infections included infections of the urinary and respiratory tracts.

Historically, the standard definition of febrile morbidity for surgical patients has been the presence of a temperature higher than or equal to 100.4°F (38°C) on two occasions at least 4 hours apart during the postoperative period, excluding the first 24 hours. However, other sources have defined fever as two consecutive temperature elevations greater than 101.0°F (38.3°C) (63,64). Febrile morbidity has been estimated to occur in as many as one half of patients; however, it is often self-limited, resolves without therapy, and is usually noninfectious in origin (65). Overzealous evaluations of postoperative fever, especially during the early postoperative period, are time consuming, expensive, and sometimes uncomfortable for the patient (64). **The value of 101.0°F is more useful than 100.4°F to distinguish an infectious cause from an inconsequential postoperative fever.**

The assessment of a febrile surgical patient should include a review of the patient's history with regard to risk factors. Both the history and the physical examination should focus on the potential sites of infection (Table 20.8). The examination should include inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of intravenous catheters, and an examination of the extremities for evidence of deep venous thrombosis or thrombophlebitis. In gynecologic patients, an appropriate workup may also include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. A pelvic examination should also be performed to identify a mass consistent with a pelvic hematoma or abscess and to look for signs of pelvic cellulitis.

Table 20.8 Posthysterectomy Infections

<i>Operative Site</i>	<i>Nonoperative Site</i>
Vaginal cuff	Urinary tract
Pelvic cellulitis	Asymptomatic bacteriuria
Pelvic abscess	Cystitis
Supervaginal, extraperitoneal	Pyelonephritis
Intraperitoneal	Respiratory
Adnexa	Atelectasis
Cellulitis	Pneumonia
Abscess	Vascular
Abdominal incision	Phlebitis
Cellulitis	Septic pelvic thrombophlebitis
Simple	
Progressive bacterial synergistic	
Necrotizing fasciitis	
Myonecrosis	

Patients with fever in the early postoperative period should have an aggressive pulmonary toilet, including incentive spirometry (64). If the fever persists beyond 72 hours postoperatively, additional laboratory and radiologic data may be obtained. The evaluation may include complete and differential white blood cell counts and a urinalysis. In one study, a routine urine culture had a yield of only 9%; therefore, cultures should not be analyzed unless indicated by the urinalysis results or symptoms (63). Routine chest radiography has a yield of 12.5% and should be performed in asymptomatic patients as well as those with signs and symptoms localizing to the lung (63). Blood cultures can also be obtained but will most likely be of little yield unless the patient has a high fever (102°F). In patients with costovertebral angle tenderness, IVP may be indicated to rule out the presence of ureteral damage or obstruction from surgery, particularly in the absence of laboratory evidence of urinary tract infection. Patients who have persistent fevers without a clear localizing source should undergo CT scanning of the abdomen and pelvis to rule out the presence of an intra-abdominal abscess. Finally, if fever persists in patients who have had gastrointestinal surgery, a barium enema or upper gastrointestinal studies with small bowel assessment may be indicated late in the course of the first postoperative week to rule out an anastomotic leak or fistula.

Urinary Tract Infections

Historically, the urinary tract has been the most common site of infection in surgical patients (62). However, the incidence reported in the more recent gynecologic literature has been less than 4% (65,66). This decrease in urinary tract infections is most likely the result of increased perioperative use of prophylactic antibiotics. The incidence of postoperative urinary tract infection in gynecologic surgical patients not receiving prophylactic antibiotics has been confirmed to be as high as 40% (67), and **even a single dose**

P.695

of perioperative prophylactic antibiotic has been shown to decrease the incidence of postoperative urinary tract infection from 35% to 4% (68).

Symptoms of a urinary tract infection may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, other symptoms include headache, malaise, nausea, and vomiting. A urinary tract infection is diagnosed on the basis of microbiology and has been defined as the growth of 10^5 organisms/mL of urine cultured. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most frequent pathogen. Other pathogens include *Klebsiella*, *Proteus*, and *Enterobacter* species. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of urinary tract infections in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication (69). Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, has been implicated as a main cause of urinary tract contamination (70). In fact, more than one million catheter-associated urinary tract infections occur yearly in the United States, and **catheter-associated bacteria remains the most common etiology of gram-negative bacteremia in hospitalized patients.**

Bacteria adhere to the surface of urinary catheters and grow within bile films, which appear to protect embedded bacteria from antibiotics, making treatment less effective. Therefore, the use of urinary tract catheters should be minimized. An indwelling catheter should be removed or replaced in a patient undergoing treatment for catheter-related infections.

The treatment of urinary tract infection includes hydration and antibiotic therapy. Commonly prescribed and effective antibiotics include *penicillin*,

sulfonamides, cephalosporins, fluoroquinolones, and nitrofurantoin. The choice of antibiotic should be based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of *E. coli* strains are resistant to *ampicillin*. For uncomplicated urinary tract infections, an antibiotic that has good activity against *E. coli* should be given in the interim while awaiting results of the urine culture and sensitivity data.

Patients who have a history of recurrent urinary tract infections, those with chronic indwelling catheters (Foley catheters or ureteral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as *Klebsiella* and *Pseudomonas*. Chronic use of *fluoroquinolones* for prophylaxis is not advised because these agents are notorious for inducing antibiotic-resistant strains of bacteria.

Pulmonary Infections

The respiratory tract is an uncommon site for infectious complications in gynecologic surgical patients. In one study only six cases of pneumonia occurred in more than 4,000 women who underwent elective hysterectomy (65). This low incidence is probably a reflection of the young age and good health status of gynecologic patients in general. In acute care facilities, pneumonia is a frequent hospital-acquired infection, particularly in elderly patients (71). Risk factors include extensive or prolonged atelectasis, preexistent COPD, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, and nasogastric suction (71). In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures. The role of prophylactic antibiotics remains unclear.

A significant percentage (40%–50%) of cases of hospital-acquired pneumonia is caused by gram-negative organisms. These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx has been shown to be increased in patients in acute care facilities and has been associated with the presence

of nasogastric tubes, pre-existing respiratory disease, mechanical ventilation, tracheal intubation, and paralytic ileus as a result of microbial overgrowth in the stomach (72).

Interestingly, the use of antimicrobial drugs seems to significantly increase the frequency

of colonization of the oral pharynx with gram-negative bacteria.

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, chest radiography is probably of little benefit in patients at low risk for postoperative pulmonary complications. In patients with pulmonary findings or with risk factors for pulmonary complications, chest radiography should be performed. A sputum sample should also be obtained for Gram stain and culture. The treatment should include postural drainage, aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against both gram-positive and gram-negative organisms. In patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against *Pseudomonas* organisms.

Phlebitis

Intravenous catheter-related infections are common; the reported incidence is 25% to 35% (73). The intravenous site should be inspected daily, and the catheter should be removed if there is any associated pain, redness, or induration. Unfortunately, phlebitis can occur even with close surveillance of the intravenous site. In one study, more than 50% of the cases of phlebitis became evident more than 12 hours after discontinuation of intravenous catheters (74). In addition, less than one third of patients had symptoms related to the intravenous catheter site 24 hours before the diagnosis of phlebitis.

Intravenous catheters should be inserted using sterile technique, and they should be changed frequently. The institution of intravenous therapy teams has decreased the incidence of phlebitis by as much as 50% (73). This decrease is related not so much to surveillance of the intravenous catheter site as it is to frequent changing of intravenous catheters. The incidence of catheter-related phlebitis increases significantly after 72 hours. Therefore, intravenous catheters should be changed at least every 3 days.

Phlebitis can be diagnosed based on the presence of fever, pain, redness, induration, or a palpable venous cord. Occasionally, suppuration will be present. Phlebitis is usually self-limited and resolves within 3 to 4 days. The treatment includes application of warm, moist compresses and prompt removal of any catheters from the infected vein. Antibiotic therapy with antistaphylococcal agents should be instituted for catheter-related sepsis. Excision or drainage of an infected vein rarely is necessary.

Wound Infections

The results of a prospective study of more than 62,000 wounds were revealing in regard to the epidemiology of wound infections (75). The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, whereas the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with *hexachlorophene* slightly lowered the infection rate for clean wounds, whereas preoperative shaving of the wound site with a razor increased the infection rate. A 5-minute wound preparation immediately before surgery was as effective as preparation for 10 minutes. The wound infection rate increased with the duration of preoperative hospital stay as well as with the duration of surgery. In addition, incidental appendectomy increased the risk of wound infection in patients undergoing clean surgical procedures. The study concluded that **the incidence of wound infections could be decreased by short preoperative hospital stays, hexa-chlorophene showers before surgery, minimizing shaving of the wound site, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound infection rates.** A program instituting

P.697

these conclusions led to a decrease in the clean wound infection rate from 2.5% to 0.6% over an 8-year period. The wound infection rate in most gynecologic services has been lower than 5%, reflective of the clean nature of most gynecologic operations.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include fever, erythema, tenderness, induration, and purulent drainage. Wound infections that occur on postoperative days 1 through 3 are generally caused by streptococcal and *Clostridia* infections. The management of wound infections is mostly mechanical and involves opening the infected portion of the wound above the fascia, with cleansing and debridement of the wound edges as necessary. Wound care, consisting of debridement and dressing changes 2 to 3 times daily with mesh gauze, will promote growth of granulation tissue, with gradual filling in of the wound defect by secondary intention. Clean, granulating wounds

can often be secondarily closed with good success, shortening the time required for complete wound healing.

The technique of delayed primary wound closure can be used in contaminated surgical cases to lower the incidence of wound infection. Briefly, this technique involves leaving the wound open above the fascia at the time of the initial surgical procedure. Vertical interrupted mattress sutures through the skin and subcutaneous layers are placed 3 cm apart but are not tied. Wound care is instituted immediately after surgery and continued until the wound is noted to be granulating well. Sutures may then be tied and the skin edges further approximated using sutures or staples. **Using this technique of delayed primary wound closure, the overall wound infection rate has been shown to be decreased from 23% to 2.1% in high-risk patients (76).**

Pelvic Cellulitis

Vaginal cuff cellulitis is present to some extent in most patients who have undergone hysterectomy. It is characterized by erythema, induration, and tenderness at the vaginal cuff. Occasionally, a purulent discharge from the apex of the vagina may also be present. The cellulitis is often self-limited and does not require any treatment. Fever, leukocytosis, and pain localized to the pelvis may accompany severe cuff cellulitis and most often signifies extension of the cellulitis to adjacent pelvic tissues. In such cases, broad-spectrum antibiotic therapy should be instituted with coverage for gram-negative, gram-positive, and anaerobic organisms. If purulence at the vaginal cuff is excessive or if there is a fluctuant mass noted at the vaginal cuff, the vaginal cuff should be gently probed and opened with a blunt instrument. The cuff can then be left open for dependent drainage or, alternatively, a drain can be placed into the lower pelvis through the cuff and removed when drainage, fever, and symptoms in the lower pelvic region have resolved.

Intraabdominal and Pelvic Abscess

The development of an abscess in the surgical field or elsewhere in the abdominal cavity is an uncommon complication after a gynecologic surgery. It is most likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary complication of hematomas. **The causative pathogens in patients who have**

intra-abdominal abscesses are usually polymicrobial in nature. The aerobes most commonly identified include *E. coli*, *Klebsiella*, *Streptococcus*, *Proteus*, and *Enterobacter*. Anaerobic isolates are also common, usually from the *Bacteroides* group. These pathogens arise mainly from the vaginal tract but also can be derived from the gastrointestinal tract, particularly when the colon has been entered at the time of surgery.

Intra-abdominal abscess is sometimes difficult to diagnose. The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. For abscesses above the pelvis, the diagnosis will depend on radiologic confirmation.

P.698

Ultrasonography can occasionally delineate fluid collections in the upper abdomen as well as in the pelvis. However, bowel gas interference makes visualization of fluid collections or abscesses in the midabdomen difficult to distinguish. **Computed tomography scanning is, therefore, much more sensitive and specific for diagnosing intra-abdominal abscesses and often is the radiologic procedure of choice.** Occasionally, if conventional radiologic methods fail to identify an abscess and the index of suspicion for an abscess remains high, labeled leukocyte scanning may be useful for locating the infected focus.

Standard therapy for intra-abdominal abscess is evacuation and drainage combined with appropriate parenteral administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can often be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance has obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via transperineal, transrectal, or transvaginal approaches. The catheter is left in place until drainage decreases. Transperineal and transrectal drainage of deep pelvic abscesses has been successful in 90% to 93% of patients, obviating the need for surgical management (77,78). **For those patients in whom radiologic drainage is not successful, however, surgical exploration and evacuation are indicated.** The standard approach to initial antibiotic therapy has been the combination of *ampicillin*, *gentamicin*, and *clindamycin*. Adequate treatment can also be achieved with currently available broad-spectrum single agents (including the broad-spectrum *penicillin*), second- and third-generation cephalosporins, *levofloxacin* and

metronidazole, and the *sulbactam-clavulanic acid*-containing preparations (79,80,81).

Necrotizing Fasciitis

Necrotizing fasciitis is an uncommon infectious disorder; approximately 1,000 cases occur annually in the United States (82). The disorder is characterized by a rapidly progressive bacterial infection that involves the subcutaneous tissues and fascia while characteristically sparing underlying muscle. Systemic toxicity is a frequent feature of this disease, as manifested by the presence of dehydration, septic shock, disseminated intravascular coagulation, and multiple organ system failure.

The pathogenesis of necrotizing fasciitis involves a polymicrobial infection of the dermis and subcutaneous tissue. Hemolytic *streptococcus* was initially believed to be the primary pathogen responsible for the infection in necrotizing fasciitis (83). However, it is now evident that numerous other organisms are often cultured in addition to *streptococcus*, including other gram-positive organisms, coliforms, and anaerobes (83,84,85,86,87). Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. In addition, noninflammatory intravascular coagulation or thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin (86,87). Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation can cause septic shock, acid-base disturbances, and multiple organ impairment.

The diagnostic criteria for necrotizing fasciitis include extensive necrosis of the superficial fascia and subcutaneous tissue with peripheral undermining of the normal skin, a moderate to severe systemic toxic reaction, the absence of muscle involvement, *Clostridia* in wound and blood culture, major vascular occlusion, intensive leukocytic infiltration, and necrosis of subcutaneous tissue (88).

Most patients with necrotizing fasciitis suffer pain, which in the early stages of the disease is often disproportionately greater than that expected from the degree of

cellulitis present. Late in the course of the infection, the involved skin may actually be anesthetized secondary to necrosis of superficial nerves. Temperature abnormalities, both hyperthermia and hypothermia, are common concomitant with the release of bacterial toxins as well as with bacterial sepsis, which is present in up to 40% of patients (89). The involved skin is initially tender, erythematous, and warm. Edema develops, and the erythema spreads diffusely, fading into normal skin, characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. Eventually, as necrosis develops, the skin becomes gangrenous and may slough spontaneously. Most patients will have leukocytosis and acid-base abnormalities. Finally, subcutaneous gas may develop, which can be identified by palpation and by radiography. The finding of subcutaneous gas by radiography is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include *Enterobacter*, *Pseudomonas*, anaerobic streptococci, and *Bacteroides*, which, unlike clostridial infections, spare the muscles underlying the affected area (90). A tissue biopsy specimen for Gram stain and aerobic and anaerobic culture should be obtained from the necrotic center of the lesion to identify the etiologic organisms (87). Although necrotizing fasciitis often is diagnosed during surgery, a high index of suspicion as well as liberal use of frozen-section biopsy can often provide an early life-saving diagnosis and minimize morbidity (91).

Predisposing risk factors for necrotizing fasciitis include diabetes mellitus, alcoholism, an immunocompromised state, hypertension, peripheral vascular disease, intravenous drug abuse, and obesity (82,85,86,90,92). The most frequent site of infection has been in the extremities (87), but the infection can occur anywhere in the subcutaneous tissues, including the head and neck, trunk, and perineum. Necrotizing fasciitis has been known to occur after trauma, surgery, burns, and lacerations; as a secondary complication in perirectal infections or Bartholin duct abscesses; and *de novo* (82,83,86,87,91). Increased age, delay in diagnosis, inadequate debridement during initial surgery, extensive disease at the time of diagnosis, and the presence of diabetes mellitus are all factors that have been associated with an increased likelihood of mortality from necrotizing fasciitis (82,89). Early diagnosis and aggressive management of this lethal disease have led to improved survival. In an earlier series, the mortality rate was consistently higher than 30%; in more recent series, the mortality rate has decreased to less than 10% (90,93,94).

Successful management of necrotizing fasciitis involves early recognition,

immediate initiation of resuscitative measures (including correction of fluid, acid-base, electrolyte, and hematologic abnormalities), aggressive surgical debridement and redebridement as necessary, and broad-spectrum antibiotic therapy. Many patients will benefit from central venous monitoring, as well as from high-caloric nutritional support.

During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often will confirm the diagnosis. Multiple incisions can be made sequentially toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can then be packed and sequentially debrided on a daily basis as necessary until healthy tissue is displayed at all margins. **Hyperbaric oxygen therapy may be of some benefit, particularly in patients for whom culture results are positive for anaerobic organisms.** Retrospective nonrandomized studies have demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appear to significantly decrease both wound morbidity and overall mortality in patients with necrotizing fasciitis (82,95). The benefit of hyperbaric therapy shown in one study was remarkable, given that patients

P.700

receiving hyperbaric oxygen were sicker and had a higher incidence of diabetes mellitus, leukocytosis, and shock (82).

After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss. Interestingly, temporary biologic closure of open wounds also seems to decrease bacterial growth (96). Amniotic membranes have also been shown to be an effective wound covering in patients with necrotizing fasciitis (92). A new technology that has been demonstrated in laboratory and clinical studies to significantly improve wound healing is a vacuum-assisted closure (VAC) method that uses a subatmospheric pressure technique (97,98). In situations in which spontaneous closure is not likely, the VAC device may allow for the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Finally, skin flaps can be mobilized to help cover open wounds once the infections have resolved and granulation has begun.

Gastrointestinal Preparation

Preparation of the lower gastrointestinal tract before elective gynecologic surgery has several goals. In most gynecologic surgery, when the gastrointestinal tract is not entered, mechanical preparation of the bowel reduces gastrointestinal contents and thus allows more room in the abdomen and pelvis, facilitating the surgical procedure. If a rectosigmoid colon enterotomy occurs, the mechanical bowel preparation eliminates formed stool and reduces the risk of bacterial contamination, thus reducing infectious complications. Mechanical bowel preparation may be accomplished as presented in (Table 20.9). The traditional use of laxatives and enemas requires at least 12 to 24 hours and generally causes moderate abdominal distention and crampy pain. Randomized trials comparing traditional mechanical bowel preparation with oral gut lavage (*PEG electrolyte solution, GoLYTELY*) have found that the use of approximately 4 L of *GoLYTELY* (administered until the rectal effluent is clear) provides more complete, faster, and more comfortable bowel preparation (99). However, the ingestion of 4 L of fluid is problematic for many patients. **An alternative mechanical preparation method is the use of oral sodium phosphate (*Phospho-Soda*). When evaluated in a randomized trial comparing the 4 L of *GoLYTELY* with oral sodium phosphate, colonoscopic examination disclosed that both methods were equally effective in colonic cleansing, and more patients preferred the sodium phosphate method (100).**

Preoperative Day 2 Clear liquid diet

Preoperative Day 1 Clear liquid diet

Mechanical Prep

Fleet Phospho-Soda Saline Laxative (3 oz. bottle)
(one bottle of laxative 1 p.m. and another at 7 p.m.)
Fleet enemas until no solid stool in p.m. (Optional)

Antibiotic Prep (Optional)

Neomycin (oral), 1 g q 4 h for three doses (4, 8, 12 p.m.)
Erythromycin (oral), 1 g q 4 h for three doses

Day of Surgery Fleet enemas until clear (Optional)

High infection rates after colonic surgery have led to investigation of methods aimed at reducing these significant complications. Although mechanical bowel preparation is an essential part of all colonic surgery preparation regimens, it does not reduce the infection rate satisfactorily. Reduction of the number of pathogenic flora in the colon is the primary strategy to reduce infection after colonic surgery. The colon has the greatest concentration of bacteria in the body, including both aerobes and anaerobes. Anaerobes outnumber aerobes by 1,000:1. After reducing the bacterial load by mechanical preparation, the administration of antibiotics can further reduce the bacterial count in the colon. Of the many trials reported, the most widely accepted regimen combines *erythromycin* base and *neomycin* administered orally (see Table 20.9) (101,102,103). Many surgeons substitute *metronidazole* for the *erythromycin*; there is no significant difference in infection rates, but patients tolerate *metronidazole* better than *erythromycin*. **The use of oral antibiotics 24 hours before colonic resection has reduced the infection rate from approximately 40% to 5% to 10% in randomized trials.** Because these oral antibiotics are poorly absorbed and many do little to reduce infection from vaginal contamination, an intravenous antibiotic (first-generation cephalosporin) can be added to the preoperative regimen. **Antibiotic bowel prophylaxis should be used for patients who are likely to undergo colorectal surgery (pelvic exenteration, ovarian cancer debulking) and those who are at high risk for rectal injury (such as severe cases of endometriosis or pelvic inflammatory disease).**

Postoperative Gastrointestinal Complications

Ileus

Following abdominal or pelvic surgery, most patients will experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of gastrointestinal motility occurs is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract and prolonged surgical procedures. Infection, peritonitis, and electrolyte disturbances may also result in ileus. For most patients undergoing common gynecologic operations, the degree of ileus

is minimal, and gastrointestinal function returns relatively rapidly, allowing the resumption of oral intake within a few days of surgery. Patients who have persistently diminished bowel sounds, abdominal distention, and nausea and vomiting require further evaluation and more aggressive management.

Ileus is usually manifested by abdominal distention and should be evaluated initially by physical examination. Pertinent points of the abdominal examination include assessment of the quality of bowel sounds and palpation in search of tenderness or rebound. The possibility that the patient's signs and symptoms may be associated with a more serious intestinal obstruction or other intestinal complication must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. **Abdominal radiography to evaluate the abdomen in the flat (supine) position as well as in the upright position usually will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops of small and large bowel as well as air-fluid levels while the patient is in the upright position.** Sometimes, massive dilation of the colon or stomach may be noted. The remote possibility of distal colonic obstruction suggested by a dilated cecum should be excluded by rectal examination, proctosigmoidoscopy, or barium enema. In the postoperative gynecology patient, especially in the upright position, the flat plate of the abdomen may also show evidence of free air. This common finding following surgery lasts 7 to 10 days in some instances and is not indicative of a perforated viscus in most patients.

P.702

The initial management of a postoperative ileus is aimed at gastrointestinal tract decompression and maintenance of appropriate intravenous replacement fluids and electrolytes.

- **A nasogastric tube should be used to evacuate the stomach of its fluid and gaseous contents.** Prolonged nasogastric suction continues to remove swallowed air, which is the most common source of air in the small bowel. Some clinicians prefer to use a longer small intestinal tube (Cantor or Miller-Abbott tube) (103). This tube, which usually has a mercury-filled bag on its distal tip, may be propelled by peristalsis through the pylorus and into the small bowel, thus allowing better evacuation of the small bowel. The disadvantage of long tubes is that they take a longer time to become positioned and may not enter the small bowel as

a result of the decreased intestinal motility associated with ileus.

- **Fluid and electrolyte replacement must be adequate to keep the patient well perfused.** Significant amounts of third-space fluid loss occur in the bowel wall, the bowel lumen, and the peritoneal cavity during the acute episode. Gastrointestinal fluid losses from the stomach may lead to a metabolic alkalosis and depletion of other electrolytes as well. Careful monitoring of serum chemistry levels and appropriate replacement are necessary.
- **Most cases of severe ileus will begin to improve over a period of several days.** In general, this improvement is recognized by reduction in the abdominal distention, return of normal bowel sounds, and passage of flatus or stool. Follow-up abdominal radiographs should be obtained as necessary for further monitoring.
- **When the gastrointestinal tract function appears to have returned to normal, the nasogastric tube may be removed and a liquid diet may be instituted.**
- **If a patient shows no evidence of improvement during the first 48 to 72 hours of medical management, other causes of ileus should be sought.** Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized gastrointestinal tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. With persistent ileus, the use of water-soluble upper gastrointestinal contrast studies may assist in the resolution, but prospective randomized data regarding this maneuver are lacking.

Small Bowel Obstruction

Obstruction of the small bowel following major gynecologic surgery occurs in approximately 1% to 2% of patients (104). The most common cause of small bowel obstruction is adhesions to the operative site. If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result from distention, ileus, or bowel wall edema. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia and an unrecognized defect in the small bowel or

large bowel mesentery. **Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.** Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distention, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

In most cases of small bowel obstruction following gynecologic surgery, the obstruction is only partial and the symptoms usually resolve with conservative management.

- **Further evaluation after several days of conservative management may be necessary.** Evaluation of the gastrointestinal tract with barium enema and an

P.703

upper gastrointestinal study with small bowel assessment are appropriate. In most cases, complete obstruction is not documented, although a narrowing or tethering of the segment of small bowel may indicate the site of the problem.

- **Further conservative management with nasogastric decompression and intravenous fluid replacement may allow time for bowel wall edema or torsion of the mesentery to resolve.**

- **If resolution is prolonged and the patient's nutritional status is marginal, the use of TPN may be necessary.**

- **Conservative medical management of postoperative small bowel obstruction usually results in complete resolution.** However, if persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to evaluate surgically and manage the obstruction. In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require

resection and reanastomosis.

Colonic Obstruction

Postoperative colonic obstruction following surgery for most gynecologic conditions is exceedingly rare. It is almost always associated with a pelvic malignancy, which in most cases will have been known at the time of the initial operation. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients, and it is caused by extrinsic impingement on the colon by the pelvic malignancy. Intrinsic colonic lesions may be undetected, especially in a patient with some other benign gynecologic condition. When colonic obstruction is manifested by abdominal distention and abdominal radiography reveals a dilated colon and enlarging cecum, further evaluation of the large bowel is required by barium enema or colonoscopy. **Dilation of the cecum to more than 10 to 12 cm in diameter as viewed by abdominal radiography requires immediate evaluation and surgical decompression by performing colectomy or colostomy.** Surgery should be performed as soon as the obstruction is documented. Conservative management of colonic obstruction is not appropriate because the complication of colonic perforation has an exceedingly high mortality rate.

Diarrhea

Episodes of diarrhea often occur following abdominal and pelvic surgery as the gastrointestinal tract returns to its normal function and motility. However, prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis. Excessive amounts of diarrhea should be evaluated by abdominal radiography and stool samples tested for the presence of ova and parasites, bacterial culture, and *Clostridium difficile* toxin. Proctoscopy and colonoscopy may also be advisable in severe cases. Evidence of intestinal obstruction should be managed as outlined previously. Infectious causes of diarrhea should be managed with the appropriate antibiotics as well as fluid and electrolyte replacement. ***C. difficile*-associated pseudomembranous colitis may result from exposure to any antibiotic. Discontinuation of these antibiotics (unless they are needed to treat another severe infection) is advisable, along with the institution of appropriate**

therapy. Oral *metronidazole* is a suitable agent for instituting therapy and is less expensive than *vancomycin*. Therapy should be continued until the diarrhea abates, and several weeks of oral therapy may be required to obtain complete resolution of the pseudomembranous colitis.

Fistula

Gastrointestinal fistulas are relatively rare following gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, or surgical injury to the large or

P. 704

small bowel that was improperly repaired or unrecognized. Signs and symptoms of gastrointestinal fistula are often similar to those of small bowel obstruction or ileus, except that a fever is usually a more prominent component of the patient's symptoms. When fever is associated with gastrointestinal dysfunction postoperatively, evaluation should include early assessment of the gastrointestinal tract to confirm its continuity. **When fistula is suspected, the use of water-soluble gastrointestinal contrast material is advised to avoid the complication of barium peritonitis.** Evaluation with abdominal pelvic CT scan may also assist in identification of a fistula and associated abscess. **Recognition of an intraperitoneal gastrointestinal leak or fistula formation usually requires immediate surgery, unless the fistula has drained spontaneously through the abdominal wall or vaginal cuff.**

An enterocutaneous fistula arising from the small bowel and draining spontaneously through the abdominal incision may be managed successfully with medical therapy. Therapy should include nasogastric decompression, replacement of intravenous fluids as well as TPN, and appropriate antibiotics to treat an associated mixed bacterial infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 2 weeks. Some authors have suggested the use of *somatostatin* to decrease intestinal tract secretion and allow earlier healing of the fistula. In some cases, the fistula will close spontaneously with this mode of management. If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary.

A *rectovaginal fistula* that occurs following gynecologic surgery is usually the result of

surgical trauma that may have been aggravated by the presence of extensive adhesions in the rectovaginal septum associated with endometriosis, pelvic inflammatory disease, or pelvic malignancy. **A small rectovaginal fistula may be managed with a conservative medical approach, in the hope that decreasing the fecal stream will allow closure of the fistula.** A small fistula that allows continence except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. Large rectovaginal fistulas for which there is no hope of spontaneous closure are best managed by performing an initial diverting colostomy followed by repair of the fistula after inflammation has resolved. After the fistula closure is healed and deemed successful, the colostomy can be closed.

Thromboembolism

Risk Factors

Deep venous thrombosis and pulmonary embolism are largely preventable, yet remain a significant complication in postoperative patients. The magnitude of this problem is relevant to the gynecologist, because **40% of all deaths following gynecologic surgery are directly attributed to pulmonary emboli** (105), and it is the most frequent cause of postoperative death in patients with uterine or cervical carcinoma (106).

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include a hypercoagulable state, venous stasis, and vessel endothelial injury. Risk factors include major surgery; advanced age; nonwhite race; malignancy; history of deep venous thrombosis, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; a history of radiation therapy; and hypercoagulable states, such as factor V Lieden, pregnancy, use of oral contraceptives, estrogens, or *tamoxifen*. Intraoperative factors associated with postoperative deep venous thrombosis included increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors to provide the appropriate level

of venous thrombosis prophylaxis (107,108). A general outline of levels of thromboembolism risk are listed in Table 20.10.

Table 20.10 Thromboembolism Risk Stratification*Low Risk*

Minor surgery

No other risk factors^a*Moderate Risk*

Age >40 years and major surgery

Age <40 years with other risk factors^a and major surgery*High Risk*

Age >60 years and major surgery

Cancer

History of deep venous thrombosis or pulmonary embolism

Thrombophilias

Highest Risk

Age >60 and cancer or history of venous thromboembolism

^aRisk factors: obesity, varicose veins, history of deep venous thrombosis or pulmonary embolism, current estrogen, *tamoxifen*, or oral contraceptive use.

Prophylactic Methods

A number of prophylactic methods have been shown to significantly reduce the incidence of deep venous thrombosis, and a few studies have included a large enough patient population to show a reduction in fatal pulmonary emboli. The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patients, and inexpensive.

Low-Dose Heparin

The use of small doses of subcutaneously administered *heparin* for the prevention of deep venous thrombosis and pulmonary embolism is the most widely studied of all prophylactic methods. **More than 25 controlled trials have demonstrated that *heparin* given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively**

is effective in reducing the incidence of deep venous thrombosis. The value of low-dose *heparin* in preventing fatal pulmonary emboli was established by a randomized, controlled, multicenter international trial, which demonstrated a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose *heparin* every 8 hours postoperatively (109). Trials of low-dose *heparin* in gynecologic surgery patients have shown a significant reduction in postoperative deep venous thrombosis.

Although low-dose *heparin* is considered to have no measurable effect on coagulation, most large series have noted an increase in the bleeding complication rate, especially a higher incidence of wound hematoma (110). Although relatively rare, thrombocytopenia is associated with low-dose *heparin* use and has been found in 6% of patients after gynecologic surgery (110). If patients remain on low-dose *heparin* for more than 4 days, it is reasonable to check their platelet count to assess the possibility of *heparin*-induced thrombocytopenia.

Low-Molecular-Weight Heparin

Low-molecular-weight heparins (LMWH) are fragments of *heparin* that vary in size from 4,500 to 6,500 daltons. When compared with unfractionated *heparin*, *LMWH* have more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time and possibly also leading to fewer bleeding complications (111). An increased half-life of 4 hours results in increased bioavailability when compared with unfractionated *heparin*. The increase in half-life of *LMWH* also allows the convenience of once-a-day dosing.

Randomized controlled trials have compared *LMWH* with unfractionated *heparin* in patients undergoing gynecologic surgery. In all studies, there was a similar incidence of deep venous thrombosis (DVT). Bleeding complications were also similar between the unfractionated *heparin* and *LMWH* groups (112). A meta-analysis of general surgery and gynecological surgery patients from 32 trials likewise indicated that daily *LMWH* administration is as effective as unfractionated *heparin* in DVT prophylaxis without any difference in hemorrhagic complications (113).

Mechanical Methods

Stasis in the veins of the legs occurs while the patient is undergoing surgery and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, plus the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative DVT. Prospective studies of the natural history of postoperative DVT have shown that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery (114).

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis.

Elastic Stocking

Controlled studies of graduated pressure stockings are limited but do suggest modest benefit when they are carefully fitted (115). Poorly fitted stockings may be hazardous to some patients who develop a tourniquet effect at the knee or mid thigh (106). Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes. The simplicity of elastic stockings and the absence of significant side effects are probably the two most important reasons that they are often included in routine postoperative care.

External Pneumatic Compression

The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent external compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. Various pneumatic compression devices and leg sleeve designs are available, and the current literature has not demonstrated superiority of one system over another. **Calf compression during and after gynecologic surgery significantly reduces the incidence of DVT on a level similar to that of low-dose *heparin*.** In addition to increasing venous flow and pulsatile emptying of the calf veins, external pneumatic compression also appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant (116).

The duration of postoperative external pneumatic compression has differed in various trials. External pneumatic compression may be effective when used in the operating room and for the first 24 hours postoperatively in patients with benign conditions who will ambulate on the first postoperative day (116,117).

External pneumatic compression used in patients undergoing major surgery for gynecologic malignancy has been found to reduce the incidence of postoperative venous thromboembolic complications by nearly threefold (118), but only if calf compression was applied intraoperatively and for the first 5 postoperative days (119). Patients with gynecologic malignancies may remain at risk for a longer period than general surgical patients because of stasis and hypercoagulable states; therefore, these patients appear to benefit from longer use of external pneumatic compression.

External pneumatic leg compression has no significant side effects or risks and is considered slightly more cost-effective when compared with pharmacologic methods of prophylaxis (120). Of course, compliance in wearing the leg compression while in bed is of utmost importance, and the patient and nursing staff should be educated to the proper regimen for maximum benefit.

Management of Postoperative Deep Venous Thrombosis and Pulmonary Embolism

Because pulmonary embolism is the leading cause of deaths following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens is an essential part of management (105,106,121). In addition, the early recognition of DVT and pulmonary embolism and immediate treatment are critical. Most pulmonary emboli arise from the deep venous system of the leg following gynecologic surgery; the pelvic veins are a known source of fatal pulmonary emboli as well.

The signs and symptoms of DVT of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not actually have

DVT (122). Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities (123). Because of the lack of specificity when signs and symptoms are recognized, additional tests should be performed to establish the diagnosis of DVT.

Diagnosis

Doppler Ultrasound

B-mode duplex Doppler imaging is currently the most common technique for the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity. With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly (124). Compression of the vein with the ultrasound probe tip allows assessment of venous collapsibility; the presence of a thrombus diminishes vein wall collapsibility. It should be recognized that Doppler imaging is less accurate when evaluating the calf and the pelvic veins.

Venography

Although venography has been the standard technique for diagnosis of DVT, other diagnostic studies are accurate when performed by a skilled technologist and, in most patients, may replace the need for routine contrast venography. Venography is moderately uncomfortable, requires the injection of a contrast material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients (125). However, if the results of noninvasive imaging are normal or inconclusive and the clinician remains concerned given clinical symptoms, venography should be performed to obtain a definitive answer.

Magnetic Resonance Venography (MRV)

In addition to having a sensitivity and specificity comparable to venography, MRV may detect thrombi in pelvic veins that are not imaged by venography (126). The primary drawback to MRV is the time involved in examining the lower extremity and pelvis as well as the expense of this technology.

Treatment

Deep Venous Thrombosis

The treatment of postoperative DVT requires the immediate institution of anticoagulant therapy. Treatment may be with either *unfractionated heparin* or *LMWH*, followed by 6 months of oral anticoagulant therapy with *warfarin (Coumadin)*.

Unfractionated Heparin

After venous thromboembolism is diagnosed, *unfractionated heparin* should be initiated to prevent proximal propagation of the thrombus and allow physiological thrombolytic pathways to dissolve the clot. An initial bolus of 80 units per kilogram is given intravenously, followed by a continuous infusion of 1,000 to 2,000 units per hour (18 units/kg/hour). ***Heparin dosage is adjusted to maintain activated partial thromboplastin time (APTT) levels at a therapeutic level 1.5 to 2.5 times the control value.*** Initial APTT should be measured after 6 hours of *heparin* administration and the dose adjusted as necessary. Patients having subtherapeutic APTT levels in the first 24 hours have a risk of recurrent thromboembolism 15 times the risk of patients with appropriate levels. Patients, therefore, should be managed aggressively using intravenous *heparin* to achieve prompt anticoagulation. A weight-based nomogram is helpful in achieving a therapeutic APTT level (Table 20.11) (127). ***Oral anticoagulant (warfarin) administration should be started on the first day of heparin infusion. The international normalized ration (INR) should be monitored daily until a therapeutic level is achieved (2.0–3.0).*** The change in the INR resulting from *warfarin* administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, *heparin* should be administered until the INR has been maintained in a therapeutic range for at least 2 days, confirming proper *warfarin* dose. Intravenous *heparin* may be discontinued in 5 days if an adequate IRN level has been established.

Table 20.11 Heparin Administration for Treatment of Deep Venous Thrombosis or Pulmonary Embolism: Weight-Based Nomogram

<i>Time of Administration</i>	<i>Dose</i>
Initial dose	80-U/kg bolus, then 18 U/kg/h
The APTT^a should be measured every 6 h and the heparin dose adjusted as follows:	
APTT <35 seconds (<1.2 × control)	80-U/kg bolus, then 4 U/kg/h
APTT 35–45 seconds (1.2–1.5 × control)	40-U/kg bolus, then 2 U/kg/h
APTT 46–70 seconds (1.5–2.3 × control)	No change
APTT 71–90 seconds (2.3–3 × control)	Decrease infusion rate by 2 U/kg/h
APTT >90 seconds (>3 × control)	Hold infusion for 1 h, then decrease infusion rate by 3 U/kg/h

^aAPTT, activated partial thromboplastin time.

Reprinted from **Raschke RA, Reilly BM, Guidry JR, et al.** The weight-based heparin dosing nomogram compared with a "standard care" nomogram. *Ann Intern Med* 1993;119:874–881, with permission.

Low-Molecular-Weight Heparin

Two LMWH preparations (*exoxaparin* and *daltaparin*) have been shown to be effective in the treatment of venous thromboembolism and have a cost-effective advantage over intravenous *heparin* in that they may be administered in the outpatient setting.

The dosages used in treatment of thromboembolism are unique and weight-adjusted according to each LMWH preparation. Because LMWH have a minimal effect on APPT, serial laboratory monitoring of these levels is not necessary. Similarly, monitoring of anti-Xa activity (except in difficult cases or those with renal impairment) has not been shown to be of significant benefit in a dose adjustment of

P. 709

LMWH. The increased bioavailability associated with LMWH allows for twice-a-day dosing, potentially making outpatient management for a subset of patients an option. **A meta-analysis involving more than 4,000 patients from 22 trials suggests that LMWH is more effective, safer, and less costly when compared with unfractionated heparin in preventing recurrent thromboembolism (128).**

Pulmonary Embolism

Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. **The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism.** Many times, however, the signs are much more subtle and may be suggested only by a persistent tachycardia or a slight elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest x-ray, electrocardiography, and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by ventilation-perfusion lung scan, or a spiral CT scan of the chest. Unfortunately, a high percentage of lung scans may be interpreted as "indeterminate." In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be performed to document or exclude the presence of a pulmonary embolism.

The treatment of pulmonary embolism is as follows:

- Immediate anticoagulant therapy, identical to that outlined for the treatment of DVT, should be initiated.
- Respiratory support, including oxygen and bronchodilators and an intensive care setting, may be necessary.
- Although massive pulmonary emboli are usually quickly fatal, pulmonary embolectomy has been performed successfully on rare occasions.
- Pulmonary artery catheterization with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.
- Vena cava interruption may be necessary in situations in which anticoagulant therapy is

ineffective in the prevention of rethrombosis and repeated embolization from the lower extremities or pelvis. A vena cava umbrella or filter may be inserted percutaneously above the level of the thrombosis and caudad to the renal veins. In most cases, however, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient's own endogenous thrombolytic mechanisms to lyse the pulmonary embolus.

Management of Medical Problems

Endocrine Disease

The three most frequent endocrine disorders that occur in patients undergoing gynecologic surgery are diabetes mellitus, thyroid disease, and adrenal abnormalities. The pathophysiology of these disorders aids in understanding the effects of surgery on patients with these problems.

Diabetes Mellitus

According to the American Diabetes Association, 9.3 million American women, or 8.7% of all women older than 20 years, suffer from diabetes (129). Approximately 50% of

P.710

individuals with diabetes mellitus (DM) will have surgery during their life (130). Many of these procedures are a direct result of the complications of DM: retinopathy, nephropathy, large- and small-vessel occlusive disease, and coronary artery disease. It is the direct effect of DM on the end organs that determines the risk of surgery rather than the type or duration or the control of the condition itself. Diabetes mellitus is a complicated medical disorder of glucose metabolism that is related to a lack of production of or resistance to *insulin*.

Patients with DM experience exaggerated hyperglycemia during surgery. This hyperglycemia is multifactorial in origin and is secondary to increased catecholamine production, which inhibits pancreatic release of insulin and causes increased insulin resistance at the end organs. Elevations in instrumental hormones, such as cortisol, growth hormone, and glucagon, also enhance gluconeogenesis and glycogenolysis (131). Goals of the preoperative assessment and perioperative management are to ensure metabolic homeostasis

and to anticipate problems arising from pre-existing complications.

Preoperative Risk Assessment

Preoperative risk assessment for diabetes should begin with a review of systems. Nocturia, polyuria, polydipsia, glucosuria, obesity, previous gestational diabetes, ethnicity, and family history are relevant aspects of the history. The current recommendations for establishing a diagnosis of diabetes are as follows (132):

- Polyuria, polydipsia, unexplained weight loss with a random nonfasting glucose of >200 mg/dL, *or*
- Fasting glucose >126 mg/dL, *or*
- Two-hour postprandial 75 g glucose drink with serum glucose >200 mg/dL

Confirmation of the diagnosis requires a second test on a different day.

Preoperative risk assessment in the previously diagnosed individual with diabetes should begin with the knowledge of the patient's routine glucose management strategies, medications, and baseline hemoglobin A_{1c} (133). The presence of end-organ complications of diabetes should also be documented.

Large- and small-vessel arterial occlusive disease is the single most important risk factor in the preoperative setting.

A careful history and physical examination should be performed to determine the presence or absence of coronary artery or cerebral vascular disease (130). When extended surgery is possible, as with surgery for gynecologic cancer, exercise stress testing or dipyridamole-thallium imaging should be considered to rule out occult coronary artery disease. Preoperative and intraoperative administration of beta-blockers should be considered for patients undergoing surgery (134). Assessment of end-organ disease in the retina, kidney, and carotid arteries or evidence of peripheral vascular disease by the presence of foot ulcers should alert the clinician to the presence of small-or

Imaging studies using contrast dye should be avoided and alternative testing should be performed to reduce the incidence of acute tubular necrosis. If a contrast study must be performed, adequate hydration both before and after the procedure is essential, and oral metformin should be withheld for 24 to 48 hours after the procedure.

Preoperative evaluation should include examination of the skin and urine sediment to detect asymptomatic infection. Wound infections, skin infections, pneumonia, and urinary tract infections account for two thirds of the postoperative complications in patients with diabetes (131). There is a known predisposition for patients with DM to have gram-negative and staphylococcal pneumonia as well as an increased incidence of gram-negative and

P.711

group B streptococcal sepsis (135). Seven percent of individuals with diabetes will have postoperative gram-negative sepsis, a rate approximately seven times higher than of the nondiabetic population. These complications occur more often in patients with poor glucose control, probably caused by impaired leukocyte function in the presence of hyperglycemia (136,137). Individuals with DM have an increased risk of wound dehiscence and wound infection, as well as decreased amounts of collagen formation, fibroblast growth, and capillary growth, presumably secondary to the pathophysiology of small-vessel disease (138,139,140). Autonomic neuropathy has been documented in patients with DM, and these autonomic impairments can lead to intraoperative hypotension, cardiac arrhythmias, and sudden death as well as abnormal motility of the esophagus, stomach, and small intestine (131). Peripheral sensory and motor neuropathies may or may not be present. The presence of any manifestations of autonomic neuropathy intraoperatively should prompt close monitoring of the affected organ system in the postoperative period.

The traditional goal for glucose control during surgery is to maintain the glucose level between 150 mg/dL and 200 mg/dL. Perioperative hyperglycemia (greater than 250 mg/dL) is associated with increased susceptibility to infection and poor wound healing. Extreme hyperglycemia predisposes type I DM patients to metabolic acidosis, and surgery should be canceled until normal acid-base balance has been documented. Hyperosmolar hyperglycemic nonketotic states must be recognized before surgery. Electrolyte disturbances, especially those related to sodium and potassium, should be corrected preoperatively. Hypoglycemia should be avoided during the perioperative period.

The history and type of DM are important factors to consider when devising a perioperative management plan. Patients with noninsulin-dependent diabetes (type II) whose condition is controlled with oral hypoglycemic agents or diet are best treated with intravenous fluids containing no dextrose and generally should not be given insulin intraoperatively. Oral administration of hypoglycemic agents should be discontinued approximately 24 hours before the surgery, and hyperglycemic episodes in the perioperative period are treated with sliding-scale regular *insulin* only for blood sugar levels in excess of 250 mg/dL.

Insulin-dependent or type I diabetes poses a more difficult problem. Preoperatively, the goals include avoiding ketoacidosis and hypoglycemia, as well as, to a lesser extent, hyperglycemia. Traditionally, approximately one third to one half of the patient's usual daily dose of NPH insulin (intermediate acting) is given subcutaneously the morning of surgery. An infusion of 5% dextrose is then given intraoperatively and additional regular insulin can be administered in the operating room. Alternatively, a continuous infusion of insulin and glucose in a fixed ratio has been advocated (130).

The patient is much more prone to significant hypoglycemia, however, when a continuous infusion of insulin is given. Because of the severe implications associated with intraoperative hypoglycemia, this method may pose additional risks. There is no single regimen that is clearly superior for the intraoperative management of type I diabetic patients. However, a continuous intravenous *insulin* infusion is indicated for patients with unstable type I diabetes, those who require emergency surgery while in ketoacidosis, and those undergoing long, complex procedures (136). Consultation with endocrine and anesthesia colleagues can be helpful in managing these complex regimens.

Postoperative Management

Postoperative monitoring of patients with DM includes careful monitoring of serum glucose levels.

If an intravenous insulin regimen has been used, blood glucose levels must be checked every 1 to 2 hours. If a sliding-scale insulin administration is to be used, blood glucose should be checked and documented approximately every 6 hours until the patient is eating and stable on her preoperative regimen. The serum glucose level should be maintained at less than 250 mg/dL, and ideally in the "inpatient glycemic 'hot spot'" between 100 and 200 mg/dL (130).

It is essential to prevent the development of severe hypoglycemia or hyperglycemia and the associated complications of diabetic ketoacidosis or a hyperosmolar state. Rigorous perioperative management may obviate some of the infectious and wound-healing complications that are more common in these patients (138). In one study, compulsive control of blood glucose contributed to a decreased overall mortality in myocardial infarction patients (141).

Thyroid Syndromes

Thyroid dysfunction should be suspected in any patient with a history of hyperthyroidism, use of thyroid replacement medication or antithyroid medication, prior thyroid surgery, or radioactive iodine therapy.

Hyperthyroidism

Diffuse toxic goiter (Grave's disease) is the most common cause of hyperthyroidism and results from abnormal stimulation of the thyroid gland by antithyroid antibodies. Any signs or symptoms suggestive of weight loss, tachycardia, atrial fibrillation, goiter, or proptosis should initiate a more extensive laboratory evaluation of thyroid function. Total thyroxin, free T₃, free thyroxin (T₄), and thyroid-stimulating hormone (TSH) tests are useful in diagnosis.

In hyperthyroidism, the free T₄ level will be elevated, and the TSH level will be suppressed (134). A new diagnosis of hyperthyroidism necessitates postponement of elective surgery until adequate treatment with antithyroid medication because of the risk of thyroid storm. **Ideally, an euthyroid state should be maintained for 3 months before elective surgery.** In emergent situations, beta-blockers can be used to counter sympathomimetic drive such as palpitations, diaphoresis, and anxiety. Antithyroid medications such as *propylthiouracil (PTU)* or *radioactive iodine* do not render patients euthyroid quickly enough for urgent surgery. *Radioactive iodine* requires 6 to 18 weeks to establish a euthyroid state (134). When thyroid dysfunction is corrected and maintained for several months, elective surgery can proceed without additional perioperative monitoring. Antithyroid medications should be resumed with return of bowel function. If a prolonged delay in resumption of oral intake is encountered, *PTU* and *methimazole* can

be administered rectally (142). **When time does not permit establishment of a euthyroid state preoperatively, oral administration of PTU and a beta-blocker can be implemented for 2 weeks before surgery, and with careful monitoring, optimal results can be achieved** (140). Alternatively, oral *beta-blockers*, *glucocorticoids*, and *sodium iopanoate* can be used for 5 days, followed by surgery on the day 6 (142). In the emergent setting, however, close monitoring of the patient for tachycardia, arrhythmias, and hypertension is necessary. *Beta-blockers* can control these symptoms until definitive therapy can be initiated after recovery from surgery. Any signs suggestive of the development of thyroid storm—including hemodynamic instability, tachycardia, arrhythmias, hyperreflexia, diarrhea, fever, delirium, or congestive heart failure—mandate transfer to an intensive care setting for optimal monitoring and management in consultation with a medical endocrinologist. Such thyroid instability can be triggered by underlying infection, which requires diagnosis and treatment to facilitate management of this medical emergency. The mortality rate from thyroid storm has been reported to be between 10% and 75% (142). Treatment of thyroid storm consists of *beta-blockers*, *thioamides*, *iodine*, *iodinated contrast agents*, and *corticosteroids* (131). *Aspirin* should not be given for fever in the patient with thyroid storm because it may interfere with the protein binding of T₄ and T₃, resulting in increased free serum concentrations (131).

Hypothyroidism

The incidence of hypothyroidism is approximately 1% in the adult population, and 5% in adults older than 50 years (134). **In women older than 60 years, the incidence of hypothyroidism may approach 6%** (143). **Hypothyroidism is 10 times more common in women than in men** (134). Many such cases are secondary to previous antithyroid

P.713

therapy (*radioactive iodine* or thyroidectomy) for hyperthyroidism. The most common primary cause of hypothyroidism is Hashimoto's thyroiditis, an autoimmune condition (134). A history of lethargy, cold intolerance, lassitude, weight gain, fluid retention, constipation, dry skin, hoarseness, periorbital edema, and brittle hair can be indicative of inadequate thyroid function. In this setting, physical findings of increased relaxation phase of deep tendon reflexes, cardiomegaly, pleural or pericardial effusions, or peripheral edema should stimulate further investigation of thyroid function by assessment of TSH and free T₄ levels.

Hypothyroidism decreases cardiac output by 30% to 50% as a result of decreased stroke volume and heart rate (144). Hyponatremia may also be associated with hypothyroidism because of the inability of the kidney to excrete water (144). When elective surgery is planned for severely hypothyroid patients, surgery should be postponed until thyroid replacement therapy has been initiated (134). In patients with mild or moderate hypothyroidism, the delay of surgery is controversial (134).

For young patients with mild to moderate hypothyroidism, a starting dose of 1.6 µg/kg of thyroid hormone replacement can be given. In elderly patients, *thyroxin* dosage (0.025 mg once a day) should be doubled every 2 weeks until the patient is taking a dose of 0.15 mg daily (143). **Dosage levels can ultimately be titrated against TSH levels.** In severely hypothyroid patients requiring urgent or emergent surgery, intravenous T₃ or T₄ may be given, along with intravenous *corticosteroids* to avoid consequences of unrecognized adrenal insufficiency (131,134).

In the immediate postoperative setting, T₄ therapy can be held for 5 to 7 days while waiting for return of bowel function because the half-life of circulating T₄ is approximately 5 to 9 days (131). If more than 5 to 7 days of decreased bowel function are expected, T₄ can be given by the intramuscular or intravenous route at approximately 80% of the oral dose (143,144).

Adrenal Insufficiency

Adrenal insufficiency may result in catastrophic postoperative complications, including death. The most common cause of adrenal insufficiency in the surgical patient is secondary to the exogenous use of *corticosteroids*. Therefore, the physician should ascertain whether a patient has used exogenous steroids for asthma, malignant conditions, arthritis, or irritable bowel syndrome. The type of steroid use, the route, the dose, the duration, and the temporal relationship to the timing of the surgical procedure must be determined. The type of surgical procedure and its associated stress should also be taken into consideration. The use of high doses of exogenous steroids for prolonged periods can cause circulatory collapse, and they have adverse effects on wound healing and immunocompetence.

The daily replacement dose of cortisol is approximately 5 to 7.5 mg of prednisone. Suppression of the hypothalamic–pituitary–adrenal axis by

exogenous steroids for more than a few weeks may produce relative adrenal insufficiency. When systemic steroids are used for longer periods, adrenal insufficiency may persist for up to 1 year. Short courses of low-dose oral steroids (less than 5 mg of *prednisone* in a single morning dose for any duration of time, alternate-day dosing of short-acting glucocorticoids, and any dose of corticosteroids given for less than 3 weeks) are not thought to cause clinically significant suppression of the hypothalamic–pituitary–adrenal axis (131).

If either the dose or duration of glucocorticoid administration exceeds the preceding regimen, biochemical tests have been recommended to preoperatively evaluate the function of the adrenal gland. The easiest and safest test to assess hypothalamic–pituitary–adrenal function is the cosyntropin stimulation test. *Cosyntropin*, a synthetic analog of adrenocorticotropic hormone, is given in a dose of 250 µg (0.25 mg) intravenously, and a blood sample is collected 30 minutes after the injection and assayed for plasma cortisol. A plasma cortisol value of greater than 18 to 20 µg/dL indicates adequate adrenal function (134). If the history regarding exogenous steroid use is unclear, the cosyntropin stimulation test should

P.714

be considered as a preoperative test to determine if the patient will need perioperative glucocorticoid coverage. The amount of glucocorticoid replacement should be equivalent to the normal physiologic response to surgical stress (Table 20.12) (145).

Table 20.12 Guidelines for Adrenal Supplementation Therapy^a

<i>Medical or Surgical Stress</i>	<i>Corticosteroid Dosage</i>
Minor	
Inguinal hernia repair	25 mg of hydrocortisone or 5 mg of methylprednisolone IV on day of procedure only
Colonoscopy	
Mild febrile illness	
Mild-moderate nausea/vomiting	
Gastroenteritis	
Moderate	

Open cholecystectomy Hemicolectomy Significant febrile illness Pneumonia Severe gastroenteritis	50–75 mg of hydrocortisone or 10–15 mg of <i>methylprednisolone</i> IV on day of procedure Taper quickly over 1–2 days to usual dose
Severe	
Major cardiothoracic surgery Whipple procedure Liver resection Pancreatitis	100–150 mg of <i>hydrocortisone</i> or 20–30 mg of <i>methylprednisolone</i> IV on day of procedure Rapid taper to usual dose over next 1–2 days
Critically Ill	
Sepsis-induced hypotension or shock	50–100 mg of <i>hydrocortisone</i> IV every 6–8 h or 0.18 mg/kg/h as a continuous infusion + 50 µg/d of <i>fludrocortisone</i> until shock resolved. May take several days to a week or more, then gradually taper, following vital signs and serum sodium.
IV, intravenously.	
<p>^aPatients receiving 5 mg/d or less of <i>prednisone</i> should receive their normal daily replacement but do not require supplementation. Patients who receive greater than 5 mg/d of <i>prednisone</i> should receive the above therapy in addition to their maintenance therapy.</p> <p>Reprinted from Coursin DB, Wood KE. Corticosteroid supplementation for adrenal insufficiency. <i>JAMA</i> 2002;287:236–240, with permission.</p>	

For minor surgical stress, such as colonoscopy, the glucocorticoid target is approximately 25 mg of *hydrocortisone* equivalent on the day of the procedure (145). For moderate surgical stress, for example, open cholecystectomy, the glucocorticoid target is 50 to 75 mg of *hydrocortisone* equivalent on the day of the procedure and tapered quickly for 1 to 2 days (145). The patient should receive her normal daily dose preoperatively, followed by 50 mg of *hydrocortisone* intravenously administered intraoperatively. For major surgical stress, such as liver resection, the glucocorticoid target range is 100 to 150 mg *hydrocortisone* equivalent on the day of the procedure, tapering rapidly over the next 1 to 2 days to the usual dosage (145). The patient should receive her normal daily dose preoperatively.

Administration of high-dose steroids should be stopped as soon as possible postoperatively because they can inhibit wound healing and promote infection. Hypertension and glucose intolerance also can develop. When a prolonged or involved procedure is performed and longer steroid use is necessary, careful tapering may be required. The previously recommended approach was to halve the dose of *hydrocortisone* on a daily basis until a dose of 25 mg is reached. Eliminating one daily dose each day until the drug has been stopped has been considered the safest method of withdrawal; however, no

P.715

consensus on the timing or duration of steroid tapering currently exists. Addison's disease is uncommon but should be considered in the differential diagnosis if the patient develops perioperative hypotension after steroids are withdrawn. In addition to blood and isotonic fluid replacement, a "stress" dose of steroids should be given if adrenal insufficiency is suspected and sepsis and hypovolemia have been excluded.

Cardiovascular Diseases

The incidence of perioperative cardiovascular complications has decreased markedly as a result of improvements in preoperative detection of high-risk patients, preoperative preparation, and surgical and anesthetic techniques (146).

Preoperative Evaluation

The goal of a preoperative cardiac evaluation is to determine the presence of heart disease, its severity, and the potential risk to the patient during the perioperative period. Every patient should be questioned about symptoms of cardiac disease including chest pain, dyspnea on exertion, peripheral edema, wheezing, syncope, claudication, or palpitations. Patients with a history of cardiac disease should be evaluated for worsening of symptoms, which indicates progressive or poorly controlled disease. Records of previous treatment should be obtained. Prescriptions for antihypertensive, anticoagulant, antiarrhythmic, antilipid, or antianginal medications may be the only indication of cardiac problems. In patients without known heart disease, the presence of DM, hyperlipidemia, hypertension, tobacco use, or a family history of heart disease identifies patients at higher risk for heart disease who should be more carefully screened.

On physical examination, the presence of findings such as hypertension, jugular venous distention, laterally displaced point of maximum impulse, irregular pulse, third heart sound, pulmonary rales, heart murmurs, peripheral edema, or vascular bruits should prompt a more complete evaluation. Laboratory evaluation of patients with known or suspected heart disease should include a blood count and serum chemistry analysis. Patients with heart disease tolerate anemia poorly. Serum sodium and potassium levels are particularly important in patients taking diuretics and digitalis. Blood urea nitrogen and creatinine values provide information on renal function and hydration status. Assessment of blood glucose levels may detect undiagnosed DM. Chest radiography and electrocardiography are mandatory as part of the preoperative evaluation, and the results may be particularly helpful when compared with those of previous studies.

Coronary Artery Disease

Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. In an adult population without a prior history of myocardial infarction, the incidence of myocardial infarction following surgery is 0.1% to 0.7% (147). In patients who have had a prior myocardial infarction, however, the reinfarction rate is 2.8% to 7% (148). The risk of reinfarction is inversely proportional to the length of time between infarction and surgery. At 3 months or less, the risk of reinfarction is 5.7%, and from 3 to 6 months, the rate falls to 2.3%. Six months after myocardial infarction, the reinfarction rate is 1.5% (147). Fortunately, careful perioperative management can lower the reinfarction rate even in patients who have had recent infarctions. Perioperative myocardial infarction is associated with a mortality rate of 26% to 70% (149).

Because of the high mortality and morbidity associated with perioperative myocardial infarction, much effort has been made to predict perioperative cardiac risk. **A prospective evaluation of preoperative cardiac risk factors using a multivariate analysis identified independent cardiac risk factors for patients undergoing noncardiac surgery (149).** Using these factors, a cardiac risk index was created that placed a patient in one of four risk classes. This cardiac risk index was then further modified and validated prospectively, resulting in the most current tool for clinical risk assessment in nonemergent major

noncardiac surgery, the Revised Cardiac Risk Index (150). Risk factors include high-risk surgical procedures, history of ischemic heart disease, history of congestive heart failure, history of transient ischemic attack or stroke, preoperative insulin therapy, and preoperative serum creatinine levels greater than 2.0 mg/dL. Depending on the number of risk factors, the risk of major cardiac events (myocardial infarction, cardiac arrest, pulmonary edema, and complete heart block) range from 0.5% to 9.1% (Table 20.13).

Table 20.13 Major Cardiac Event Rates by the Revised Cardiac Risk Index

Class	(number of risk factors)	Events/Patient	Event Rate% (95% CI)
I	(0)	2/488	0.4 (0.05, 1.5)
II	(1)	5/567	0.9 (0.3, 2.1)
III	(2)	17/258	6.6 (3.9, 10.3)
IV	(3)	12/109	11.0 (5.8, 18.4)

CI, confidence interval.

Adapted from **Lee TH, Marcantonio ER, Mangione CM, et al.** Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation* 1999;100:1043–1049.

Risk assessment is stratified into three major categories: (i) clinical predictors, (ii) functional capacity, and (iii) surgery-specific risk (151). Clinical predictors of increased perioperative cardiac risk are divided into major, intermediate, and minor factors (Table 20.14). The patient's functional status is assessed by a thorough history (Table 20.15), and self-reported exercise tolerance can be used to predict perioperative risk (152). **Patients with**

P.717

poor functional capacity have higher perioperative cardiac risk and should be considered for preoperative cardiac function testing (148). Surgery-specific risk is subdivided into high-risk procedures (emergent major operations, aortic and vascular procedures, and prolonged surgical procedures associated with large fluid shifts or blood loss), intermediate-risk procedures (other intraperitoneal operations),

and low-risk procedures (endoscopic surgery, breast surgery, and superficial procedures).

Table 20.14 Clinical Predictors of Increased Perioperative Cardiovascular Risk

Major

Unstable coronary syndromes (acute or recent MI, unstable or severe angina)
 Decompensated congestive heart failure
 Significant arrhythmias (high-grade AV block, symptomatic ventricular arrhythmias, supraventricular arrhythmias with uncontrolled ventricular rate)
 Severe valvular disease

Intermediate

Mild angina
 Prior myocardial infarction (more than 1 month before planned surgery)
 Compensated or prior congestive heart failure
 Diabetes mellitus
 Renal insufficiency

Minor

Advanced age
 Abnormal ECG (LVH, LBBB, ST-T abnormalities)
 Rhythm other than sinus
 Low functional capacity
 History of stroke
 Uncontrolled systemic hypertension

MI, myocardial infarction; AV, atrioventricular; ECG, electrocardiogram; LVH, left ventricular hypertrophy; LBBB, left bundle branch block.

Adapted from **Eagle KA, Berger PB, Calkins H, et al.** ACC/AHA guideline update for perioperative cardiovascular evaluation for noncardiac surgery: executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2002; 105: 1257–1267.

Table 20.15 Functional Capacity Assessment from Clinical History

Excellent

Carry 24 lb up eight steps
 Carry objects that weigh 80 lb
 Outdoor work (shovel snow, spade soil)
 Recreation (ski, basketball, squash, handball, jog or walk 5 mph)

Moderate

Have sexual intercourse without stopping
 Walk at 4 mph on ground level
 Outdoor work (garden, rake, weed)
 Recreation (roller-skate, dance)

Poor

Shower and dress without stopping
 Basic housework
 Walk 2.5 mph on level ground
 Recreation (golf, bowl)

Adapted from **Mehta RH, Bossone E, Eagle KA**. Perioperative cardiac risk assessment for noncardiac surgery. *Cardiologia* 1999;44:409–418.

In an effort to quantitate preoperative cardiac risk, several tests have been used to assess cardiovascular function. **Exercise stress testing before surgery can identify patients who have ischemic heart disease not apparent at rest.** These patients have been shown to be at increased risk of developing cardiac complications in the perioperative period. In a study of patients undergoing peripheral vascular surgery, a high-risk group of patients was identified who had ischemic electrocardiographic changes when they exercised to less than 75% of their maximal predicted heart rate. In this group, the incidence of perioperative myocardial infarction was 25%, and the overall cardiac mortality rate was 18.5%. Conversely, no perioperative infarctions occurred in patients who were able to exercise to more than 75% of their maximal predicted heart rate and who had no electrocardiographic evidence of ischemia (153). However, the prognostic value of stress testing was not supported in another prospective study that found that only an abnormal preoperative resting electrocardiography result was an independent risk factor (154). The exercise stress test must be selectively applied to a high-risk population because its predictive

value depends on the prevalence of the disease. Therefore, it is not prudent to screen all patients preoperatively; it is preferable to rely on a careful history to identify patients with symptoms of cardiac disease for whom the test would be most predictive.

Exercise stress testing is limited in some patients who cannot exercise because of musculoskeletal disease, pulmonary disease, or severe cardiac disease. *Dipyridamole-thallium scanning* may be used to overcome the limitations of exercise stress testing. This study has a high degree of sensitivity and specificity, and it relies on the ability of *dipyridamole* to dilate normal coronary arteries but not stenotic vessels. Normally perfused myocardium readily takes up *thallium* when it is given intravenously. Conversely, hypoperfused myocardium does not show good uptake of *thallium* when scanned 5 minutes after injection. Reperfusion and uptake of *thallium* 3 hours after injection identify viable but high-risk

P.718

myocardium. Old infarctions are identified as areas without uptake. Several studies have shown a risk of perioperative myocardial infarction in patients with areas of reperfusion of *thallium* uptake ranging from 20% to 33% (155,156). The *dipyridamole-thallium* scan is applicable to patients who are unable to exercise because it uses a medically induced "stress."

Dobutamine stress echocardiography is another test to evaluate cardiac risk in patients who are unable to exercise. This method identifies regional cardiac wall motion abnormalities after *dobutamine* infusion to identify patients at high risk for cardiac events. Positive and negative predictive values are similar to those of *dipyridamole-thallium* testing (157,158). Coronary angiography should be considered only in patients who have an indication for angiography independent of the planned surgery, such as patients with acute coronary syndromes, unstable angina, angina refractory to medical therapy, or high-risk results on noninvasive testing.

Preoperative testing should be used discriminately in intermediate-risk patients. Controversy exists regarding the accuracy of these tests to provide prognostic information beyond what is obtained from clinical risk stratification for nonvascular procedures. Diagnostic testing should not lead to unnecessary additional testing or harmful delays in surgery. **The American College of Cardiology and the American Heart Association present an updated detailed algorithm that incorporates risk-factor stratification to guide clinicians to proceed directly to surgery, obtain noninvasive testing, consider coronary angiography, or consider delay of surgery and risk-factor modification** (151).

It is rare for patients who are younger than 50 years and who do not have diabetes, hypertension, hypercholesterolemia, or coronary artery disease to suffer a perioperative myocardial infarction. However, patients with coronary artery disease are at increased risk of myocardial infarction in the postoperative period. Prevention, early recognition, and treatment are important because myocardial infarctions that occur in the postoperative period have mortality rates of approximately 50% and are more lethal than those that are not associated with surgery.

Nearly two thirds of postoperative myocardial infarctions occur during the first 3 days postoperatively. Although the pathophysiologic factors are complex, the causes of postoperative myocardial ischemia and infarction are related to decreased myocardial oxygen supply coupled with increased myocardial oxygen requirements. In postoperative patients, conditions that decrease oxygen supply to the myocardium include tachycardia, increased preload, hypotension, anemia, and hypoxia (159). Conditions that increase myocardial oxygen consumption are tachycardia, increased preload, increased afterload, and increased contractility. Tachycardia and increased preload are the most important causes of ischemia, because both conditions decrease oxygen supply to the myocardium while simultaneously increasing myocardial oxygen demand. Tachycardia decreases the diastolic time, which, when the coronary arteries are perfused, decreases the volume of oxygen available to the myocardium. Increased preload increases the pressure exerted by the myocardial wall on the arterioles within it, thus decreasing myocardial blood flow.

Other factors associated with perioperative myocardial ischemia include physiologic responses to the stress of intubation, intravenous or intra-arterial line placement, emergence from anesthesia, pain, and anxiety. This stress results in catecholamine stimulation of the cardiovascular system, resulting in increased heart rate, blood pressure, and contractility, which may induce or worsen myocardial ischemia. Loss of intravascular volume because of third spacing of fluids or postoperative hemorrhage can also induce ischemia.

Postoperative myocardial infarction is often difficult to diagnose. Chest pain, which is present in 90% of nonsurgical patients with myocardial infarction, may be present in only

50% of patients with postoperative infarction because myocardial pain may be masked by coexisting surgical pain and the use of analgesia (147). Thus, it is important to maintain a high

level of suspicion for postoperative infarction in patients with coronary artery disease. The presence of arrhythmia, congestive heart failure, hypotension, dyspnea, or elevations of pulmonary artery pressure may indicate infarction and should prompt a thorough cardiac investigation and electrocardiographic monitoring. **Measurement of creatinine phosphokinase myocardial band (CPK-MB) isoenzyme and troponin T levels are the most sensitive and specific indicators of myocardial infarction, and assessments should be obtained for all patients suspected of myocardial infarction.**

Despite the high incidence of silent myocardial infarction, routine use of postoperative electrocardiography (ECG) for all patients with cardiovascular disease is controversial. Many patients will exhibit P-wave changes that spontaneously resolve and do not represent ischemia or infarction. Conversely, patients with proven myocardial infarctions may show few, if any, ECG abnormalities. Currently, the American College of Cardiology and American Heart Association recommend postoperative surveillance of perioperative myocardial infarction in patients with known or suspected coronary artery disease (151). A recent study of patients older than 50 years undergoing major noncardiac surgery found that immediate postoperative ECG may be a valuable tool in patients who have lower risks when undergoing major noncardiac surgery (160). However, this is a preliminary study, and further investigation is warranted. If routine screening of asymptomatic patients is desired, ECG should be performed 24 hours following surgery because significant ECG changes that occur immediately postoperatively will persist for 24 hours. It is prudent to continue serial ECG assessments for at least 3 days postoperatively.

Postoperative management of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium as well as decreasing myocardial oxygen utilization. Most patients benefit from supplemental oxygen in the postoperative period, although special care should be exercised in patients with COPD. Oxygenation can easily be monitored by pulse oximetry. Anemia is detrimental because of loss of oxygen-carrying capacity as well as resultant tachycardia and should, therefore, be carefully corrected in high-risk patients.

Patients with coronary artery disease may benefit from pharmacologic control of hyperadrenergic states that result from increased postoperative catecholamine production. Beta-blockers decrease heart rate, myocardial contractility, and systemic blood pressure, all of which are increased by adrenergic stimulation. Perioperative

use of β_1 selective beta-blocker has been shown to significantly reduce perioperative ischemia, myocardial infarction, and overall mortality caused by cardiac death and congestive heart failure in the perioperative period (161,162,163). Perioperative beta-blocker therapy is recommended for patients with at least two of the following minor risk factors: age 65 years or older, hypertension, current smoker, serum cholesterol at least 240 mg/dL, or DM not requiring *insulin* therapy (162). Therapy also is recommended for patients having any one of the risk factors defined by the Revised Cardiac Risk Index (150). The timing and optimal duration of beta-blocker therapy remains an area of uncertainty. Current evidence suggests initiating therapy at least 1 week before surgery and continuing throughout the hospitalization. For patients receiving beta-blockade therapy before surgery, therapy should be continued in the perioperative period because abrupt withdrawal results in a rebound hyperadrenergic state.

Although prophylactic nitrates have been used in the perioperative period for many years, this practice remains controversial. *Nitroglycerin* enhances blood flow to ischemic areas, increases collateral flow, increases myocardial oxygenation, and reduces angina (164,165,166,167). The route of administration, dosage, and duration of therapy are controversial; thus, perioperative treatment with nitrates should be initiated in consultation with a cardiologist. Likewise, calcium-channel blockers have not proved useful in the prophylaxis of perioperative myocardial ischemia (168).

Congestive Heart Failure

Patients with congestive heart failure (CHF) face a substantially increased risk of myocardial infarction during and after surgery (149). The postoperative development of pulmonary edema is a grave prognostic sign and results in death in a high percentage of patients (169). Because patients with heart failure at the time of surgery are significantly more likely to develop pulmonary edema perioperatively, every effort should be made to diagnose and treat CHF before surgery (170). The signs and symptoms of CHF are listed in Table 20.16 and should be assessed based on preoperative history and physical examination. Patients who are able to perform usual daily activities without developing CHF are at limited risk of perioperative heart failure.

Table 20.16 Signs and Symptoms of Congestive Heart Failure

- | |
|---|
| 1. Presence of an S ₃ gallop |
| 2. Jugular venous distention |
| 3. Lateral shift of the point of maximal impulse |
| 4. Lower-extremity edema |
| 5. Basilar rales |
| 6. Increased voltage on electrocardiogram |
| 7. Evidence of pulmonary edema or cardiac enlargement on chest radiograph |
| 8. Tachycardia |

To prevent severe postoperative complications, CHF must be corrected

preoperatively. Treatment usually relies on aggressive diuretic therapy, although care must be taken to avoid dehydration, which may result in hypotension during the induction of anesthesia. Hypokalemia can result from diuretic therapy and is especially deleterious to patients who are also taking digitalis. In addition to diuretics and *digitalis*, treatment often includes the use of preload- and afterload-reducing agents. Optimal use of these drugs and correction of CHF may be aided by consultation with a cardiologist. In general, it is preferable to continue the usual regimen of cardioactive drugs throughout the perioperative period.

Postoperative CHF results most frequently from excessive administration of intravenous fluids and blood products.

Other common postoperative causes are myocardial infarction, systemic infection, pulmonary embolism, and cardiac arrhythmias. The cause of postoperative heart failure must be diagnosed because, to be successful, treatment should be directed simultaneously to the underlying cause. Postoperative diagnosis of CHF is often more difficult than preoperative diagnosis because the signs and symptoms of CHF are not specific and may result from other causes. The most reliable method of detecting CHF is chest radiography, in which the presence of cardiomegaly or evidence of pulmonary edema is a helpful diagnostic feature.

Acute postoperative CHF frequently manifests as pulmonary edema. Treatment of

pulmonary edema may include the use of intravenous *furosemide*, supplemental oxygen, *morphine sulfate*, and elevation of the head of the bed. Intravenous *aminophylline* may be useful if cardiogenic asthma is present. Electrocardiography, in addition to laboratory evaluation, including arterial blood gas, serum electrolyte, and renal function chemistry measurements, should be obtained expediently. If the patient's condition does not improve rapidly, she should be transferred to an intensive care unit.

Arrhythmias

Nearly all arrhythmias found in otherwise healthy patients are asymptomatic and of limited consequence. In patients with underlying cardiac disease, however, even

P.721

brief episodes of arrhythmias may result in significant cardiac morbidity and mortality.

Preoperative evaluation of arrhythmias by a cardiologist and anesthesiologist is important because many anesthetic agents as well as surgical stress contribute to the development or worsening of arrhythmias. In patients undergoing continuous electrocardiographic monitoring during surgery, a 60% incidence of arrhythmias, excluding sinus tachycardia, has been reported (171). **Patients with heart disease have an increased risk of arrhythmias, most commonly ventricular arrhythmias** (171). Conversely, patients without cardiac disease are more likely to develop supraventricular arrhythmias during surgery. Patients taking antiarrhythmic medications before surgery should continue taking those drugs during the perioperative period. Initiation of antiarrhythmic medications is rarely indicated preoperatively, but consultation with a cardiologist is recommended for patients in whom arrhythmias are detected before surgery.

Patients with first-degree atrioventricular (AV) block or asymptomatic Mobitz I (Wenckebach) second-degree AV block require no preoperative therapy. Conversely, a pacemaker is appropriate in patients with symptomatic Mobitz II second- or third-degree AV block before elective surgery (172). In emergency situations, a pacing pulmonary artery catheter can be used. Before performing surgery on patients with a permanent pacemaker, the type and location of the pacemaker should be determined because electrocautery units may interfere with demand-type pacemakers (173). **When performing gynecologic surgery on patients with pacemakers, it is preferable to place the electrocautery unit ground plate on the leg**

to minimize interference. In patients with a demand pacemaker in place, the pacemaker should be converted preoperatively to the fixed-rate mode.

Surgery is not contraindicated in patients with bundle branch blocks or hemiblocks. Complete heart block rarely develops during noncardiac surgical procedures in patients with conduction system disease (174,175,176). However, the presence of a left bundle branch block may indicate the presence of aortic stenosis, which can increase surgical mortality if it is severe.

Valvular Heart Disease

Although there are many forms of valvular heart disease, primarily two types—aortic and mitral stenosis—are associated with significantly increased operative risk (177). Patients with significant aortic stenosis appear to be at greatest risk, which is further increased in the presence of atrial fibrillation, congestive heart failure, or coronary artery disease. Significant stenosis of aortic or mitral valves should be repaired before elective gynecologic surgery (148).

Severe valvular heart disease usually is evident during physical exertion. Common findings in such patients are listed in Table 20.17. The classic history presented by patients with severe aortic stenosis includes exercise dyspnea, angina, and syncope, whereas symptoms of mitral stenosis are paroxysmal and effort dyspnea, hemoptysis, and orthopnea. Most patients have a remote history of rheumatic fever. Severe stenosis of either valve is considered to be a valvular area of less than 1 cm², and diagnosis can be confirmed by echocardiography or cardiac catheterization.

Table 20.17 Signs and Symptoms of Valvular Heart Disease

Aortic stenosis

1. Systolic murmur at right sternal border, which radiates into carotids
2. Decreased systolic blood pressure
3. Apical heave
4. Chest radiograph with calcified aortic ring, left ventricular enlargement
5. Electrocardiogram with high R waves, depressed T waves in lead I, and precordial leads

Mitral stenosis

1. Precordial heave
2. Diastolic murmur at apex
3. Mitral opening snap
4. Suffused face and lips
5. Chest radiograph with left atrial dilation
6. Electrocardiogram with large P waves and right axis deviation

Patients with valvular abnormalities have been subdivided by the American Heart Association into risk groups for the development of subacute bacterial endocarditis following surgery (61). Patients with prosthetic valves are classified as high risk, whereas patients with mitral valve prolapse with regurgitation, history of rheumatic heart disease, or bicuspid aortic valve are considered at moderate risk. **Patients in both high- and moderate-risk groups should receive prophylactic antibiotics immediately preoperatively to prevent subacute bacterial endocarditis** (see Table 20.7).

P.722

Patients with aortic and mitral stenosis tolerate sinus tachycardia and other tachyarrhythmias poorly. In patients with aortic stenosis, sufficient levels of *digitalis* should be provided to correct preoperative tachyarrhythmias, and *propranolol* may be used to control sinus tachycardia. Patients with mitral valve stenosis often have atrial fibrillation and, if present, *digitalis* should be used to reduce rapid ventricular response.

Patients with mechanical heart valves usually tolerate surgery well (178). These patients should receive antibiotic prophylaxis (see Table 20.7), and anticoagulant therapy should be discontinued during the perioperative period. If the patient is taking *aspirin* therapy, it should be discontinued 1 week before the procedure and restarted as soon as it is considered safe by

the surgeon. Usually, *warfarin* (*Coumadin*) is withheld 72 hours before surgery, and anticoagulation is obtained by intravenous administration of *heparin* once the INR falls below 2.0 (179,180). *Heparin* is discontinued 6 to 8 hours before surgery and resumed when the risk of bleeding is low and continued until the patient is returned to *warfarin* maintenance therapy (180,181). Alternatively, *warfarin* can be stopped 72 hours before the procedure and restarted within 24 hours of the procedure (182). **The American College of Cardiology and American Heart Association Guidelines recommend perioperative heparinization in patients who have more thrombogenic valves, recent thrombosis, or embolus (arbitrarily within 1 year); those with more than three of the following risk factors: atrial fibrillation, previous thromboembolism, hypercoagulable condition, and mechanical prosthesis; or those with one risk factor and a mechanical valve in the mitral position** (180). Both methods of management have essentially no risk of thromboembolic complications and bleeding complication rates of approximately 15%.

In the postoperative period, patients with mitral stenosis should be carefully monitored for pulmonary edema because they may not be able to compensate for the amount of intravenous fluid administered during surgery. Patients with mitral stenosis also frequently have pulmonary hypertension and decreased airway compliance. Therefore, they may require more pulmonary support and therapy postoperatively, including prolonged mechanical ventilation.

For patients with significant aortic stenosis, it is imperative that a sinus rhythm be maintained during the postoperative period. Even sinus tachycardia can be deleterious

 P.723

because it shortens the diastolic time. Bradycardia less than 45 beats per minute should be treated with *atropine*. Supraventricular dysrhythmias may be controlled with *verapamil* or direct-current cardioversion. Particular attention should be provided to the maintenance of proper fluid status, digoxin levels, electrolyte levels, and blood replacement.

Hypertension

Patients with controlled essential hypertension have no increased risk of perioperative cardiac morbidity or mortality (170). However, patients with concomitant heart disease are at elevated risk and should be completely evaluated by a cardiologist preoperatively. Laboratory studies should include an ECG, chest radiography,

blood count, urinalysis, and serum electrolytes and creatinine measurement.

Antihypertensive medications should be continued perioperatively. Of note, beta-blockers should be continued, parenterally if necessary, to avoid rebound tachycardia, hypercontractility, and hypertension.

Patients with diastolic pressures higher than 110 mm Hg or systolic pressures higher than 180 mm Hg should receive medication to control their hypertension before surgery. Chronically hypertensive patients are very susceptible to intraoperative hypotension because of impaired autoregulation of blood flow to the brain and, therefore, require a higher mean arterial pressure to maintain adequate perfusion (183). Conversely, during induction of anesthesia, episodes of hypertension occur, and such episodes are seen more frequently in patients with baseline hypertension.

Postoperative hypertension is usually treated parenterally because gastrointestinal absorption may be diminished, and transdermal absorption can be erratic in patients who are cold and rewarming. Commonly used parenteral antihypertensives are listed in Table 20.18.

Table 20.18 Common Parenteral Antihypertensives

<i>Drug</i>	<i>Route</i>	<i>Initial Dose</i>	<i>Onset</i>	<i>Duration</i>	<i>Side Effects</i>
<i>Nitroprusside</i>	IV infusion	0.5 µg/min	Immediate	2–5 min	Tachycardia, nausea
<i>Labetalol</i>	IV infusion	20 mg	5–10 min	4 h	Bronchospasm, dizziness, nausea
<i>Esmolol</i>	IV infusion	50 µg/min	2 h	9 min	Headache, somnolence, dizziness, hypotension
<i>Nifedipine</i>	Sublingual	10 mg	5 min	2 min	Hypotension, headache, dizziness, nausea, peripheral edema
<i>Verapamil</i>	IV infusion	5–10 mg	3–5 min	2–5 h	Nausea, headache, hypotension, dizziness, pulmonary edema
IV, intravenous.					

Hemodynamic Monitoring

Hemodynamic monitoring has become integral to the perioperative management of patients

with cardiovascular and pulmonary disease. The major impetus for this advancement resides in the need for the quantitative estimate of cardiac function, resulting in the development of bedside pulmonary artery catheterization. The impact of monitoring of cardiac function is demonstrated by the significant reduction of myocardial infarctions in high-risk patients who are aggressively monitored for 72 to 96 hours postoperatively (147).

Before the development of the pulmonary artery catheter, central venous pressure (CVP) measurement was used to assess intravascular volume status and cardiac function. To measure the CVP, a catheter is placed in the central venous system, most frequently the superior vena cava. A water manometer or a calibrated pressure transducer is connected to the CVP line, thus allowing an estimation of right atrial pressure to be obtained. Right atrial pressure is determined by the balance between cardiac output and venous return.

P.724

Cardiac output is determined by heart rate, myocardial contractility, preload, and afterload. Thus, if the pulmonary vascularity and left ventricular function are normal, the CVP accurately reflects the left ventricular end-diastolic pressure (LVEDP). The LVEDP reflects cardiac output or systemic perfusion and has been considered the standard estimator of left ventricular pump function. Venous return is determined primarily by the mean systemic pressure, which propels blood toward the heart, balanced against resistance to venous return, which acts in the opposite direction. Thus, if right ventricular function is normal, the CVP accurately reflects intravascular volume.

Left and right ventricular function is frequently abnormal or discordant; therefore, the relationship of CVP to cardiac function and to intravascular volume is not maintained. When this occurs, measurement of pulmonary artery occlusion pressure is required to accurately assess volume status and cardiovascular function. The use of a pulmonary artery catheter also allows detection of changes in cardiovascular function with more sensitivity and rapidity than clinical observation.

The balloon-tipped pulmonary artery catheter (Swan-Ganz catheter) can measure pulmonary artery and pulmonary artery occlusion pressures (184). The catheter can measure cardiac output, be used to perform intracavitary electrocardiography, and provide temporary cardiac pacing. The standard pulmonary artery occlusion catheter is a 7-French, radiopaque, flexible, polyvinyl chloride, 4-lumen catheter with a 1.5-mL latex balloon at its distal tip. Most often, a

right internal jugular cannulation is used for placement of the catheter, because this site provides the most direct access into the right atrium and has fewer complications when compared with a subclavian route of placement. After the catheter is placed into the right atrium, the balloon is inflated, and the catheter is pulled by blood flow through the right ventricle into the pulmonary artery. The position of the catheter can be identified and followed by the various pressure waveforms generated by the right atrium, right ventricle, and pulmonary artery. As the catheter passes through increasingly smaller branches of the pulmonary artery, the inflated balloon eventually occludes the pulmonary artery.

The distal lumen of the catheter, which is beyond the balloon, measures left atrial pressure (LAP) and, in the absence of mitral valvular disease, LAP approximates LVEDP. Thus, pulmonary–capillary wedge pressure (PCWP) equals the LAP, which equals LVEDP and is normal at 8 to 12 mm Hg. Additionally, because the standard pulmonary artery catheter has an incorporated thermistor, thermodilution studies can be performed to determine cardiac output. This thermodilution method is performed by injecting cold 5% dextrose in water through the proximal port of the catheter, which cools the blood entering the right atrium. The change in temperature measured at the more distal thermistor (4 cm from the catheter tip) generates a curve proportional to cardiac output. Knowledge of the cardiac output is helpful in establishing cardiovascular diagnoses. For example, a patient with hypotension, low-to-normal wedge pressure, and a cardiac output of 3 L/minute is most likely hypovolemic. Conversely, the same patient with a cardiac output of 8 L/minute is probably septic with resultant low systemic vascular resistance.

Pulmonary artery catheters are associated with a small but significant complication rate. The complications can be grouped into those occurring during venous cannulation and those resulting from the catheter or its placement. The most common problems encountered during venous access are cannulation of the carotid or subclavian artery and introduction of a pneumothorax. Problems resulting from the catheter itself include dysrhythmias, sepsis, and disruption of the pulmonary artery. Pulmonary artery catheters should be placed under the supervision of experienced personnel in a setting in which complications can be rapidly diagnosed and treated.

The effect of pulmonary artery catheter use on patient outcome has become controversial. In 1996, a reevaluation of pulmonary artery catheters and initiation of randomized clinical

trials to assess their benefit was recommended (185). At that time, others published a large study demonstrating a higher mortality rate in patients who received a pulmonary artery catheter than those that did not have a pulmonary artery catheter (186). The design of this study was questionable, however, and it was retrospective and not randomized. A meta-analysis evaluating 12 randomized clinical trials showed a statistically significant reduction in morbidity (63% versus 74%, $P < 0.01$) in the pulmonary artery catheter group, but no significant difference in mortality (187). Finally, in a recent randomized blinded controlled trial of 1,994 high-risk (American Society of Anesthesiologists class III or IV risk) subjects 60 years of age or older undergoing urgent or elective major noncardiac surgery, therapy guided by pulmonary artery catheters showed no benefit over standard care with central venous catheters (188). Therefore, **routine preoperative use of pulmonary artery catheters in noncardiac surgery patients is no longer indicated.**

Hematologic Disorders

The presence of hematologic disorders, although uncommon in gynecologic patients, significantly affects operative morbidity and mortality and, therefore, should be considered routinely in preoperative evaluation. Preoperative assessment should include consideration of anemia, platelet and coagulation disorders, white blood cell function, and immunity.

Anemia

Moderate anemia is not in itself a contraindication to surgery because it can be corrected by transfusion. If possible, surgery should be postponed until the cause of the anemia can be identified and the anemia corrected without resorting to transfusion. **Current anesthetic and surgical practice ideally recommend a hemoglobin level of greater than 10 g/dL or a hematocrit of greater than 30%. Such numbers are only guidelines and should be applied on an individual basis.** Oxygen-carrying capacity and tissue oxygenation is provided by the circulating blood volume. Usually this capacity is reflected by the hemoglobin level and hematocrit. Under certain circumstances, however, this is not the case. After an acute blood loss or before plasma expansion by extracellular fluid has occurred, hematocrit measurements may be normal despite a low circulating blood volume.

Conversely, overhydration may result in low hematocrit and hemoglobin levels despite adequate

red blood cell mass.

Individual tolerance of anemia depends on overall physical fitness and cardiovascular reserve. The effects of anemia depend on its magnitude, the rate at which it occurs, the oxygen requirement of the patient, and the ability of physiologic mechanisms to compensate (189). Maintenance of adequate tissue perfusion requires an increase in cardiac output as hemoglobin concentration falls (190). A patient with ischemic heart disease will not tolerate anemia as well as a healthy young patient. Therefore, the presence of cardiac, pulmonary, or other serious illness justifies a more conservative approach to the management of anemia. Conversely, patients with long-standing anemia may have normal blood volume levels and tolerate surgical procedures well. There is no evidence that mild to moderate anemia increases perioperative morbidity or mortality (191).

Patients with normal hematocrit levels may store three or more units of autologous blood preoperatively to reduce the need for allogenic blood transfusion and minimize the risk of infections and immunologic problems (192). *Recombinant human erythropoietin* may increase collection and reduce preoperative anemia in these patients (193,194). Further, intraoperative blood collection and homologous transfusion can be employed to limit the need for allogenic blood transfusion.

Autologous blood donation has been advocated as a safer alternative for the patient; however, the use of preoperative autologous blood donation has come under scrutiny (195).

Preoperative autologous blood may lead to more liberal blood transfusion, iatrogenic anemia, volume overload, and bacterial contamination (196). Furthermore,

P.726

preoperative autologous blood donation is poorly cost-effective (197). The National Heart, Lung, and Blood Institute does not recommend collection of autologous blood for procedures with a likelihood of transfusion less than 10%, such as uncomplicated abdominal and vaginal hysterectomies (198).

Platelet and Coagulation Disorders

Surgical hemostasis is provided by platelet adhesion to injured vessels, which plugs the opening as the coagulation cascade is activated, resulting in the formation of fibrin clots. Thus, functional platelets and coagulation pathways are necessary to prevent excessive surgical

bleeding. Platelet dysfunction is encountered preoperatively more frequently than coagulation disorders.

Platelets may be deficient in both number and function. The normal peripheral blood count is 150,000 to 400,000 per mm^3 , and the normal life span of a platelet is approximately 10 days. Although there is no clear-cut correlation between the degree of thrombocytopenia and the presence or amount of bleeding, several generalizations can be made. If the platelet count is higher than $100,000/\text{mm}^3$ and the platelets are functioning normally, there is little chance of bleeding during surgical procedures. Patients with a platelet count higher than $75,000/\text{mm}^3$ almost always have normal bleeding times, and a platelet count higher than $50,000/\text{mm}^3$ is probably adequate. **A platelet count lower than $20,000/\text{mm}^3$ will often be associated with severe and spontaneous bleeding.** Platelet counts higher than $1,000,000/\text{mm}^3$ are often, paradoxically, associated with bleeding.

If the patient's platelet count is lower than $100,000/\text{mm}^3$, an assessment of bleeding time should be obtained. If the bleeding time is abnormal and surgery must be performed, an attempt should be made to raise the platelet count by administering platelet transfusions immediately before surgery. In patients with immune destruction of platelets, human leukocyte antigen (HLA)-matched donor-specific platelets may be required to prevent rapid destruction of transfused platelets. If surgery can be postponed, a hematology consultation should be obtained to identify and treat the cause of the platelet abnormality.

Abnormally low platelet counts result from either decreased production or increased consumption of platelets. Although there are numerous causes of thrombocytopenia, most are exceedingly uncommon. Decreased platelet production may be drug induced and has been associated with the use of *sulfonamides, cinchona alkaloids, thiazide diuretics, NSAIDs, gold salts, penicillamine, anticonvulsants, and heparins* (199). Decreased platelet count is a feature of several diseases, including vitamin B₁₂ and folate deficiency, aplastic anemia, myeloproliferative disorders, renal failure, and viral infections. Inherited congenital thrombocytopenia is extremely rare. More commonly, thrombocytopenia results from immune destruction of platelets by diseases such as idiopathic thrombocytopenia purpura and collagen vascular disorders. **Consumptive thrombocytopenia is a feature of disseminated intravascular coagulation, which is encountered most frequently in conjunction with sepsis or malignancy in the preoperative population.**

Platelet dysfunction most often is acquired, but may be inherited. Occasionally, a patient with von Willebrand's disease, the second most common inherited disorder of coagulation, may be encountered in the preoperative setting. More commonly, however, platelet dysfunction results from the use of drugs (e.g., *aspirin* and *amitriptyline*), and in patients with resulting prolonged bleeding times. the drug should be withheld for 7 to 10 days before surgery. Uremia and hepatic diseases can also affect platelet function.

Platelet dysfunction is more difficult to diagnose than abnormalities of platelet count. A history of easy bruising, petechiae, bleeding from mucous membranes, or prolonged bleeding from minor wounds may signify an underlying abnormality of platelet function. Such dysfunction can be identified with the help of a bleeding time, but full characterization of

P. 727

the underlying etiology should be carried out with hematologic consultation. If at all possible, surgery should be postponed until therapy has been instituted.

Similarly, disorders of the coagulation cascade often are diagnosed through a personal or family history of excessive bleeding during minor surgery, childbirth, or menses. Many women with menorrhagia are referred for surgical intervention and require a thorough preoperative evaluation for possible inherited disorders of hemostasis, such as factor VIII (hemophilia), factor IX (Christmas disease), factor XI deficiencies, and von Willebrand's disease. Von Willebrand's disease is the most common hereditary bleeding disorder, with prevalence in the general population of 0.8% to 1.3% (200,201). In women with menorrhagia, the prevalence of von Willebrand's disease increases to 13% to 20% (202,203). Identified women can potentially be treated effectively with *desmopressin* nasal spray, thus avoiding unanticipated or excessive bleeding during surgery. In the absence of a genetic diagnosis, the diagnosis of von Willebrand's disease is difficult and involves a combination of clinical and laboratory assessments, including von Willebrand factor antigen and von Willebrand factor functional activity or ristocetin cofactor assay. Physiologic fluctuations occur with von Willebrand factor levels, requiring repeat testing and consultation or referral to a hematologist. Nevertheless, it is recommended that women presenting with menorrhagia without obvious pelvic abnormalities should be routinely screened for inherited bleeding disorders before undergoing invasive procedures.

There are few commonly prescribed drugs that affect coagulation factors, the exceptions being *warfarin* and *heparin*. Disease states that may be associated with decreased coagulation

factor levels are primarily liver disease, vitamin K deficiency (secondary to obstructive biliary disease, intestinal malabsorption, or antibiotic reduction of bowel flora), and disseminated intravascular coagulation.

Preoperative laboratory screening for coagulation deficiencies is controversial. Routine screening is not warranted in patients who do not have historical evidence of a bleeding problem (204). However, patients who are seriously ill or who will be undergoing extensive surgical procedures should undergo testing preoperatively to determine prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count.

White Blood Cells and Immune Function

Abnormally high or low white blood cell counts are not an absolute contraindication to surgery; however, they should be considered relative to the need for surgery. Evaluation of an elevated or decreased white blood cell count should be undertaken before elective surgery. Clearly, **patients with absolute granulocyte counts lower than 1,000/mm³ are at increased risk of severe infection and perioperative morbidity and mortality and should undergo surgery only for life-threatening indications** (205).

Blood Component Replacement

Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Although the primary cause of the bleeding is usually lack of surgical hemostasis, other factors, including deranged coagulation, may compound the problem. Such coagulopathy can result from massive transfusion (less than one blood volume) and is thought to be due to dilution of platelets and labile coagulation factors by platelet- and factor-poor packed red blood cells (PRBCs), fibrinolysis, and disseminated intravascular coagulation.

Reports of massive transfusions in soldiers reveal that for those in whom thrombocytopenia developed following red blood cell replacement, bleeding diatheses that responded to infusion of fresh blood but not fresh-frozen plasma (FFP) also developed (206). The investigators concluded that dilutional thrombocytopenia is a major cause of posttransfusion bleeding. However, more recently, in a prospective, randomized, double-blind study, prophylactic platelet administration during massive transfusion was not helpful (207).

Although it seems that these studies are contradictory, they demonstrate the need for obtaining platelet counts during transfusion of large amounts of blood. If clinical evidence of excessive bleeding exists and the platelet count is lower than $100,000/\text{mm}^3$, platelets should be transfused because they are consumed during surgery, and higher levels are required to maintain hemostasis following surgery.

Packed red blood cells, which may be stored for several weeks, are used for most postoperative transfusions. Most clotting factors are stable for long periods. The exceptions are factors V and VIII, which decrease to 15% and 50% of normal, respectively. Despite this loss, these factors rarely decrease below levels required for hemostasis. In 1985, a National Institutes of Health consensus conference concluded that there was little or no scientific evidence to support the use of FFP for bleeding diatheses following multiple blood transfusions except in the presence of clinical bleeding, platelet count higher than $100,000/\text{mm}^3$, and a partial thromboplastin time greater than 1.5 times control. A task force of the American Society of Anesthesiologists (208) recently **recommended critical values for replacement in patients with massive transfusion and microvascular bleeding:**

- **Platelet transfusion usually is indicated for counts less than $50,000/\text{mm}^3$ (with intermediate platelet counts, i.e., $50,000/\text{mm}^3$ - $100,000/\text{mm}^3$, the transfusion of platelet concentrates should be based on the risk of more significant bleeding).**
- **Fresh frozen plasma therapy is indicated if the prothrombin or activated partial thromboplastin time values exceed 1.5 times the normal values.**
- **Cryoprecipitate transfusion is indicated if fibrinogen concentrations decrease to less than 80 to 100 mg/dL.**

Cryoprecipitate transfusions are recommended for prophylaxis in nonbleeding perioperative

patients with fibrinogen deficiencies or von Willebrand's disease refractory to *DDAVP*, and bleeding patients with von Willebrand's disease (208).

Donor blood is stored in the presence of citrate, which chelates calcium to prevent clotting, increasing the theoretical risk of hypocalcemia following massive transfusion. However, citrate is metabolized at a rate equivalent to 20 units of blood transfused per hour; thus, routine supplementation of calcium is unnecessary. Close monitoring of calcium levels is required in patients with hypothermia, liver disease, or hyperventilation because citrate metabolism may be slowed. Hepatic metabolism of citrate to bicarbonate can result in metabolic alkalosis following transfusion, resulting in subsequent hypokalemia, despite the high level of extracellular potassium in stored blood.

Pulmonary Disease

In patients undergoing abdominal surgery, several pulmonary physiologic changes manifest secondary to immobilization, anesthetic irritation of the airways, and the splinting of breathing that inevitably occurs secondary to incisional pain. Pulmonary physiologic changes include a decrease in the functional residual capacity (FRC), an increase in ventilation perfusion mismatching, and impaired mucociliary clearance of secretions from the tracheobronchial tree (209). In multivariate regression analyses, **definite risk factors for postoperative pulmonary complications include the following** (210):

- **Upper abdominal, thoracic, or abdominal aortic aneurysm surgery**
- **Surgical procedure time longer than 3 hours**
- **American Society of Anesthesiologists class greater than 2**
- **Previous COPD**

Smoking within 2 months of surgery

•

Use of *pancuronium* for general anesthesia

Probable risk factors include general anesthesia, preoperative PaCO₂ greater than 45 mm Hg, and emergency surgery. Risk factors that could possibly increase the postoperative risk are upper respiratory infection, abnormal chest x-ray, and elderly age (older than 70 years). Preoperative spirometry is of unproven value in patients in whom the risk of postoperative pulmonary complications is low. In high-risk patients, preoperative spirometry should be performed with and without bronchodilators to identify patients who may benefit from preoperative treatment with inhaled β_2 agonists and steroids.

These patients include those with a history of chronic cough or dyspnea, evidence of pulmonary abnormalities by either physical examination or chest x-ray, and a history of COPD, as well as patients with a significant history of smoking. The spirometric abnormalities most often associated with postoperative atelectasis and pneumonia are shown in Table 20.19. Reduction of the forced expiratory volume in 1 second (FEV 1) is an important parameter to note on pulmonary function tests (209). The routine performance of preoperative arterial blood gas measurements does not improve assessment of risk (209). Noninvasive pulse-oximetry measurements can detect patients with hypoxemia (209). The presence of hypercarbia on arterial blood gas measurements also does not predict postoperative pulmonary complications (211).

Table 20.19 Predictors of Postoperative Pulmonary Complications^a

<i>Parameter</i>	<i>Value</i>
Maximal breathing capacity	<50% predicted
FEV ₁	<1 L
FVC	<70% predicted
FEV ₁ /FVC	<65% predicted
Pao ₂	<60 mm Hg
Paco ₂	>45 mm Hg

^a*Complication* defined as atelectasis or pneumonia.

FEV₁, forced expiration volume; FVC, forced vital capacity; Pao₂, partial pressure of oxygen, arterial; Paco₂, partial pressure of carbon dioxide, arterial.

Adapted from **Blosser SA, Rock P.** Asthma and chronic obstructive lung disease. In: **Breslow MJ, Miller CJ, Rogers MC,** eds. *Perioperative management*. St. Louis, MO: Mosby, 1990:259–280.

Young, healthy patients rarely have abnormal chest x-rays. Therefore, chest x-rays should not be performed routinely in these patients. Most patients with abnormal chest x-rays have history or physical examination findings suggestive of pulmonary disease. Chest x-rays should be limited to patients older than 40 years of age, with a history of smoking or of pulmonary disease, who have evidence of cardiopulmonary disease, and in whom a metastatic malignancy is suspected. Although they have limited usefulness in predicting postoperative pulmonary complications, chest x-rays provide a valuable baseline in elderly patients, patients with chronic pulmonary diseases (209), and those with known lung metastases.

Asthma

Asthma affects approximately 5% to 7% of individuals in the United States (212). It is characterized by a history of episodic wheezing, physiologic evidence of reversible obstruction of the airways either spontaneously or following bronchodilator therapy, and pathologic evidence of chronic inflammatory changes in the bronchial submucosa. Asthma is not a disease of airway physiology in which hypertrophy and increased contractility of bronchial smooth muscle is the dominant lesion; rather, it is an inflammatory disease

affecting the airways that secondarily results in epithelial damage, leukocytic infiltration, and increased sensitivity of the airways to a number of different stimuli. The treatment of asthma is directed toward relaxing the airways and alleviating inflammation with corticosteroids (212).

Multiple stimuli have been noted to precipitate or exacerbate asthma, including environmental allergens or pollutants, respiratory tract infections, exercise, cold air, emotional stress, nonselective beta-adrenergic blockers, and aspirin (213). Management of asthma includes removal of the inciting stimuli as well as use of appropriate pharmacologic therapy. The optimal therapy for asthma involves not only managing the acute symptoms but also long-term management of the inflammatory component of the disease.

Pharmacotherapy of Asthma

The recognition of asthma as an inflammatory condition that should be treated with anti-inflammatory agents has led to the use of corticosteroids for treatment. Because corticosteroids inhibit mediator release from eosinophils and macrophages, inhibit the late response to allergens, and reduce hyperresponsiveness of the bronchioles, they have become the first-line therapy for chronic asthma (214). **Inhaled steroids have greatly reduced the steroid dose required to achieve optimal results.** The steroid effect is dose related, but many patients with asthma can achieve control using low-dose inhaled steroids. Onset of action is slow (several hours), and up to 3 months of steroid therapy may be required for optimal improvement of bronchial hyperresponsiveness. Even with acute bronchospasm, steroid treatment can enhance the beneficial effect of beta-adrenergic treatment. During acute exacerbations of asthma, a short course of oral steroids, in addition to inhaled steroids, may be necessary. For adults with chronic asthma, however, only a minority will require chronic oral steroid therapy. Patients taking oral steroids should receive intravenous steroid support perioperatively to avoid adrenal insufficiency.

Beta₂-adrenergic agonists remain the first-line drugs for acute asthma attacks.

These drugs, inhaled 4 to 6 times daily, rapidly relax smooth muscle in the airways and are effective for up to 6 hours. Studies of beta₂ agonists in chronic asthma, however, have failed to show any influence of these agents on the inflammatory component of asthma. Furthermore,

it has been suggested that the long-term use of this class of drugs can lead to a worsening of asthma (214). Thus, beta₂ agonists are now recommended for use for short-term relief of bronchospasm ("rescue inhalers") or as first-line treatment for patients with very infrequent symptoms or symptoms provoked solely by exercise (215).

Methylxanthines, such as *theophylline*, have been relegated to third-line status in the management of asthma. It is doubtful whether these drugs have any additional benefit in patients who are using maximal inhaler therapy. *Theophylline* toxicity can develop when other drugs such as *ciprofloxacin*, *erythromycin*, *allopurinol*, *inderal*, or *cimetidine* are concomitantly administered (212).

Anticholinergic agents are weak bronchodilators that work via inhibition of muscarinic receptors in the smooth muscle of the airways. The quaternary derivatives such as *ipratropium bromide* (*Atrovent*) are available in an inhaled form that is not absorbed systemically. Anticholinergic drugs may provide additional benefit in conjunction with standard steroid and bronchodilator therapy but should not be used as single-agent therapy because they do not inhibit mast cell degranulation, do not have any effect on the late response to allergens, and do not have an anti-inflammatory effect.

Cromolyn sodium is highly active in the treatment of seasonal allergic asthma in children and young adults. It is usually not as effective in older patients or in patients in whom asthma is not allergic in nature (215). The drug is taken by inhalation but has a relatively

P.731

short duration of action (3–4 hours). It has a mild anti-inflammatory effect but is less effective than inhaled cortical steroids, and its role as a single agent is limited.

Perioperative Management of Asthma

In patients with asthma, elective surgery should be postponed whenever possible until pulmonary function and pharmacotherapeutic management are optimized.

The preoperative evaluation may include pulmonary function testing and arterial blood gases depending on the severity of the symptoms and concern regarding ventilation and oxygenation. Preoperative chest physiotherapy, bronchodilator therapy, systemic hydration, and appropriate antibiotics will improve the reversible components of asthma (216). For

mild asthma, the use of inhaled beta-adrenergic agonists preoperatively may be all that is required. For chronic asthma, optimization of steroid therapy will greatly decrease alveolar inflammation and bronchiolar hyperresponsiveness. Inhaled beta₂ agonists should be added to therapy as needed for further control of asthma. Each drug prescribed should be used in maximal dosage before adding an additional agent. For patients undergoing emergent surgery who have significant bronchoconstriction, a multimodal approach should be instituted, including aggressive bronchodilator inhalation therapy, intravenous *aminophylline*, as well as steroid therapy. Ideally, steroid therapy can be instituted 3 to 6 days preoperatively. In all patients with asthma, pharmacotherapeutic response can be monitored with pulmonary function testing as demonstrated by an improvement in the peak expiratory flow rate (215).

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease is the greatest risk factor for the development of postoperative pulmonary complications. The term *COPD* has been used to encompass both chronic bronchitis and emphysema, disease entities that often occur in tandem. Cigarette smoke is implicated in the pathogenesis of both, and any treatment plan must include cessation of smoking (217). Chronic bronchitis is defined as the presence of productive cough on most days for at least 3 months per year and for at least 2 successive years (218). It is characterized by chronic airway inflammation and excessive mucus production. The histologic changes of emphysema include destruction of alveolar septa and distension of airspaces distal to terminal alveoli. The destruction of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, significant ventilation-perfusion mismatching, and an ineffective cough (219). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

Patients with COPD and a history of heavy smoking account for most postoperative pulmonary complications in gynecologic surgical patients. The severity of COPD can be determined preoperatively via a thorough history, physical examination, pulmonary function tests, and arterial blood gas assessment. Preoperative evaluation should be performed to assess reversible components of COPD, such as bronchospasm or infection.

The severity of COPD can be quantitated with pulmonary function testing (217). Typically,

forced expiratory volume (FEV_1), forced vital capacity (FVC), FEV_1/FVC . In patients considered to be at high risk, the incidence of complications was highest in those undergoing abdominal surgery (92%) or thoracic surgery (78%) and lowest in those undergoing surgery outside the abdomen (26%). The current American College of Physicians guidelines list the following indications for preoperative spirometry: lung resection; coronary artery bypass or upper abdominal surgery in a patient with a positive smoking history or dyspnea; and lower abdominal surgery in a patient with uncharacterized pulmonary symptoms or history of pulmonary disease without recent spirometry within 60 days, especially if the surgery will be extensive, prolonged, or require strenuous postoperative rehabilitation (220).

P.732

Older data suggest that arterial blood gas measurements may show varying degrees of hypoxemia and hypercapnia and can be used for prognostic purposes; PaO_2 levels lower than 70 mm Hg and $PaCO_2$ levels higher than 45 mm Hg are associated with an increase in the risk of postoperative pulmonary complications and the need for mechanical ventilation postoperatively (221). $PaCO_2$ levels higher than 50 mm Hg are associated with increased postoperative respiratory failure and should caution against elective surgery (216).

The preoperative preparation of the patient at risk for postoperative pulmonary complications should include cessation of smoking for as long as possible preoperatively; whereas 2 to 3 days of smoking abstinence are sufficient for carboxyhemoglobin levels to return to normal (209). One to two weeks of cessation decreases sputum volume (209). Two months of smoking abstinence is required to significantly lower the risk of postoperative pulmonary complications (209). Longer periods of abstinence can thus be counseled in patients undergoing elective surgery.

In patients with severe COPD, maximum improvement in airflow limitation can be achieved with a therapeutic trial of high-dose oral corticosteroids followed by a 2-week trial of high-dose inhaled steroid (*beclomethasone* 1.5 mg/day or the equivalent) in addition to inhaled bronchodilator therapy. Ideally, oral and inhaled steroid therapy should be initiated 1 to 2 weeks preoperatively. Inhaled steroids, in particular, address the inflammatory component of COPD. Oral steroid therapy initiated preoperatively should be maintained throughout the perioperative period and then tapered postoperatively. Beta-adrenergic agonist therapy can

be initiated at least 72 hours preoperatively and is beneficial in patients who have demonstrated either clinical or spirometric improvement on bronchodilators.

Patients with COPD and an active bacterial infection suggested by purulent sputum should undergo a full course of antibiotic therapy before surgery. The antibiotic used should cover the most likely etiologic organisms, *Streptococcus pneumoniae* and *Haemophilus influenzae*. In any patient with acute upper respiratory infection, surgery should be delayed if possible. The use of antibiotics to sterilize the sputum in the absence of evidence of an acute infection should be avoided because this practice may lead to bacterial resistance.

Instruction in deep breathing maneuvers and chest physical therapy are easily instituted, and these measures can be started the evening before surgery (222). These prophylactic measures (smoking cessation, pharmacotherapies, and aggressive pulmonary toilet) should be instituted preoperatively and continued postoperatively to minimize the incidence of atelectasis and pneumonia.

Postoperative Pulmonary Management

Atelectasis

Atelectasis accounts for more than 90% of all postoperative pulmonary complications.

The pathophysiology involves a collapse of the alveoli, resulting in ventilation-perfusion mismatching, intrapulmonary venous shunting, and a subsequent drop in the PaO₂. Collapsed alveoli are susceptible to superimposed infection, and if managed

improperly, atelectasis will progress to pneumonia. Patients with atelectasis have a decreased FRC as well as decreased lung compliance, resulting in increased work during breathing. Despite the decrease in PaO₂, the PCO₂ remains unaffected unless atelectatic changes progress to large volumes of the lung or pre-existing lung disease is present.

Physical findings associated with atelectasis may include a low-grade fever. Auscultation of the chest may reveal decreased breath sounds at the bases or dry rales upon inspiration. Percussion of the posterior thorax may suggest elevation of the diaphragm.

Radiologic findings include the presence of horizontal lines or plates on posteroanterior chest x-rays, occasionally with adjacent areas containing hyperinflation. These changes are most pronounced during the first 3 postoperative days.

Therapy for atelectasis should be aimed at expanding the alveoli and increasing the FRC. The most important maneuvers are those that promote maximal inspiratory pressure, which is maintained for as long as possible. This exercise promotes not only an expansion of the alveoli but also secretion of surfactant, which stabilizes alveoli. It can be achieved with aggressive supervised use of incentive spirometry, deep breathing exercises, coughing, and in some cases, the use of positive expiratory pressure with a mask (continuous positive airway pressure). Oversedation should be avoided, and patients should be encouraged to ambulate and change positions frequently. Fiberoptic bronchoscopy for removal of mucopurulent plugs should be reserved for patients who fail to improve with the usual measures.

Cardiogenic (High-Pressure) Pulmonary Edema

Cardiogenic pulmonary edema can result from myocardial ischemia, myocardial infarction, or from intravascular volume overload, particularly in patients who have low cardiac reserve or renal failure. The process usually begins with an increase in the fluid in the alveolar septa and bronchial vascular cuffs, ultimately seeping into the alveoli. Complete filling of the alveoli impairs secretion and production of surfactant. Concomitant with alveolar flooding, there is a decrease in lung compliance, impairment of the oxygen diffusion capacity, and an increase in the arteriolar–alveolar oxygen gradient. Ventilation-perfusion mismatching in the lung results in a decrease in the PaO_2 , resulting eventually in decreased oxygenation of the tissues and impairment of cardiac contractility.

Symptoms may include tachypnea, dyspnea, wheezing, and use of the accessory muscles of respiration. Clinical signs may include distention of the jugular veins, peripheral edema, rales upon auscultation of the lungs, and an enlarged heart. Radiographic findings may include the presence of bronchiolar cuffing, as well as increased interstitial fluid markings extending to the periphery of the lung. The diagnosis can be further confirmed with the use of central hemodynamic monitoring, which will denote an elevated central venous pressure and, more specifically, an elevation in the pulmonary capillary wedge pressure.

The patient's volume status should be evaluated thoroughly. In addition, myocardial ischemia

or infarction should be ruled out by performing ECG and analyzing cardiac enzyme levels. The management of cardiogenic pulmonary edema includes oxygen support, aggressive diuresis, and afterload reduction to increase the cardiac output. In the absence of myocardial infarction, an inotropic agent may be used. Mechanical ventilation should be reserved for cases of acute respiratory failure.

Noncardiogenic Pulmonary Edema (Adult Respiratory Distress Syndrome)

In contrast with cardiogenic pulmonary edema, in which alveolar flooding is a result of an increase in the hydrostatic pressure of the pulmonary capillaries, alveolar flooding in patients with adult respiratory distress syndrome (ARDS) is the result of an increase in pulmonary capillary permeability. The primary pathophysiologic process is one of damage to the capillary side of the alveolar–capillary membrane. This damage results in rapid movement of fluid containing high concentrations of protein from the capillaries to the pulmonary parenchyma and alveoli. Lung compliance decreases and oxygen diffusion capacity is impaired, resulting in hypoxemia. If not managed aggressively, respiratory failure may result. Even when managed aggressively, the mortality rate

P.734

associated with ARDS is high. There are a number of causes as well as several distinct states of ARDS. **The causes of ARDS include shock, sepsis, massive nonlung trauma (as from fractures or burns), multiple red blood cell transfusions, aspiration injury, inhalation injury, pneumonia, pancreatitis, disseminated intravascular coagulation, and fat emboli** (216). Irrespective of the cause, which should be identified and treated if possible, the evolving clinical picture and management are very similar.

Clinically, ARDS passes through several stages. Initially, patients develop tachypnea and dyspnea with no remarkable findings on clinical evaluation or on chest x-ray. Chest x-rays will eventually reveal bilateral diffuse pulmonary infiltrates. As lung compliance becomes impaired, functional residual capacity, tidal volume, and vital capacity decrease. The PaO₂ decreases and, characteristically, increases only marginally with oxygen supplementation. An attempt should be made to maintain the arterial oxygen level above 90%. This may be achievable initially by administering oxygen by mask. For patients with severe

hypoxemia, endotracheal intubation with positive-pressure ventilation should be instituted. Guidelines for initial ventilatory support are changing, and new lung-protective ventilation strategies are being advocated. One strategy advocates the use of high positive end-expiratory pressure (PEEP), low tidal volume, permissive hypercapnia, and pressure-limited ventilatory modes. The low tidal volume strategy may confer a survival advantage, and available data support its use in patients with ARDS (223). Multicenter ARDSNet trials are currently under way to assess differences in PEEP and FIO₂ levels and the use of corticosteroids. Analysis of a recent ARDSNet trial found no difference in the application of high or low levels of PEEP, holding tidal volume and end-inspiratory pressure stable at 30 cm of water (224). Attempts to manage and treat the cause of ARDS must also include aggressive efforts toward hemodynamic and circulatory resuscitation in patients with shock. Nosocomial pneumonia is present in 50% of patients with ARDS, and broad-spectrum antibiotic therapy should be administered appropriately for patients with suspected pneumonia or sepsis. Patients who have disseminated intravascular coagulopathy may require replacement with cryoprecipitate or FFP. Other measures for general care should include the placement of a nasogastric tube, gastric acid suppression with H₂ blockers, and administration of steroids in patients with the fat emboli syndrome.

Hemodynamic monitoring is invaluable and should be initiated early in the course of the disease process in the appropriate intensive care unit setting. Patients with any evidence of fluid overload should receive aggressive diuresis, whereas others may require fluid resuscitation for maintenance of tissue perfusion while the pulmonary-capillary wedge pressure is maintained below 15 mm Hg. Pulmonary wedge pressure may be falsely elevated when PEEP is being applied. The goal of management is to maintain the lowest pulmonary-capillary wedge pressure, with acceptable cardiac output and blood pressure. In the setting of hypotension and oliguria, inotropic support with dopamine or dobutamine or both is helpful.

With aggressive management, particularly if the inciting cause is identified and treated, ARDS can be reversed during the first 48 hours with few sequelae. After the first 48 hours, however, progression of the ARDS will cause lung damage that may leave residual pulmonary fibrosis. With progression beyond 10 days, multiorgan system failure occurs, and mortality is higher than 80% (223).

Renal Disease

The need for surgical intervention in patients with renal impairment has resulted in the development of a very specialized medical approach to their care. Special precautions are necessary to compensate for the kidney's impaired ability to regulate fluids and electrolytes and excrete metabolic waste products. Equally important are the unique problems that develop in patients with chronic renal impairment, including an increased risk of sepsis, coagulation defects, impaired immune function and wound healing, and a

P.735

propensity to develop specific acid-base abnormalities. Special consideration must be given to a variety of different medications, anesthetic agents, and numerous hematologic and nutritional factors that are important in the successful surgical care of patients with renal insufficiency.

Management of fluid levels and cardiovascular hemodynamics in patients with acute or chronic renal impairment is paramount. Intravascular fluid volume changes that lead to hypertension or hypotension are very common in these patients and often are difficult to manage secondary to autonomic dysfunction, acidosis, and other problems that are inherent to the underlying kidney disease. Patients undergoing dialysis in whom major abdominal or pelvic surgery is contemplated should be treated using a Swan-Ganz catheter intraoperatively and postoperatively. The results of physical examination and CVP monitoring correlate poorly with left cardiac filling pressures. Swan-Ganz catheter measurements will help guide fluid replacement and avoid volume overload. Invasive hemodynamic monitoring should be continued as needed throughout the first postoperative week because third spacing will occur during this period.

Postoperative dialysis usually is necessary to avoid problems associated with fluid overload and hyperkalemia. Dialysis-dependent patients should undergo dialysis approximately 24 hours following surgery. A short-lived but rather significant fall in the number of platelets occurs during dialysis, and *heparin* is used in hemodialysis equipment to prevent clotting. Because of these factors and concerns about postoperative bleeding, dialysis is usually avoided during the first 12 to 24 hours following surgery. Although ischemic heart disease is the most common cause of death in patients with renal insufficiency, it is not a major cause of perioperative mortality (225). A large percentage of perioperative deaths of patients with renal insufficiency are associated with hyperkalemia that is controlled most

Patients with chronic renal failure are at an increased risk for postoperative infections resulting from abnormalities in neutrophil and monocyte function (227). Appropriate preoperative antibiotic prophylaxis and accurate assessment of nutritional status help lower the incidence of postoperative infectious complications.

The major hematologic concern in patients with chronic renal insufficiency is the increased incidence of bleeding. These bleeding problems are secondary to abnormal bleeding times and, in particular, disorders of platelet function related to a decreased amount of factor VIII and von Willebrand antigen in the serum of uremic patients. Anemia, which is common in patients with renal insufficiency, can contribute to prolonged bleeding times (228). Abnormalities in arachidonic acid metabolism, acquired platelet storage pool deficiency, and disturbed regulation of platelet calcium content all contribute to an increased tendency for uremic patients to have significant bleeding during surgery (229). Therefore, the bleeding time should be routinely checked preoperatively in these patients, and abnormalities should be corrected before surgery. Options for the correction of bleeding time in uremic patients include infusion of *desmopressin* or *cryoprecipitate*, both of which act to increase plasma levels of factor VIII and von Willebrand antigen (230,231).

Normal renal function is essential for maintenance of acid-base balance in the body. Patients with renal insufficiency can have a normal anion gap or an elevated anion gap acidosis. When mild renal insufficiency develops, a normal anion gap is present, whereas in more significant and severe renal dysfunction, an elevated anion gap acidosis occurs. Hemodialysis corrects metabolic acidosis. If a patient is severely acidotic (pH <7.15) and emergency surgery is planned, correction of the blood pH to 7.25 using intravenous *sodium bicarbonate* is indicated. However, correction of metabolic acidosis should be carried out slowly, because in patients with hypocalcemia, seizures may be precipitated (231). It is also important to exclude other causes of elevated anion gap acidosis, such as ketoacidosis

secondary to diabetes, lactic acidosis secondary to infection, or in rare instances, poisoning with *ethylene glycol*, *methanol*, or *aspirin*.

Impaired kidney function causes phosphate retention by the kidney and impaired vitamin D metabolism. Therefore, hypocalcemia is common in patients with renal insufficiency, but tetany and other signs of hypocalcemia are relatively uncommon because metabolic

acidosis increases the level of ionized calcium. Oral phosphate binders, such as *aluminum hydroxide* (1–2 g per meal), and dietary phosphate restriction (1 g per day) is the usual treatment for hypocalcemia–hyperphosphatemia in patients with renal insufficiency. In chronic situations, because of central nervous system toxicity associated with elevated aluminum levels, it is preferable to treat hypocalcemia–hyperphosphatemia with large doses of *calcium carbonate* (6–12 g per day) rather than with the standard aluminum-containing antacids (232).

Approximately 20% of patients with renal insufficiency will exhibit clinical evidence of protein calorie malnutrition. Vitamin deficiencies, most notably with water-soluble vitamins, also occur with dialysis. Nutritional disturbances in patients with chronic renal insufficiency arise secondary to deficiencies in protein intake, and studies have shown that, in patients with chronic renal insufficiency, their kidneys are hyperfiltrating (233). Postoperatively, both protein and caloric intake may need to be increased dramatically to meet catabolic demands in surgical patients. As much as 1.5 g/kg of protein and 45 kcal/kg of calories may be needed (233).

Wound healing is impaired in patients with chronic renal failure, and wound dehiscence and evisceration are potential problems. Wound healing is most appropriately aided by nutritional assessment preoperatively and maintenance of adequate caloric and protein intake in the perioperative setting. Antibiotic prophylaxis should be used in these patients, and uremia should be treated with dialysis as indicated. A running mass-closure of the midline vertical incision with continuous monofilament sutures should be used to further decrease the risk of wound dehiscence and evisceration (234).

Patients with chronic renal disease have an altered ability to excrete drugs and are prone to significant metabolic derangements secondary to the altered bioavailability of many commonly used medications. Because of this, as well as the effect of dialysis on drug pharmacokinetics, the gynecologic surgeon and nephrologist must be aware of the lowered metabolism and bioavailability of narcotics, barbiturates, muscle relaxants, antibiotics, and other drugs that require renal clearance. Of particular note is the inability of patients with renal insufficiency to clear the neuromuscular blockade caused by *pancuronium* (235). Care must be taken with *D-tubocurarine*, especially if repeated doses are given (236). *Midazolam*, *propofol*, *vecuronium*, and *atracurium* have been used safely in patients with renal failure (231). *Succinylcholine* has been reported to cause significant hyperkalemic responses in

patients with renal failure (237). When *succinylcholine* is used in patients with chronic renal insufficiency, careful monitoring of the serum potassium level is necessary (238).

Perioperative acute renal failure in previously normal patients may be caused by decreased renal perfusion, nephrotoxins, or both. Patients with impaired cardiac function, intravascular volume depletion, sepsis, or hypotension fall under the first category. Nephrotoxic medications such as *aminoglycosides*, chemotherapeutic agents such as *cisplatin*, or iodinated contrast agents fall under the second category (239,240,241). The risk of renal impairment becomes cumulative if more than one of these factors exist at the same time, and especially if a variety of factors are associated with intervascular volume depletion (242). Several measurements should be used to avoid acute renal failure. All nephrotoxic drugs should be discontinued when possible. When it is not practical to withdraw medication, strict attention should be paid to the pharmacokinetic characteristics of each drug as well as to the regular measurements of serum creatinine levels. Patients with diabetes should be

P.737

given reduced doses of radiocontrast agents and should be well hydrated because they are particularly susceptible to renal injury from these materials (243). Volume repletion is essential to lower the incidence of renal impairment (244).

Liver Disease

Management of perioperative problems in gynecologic patients with liver disease requires a comprehensive understanding of normal liver physiology and the pathophysiology underlying diseases of the liver that may complicate surgery or recovery. **Patients with liver disease often have numerous complicated problems involving nutrition, coagulation, wound healing, encephalopathy, and infection.**

History and Physical Examination

Patients with a history of alcohol abuse, drug use, hepatitis, jaundice, blood product exposure, or a family member with liver disease should undergo biochemical evaluation. During the physical examination, note should be made of any jaundice, signs of muscle wastage, ascites, right upper quadrant tenderness, or hepatomegaly.

Laboratory Testing

The biochemical profile (alkaline phosphatase, calcium, lactic acid dehydrogenase, bilirubin, serum glutamic-oxaloacetic transaminase, cholesterol, uric acid, phosphorous, albumin, total protein, and glucose) has not been shown to be useful for routine preoperative evaluation (245). Mild abnormalities can result in further extensive testing that requires consultation, delays in surgery, and increased cost without net benefit. A possible exception is selected use of biochemical testing when the history or physical examination reveals abnormalities. Patients with known liver disease should undergo albumin and bilirubin testing using the Child's risk classification (Table 20.20). This system was originally designed to predict mortality following portosystemic shunt surgery. It divides patients into three classes of severity based on five easily assessed clinical parameters. Measurement of prothrombin time may also be helpful in patients with significant histories of liver disease. If a history of hepatitis is ascertained, the patient should be tested for serum aminotransferase, alkaline phosphatase, bilirubin, and albumin levels. Serologic documentation of hepatitis is also important. If a patient has a known malignancy, biochemical testing of the liver may be of some benefit as a screen for metastatic disease, although this has not been proved conclusively.

Table 20.20 Child's Classification of Liver Dysfunction

<i>Parameter</i>	<i>Child Classification</i>		
	<i>A</i>	<i>B</i>	<i>C</i>
<i>Bilirubin</i>	<2.0	2.0–3.0	>3.0
<i>Albumin</i>	>3.5	3.0–3.5	<3.0
<i>Ascites</i>	None	Easily controlled	Poor controlled
<i>Encephalopathy</i>	None	Mild	Advanced
<i>Nutritional status</i>	Excellent	Good	Poor

Anesthesia

With few exceptions, most anesthetic agents, including those administered by epidural or spinal routes, reduce hepatic blood flow and decrease oxygenation of the liver. Other perioperative factors—hemorrhage, intraoperative hypotension, hypercarbia, congestive heart failure, and intermittent positive pressure ventilation, especially in critically ill patients—lead to decreased hepatic perfusion and hypoxia (246).

P.738

Drug Metabolism

Patients with altered liver function should be carefully monitored because of the prolonged action of many medications used during surgery. In addition to impaired metabolism, hypoalbuminemia decreases drug binding, which alters serum levels and biliary clearance rates. The degree of hepatic metabolism varies greatly, depending on the type of medication being considered. For inhalation anesthetics, *isoflurane* is preferred because it undergoes minimal hepatic metabolism in comparison with *halothane* or *enflurane*. Narcotics, induction agents, sedatives, and neuromuscular blocking agents all undergo abnormal metabolism in patients with decompensated liver disease. *Diazepam*, *meperidine*, and *phenobarbital* cause prolonged depression of consciousness and may precipitate hepatic encephalopathy because of their altered rates of clearance. *Sufentanil* and *oxazepam* are the preferred narcotics, and *benzodiazepine* should be used for patients with altered liver function. Muscle relaxants, such as *D-tubocurarine*, *pancuronium*, and *vecuronium*, cause prolonged neuromuscular blockade in patients with impaired liver function and are not ideal drugs to use in this situation. *Atracurium* is not metabolized by the liver and, therefore, is the preferred muscle relaxant for patients with abnormal hepatic function. *Succinylcholine* metabolism is prolonged in patients with hepatic dysfunction and must be used with great caution (247).

Determination of Operative Risk

Although it is well known that acute hepatobiliary damage results in increased morbidity and mortality in the surgical patient, estimating the operative risk in patients with hepatic dysfunction is difficult based on the history and physical examination. **The most**

accurate method for risk assessment of surgery in patients with hepatic dysfunction is Child's classification (see Table 20.20). Using this system, accurate assessment of morbidity and mortality can be directly related to the degree of liver dysfunction (248). The Child's classification has been shown to be useful for patients undergoing a variety of different types of abdominal surgery. Operative mortalities of 10%, 31%, and 76% have been reported for each of the three Child's classifications, respectively (249). The major cause of perioperative death was sepsis. This classification correlated significantly with postoperative complications such as bleeding, renal failure, wound dehiscence, and sepsis.

Acute Viral Hepatitis

Acute viral hepatitis poses an increased risk of operative complications and perioperative mortality and, therefore, elective surgery is contraindicated (250).

Elective surgery should be delayed for approximately 1 month after the results of all biochemical tests have returned to normal (251). In patients with ectopic pregnancy, hemorrhage, or bowel obstruction secondary to malignancy, however, surgical intervention must take place before normalization of serum transaminase levels (250). In these situations, the perioperative morbidity (12%) and mortality (9.5%) rates are much higher than when they are performed under ideal situations (247).

Chronic Hepatitis

Chronic hepatitis is a group of disorders characterized by inflammation of the liver for at least 6 months. The disease is divided by morphologic and clinical criteria into chronic persistent hepatitis and chronic active hepatitis. A liver biopsy is usually required to establish the extent and type of injury. The surgical risk in these patients correlates most closely with the severity of disease. The risk of surgery in patients with asymptomatic or mild disease is minimal in contrast to a significant risk for those patients who have symptomatic chronic active hepatitis (252). Elective surgery is contraindicated in symptomatic patients, and nonelective surgery is associated with significant morbidity (251). In the nonelective situation, patients taking long-term *glucocorticoid* therapy should be given appropriate stress coverage with a higher dose of *glucocorticoids* during the perioperative period. Preoperatively, patients who are not taking steroids should receive *prednisone* and *azathioprine*, which have been shown to reduce the perioperative

risk of complications and may result in remission in as many as 80% of patients (253). More recently, a controlled randomized trial of *prednisone* and *interferon- α* has shown regression of the hepatitis B (HBV) core antigen and HBV viral DNA replication in approximately 30% of patients (254). Current strategies for treating chronic HBV also include the use of nucleoside analogs such as *lamivudine* and *adefovir* (255,256). *Pegylated interferon* and *ribavirin* are used in the standard treatment of hepatitis C (HCV) (257). Consideration should be given to using these medications for patients in whom surgery cannot be avoided but is not emergent.

Asymptomatic carriers of the HBV (individuals who test positive for the HBV surface antigen) are not at increased risk for postoperative complications in the absence of elevated aminotransferase levels and liver inflammation. There is, however, a significant risk to the health care professional operating on these individuals. In cases of needlestick in which the patient's hepatitis status is unknown, both the health care worker and the patient should be tested for HCV antibody and HBV serologic markers. If markers for HBV infection are present, *hepatitis B immune globulin* should be administered to unvaccinated medical personnel. A vaccination series should then be initiated during the early postoperative period. If the health care worker is immune (surface antibody positive), no treatment is necessary (247). All medical personnel, and especially those in the surgical subspecialties, should receive a full course of recombinant hepatitis B vaccine as recommended by the Centers for Disease Control and Prevention (258).

Alcoholic Liver Disease

Alcoholic liver disease encompasses a spectrum of diseases including fatty liver, acute alcoholic hepatitis, and cirrhosis. Elective surgery is not contraindicated in patients with fatty liver because liver function is preserved. **If nutritional deficiencies are discovered, they should be corrected before elective surgery.** Acute alcoholic hepatitis is characterized on biopsy by hepatocyte edema, polymorphonuclear leukocyte infiltration, necrosis, and the presence of Mallory bodies. Elective surgery in these patients is contraindicated (259). Abstinence from alcohol for approximately 6 to 12 weeks along with clinical resolution of the biochemical abnormalities are recommended before surgery is considered. Severe alcoholic hepatitis may persist for several months despite abstinence and, if any question of continued activity exists, a liver biopsy should be repeated (260). In cases of urgent or emergent surgery

on patients with alcohol dependence, administration of tapered doses of *benzodiazepine* is appropriate as prophylaxis against alcohol withdrawal.

Cirrhosis

Cirrhosis is an irreversible liver lesion characterized histologically by parenchymal necrosis, nodular degeneration, fibrosis, and a disorganization of hepatic lobular architecture. The most serious complication of cirrhosis is portal venous hypertension, which ultimately leads to bleeding from esophageal varices, ascites, and hepatic encephalopathy. Conventional liver biochemical test results correlate poorly with the degree of liver impairment in patients with cirrhosis. Hepatic dysfunction, however, may be somewhat quantitated by low albumin levels and prolonged prothrombin times.

Surgical risk is clearly increased in patients with advanced liver disease, although it is substantially greater in emergency surgery than in elective surgery.

Perioperative mortality correlates with the severity of cirrhosis and can be estimated through the use of the Child's classification (see Table 20.20). In patients with Child's class A cirrhosis, surgery can usually be performed without significant risk, whereas in patients with Child's class B or C, surgery poses a major risk and requires careful preoperative consideration.

Preoperative preparation should include the following measures: (i) optimizing nutritional status by enteral and parenteral nutrition and supplementation with B₁, (ii) correcting coagulopathy with administration of FFP or cryoprecipitate or both, (iii) minimizing pre-existing encephalopathy, (iv) preventing sepsis from spontaneous bacterial peritonitis by

P.740

administering prophylactic antibiotic therapy, and (v) optimizing renal function and carefully correcting electrolyte abnormalities (261). Meticulous preoperative preparation focused on correcting abnormalities associated with advanced liver disease may improve surgical outcomes (262).

Gynecologic Endoscopy

Malcolm G. Munro

Andrew I. Brill

William H. Parker

- Positioning of the insufflation needle, the primary trocar, and the cannula are best accomplished with the patient in an unaltered horizontal position.
- Proper patient selection is critical for laparoscopic management of ovarian cysts because of concerns about an adverse effect on prognosis with malignant tumors.
- Laparoscopic myomectomy often requires laparoscopic suturing; thus, more technical skills are needed than with many other endoscopic procedures.
- Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter.
- Patients recovering from laparoscopic surgery usually feel better every day. Pain diminishes, gastrointestinal function improves rapidly, and fever is extremely unusual. Therefore, if a patient's condition is not improving, possible complications of anesthesia or surgery should be considered.

The incidence of unintended electrosurgical activation injuries can be reduced if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use.

Endoscopy is a procedure that uses a narrow telescope to view the interior of a viscus or preformed space. Although the first medical endoscopic procedures were performed more than 100 years ago, the potential of this method has only recently been realized. Endoscopes are currently used to perform a variety of operations. **In gynecology, endoscopes are used most often to diagnose conditions by direct visualization of the peritoneal cavity (laparoscopy) or the inside of the uterus (hysteroscopy).**

When used appropriately, endoscopic surgery offers the benefits of reduced pain, improved cosmesis, lower cost, and faster recovery. The indications for endoscopic

P.750

surgery are outlined here and described in more detail in the appropriate chapters. The technology, potential uses, and complications of laparoscopy and hysteroscopy are summarized here.

Laparoscopy

The past three decades have witnessed rapid progress and technologic advances in laparoscopy (1,2,3,4,5,6,7,8,9,10,11,12). Operative laparoscopy was developed in the 1970s, and in the early 1980s, laparoscopy was first used to direct the application of electrical or laser energy for the treatment of advanced stages of endometriosis (6,7). The use of high-resolution, lightweight video cameras in operative laparoscopy has made it easier to view the pelvis during the performance of complex procedures (7,8,9,10). Subsequently, many other procedures that previously were performed using traditional techniques, such as hysterectomy, became feasible with the laparoscope (11). However, the endoscopic approach may have drawbacks in some patients. Although some laparoscopic procedures appear to reduce the cost and morbidity associated with surgery, others have not been shown to be effective replacements for more traditional operations. The techniques and indications for operative endoscopy are evolving.

Diagnostic Laparoscopy

The objective lens of a laparoscope can be positioned to allow wide-angle or magnified views of the peritoneal cavity. The clarity and illumination of the optics allow a better appreciation of fine detail than is possible with the naked eye. Laparoscopy is the standard method for the diagnosis of endometriosis and adhesions because no other imaging technique provides the same degree of sensitivity and specificity.

There are limitations to laparoscopy, however. The view of the operative field may be restricted, and if tissue or fluid becomes attached to the lens, vision may be obscured. Also, soft tissues, intramural myomas, or the inside of a hollow viscus cannot be palpated. For assessment of these tissues, an imaging modality, such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) scans, is superior. **Because of its ability to view soft tissue, ultrasonography is more accurate than laparoscopy for the evaluation of the inside of adnexal masses. The intraluminal contour of the uterus can be shown only by hysteroscopy or contrast imaging. Ultrasonography, in combination with serum assays of β -human chorionic gonadotropin (β -hCG) and progesterone, can be used to diagnose ectopic pregnancy, usually allowing medical therapy to be given without laparoscopic confirmation** (12). As a result of

the advances in blood tests and imaging technology, laparoscopy is more often used to confirm a clinical impression than for initial diagnosis.

Laparoscopy may disclose abnormalities that are not necessarily related to the patient's problem. Although endometriosis, adhesions, leiomyomas, and small cysts in the ovaries are common, they are frequently asymptomatic. Thus, **diagnostic laparoscopy must be performed prudently**, interpreting findings in the context of the clinical problem and other diagnoses.

Therapeutic (Operative) Laparoscopy

The role of laparoscopy in the operative management of gynecologic conditions is evolving. Many procedures previously performed as traditional abdominal and vaginal operations are feasible with laparoscopy. Operative laparoscopy has the benefit of shorter hospital stays, less postoperative pain, and faster return to normal activity. In addition to

P.751

the benefits of endoscopic procedures in general, adhesions are less likely to form with laparoscopic surgery than with laparotomy. Because sponges are not used, the amount of direct peritoneal trauma is reduced substantially, and contamination of the peritoneal cavity is minimized. The lack of exposure to air allows the peritoneal surface to remain more moist and, therefore, less susceptible to injury and adhesion formation.

Despite these advantages, there are potential limitations: exposure of the operative field can be reduced, small instruments are required and can be used only through fixed ports, the ability to manipulate the pelvic viscera is limited, and the caliber of the suture required may be larger than otherwise desired. In many cases, the cost of hospitalization increases, despite a shortened stay, because of prolonged operating room time and the use of more expensive surgical equipment and supplies. Efficacy may be reduced if a surgeon cannot adequately replicate the abdominal operation. In some patients, there is an increased risk of complications, which can be attributed to the innate limitations of laparoscopy, the level of surgical expertise, or both. With an adequate combination of ability, training, and experience, however, operative time and complications are comparable to those of traditional abdominal surgery.

Tubal Surgery

Sterilization

Laparoscopic sterilization has been extensively used since the late 1960s and can be performed under general anesthesia. The fallopian tubes can be occluded by suture, clips, or Silastic rings, but electrosurgical desiccation with bipolar energy is the technique used most often (see Chapter 10). With operative laparoscopy, only one incision is required. Otherwise, a second port is needed for the introduction of the occluding instrument. Patients remain in the hospital for several hours, even when general anesthesia is used. Postoperative pain is usually minor and related to the effects of the anesthesia, gas that remains in the peritoneal cavity (shoulder pain, dyspnea), and in the case of occlusive devices, pain at the surgical site. These effects normally disappear within a few days. The failure rate is about 5.4 per 1,000 woman-years (13,14).

Ectopic Gestation

Medical therapy with *methotrexate* is considered first-line therapy for tubal pregnancies that meet the following criteria: no cardiac activity, tubal mass smaller than 5 cm confirmed

by ultrasonography, and β -hCG level less than 1,000 (15). **Ectopic gestation can be managed by using laparoscopy to perform the same procedures done with laparotomy, including salpingotomy, salpingectomy, and segmental resection of a portion of the oviduct** (see Chapter 18) (16). Salpingotomy is performed with scissors, a laser, or an electrosurgical electrode after carefully injecting the mesosalpinx with a dilute *vasopressin*-containing solution (20 units per 100 mL of normal saline). For salpingectomy, the vascular pedicles are usually secured with electrosurgical desiccation, ligatures, clips, or a combination thereof. Tissue is removed from the peritoneal cavity through one of the ports of the laparoscope.

When salpingotomy is performed, regardless of the route, there is about a 5% chance that trophoblastic tissue remains. In such instances, medical treatment with *methotrexate* is considered appropriate (see Chapter 18). Consequently, β -hCG levels should be measured weekly until there is confidence that complete excision has occurred (17,18).

Ovarian Surgery

Ovarian Masses

Laparoscopic removal of selected ovarian masses is a well-established procedure (19,20). However, proper patient selection is critical for laparoscopic management of tumors because of its adverse effect on prognosis with malignant tumors (21). Preoperative ultrasonography is mandatory. Sonolucent lesions with thin

P.752

walls and no solid components are at very low risk for malignancy and, therefore, are suitable for laparoscopic removal. For postmenopausal women, the measurement of CA125 levels is useful in identifying candidates for laparoscopic management (22,23). Lesions with ultrasonographic findings suggestive of mature teratoma (dermoid), endometrioma, or hemorrhagic cyst with acute pain may also be suitable for endoscopic management (24).

Ovarian tumors should be assessed by frozen histologic section, and any malignancy should be managed expeditiously by laparotomy (20,23).

The technique for performing laparoscopy for oophorectomy and cystectomy is similar to that used for laparotomy (17). For cystectomy, scissors are used to incise the ovarian capsule, and blunt dissection or aquadissection are used to separate the cyst from the ovary. If oophorectomy is performed, the vascular pedicles are ligated with sutures, clips, linear cutting staplers, electrosurgical desiccation, or a combination thereof. The ureter should be identified and should be clear of the pedicle to be ligated. Cysts that appear to be benign may be drained before extraction through either a laparoscopic cannula or, rarely, a posterior colpotomy. If there is concern about the impact of spilled cyst contents, the specimen should be removed in a retrieval bag inserted into the peritoneal cavity.

Although in the past the ovary has routinely been closed after cystectomy, this practice may be unnecessary and could contribute to the formation of adhesions (25). However, complete disruption of the ovarian cortex after removal of large cysts may make closure necessary, in which case the edges of the ovarian incision can be sutured.

Other Ovarian Surgery

Ovarian torsion, previously treated by laparotomy and oophorectomy, often can be managed laparoscopically (26,27). Even if there is apparent necrosis, the adnexa can be untwisted, usually with preservation of normal ovarian function (28). Performing a cystectomy at the same time the ovary is untwisted greatly reduces the likelihood that ovarian function will

be maintained. Rarely is adnexectomy indicated.

Polycystic ovarian syndrome can be treated laparoscopically using electrosurgery and laser vaporization to perform ovarian drilling. This procedure reduces stromal tissue and may lead to a temporary return to normal ovulation (29,30,31). Although such procedures have been shown to be successful, postoperative adhesions form in 15% to 20% of patients, which underscores the need to first exhaust medical treatment (32,33).

Uterine Surgery

Myomectomy

Laparoscopic myomectomy, although feasible, is difficult to perform. Its efficacy is yet to be established, especially as it relates to the treatment of infertility and menorrhagia (34,35). Laparoscopic myomectomy often requires laparoscopic suturing and, thus, requires more technical skills than many other endoscopic procedures.

Unless the myoma involves the endometrial cavity, it is unlikely to contribute to heavy menstrual bleeding. Leiomyomas that cause pressure are often large and may be located in or near vital vascular structures. Myomectomy should be performed only when indicated (as opposed to expectant or medical management, which may be appropriate for some women with leiomyomas), and laparotomy should be used if there are technical limitations (36). **Patients who have pedunculated or subserosal leiomyomas that cause bothersome discomfort or pain in association with torsion are candidates for laparoscopic excision** (17,37).

P.753

Hysterectomy

For women who require hysterectomy, the appropriate route of surgery is determined by anatomical considerations, the type of pathology expected, patient preference, and physician experience and training. Laparoscopic hysterectomy offers no advantage for women in whom vaginal hysterectomy is possible because the endoscopic approach is more expensive and has a higher risk for postoperative morbidity (38,39). However, 75% of the approximately 600,000 hysterectomies performed in the United States are abdominal hysterectomies. Indications for choosing an abdominal approach are known or suspected pelvic adhesions or endometriosis, leiomyomata, the presence of adnexal pathology, the need for mandatory removal of the adnexa, or the absence of pelvic relaxation. In many patients, hysterectomy can be performed under laparoscopic direction.

Laparoscopic hysterectomy encompasses a variety of procedures, including the facilitation of vaginal hysterectomy with variable extents of endoscopic dissection, supracervical hysterectomy by dissection, amputation and mechanical removal of the fundus, and the removal of the entire uterus with the assistance of the laparoscope (40). The procedure is performed with scissors, sutures, electricity, clips, and in some instances, linear cutting and stapling devices to dissect or ligate pedicles.

There is a slightly higher risk of complications with laparoscopic hysterectomy, and operating times may be longer and procedures more costly than with abdominal hysterectomy. As experience is gained with laparoscopic hysterectomy, these outcomes approach those of abdominal hysterectomy. When reusable instruments are employed, however, laparoscopic hysterectomy is less costly than abdominal hysterectomy (41). Most studies show less postoperative pain, shorter hospital stays, and faster postoperative recovery with laparoscopic hysterectomy than with abdominal hysterectomy (42).

One study found pain scores and quality-of-life measures, including sexual activity and physical and mental functioning, were significantly better for women who underwent laparoscopic versus abdominal hysterectomy (42). These differences were present at 6 weeks following surgery and remained at the 12-month follow-up visit.

Infertility Operations

Laparoscopic treatment of infertility includes operations used to reconstruct the normal anatomic relationships altered by an inflammatory process such as fimbrioplasty, adhesiolysis, and salpingostomy for distal obstruction (43). Fimbrioplasty is distinguished from salpingostomy because it is performed in the absence of pre-existing complete distal obstruction. Endometriosis associated with adnexal distortion can be treated by laparoscopic adhesiolysis. There is no known additional benefit of laparoscopic (or medical) treatment of coexistent active endometriosis. Laparoscopy has been superseded by ultrasound for the retrieval of oocytes for *in vitro* fertilization but is still used for procedures in which gametes (gamete intrafallopian transfer) or zygotes (zygote intrafallopian transfer) are placed into the fallopian tube.

Adhesiolysis may be accomplished by blunt or sharp dissection with scissors, laser, ultrasonic shears, or electrosurgical electrode. These instruments are usually passed through an ancillary port; when laser energy is used, the channel of the operating laparoscope may be used for this purpose. Although there has been controversy regarding the most appropriate modality for adhesiolysis, these methods are probably equally effective in appropriately trained hands.

Laparoscopic operations for the treatment of mechanical infertility are probably equally effective to similar procedures performed by laparotomy. In patients with extensive adhesions, however, the effectiveness of all procedures is limited. Assisted reproductive technologies such as *in vitro* fertilization and embryo transfer are necessary in these situations (see Chapter 30) (17,44).

P.754

Endometriosis

The laparoscopic management of endometriomas parallels that of adnexal masses, although the ultrasonographic complexity of endometriomas sometimes makes it difficult to distinguish them preoperatively from a neoplasm. The close attachment of the endometrioma to the ovarian cortex and stroma may make it difficult to find surgical dissection planes, and incomplete removal increases the risk of recurrence. There is a tendency either to compromise the function of the remaining ovary by attempting complete removal or to leave part of the endometrioma in place. Therefore, for women who want to retain their fertility, electrosurgical or laser ablative techniques may be used to treat endometriotic tissue that is adherent to the remaining ovary.

Multifocal endometriosis may be treated by mechanical excision or ablation, the latter using coagulation or vaporization with either electrical or laser energy. With proper use, each energy source creates about the same amount of thermal injury (45,46). Endometriosis frequently is deeper than appreciated initially, making excisional techniques valuable in many instances (17,44).

Pelvic Floor Disorders

Laparoscopy can be used to guide procedures to treat pelvic support defects, including culdoplasty, enterocele repair, vaginal vault suspension, paravaginal repair,

and retropubic cystourethropey for urinary stress incontinence. Although these conditions can be treated vaginally, the laparoscopic approach may offer benefits, particularly with retropubic urethropey. There is some evidence that the laparoscopic approach is effective when compared with the traditional methods (47,48). Using the same surgical principles applied during traditional pelvic floor repair, laparoscopy promises better access to key anatomical landmarks and potentially more accurate suture placement (49). Whereas apical and anterior compartment defects can be successfully corrected via laparoscopy, posterior and perineal defects are still best visualized and repaired using vaginal techniques. The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure. Because of the anatomical proximity of the pelvic ureter to the uterosacral ligament and anterolateral vagina, bilateral ureteral patency should be confirmed cystoscopically after laparoscopic vaginal vault suspension, enterocele repair, culdoplasty, cystourethropey, or paravaginal repair.

Gynecologic Malignancies

The role of laparoscopy in the management of gynecologic malignancy has not been clearly established (50,51,52). A study performed by the Gynecology Oncology Group showed that laparoscopic management of presumed stage I endometrial cancer was feasible (53), whereas another study found that women with endometrial cancer and other comorbidities had fewer complications with laparoscopically assisted vaginal hysterectomy than with laparotomy (54). The potential for laparoscopic lymphadenectomy has fostered a resurgence of interest in vaginal radical hysterectomy for stage I carcinoma of the cervix. Laparoscopy is also being investigated for the staging of early ovarian malignancy and for second-look surgery.

Patient Preparation and Communication

The rationale, alternatives, risks, and potential benefits of the selected approach should be explained to the prospective patient. She should know the likely outcome of expectant management if the procedure was not performed.

The expectations and risks of diagnostic laparoscopy, as well as those of any other procedures that may be needed, must be explained. It may be helpful to compare risks and recovery with the same procedure performed via abdominal surgery. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the

P. 755

abdominal and pelvic viscera. The possibility of conversion to laparotomy if a complication should occur or if the procedure cannot be completed via laparoscopic surgery should also be discussed. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury. The potential for these risks should be clearly presented. The patient should be given realistic expectations regarding postoperative disability. **Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery.** After diagnostic or brief operative procedures, patients can be discharged on the day of surgery and usually require 24 to 72 hours off work or school. If extensive dissection—a major surgical procedure performed laparoscopically—is necessary, or if the surgery lasts longer than 2 hours, hospital admission may be necessary, and the period of disability may be as long as 10 to 14 days.

If the procedure may involve the colon, mechanical bowel preparation should

be performed to help improve visualization and minimize the likelihood of fecal spillage if the colon is entered. The patient should arrange for a friend or family member to be present to discuss the results of the procedure with the physician and to drive her home if she is discharged the same day. Mild analgesia often is necessary.

Equipment and Technique

To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into "core competencies," which are as follows:

- Patient positioning
- Operating room organization
- Peritoneal access
- Visualization
- Manipulation of tissue and fluid
- Cutting, hemostasis, and tissue fastening
- Tissue extraction
- Incision management

Patient Positioning

Proper positioning of the patient is essential for patient safety, comfort of the operator, and optimal visualization of the pelvic organs. Laparoscopy is performed on an operating table that can be tipped to create a steep, head-down (Trendelenburg) position that allows the bowel to move out of the pelvis after the first trocar has been placed. The footrest can be dropped to allow access to the perineum. The patient is placed in the low lithotomy position, with the legs supported in stirrups and the buttocks protruding slightly from the lower edge of the table (Fig. 21.1). The thighs are usually kept in the neutral position to preserve the sacroiliac angle, reducing the tendency of bowel to slide into the peritoneal cavity. **The feet should rest flat, and the lateral aspect of the knee should be protected with padding or a special stirrup to avoid peroneal nerve injury.** The knees should be kept in at least slight flexion to minimize stretching of the sciatic nerve and to provide more stability in the Trendelenburg position. **The arms are positioned at the patient's side by adduction and pronation to allow freedom of movement for the surgeon and to lower the risk for brachial plexus injury** (Fig. 21.2). Care must be exercised to protect the patient's fingers and hands from injury when the foot of the table is

raised or lowered. After the patient is properly positioned, the bladder should be emptied with

a catheter and a uterine manipulator attached to the cervix.

Figure 21.1 Patient positioning: the low lithotomy position. The patient's buttocks are positioned so that the perineum is at the edge of the table. The legs are well supported with stirrups, with the thighs in slight flexion. Too much flexion may impede the manipulation of laparoscopic instruments while in the Trendelenburg (head-down) position.

Operating Room Organization

The arrangement of instruments and equipment is important for safety and efficiency. The orientation depends on the operation, the instruments used, and whether the surgeon is right- or left-handed. An orientation for a right-handed operator is shown in Figure 21.2.

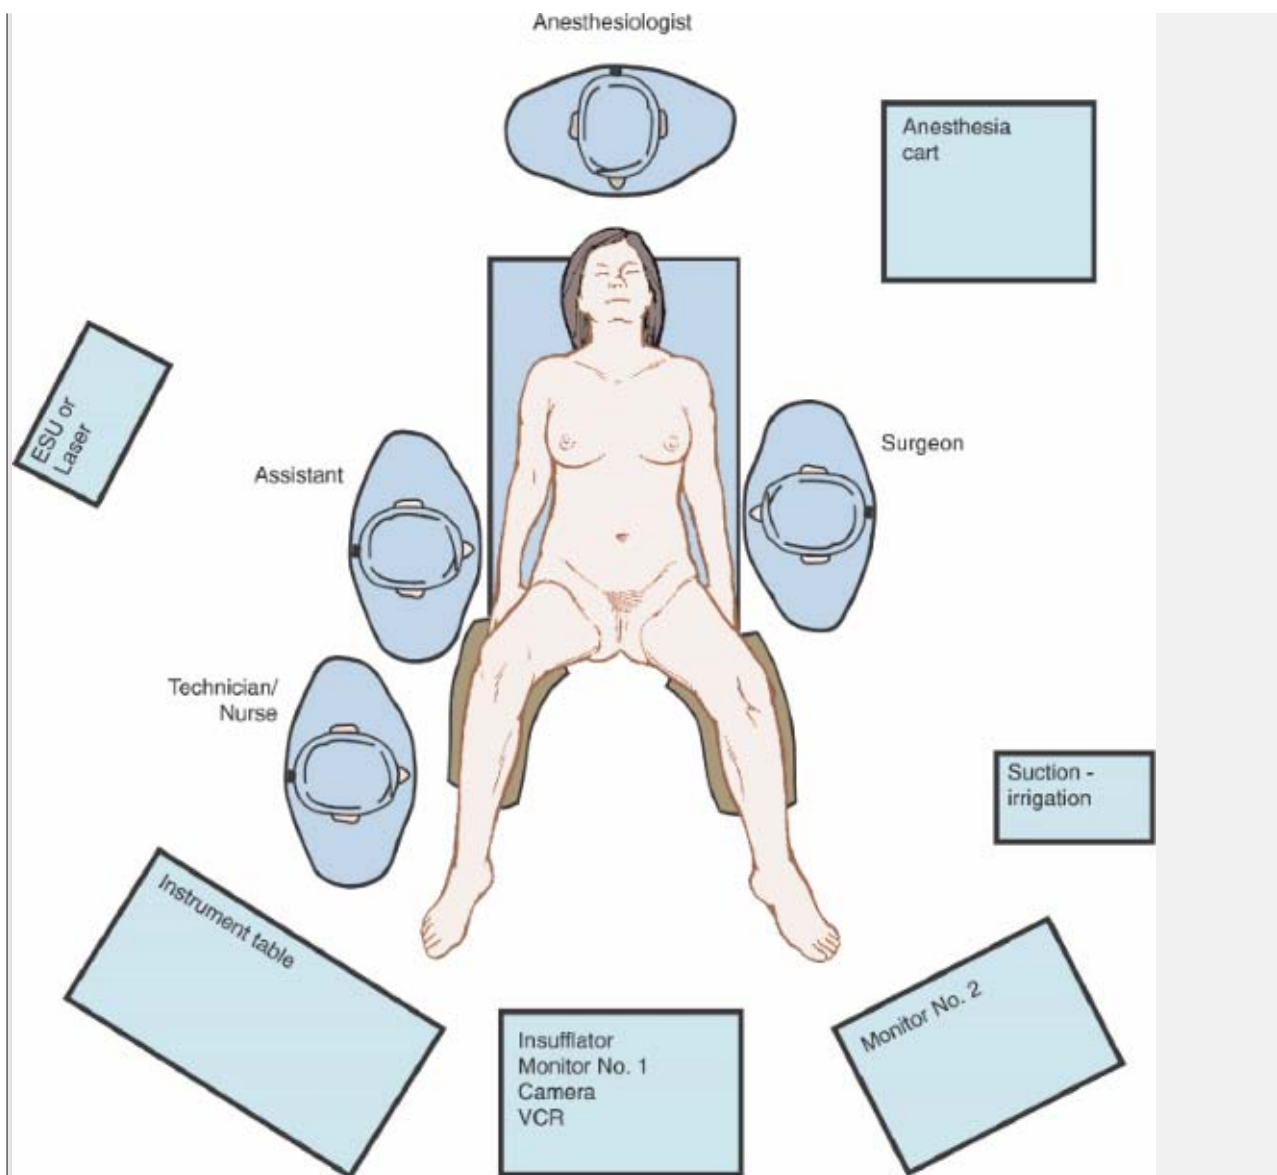

Figure 21.2 Operating room organization. The patient's arms are at the sides. The right-handed surgeon stands on the patient's left. Instruments and equipment are distributed around the patient within view of the surgeon. For pelvic surgery, the monitor should be located between the patient's legs.

For pelvic surgery, the monitor may be placed at the foot of the table within the angle formed by the patient's legs. If a second monitor is used, one may be positioned at each foot of the patient.

The surgeon usually stands by the patient's left side, at an angle facing the patient's contralateral foot. The nurse or technician and instrument table are positioned near the foot of the operating table to avoid obscuring the video monitor. The insufflator may be placed on the patient's right side, in front of the surgeon, to allow continuous monitoring of the inflation rate and intra-abdominal pressure. The electro-surgical generator may also be positioned on the patient's right side to permit visualization of the power output. When a laser is used through a second puncture site, it may also be placed to the patient's right.

When the laser is passed through the channel of an operating laparoscope, however, it may be situated on the patient's left side, beside the surgeon.

Peritoneal Access

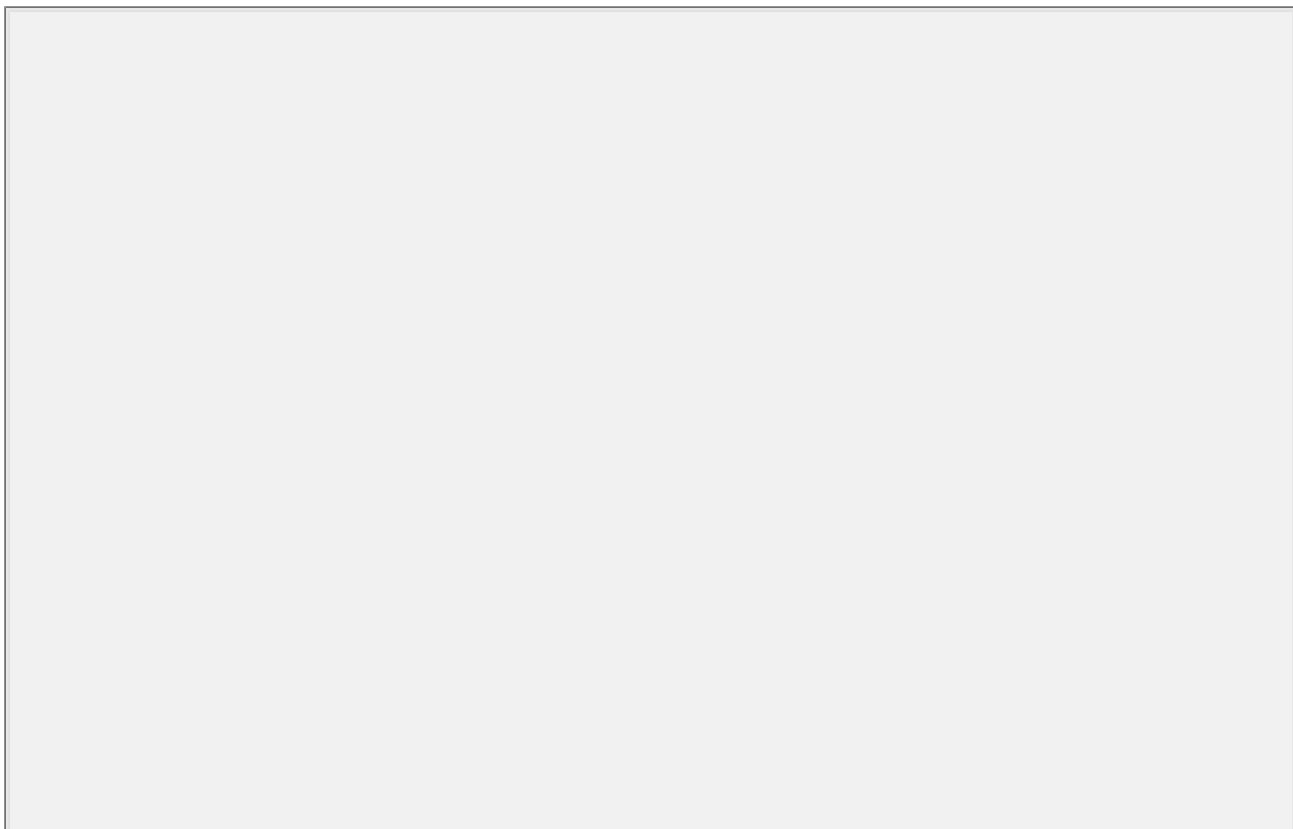

Before inserting the laparoscope, a cannula or port must be positioned in the abdominal wall to establish access to the peritoneal cavity. **The closed technique is a blind approach in which the cannula is introduced with a sharp trocar used to penetrate the abdominal layers. In open laparoscopy, entry into the peritoneal cavity is achieved with minilaparotomy using either a transverse subumbilical or midline infraumbilical incision down to the rectus fascia, to which the cannula is fixed into position with sutures or other suitable techniques.** Gynecologists have generally favored a closed technique, preinflating the peritoneal cavity with CO₂ through a hollow insufflation needle. In either case, additional cannulas are subsequently inserted by sharp trocars under direct vision to allow the use of laparoscopic hand instruments such as scissors, probes, and other manipulating devices.

P.758

Insertion of the insufflation needle and primary cannula is aided by an understanding of the normal underlying anatomy, especially the location of the larger retroperitoneal vessels (Fig. 21.3). A "safety zone" exists inferior to the sacral promontory in the area bounded cephalad by the bifurcation of the aorta, posteriorly by the sacrum, and laterally by the iliac vessels (49). In women placed in the Trendelenburg position, the great vessels are situated more cephalad and anterior, making them more vulnerable to injury unless appropriate adjustments are made in the angle of insertion (Fig. 21.4) (55). Therefore, positioning of the insufflation needle, the primary trocar,

P.759

and the cannula are best accomplished with the patient in an unaltered horizontal position. This approach also facilitates the evaluation of the upper abdomen, which is limited if the intraperitoneal contents are shifted cephalad by the head-down position.

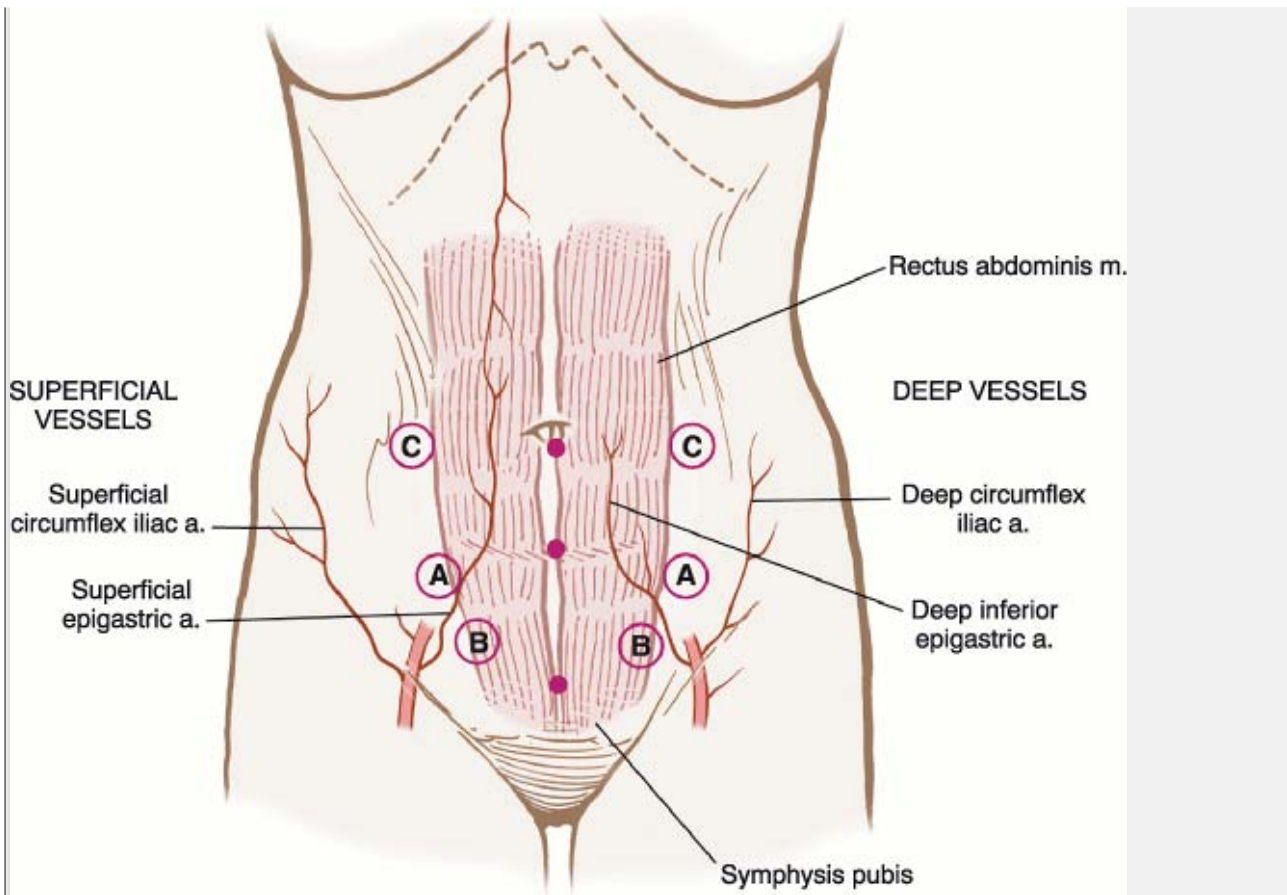

Figure 21.3 Vascular anatomy of the anterior abdominal wall. Location of the vessels that can be traumatized when inserting trocars into the anterior abdominal wall.

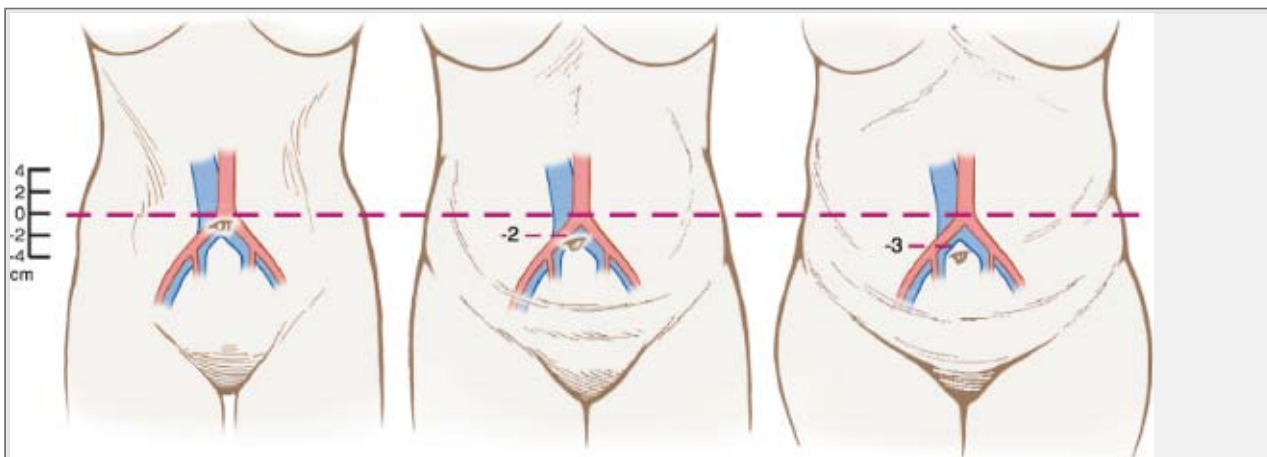

Figure 21.4 Vascular anatomy. Location of the great vessels and their changing relationship to the umbilicus with increasing patient weight (*from left to right*).

Insufflation Needles

Virtually all insufflation needles are modifications of the hollow needle designed by Verres (Fig. 21.5). In cases uncomplicated by previous pelvic surgery, the preferred site for insertion is the base of the umbilicus, where the abdominal wall is the thinnest and usually avascular.

Figure 21.5 Insufflation needle. When pressed against tissue such as fascia or peritoneum, the spring-loaded blunt obturator (*inset*) is pushed back into the hollow needle, revealing its sharpened end. When the needle enters the peritoneal cavity, the obturator springs back into position, protecting the intraabdominal contents from injury. The handle of the hollow needle allows the attachment of a syringe or tubing for insufflation of the distention gas.

A midline infraumbilical incision adequate for the needle is made at the base of the umbilicus with a small scalpel, and the abdominal wall is maximally lifted, either manually or with instruments. Elevation is accomplished manually by grasping on either side lateral to the umbilicus or midway between the umbilicus and mons pubis. Instrumentally, elevation can be achieved by affixing towel clips to the abdominal wall on either side lateral to the umbilicus or opposite one another within the edge of the umbilical incision itself (56).

Safe insertion of the insufflation needle mandates that the instrument be maintained in a midline, sagittal plane while the operator directs the tip between the iliac vessels, anterior to the sacrum but inferior to the bifurcation of the aorta and the proximal aspect of the vena cava. Because the sacral promontory is commonly covered in part by the left common iliac vein, vascular injury may still occur in the midline below the bifurcation (57).

To reduce the risk of retroperitoneal vascular injury while minimizing the chance of inadvertent preperitoneal insufflation, in women of average weight, **the insufflation needle is directed to the patient's spine at a 45-degree angle.** In heavy to obese individuals, this angle may be increased incrementally to nearly 90 degrees, accounting for the increasing thickness of the abdominal wall and the tendency of the umbilicus to gravitate caudad with increasing abdominal girth (58). The needle's shaft is held by the tips of the fingers and steadily but purposefully guided into position only far enough to allow the tip's entry into the peritoneal cavity. The tactile and visual feedback created when the needle passes through the facial and peritoneal layers of the abdominal wall may

P.760

provide guidance and help prevent overaggressive insertion attempts. This proprioceptive feedback is less apparent with disposable needles than with the classic Verres needle. With the former, the surgeon must listen to the "clicks" as the needle obturator retracts when it passes through the rectus fascia and the peritoneum. The needle should never be forced. Regardless of technique, the underlying retroperitoneal vessels are protected ultimately by limiting the depth of insertion of the insufflation needle and umbilical cannula.

In instances in which known or suspected intra-abdominal adhesions surround the umbilicus, alternative sites should be used for insufflation needle insertion. These sites include the left upper quadrant, most often at the left costal margin, the pouch of Douglas, and the fundus of the uterus (Fig. 21.6). The left upper quadrant is preferred if hepatosplenomegaly is not present and the patient has not previously had surgery in this area. In such patients, the stomach must be decompressed with a nasogastric or orogastric tube before the needle is inserted (59).

Figure 21.6 Insufflation needle and cannula insertion sites. In most instances, both the insufflation needle, if used, and the primary cannula are inserted through the umbilicus. When subumbilical adhesions are known or suspected, the insufflation needle may be placed through the pouch of Douglas or in the left upper quadrant after evacuation of the gastric contents with an orogastric tube.

Before insufflation, the operator should try to detect whether the insufflation needle has been malpositioned in the omentum, mesentery, blood vessels, or hollow organs such as the stomach or bowel. Using a syringe attached to the

insufflation needle, blood or gastrointestinal contents may be aspirated. To facilitate this examination, a small amount of saline may be injected into the syringe. If the needle is appropriately positioned, negative intra-abdominal pressure is created by lifting the abdominal wall. This negative pressure may be demonstrated by aspiration of a drop of saline placed over the open, proximal end of the needle or, preferably, by using the digital pressure gauge on the insufflator.

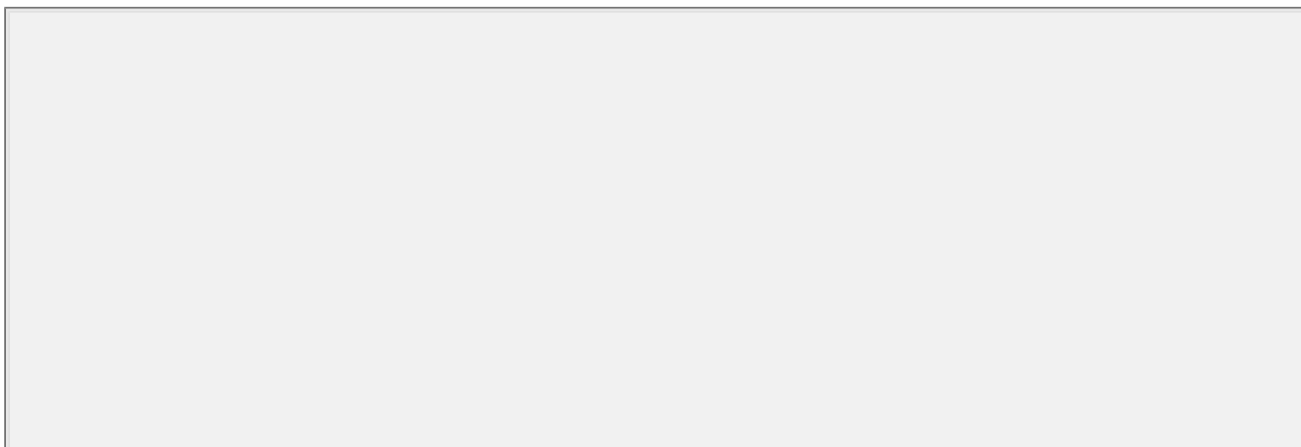

- **Additional signs of proper placement may be sought after starting insufflation. The intra-abdominal pressure reading should be low, reflecting only systemic resistance to the flow of CO₂.** Consequently, there should be little deviation from a baseline

measurement, generally less than 10 mm Hg. The pressure varies with respiration and is slightly higher in obese patients. The earliest reassuring sign is the loss of liver "dullness" over the lateral aspect of the right costal margin. However, this sign may be absent if there are dense adhesions in the area, usually the result of previous surgery. Symmetric distention is unlikely to occur when the needle is positioned extraperitoneally. Proper positioning can also be shown by lightly compressing the xiphoid process, which increases the pressure measured by the insufflator.

- **The amount of gas transmitted into the peritoneal cavity should depend on the measured intraperitoneal pressure, not the volume of gas inflated.** Intraperitoneal volume capacity varies significantly between individuals. Many surgeons prefer to insufflate to 25 mm Hg for positioning of the cannulas. This level usually provides extra volume and enough counterpressure against the peritoneum, facilitating trocar introduction and potentially reducing the chance of bowel or posterior abdominal wall and vessel trauma. After placement of the cannulas, the pressure should be dropped to 10 to 12 mm Hg, which reduces the risk of subcutaneous insufflation leading to crepitus and essentially eliminates hypercarbia or decreased venous return of blood to the heart (59,60,61).

Laparoscopic Cannulas

Laparoscopic cannulas allow the insertion of laparoscopic instruments into the peritoneal cavity while maintaining the pressure created by the distending gas (Figs. 21.7 and 21.8). Cannulas are hollow tubes with a valve or sealing mechanism at or near the proximal end. The cannula may be fitted with a Luer-type port that allows attachment to tubing connected with the CO₂ insufflator. Larger-diameter cannulas (8–12 mm) may be fitted with adapters or specialized valves that allow the insertion of smaller-diameter instruments without loss of intraperitoneal pressure.

Figure 21.7 Disposable access systems. These instruments are designed for single use. A 12-mm internal diameter blunt access system is shown in **A**. The next device (**B**) also has a 12 mm internal diameter, but has a deployable blade that is used to cut through the abdominal wall. A smaller diameter blunt conical device is shown in **C** while a sharp conical access system is presented in **D**. Both **C** and **D** have a 5 mm in inside diameter. A narrow, 2.7-mm diameter cannula is shown in **E**. The trocar for this system is a long insufflation needle with a spring deployable obturator.

Figure 21.8 Reusable access systems. **A:** is a sharp conical device while **B** represents a pyramidal-tipped design. **C** and **D** (and *inset*) are images of the so-called EndoTip device that can be positioned in the abdominal wall by simply twisting or screwing it in without the requirement of a trocar.

The trocar is a longer instrument of slightly smaller diameter that is passed through the cannula, exposing its tip. Most trocars have sharp tips, allowing penetration of the abdominal wall after a small skin incision. Many disposable trocar-cannula systems are designed with a "safety mechanism"—usually a pressure-sensitive spring that either retracts the trocar or deploys a protective sheath around its tip after passage through the abdominal wall. None of these protective devices has been shown to make insertion safer, however, and they all increase the cost of the equipment.

Following open laparoscopy, cannulas can be inserted either after the successful creation of a pneumoperitoneum (secondary puncture) or without previously instilling intraperitoneal gas (primary puncture). With open laparoscopy, there is less risk of injury to blood vessels. However, open laparoscopy cannot prevent all insertion accidents because intestine can be entered inadvertently no matter how small the incision. There is little evidence that a pneumoperitoneum is necessary, at least in the absence of pre-existing abdominal wall adhesions. Therefore, **in women with no previous surgery, the primary puncture can be performed with a sharp-tipped trocar-cannula system, which reduces operating time. The first, or primary, cannula must be of sufficient caliber to permit passage of the**

laparoscope and usually is inserted in or at the lower border of the umbilicus. The incision should be extended only enough to allow insertion of the cannula; otherwise, leakage of gas may occur around the sheath. The patient should be in an unaltered supine position during placement of the primary cannula. For the primary puncture, either the surgeon or an assistant should elevate the abdominal wall as described previously. Both

P.763

hands can be positioned on the device, using one to provide counterpressure and control to prevent "overshoot" and resultant injury to bowel or vessels. **The angle of insertion is the same as for the insufflation needle; adjustments are made according to the patient's weight and body habitus.** The laparoscope should be inserted to confirm proper intraperitoneal placement before the insufflation gas is allowed to flow. **Previous abdominal surgery increases the incidence of adhesions of the bowel to the anterior abdominal wall, frequently near the umbilicus and in the path of the primary trocar** (8,62). In such patients, another primary insertion site, such as the left upper quadrant, should be selected, even if it is used solely for conveying a narrow "scout" laparoscope, some types of which can be inserted through an insufflation needle (Fig. 21.10). Using such a laparoscope, the presence of adhesions under the incision can be excluded and the umbilical cannula can be inserted under direct vision. If adhesions are noted under the incision, appropriate placement of secondary cannulas may be used to introduce instruments for adhesiolysis. Alternate insertion sites for primary cannulas are shown in Figure 21.6.

Figure 21.10 "Scout" Laparoscope. The 2-millimeter laparoscope from Figure 21.9 and the 2.7-mm access system from Figure 21.7 are shown here assembled. The tubing is connected to inflow gas, usually carbon dioxide.

Figure 21.9 Laparoscopes. Three 0-degree laparoscopes are shown. From top to bottom, 2-mm, 5-mm and 10-mm diameter.

Ancillary Cannulas

Ancillary cannulas are necessary to perform most diagnostic and operative laparoscopic procedures. Most currently available disposable ancillary cannulas are identical to those designed for insertion of the primary cannula; however, simple cannulas without safety sheaths and insufflation ports are sufficient (Figs. 21.7D and 21.8D).

Proper positioning of these cannulas depends on a sound knowledge of the abdominal wall vascular anatomy. **For the secondary puncture, the patient should be tipped head**

P.764

down (Trendelenburg), allowing the abdominal contents to move away from the sites for secondary puncture, and thus making it unnecessary to lift the abdominal wall during secondary cannula insertion. Ancillary cannulas should always be inserted under direct vision because injury to bowel or major vessels can occur. Before insertion, the bladder should be drained with a urethral catheter. The insertion sites depend on the procedure, the disease, the patient's body habitus, and the surgeon's preference. For diagnostic laparoscopy, the most useful and cosmetically acceptable site for insertion of an ancillary cannula is in the midline of the lower abdomen, about 2 to 4 cm above the symphysis. The ancillary cannula should not be inserted too close to the symphysis because it limits the mobility of the ancillary instruments and access to the cul-de-sac. Laparoscope cannulas can become dislodged and slip out of the incision during a procedure. There are a variety of cannula attachments, called grippers, designed to prevent slippage.

Lateral placement of lower-quadrant cannulas are useful for operative laparoscopy, but the superficial and inferior epigastric vessels must be located to avoid injury (Fig. 21.3). Transillumination of the abdominal wall from within permits the identification of the superficial inferior epigastric vessels in most thin women. However, the deep inferior epigastric vessels cannot be identified by this mechanism because of their location deep to the rectus sheath. **The most consistent landmarks are the medial umbilical ligaments (obliterated umbilical arteries) and the exit point of the round ligament into the inguinal canal.** At the pubic crest, the deep inferior epigastric vessels can often be visualized between the medially located umbilical ligament and the laterally positioned exit point of the round ligament. The trocar should be inserted medial or lateral to the vessels if they are visualized. **If the vessels cannot be seen and it is necessary to position the cannula laterally, the cannula should be placed 3 to 4 cm lateral to the medial umbilical ligament or lateral to the lateral margin of the rectus abdominis muscle.** If

the insertion is placed too far laterally, it will endanger the deep circumflex epigastric artery. The risk of injury can be minimized by placing a 22-gauge spinal needle through the skin at the desired location, directly observing the entry through the laparoscope. This provides reassurance that a safe location has been identified and allows visualization of the peritoneal needle hole, which provides a precise target for inserting the trocar.

Even after a proper incision, the abdominal wall vessels can be injured if the trocar slides medially during placement. Large-diameter trocars are more likely to cause injury; therefore, the smallest cannulas necessary to perform the procedure should be used. Ancillary cannulas should not be placed too close together because this results in hindrance of the hand instruments, which compromises access and maneuverability.

Visualization

During endoscopy, the image must be transferred through an optical system. Although direct optical viewing is feasible and often used for diagnostic purposes, virtually all operative laparoscopy is performed using video guidance.

Operative versus Diagnostic Equipment

Laparoscopes used for operative purposes have a straight channel, parallel to the optical axis, for the introduction of operating instruments. This provides an additional port for the insertion of instruments and the tangential application of laser energy. However, operative endoscopes are of relatively larger caliber than diagnostic laparoscopes and have smaller fields of view and increased electrosurgical risks. Diagnostic laparoscopes permit better visualization at a given diameter and are associated with fewer electrosurgical risks.

Diameter

Narrow-diameter laparoscopes allow limited transfer of light both into and out of the peritoneal cavity; therefore, they require a more sensitive camera or a more powerful light

P.765

source for adequate illumination. Ideal illumination is provided by 10-mm diagnostic laparoscopes, but improvements in optics are making more procedures feasible with smaller-caliber devices (Fig. 21.9).

Viewing Angle

The viewing angle depicts the relationship of the visual field to the axis of the endoscope and is usually either zero or 30 degrees to the horizontal. The zero-degree scope is the standard for gynecologic surgery. However, the 30-degree angle provides some advantage in difficult situations, such as the performance of retropubic urethropexy or adhesiolysis or for surgery in the presence of large myomas.

Imaging Systems

The video camera captures the image transmitted by the endoscope and the image is transmitted to the body of the camera located outside the operative field, where it is processed and sent to a monitor and, if desired, a recording device (Fig. 21.11). The resolution capability of the monitor should be at least equal to that provided by the camera. Most monitors have the potential to display about 800 horizontal lines of resolution. The more light transmitted through the endoscope, the better the visualization. The best currently available output is achieved from

250 to 300 watts, usually using xenon or metal halide bulbs. Most camera systems are integrated with the light source to vary light output automatically, depending on the amount of exposure required. Light guides or cables transmit light from the source to the endoscope via a bundle densely packed optical fibers (fiberoptic). Fiberoptic cables lose function over time, particularly if they are mishandled, which may break the fibers.

Figure 21.11 Laparoscopic Tower. This tower comprises a monitor (A), a camera body or base unit (B) attached to a camera sensor; a light source (C) attached to a cable, which in turn will be connected with the endoscope; a still-image printer (D) and an insufflation machine (E). A video recorder is shown in (F).

Intraperitoneal Distention

Insufflation Machines

The insufflator delivers CO₂ from a gas cylinder to the patient through tubing connected to one of the ports on the laparoscope. Most insufflators can be set to maintain a predetermined intra-abdominal pressure. High flow rates (9–20 L/min) are especially useful for maintaining exposure when suction of smoke or fluid depletes the volume of intraperitoneal gas.

Laparoscopic Lifting Systems

Intraperitoneal retractors attached to a pneumatic or mechanical lifting system can be used to create an intraperitoneal space much like a tent. This “gasless” or “apneumatic” technique may have some advantages over pneumoperitoneum, particularly in patients with cardiopulmonary disease. Airtight cannulas are not necessary, and instruments do not need to have a uniform, narrow, cylindrical shape. Consequently, some conventional instruments may be used directly through the incisions.

Fluid Management

Fluid may be instilled into the peritoneal cavity through wide-caliber arthroscopy or cystoscopy tubing using pressure provided by gravity, an infusion cuff, or a high-pressure mechanical pump. The pumps deliver fluid faster than the other techniques, and the highly pressurized stream of fluid may facilitate blunt dissection (hydro- or aquadissection). Small volumes of fluid can be removed with a syringe attached to a cannula; for large volumes, it is necessary to use suction generated by a machine or a wall source.

The cannulas used for suction and irrigation depend on the irrigation fluid used and the fluid being removed. For ruptured ectopic gestations or other procedures in which there is a large amount of blood and clots, large-diameter cannulas (7–10 mm) are preferred. Cannulas with narrow tips are more effective in generating the high pressure needed for hydrodissection.

If large volumes of fluid are required, isotonic fluids should be used to avoid fluid overload and electrolyte imbalance. If electrosurgery is to be performed, however, small volumes of a nonelectrolyte-containing solution such as glycine or sorbitol can be used for hemostasis and irrigation. *Heparin* (1,000–5,000 U/L) can be added to irrigating solution to prevent blood from clotting, thus allowing it to be removed more easily.

Tissue Manipulation

Uterine Manipulators

A properly designed uterine manipulator should have an intrauterine component, or obturator, and a method for fixation of the device to the uterus. Articulation of the instrument permits acute anteversion or retroversion, both of which are extremely useful maneuvers. If the uterus is large, longer and wider obturators are used so that the manipulations can be performed more effectively. Two types of uterine manipulators are shown in Figure 21.12. A hollow obturator attached to a port allows intraoperative instillation of liquid dye to demonstrate tubal patency.

Figure 21.12 Uterine Manipulators. (Top) is the disposable "V-Care" device. At the tip is a balloon inflated to maintain the device in the endometrial cavity. Next to the tip is a cervical collar that serves to facilitate identification of the vaginal fornices and cutting of the vagina in laparoscopic total hysterectomy. The blue truncated cone maintains a seal so that gas won't leak out when culdotomy is performed. (Bottom) is the reusable Pelosi manipulator. The ring handle allows the surgeon to antevert the uterus.

Grasping Forceps

The forceps used during laparoscopy should replicate those used in open surgery. Disposable instruments generally do not have the quality, strength, and precision of nondisposable forceps (Fig. 21.13). Instruments with teeth (toothed forceps) are necessary to grasp the peritoneum or the edge of ovary securely to remove an ovarian cyst. Minimally traumatic instruments designed like Babcock clamps are needed to retract the fallopian

tube safely. Tenaculum-like instruments are desirable to retract leiomyomas or the uterus. A ratchet is useful to hold tissue without arduous hand pressure. Graspers should be insulated if unipolar electrical energy is being used for hemostasis.

Figure 21.13 Laparoscopic Instruments for Grasping and Manipulating Tissue. **A:** (*top and inset*) are 5-mm diameter graspers with a curved tip, often called “Maryland” graspers. Other reusable tips (**B**) and (**C**) may be positioned in the same handle as is shown for **A**. **D:** is a 10-mm claw grasper while (**E**) and (**F**) are 5- and 2-mm manipulating probes respectively. **G:** is a 2-mm grasping forceps.

Cutting, Hemostasis, and Tissue Fixation

Cutting can be achieved by mechanical means or by using radiofrequency electrical current, laser energy, or ultrasonic energy. The methods for maintaining or securing hemostasis include sutures, clips, linear staplers, energy sources, and topical or injectable substances. Secure apposition or tissue fixation may be accomplished with sutures, clips, or staples. With appropriate training, a skilled surgeon can obtain good results with any combination of these techniques for cutting, hemostasis, and tissue fixation. Studies in animals have not demonstrated any difference in injury characteristics when cutting is performed with either laser or radiofrequency energy (44,45,63), and randomized controlled studies have shown no differences in fertility outcomes (64). Therefore, differences in results are more likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise.

Cutting

The most useful cutting instruments are scissors (21.14 Bottom). Because it is difficult to sharpen laparoscopic scissors, most surgeons prefer disposable instruments that can be used until dull and then discarded. Another mechanical cutting tool is the linear stapler–cutter that can simultaneously cut and hemostatically staple the edges of the incision. The cost and large dimensions of the instruments limit their practical use to only a few highly selected situations, such as separation of the uterus from the ovary and fallopian tube during laparoscopic hysterectomy.

Laser and electrical sources of energy manifest their effect by conversion

of electromagnetic energy generated by a special electro-surgical unit (ESU) (Fig. 21.15) to mechanical energy which is then transformed to thermal energy. Highly focused radiofrequency energy produces vaporization or cutting, whereas less focused energy (high-current density) raises the intracellular temperature above 100° C and results in tissue vaporization or, if the instrument is moved in a linear fashion, tissue cutting. Less focused radiofrequency energy (moderate current density) elevates intracellular temperature, causing desiccation and tissue coagulation, but vaporization and cutting does not occur. Electro-surgical instruments that are narrow or pointed are capable of generating the high-power densities necessary to vaporize or cut tissue. Continuous or modulated, usually unipolar, outputs are used. For optimal results, they should be used in a noncontact fashion, following (not leading) the energy. Specially designed bipolar cutting probes are available that have one integrated electrode shaped as a needle and the other band-shaped electrode designed to be dispersive (Fig. 21.14 Top). Laparoscopic scissors with unipolar or bipolar electro-surgical attachments are designed to cut mechanically, and energy may be applied simultaneously for desiccation and hemostasis when cutting tissue that contains small blood vessels (Fig. 21.14 Bottom).

Figure 21.14 Laparoscopic Cutting Devices. *Top and inset left* is a bipolar electro-surgical spatula. *Middle and center inset* is a harmonic scalpel. This device oscillates at 55,000 Hz to cut tissue. *Bottom and inset right* are laparoscopic scissors. They may be connected if desired to an electro-surgical generator to act as a unipolar electrode.

Figure 21.15 Radiofrequency Electrosurgical Generator. Displayed is the Force FX generator with unipolar laparoscopic electrodes. The device is capable of outputting high-voltage ("coagulation") and low-voltage ("cut") waveforms for unipolar instruments as well as a low-voltage bipolar circuit for bipolar instruments.

Laser energy can be focused to vaporize and cut tissue. The most efficient laser-based cutting instrument is the CO₂ laser, which has the drawback of requiring linear transmission because light cannot be conducted effectively along bendable fibers. The potassium-titanyl-phosphate (KTP) and neodymium:yttrium, aluminum, garnet (Nd:YAG) lasers are also effective cutting tools. They are capable of propagating energy along bendable quartz fibers but have a slightly greater thermal injury risk than electrical or CO₂ laser energy. Because of such limitations and their additional expense, these lasers are of limited value.

Ultrasonic cutting is largely accomplished mechanically using a blade that oscillates back and forth in a linear fashion (Fig. 21.14 Center). The oscillation is achieved using a vibrating element located in a handle that vibrates the blade, hook, or clamp 55,000 times per second (55 kHz). The distance of the oscillation can be varied and determines the rapidity

P.770

P.771

of the cutting process. The tip of the device cuts mechanically, but there is a degree of collateral thermal tissue coagulation injury that can be used for hemostasis. In low-density tissue, the process of mechanical cutting is augmented by the process of cavitation, in which reduction of local atmospheric pressure allows vaporization of intracellular water at body temperature.

Hemostasis

Because of the visual, tactile, and mechanical limitations of laparoscopy, prevention of bleeding is important for efficient, effective, and safe procedures.

Radiofrequency electricity is the least expensive and most versatile method for achieving hemostasis during laparoscopy and can be applied with either monopolar or bipolar instruments. Regardless of the type of system, the process of electrical desiccation and coagulation is best achieved by contacting the tissue and activating the electrode using continuous low-voltage or "cutting" current. With adequate power, typically 25 watts, tissue will be heated and coagulated. Blood vessels should be compressed with the blades of the forceps before the electrode is activated so that the "heat sink" effect of flowing blood is eliminated. This also allows the opposing walls of the vessel to bond together, forming a strong tissue seal in a process called *coaptive coagulation*. Bipolar devices can be fitted with a serial ammeter that measures the current flowing through the system. When the tissue between the blades of the forceps is completely desiccated, the device is no longer able to conduct electricity, which can trigger a visual or auditory cue for the surgeon. Alternatively, the generator can be designed to stop automatically when current is no longer being conducted by the tissue between the blades of the forceps. The surgeon can reduce lateral thermal spread of radiofrequency energy by manually pulsing delivery or by simultaneously running irrigation fluid over the pedicle. Automated generators that pulse energy automatically are available and such bipolar systems can include mechanical blades to cut tissues following coagulation of the tissue (Fig. 21.16).

Figure 21.16 Displayed are two devices that both cut and coagulate or seal tissue. Top (A–C) are the ligating cutting shears (LCS) that are based on the same technology as the harmonic scalpel displayed in Figure 21.13. The bottom blade oscillates (C) while the top blade is opened to grasp the tissue and then used by the surgeon to slowly transect and seal the blood vessels in the tissue being transected. The PlasmaKinetic (D–F) is a bipolar radiofrequency device that, using electrical impedance, tells the surgeon when the tissue is coagulated. Then the orange trigger (*top*) is pushed deploying the blade (F), thereby cutting the coagulated tissue.

Control of superficial bleeding can be achieved with fulguration, the near-contact spraying of tissue with unipolar, high-voltage radiofrequency energy from the "coagulation" side of the electrosurgical generator. Care must be taken to perform laparoscopic fulguration carefully, ensuring that the entire shaft of the laparoscopic instrument is well away from bowel.

Ultrasonic instruments can be used for hemostasis as well. Those with a forcepslike end disperse the mechanical energy in a way that allows the tissue to be heated and coagulated. These so called "ligating-cutting" shears also cut when high pressure is exerted in the handle by the surgeon (Fig. 21.16 A-C).

Clips may be used with specially designed laparoscopic instruments. Nonabsorbable clips made of titanium are useful for relatively narrow vessels, and longer, self-retaining clips are generally preferred for larger vessels. Clips may be of particular value when securing relatively large vessels near an important structure such as the ureter.

Laparoscopic suturing is a method of maintaining hemostasis (65). Compared with clips or linear staplers, suturing has a relatively low cost of materials, although operating time may be longer. **The two basic methods for securing a ligature around a blood vessel are intracorporeal and extracorporeal knots, depending on where the suture is tied. Intracorporeal knots replicate the standard instrument-tied knot and are formed within the peritoneal cavity. Extracorporeal knots are created outside the abdomen under direct vision and then transferred into the peritoneal cavity by knot manipulators** (see Fig. 21.17) (66). Pretied knotted suture loops attached to long introducers, called endoloops, may also be used to secure vascular pedicles. However, care should be taken to make sure that they are tightly secured and that no other tissue is incorporated in the loop.

Figure 21.17 Laparoscopic Suturing Instruments. 3-mm and 5-mm diameter laparoscopic needle drivers are displayed in **A** and **C** while a knot manipulator is shown in **B** and inset left. The device is shown transferring a knot into the peritoneal cavity (*inset right*).

Topical agents such as microfibrillar collagen are available in 5-mm and 10-mm diameter laparoscopic applicators (see Fig. 21.13). Local injection of diluted vasopressin may be used to maintain hemostasis for myomectomy or removal of ectopic pregnancy.

Removal of Tissue

After excising tissue, it is usually necessary to remove it from the peritoneal cavity. Small samples can be pulled through an appropriate-sized cannula with grasping forceps; however, larger specimens may not fit. If the specimen is cystic, it may be drained by a needle or incised, shrinking it to a size suitable for removal through the cannula or one of the small laparoscopic incisions. **If there is any concern for malignancy, an alternative is to place the specimen in an endoscopic retrieval bag before drainage to prevent spillage** (Fig. 21.18). More solid tissue may be morcellated with scissors, ultrasonic equipment, or electrosurgery. If monopolar radiofrequency instruments are used for electrosurgical morcellation, the specimen must remain attached to the patient to preserve the integrity of the electrical circuit. Alternatively, special bipolar needles are available that do not require a dispersive electrode.

Figure 21.18 Specimen Removal Bag. This 10-mm diameter bag is positioned in the peritoneal cavity. Then, the bag is deployed (*insets*), allowing the surgeon to place specimens for removal.

Larger specimens may be removed by inserting a larger cannula through an incision in the cul-de-sac (posterior culdotomy) or by extending one of the laparoscopy incisions. With the exception of colpotomy, extension of the umbilical incision may be the most cosmetic approach because removal of the tissue can be directed from an endoscope positioned in

P.774

one of the ancillary ports. Electronic morcellators are available to remove large tissue specimens by reducing them to smaller sections (Fig. 21.19). These are especially useful for laparoscopic myomectomy and laparoscopic supracervical hysterectomy.

Figure 21.19 Electromechanical Morcellator. This device is positioned in the peritoneal cavity and attached to the power generator (*inset*). The blunt obturator is removed; a grasping instrument inserted through the lumen is used to withdraw the tissue, which is cut by a cylindrical blade. The motor is activated by a foot pedal.

Incision Management

Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter (67). Closure of the fascia should take place under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions, and the peritoneum should be included to reduce the risk of Richter's hernia. A small-caliber laparoscope passed through one of the narrow cannulas can be used to direct the fascial closure using curved needles or a ligature carrier especially designed for this purpose.

Complications

Patients recovering from laparoscopic surgery usually feel better every day. Pain diminishes, gastrointestinal function improves rapidly, and fever is extremely unusual. Therefore, if a patient's condition is not improving, possible complications of anesthesia or surgery should be considered. Laparoscopic procedures can be complicated by infections, trauma, or hemorrhage, as well as by problems associated with anesthetic use. The incidence of infection is lower than with procedures performed by laparotomy. Conversely, problems associated with visualization in conjunction with the change in anatomic perspective may increase the risk of damage to blood vessels or vital structures such as the bowel, ureter, or bladder.

Anesthetic and Cardiopulmonary Complications

A recent review of laparoscopic tubal sterilization in 9,475 women found no deaths from complications of anesthesia (68). However, the potential risks of general anesthesia include hypoventilation, esophageal intubation, gastroesophageal reflux, bronchospasm, hypotension, narcotic overdose, cardiac arrhythmias, and cardiac arrest. These risks can

P.775

be enhanced by some of the inherent features of gynecologic laparoscopy. For example, the Trendelenburg position, in combination with the increased intraperitoneal pressure provided by pneumoperitoneum, places greater pressure on the diaphragm, increasing the risk of hypoventilation, hypercarbia, and metabolic acidosis. This position, combined with anesthetic agents that relax the esophageal sphincter, promotes regurgitation of gastric content, which in turn can lead to aspiration, bronchospasm, pneumonitis, and pneumonia. Parameters of cardiopulmonary function associated with both CO₂ and N₂O insufflation include reduced PO₂, O₂ saturation, tidal volume, and minute ventilation and increased respiratory rate. The use of intraperitoneal CO₂ as a distention medium is associated with an increase in PCO₂ and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and a ventilation—perfusion mismatch (69).

Carbon Dioxide Embolus

Carbon dioxide is the most widely used peritoneal distention medium, largely because the rapid absorption of CO₂ in blood reduces the significance of gas emboli. However, if large amounts of CO₂ gain access to the central venous circulation, if peripheral vasoconstriction occurs, or if the splanchnic blood flow is decreased by excessively high intraperitoneal pressure, severe cardiorespiratory compromise may result.

The signs of CO₂ embolus include sudden and otherwise unexplained hypotension, cardiac arrhythmia, cyanosis, and heart murmurs. The end-tidal CO₂ level may increase, and findings consistent with pulmonary edema may manifest. Accelerating pulmonary hypertension may occur, resulting in right-sided heart failure.

Because gas embolism may result from direct intravascular injection through an insufflation needle, the proper placement of the insufflation needle, if used, must be ensured. Although the initial intraperitoneal pressure may be set at 20 to 30 mm Hg for port placement, it should be maintained at 8 to 12 mm for the rest of the case. The risk of CO₂ embolus also is reduced by careful hemostasis because open venous channels are the portal of entry for gas into the systemic circulation. The anesthesiologist should continuously monitor

the patient's color, blood pressure, heart sounds, heartbeat, and end-tidal CO₂ to allow early recognition of the signs of CO₂ embolus.

If CO₂ embolus is suspected or diagnosed, the surgeon must evacuate the CO₂ from the peritoneal cavity and place the patient in the left lateral decubitus position, with the head below the level of the right atrium. A large-bore central venous line should be inserted immediately to allow aspiration of gas from the heart. Because the findings are nonspecific, the patient should be evaluated for other causes of cardiovascular collapse.

Cardiovascular Complications

Cardiac arrhythmias occur relatively frequently during laparoscopic surgery and are related to a number of factors, the most significant of which are hypercarbia and acidemia. Early reports of laparoscopy-associated arrhythmia were associated with spontaneous respiration; therefore, most anesthesiologists have adopted the practice of mechanical ventilation during laparoscopic surgery. The incidence of hypercarbia is reduced by operating with intraperitoneal pressures at levels less than 12 mm Hg (70).

The risk of cardiac arrhythmia also may be reduced by using NO₂ as a distending medium (see the preceding discussion on Access). Although NO₂ is associated with a decreased incidence of arrhythmia, it also is insoluble in blood and, therefore, its use may increase the risk of gas embolus. External lifting systems avoid the complication of hypercarbia and can also provide protection against cardiac arrhythmia.

P.776

Hypotension can occur because of decreased venous return secondary to very high intraperitoneal pressure, and this condition may be potentiated by volume depletion. Vagal discharge may occur in response to increased intraperitoneal pressure, which can cause hypotension secondary to cardiac arrhythmias (71). All of these side effects should be considered when performing surgery on patients with pre-existing cardiovascular disease.

Gastric Reflux

Gastric regurgitation and aspiration can occur during laparoscopic surgery, especially in patients with obesity, gastroparesis, hiatal hernia, or gastric outlet obstruction. In these patients, the airway must be maintained with a cuffed endotracheal tube, and the stomach must be decompressed (e.g., with a nasogastric tube). The lowest necessary intraperitoneal pressure should be used to minimize the risk of aspiration. Patients should be moved out of the Trendelenburg position before being extubated. Routine preoperative administration of *metoclopramide*, H₂-blocking agents, and nonparticulate antacids also reduces the risk of aspiration.

Extraperitoneal Insufflation

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO₂ around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema can become extensive, involving the extremities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the

abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can be visualized directly. Such a finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (72,73,74).

The risk of subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation has occurred extraperitoneally, the laparoscope can be removed and the procedure can be repeated. However, difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudad to the tip of the laparoscope (75).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result. Following termination of the procedure, it is prudent to obtain a chest x-ray. The patient's condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14-16 gauge) inserted in the second intercostal space in the midclavicular line.

Electrosurgical Complications

Complications of electrosurgery occur secondary to thermal injury from unintended or inappropriate use of the active electrode, current diversion to an undesirable path,

P.777

and injury at the site of the dispersive electrode. Such complications may occur with the use of these instruments during laparoscopic, abdominal, or vaginal surgery. Active electrode injury can occur with either unipolar or bipolar instruments, whereas trauma secondary to current diversion and dispersive electrode accidents occur only with unipolar devices. Complications of electrosurgery are reduced by adherence to safety protocols coupled with a sound understanding of the principles of electrosurgery and the circumstances that can lead to injury (17).

Active Electrode Trauma

If the foot pedal is accidentally depressed, tissue adjacent to the electrode will be traumatized. Potential sites of injury include the bowel, ureter, or, if the electrode lies on the abdomen, the skin. Injury from direct extension of thermal effect can occur when the zone of vaporization or coagulation extends to large blood vessels or vital structures such as the bladder, ureter, or bowel. Bipolar instruments may reduce but do not eliminate the risk of thermal injury to adjacent tissue (76). Therefore, blood vessels should be isolated before desiccation, especially when they are near vital structures, and appropriate amounts of energy must be applied to allow an adequate margin of noncoagulated tissue.

The diagnosis of direct thermal visceral injury may be difficult. If unintended activation of the electrode occurs, nearby intraperitoneal structures should be evaluated carefully. The appearance can be affected by several factors, including the output of the generator, the type of electrode, its proximity to tissue, and the duration of its activation. The diagnosis of

visceral thermal injury is often delayed until signs and symptoms of fistula or peritonitis appear. Because these complications may not manifest until 2 to 10 days after surgery, patients should be advised to report any postoperative fever or increasing abdominal pain.

Thermal injury to the bowel, bladder, or ureter that is recognized at the time of laparoscopy should be managed immediately, taking into consideration the potential extent of the zone of coagulative necrosis (77). Incisions made with the focused energy from a pointed electrode are associated with a minimal amount of surrounding thermal injury. Prolonged or even transient contact with a relatively large-caliber electrode may produce thermal necrosis that extends several centimeters. In such cases, wide excision or resection will be necessary. The choice of route of access for any required surgical repairs depends in part on the nature of the injury and on the skills and training of the surgeon.

The incidence of unintended activation injuries can be reduced if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use. When removed from the peritoneal cavity, the instruments should be detached from the electrosurgical generator, or they should be stored in an insulated pouch near the operative field. These measures prevent damage to the patient's skin if the electrode is accidentally activated.

Current Diversion

Current diversion occurs when the radiofrequency circuit follows an unintended path between the active electrode and the electrosurgical generator. This may occur with insulation defects, direct coupling, or capacitive coupling. In older, grounded systems, current can be diverted if any part of the patient's body touches a conductive and grounded object. In any of these situations, if the power density becomes high enough, unintended and severe thermal injury can result.

Insulation Defects

If the insulation coating the shaft of an electrosurgical electrode becomes defective, it can allow current diversion to adjacent tissue, often bowel, potentially resulting in significant

P.778

injury (Fig 21.20A). Therefore, the instruments should be examined before each procedure to detect worn or obviously defective insulation. **When using monopolar laparoscopic instruments, the shaft of the device should be kept away from vital structures and, if possible, totally visible in the operative field.**

Figure 21.20 Current Diversion Secondary to Insulation Defects and Direct Coupling.

These events may occur with the use of monopolar instrumentation when there is a defect in the insulation (**A**) or, classically, to contact a conductive instrument that, in turn, touches other intraperitoneal structures. In the example depicted (**B**), the active electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.

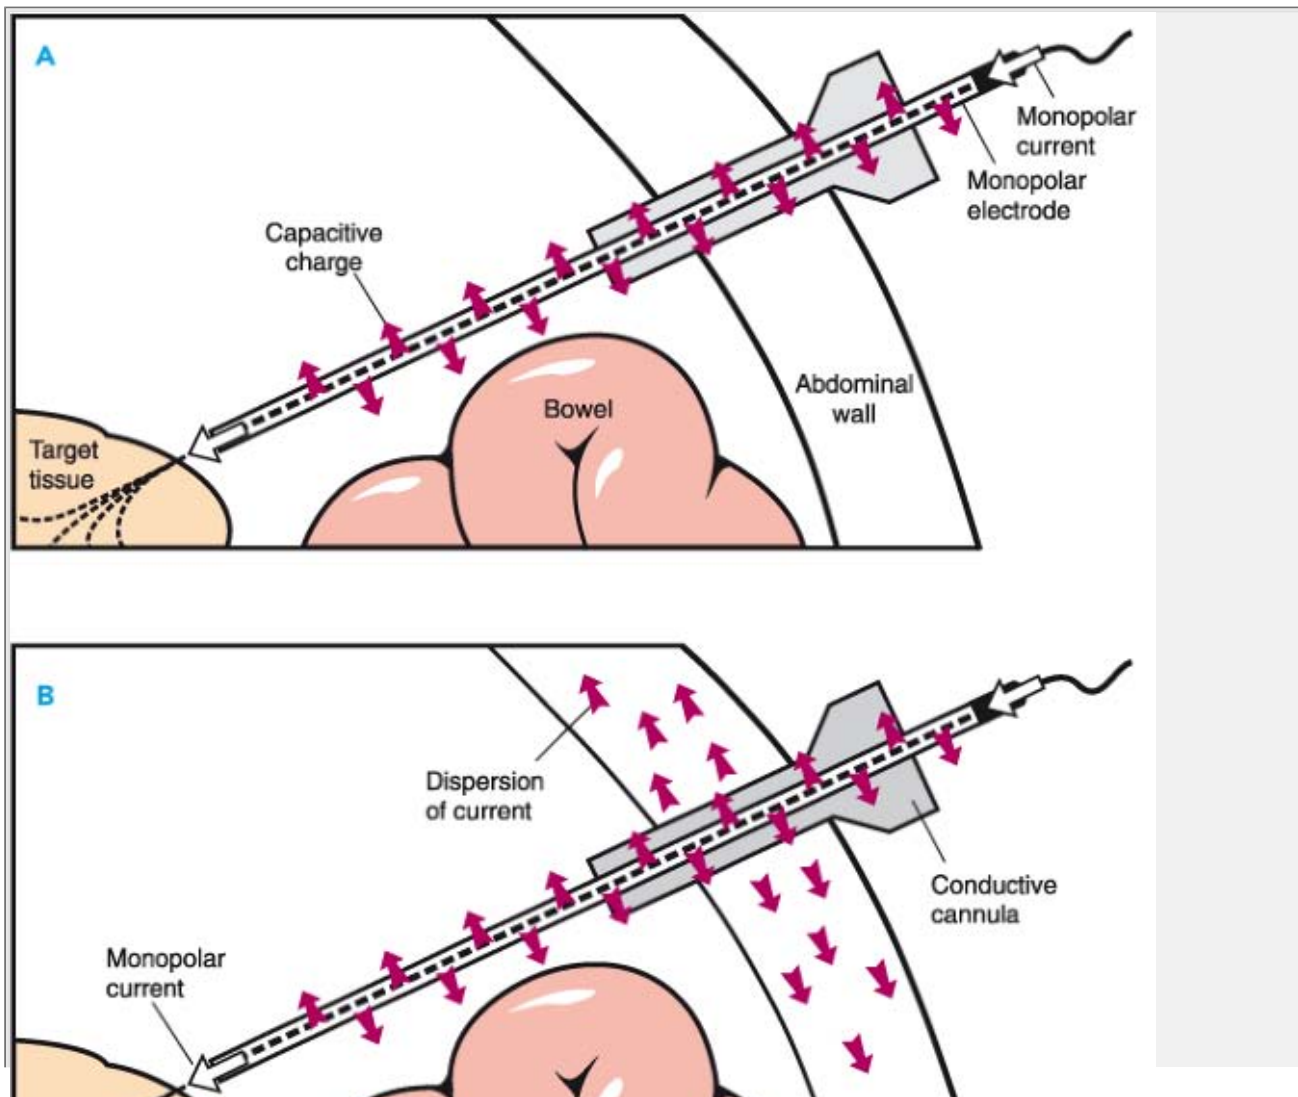

Direct Coupling

Direct coupling occurs when an activated electrode touches and energizes another uninsulated metal conductor such as a laparoscope, cannula, or other instrument. Direct coupling is often used for hemostasis when a grasping instrument is used to occlude a blood vessel while a separate activated electrode is used to provide the energy for desiccation and coagulation. If this occurs while the noninsulated device rests against structures such as bowel or the urinary tract, however, unintended injury may occur (Fig 21.20B). The risk of direct coupling can be

reduced by eliminating the simultaneous use of noninsulated instruments and monopolar electrodes. Furthermore, the surgeon should visually confirm that there is no contact with other conductive instruments before activating a monopolar electrode.

Capacitive Coupling

Capacitance is the ability of a conductor to establish an electrical current in an unconnected but nearby circuit. An electrical field is established around the shaft of any activated unipolar electrode (including the cord), a circumstance that makes the electrode a potential capacitor. This field is harmless if the circuit is completed through a dispersive, low-power density pathway (Fig. 21.21). For example, if capacitive coupling occurs between a laparoscopic electrode and a metal cannula positioned in the abdominal wall, the current is harmlessly dispersed in the abdominal wall at the point where it connects with the dispersive electrode (Fig. 21.21A). However, if the metal cannula is anchored to the skin by a nonconductive plastic retaining sleeve or "gripper" (a hybrid system), the current cannot return to the abdominal wall because the sleeve acts as an insulator (Fig. 21.21B). Instead, the capacitor will have to "look" elsewhere to complete the circuit. Therefore, bowel or any other nearby conductor can become the target of a relatively high-power density discharge (Fig. 21.21C). This mechanism can also occur when a unipolar electrode is inserted through an operating laparoscope that, in turn, is passed through a nonconductive plastic laparoscopic cannula. In this configuration, the plastic port acts as the insulator. If the electrode capacitively couples with the metal laparoscope, nearby bowel will be at risk for significant thermal injury (78).

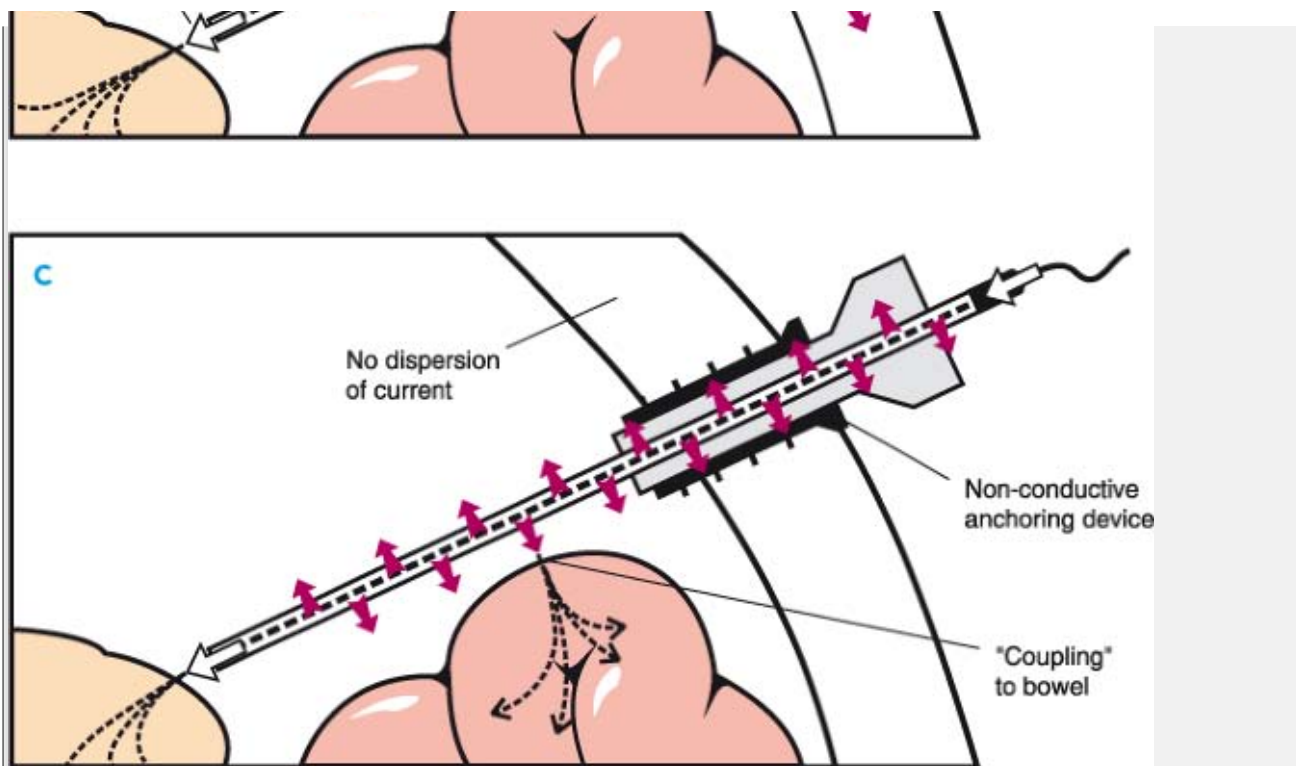

Figure 21.21 Capacitive coupling. **A:** All activated monopolar electrodes emit a surrounding charge, proportional to the voltage of the current. This makes the electrode a potential capacitor. **B:** Generally, as long as the charge is allowed to disperse through the abdominal wall, no sequelae result. However, if the “return” to the dispersive electrode is blocked by insulation, such as a plastic anchor (**C**), the current can couple to a conductive cannula or directly to bowel.

Capacitive coupling can be prevented by avoiding the use of hybrid laparoscope-cannula systems that contain a mixture of conductive and nonconductive elements. Instead, the use of all-plastic or all-metal cannula systems is preferred. When operating laparoscopes are used, all-metal cannula systems should be the rule unless there is no intent to perform unipolar electro-surgical procedures through the operating channel.

Dispersive Electrode Burns

Modern electro-surgical units are designed with isolated circuits and impedance monitoring systems that shut down the machine if dispersive electrode detachment (“patient pad”) occurs. The use of isolated-circuit electro-surgical generators with dispersive electrode monitors has virtually eliminated dispersive electrode-related thermal injury. Dispersive electrode monitoring is actually accomplished by measuring the impedance in the dispersive electrode, which should always be low because of the large surface area. Without such devices, partial detachment of the dispersive electrode could result in a thermal injury because reducing the surface area of the electrode raises the current density (Fig. 21.22).

Figure 21.22 Dispersive electrode burns. If the dispersive electrode becomes partially detached, the current density may increase to the point that a skin burn results.

Because ground-referenced machines without such safeguards are still in use, it is important to know the type of electrosurgical unit used in the operating room. If the electrosurgical generator is ground referenced and if the dispersive electrode becomes detached,

P.779

unplugged, or otherwise ineffective, the current seeks any grounded conductor, such as electrocardiograph patch electrodes or the conductive metal components of the operating table (Fig. 21.23). If the conductor has a small surface area, the current or power density may become high enough to cause thermal injury (Fig. 21.24).

Figure 21.23 Risk of ground-referenced generators. Current diversion along alternate pathways is a risk associated with ground-referenced electrosurgical generators, particularly if the dispersive electrode is detached. In the example depicted, the relatively high current density at the electrocardiogram electrode site may result in a skin burn.

Figure 21.24 Office Hysteroscopy Setup. Hysteroscopic procedures are facilitated with an electric examination table. Distension media may be positioned on an IV pole, but wide, cystoscopy tubing allows maintenance of higher intrauterine pressures suitable for viewing and performing simple procedures such as polypectomy or transcervical sterilization. A light source is necessary and a camera desirable. The camera is attached to the monitor and may be connected to a printer and/or video recorder. The camera head is attached to a flexible hysteroscope.

Hemorrhagic Complications

Great Vessel Injury

The most dangerous hemorrhagic complications are injuries to the great vessels, including the aorta and the vena cava, the common iliac vessels and their branches,

P.780

P.781

P.782

and the internal and external iliac arteries and veins. The most catastrophic injuries occur secondary to insertion of an insufflation needle or the tip of the trocars used to position the primary or ancillary cannulas. The vessels most frequently damaged are the aorta and the right common iliac artery as it branches from the aorta in the midline. The anatomically more posterior location of the vena cava and the iliac veins provides relative protection, but not immunity, from injury (79). After vascular injury, patients usually develop profound hypotension with or without hemoperitoneum. In some instances, blood is aspirated through the insufflation needle before the introduction of the distending gas. **In such instances, the needle should be left in place while immediate preparations are made to obtain blood products and perform laparotomy.** The bleeding frequently will be contained in the retroperitoneal space, which usually delays the diagnosis; consequently, hypovolemic shock may develop. To avoid late recognition, the course of each great vessel must be identified before completing the procedure. Because it is difficult to assess the volume of blood filling the retroperitoneal space, immediate laparotomy is indicated if retroperitoneal bleeding is suspected. A midline incision should be made to allow access to the great vessels. Upon entry into the peritoneal cavity, the aorta and vena cava should immediately be compressed just below the level of the renal vessels to gain at least temporary control of blood loss. The most appropriate course of action depends on the site and extent of injury. Vascular or general surgery consultation may be necessary to evaluate and repair significant vascular injuries. Although most of these injuries are small and amenable to repair with suture, some are larger and require the insertion of a vascular graft. Deaths have occurred as a result of these injuries.

Abdominal Wall Vessel Injury

The abdominal wall vessels most commonly injured during laparoscopy are the superficial inferior epigastric vessels as they branch from the femoral artery and vein and course cephalad in each lower quadrant. They are invariably damaged by the initial passage of an ancillary trocar or by the introduction of a wider device later in the procedure. The problem may be recognized immediately by the observation of blood dripping along the cannula or out through the incision. However, the bleeding may be obstructed by the cannula until it is withdrawn at the end of the operation.

The more serious injuries are those to the deep inferior epigastric vessels, which are branches of the external iliac artery and vein that course cephalad but are deep to the rectus fascia and often deep to the muscles (Fig. 21.3). More laterally located are the deep circumflex iliac vessels, which are not often encountered in laparoscopic surgery. Laceration of these vessels may cause profound blood loss, particularly when the trauma is unrecognized and causes extraperitoneal bleeding.

Signs of injury, in addition to blood dripping down the cannula, include the postoperative appearance of shock and abdominal wall discolorization or hematoma located near the incision. In some instances, the blood may track to a more distant site, presenting as a pararectal or vulvar mass. Delayed diagnosis may be prevented

by laparoscopic evaluation of each peritoneal incision after removal of the cannula.

Superficial inferior epigastric vessel trauma usually stops bleeding spontaneously; therefore, expectant management is appropriate. A straight ligature carrier can be used to repair lacerated deep inferior epigastric vessels. Alternatively, a Foley catheter may be inserted through the cannula, inflated, put on traction, and held in place with a clamp for 24 hours. If a postoperative hematoma develops, local compression should be used initially. Open removal or aspiration of the hematoma should not be undertaken because it may inhibit the tamponade effect and increase the risk of abscess. However, if the mass continues to enlarge or if signs of hypovolemia develop, the wound must be explored.

P.783

Intraperitoneal Vessel Injury

Hemorrhage may result from inadvertent entry into a vessel or failure of a specific occlusive technique. In addition to delayed hemorrhage, there may be a further delay in diagnosis at laparoscopy as a result of the restricted visual field and the temporary occlusive pressure exerted by CO₂ in the peritoneal cavity.

Inadvertent division of an artery or vein is usually evident immediately. **Transected arteries may go into spasm and bleed minutes to hours later, going unnoticed temporarily because of the limited visual field of the laparoscope. Therefore, at the end of the procedure, all areas of dissection must be carefully examined.** Carbon dioxide should be vented, which decreases the intraperitoneal pressure so that blood vessels temporarily occluded by higher pressure can be recognized.

Gastrointestinal Complications

The stomach, the small bowel, and the colon can be injured during laparoscopy. Mechanical entry into the large or small bowel can occur 10 times more often when laparoscopy is performed in patients who have had prior intraperitoneal inflammation or abdominal surgery. Loops of intestine can adhere to the abdominal wall under the insertion site and be injured (80,81).

Insufflation Needle Injuries

Needle entry into the gastrointestinal tract may be more common than reported because it often occurs unnoticed and without further complication. Gastric entry may be identified by the increased filling pressure, asymmetric distention of the peritoneal cavity, or aspiration of gastric particulate matter through the lumen of the needle. Initially, the hollow, capacious stomach may allow the insufflation pressure to remain normal. Signs of bowel entry are the same as those for gastric injury, with the addition of feculent odor.

If particulate debris is identified, the needle should be left in place, and an alternate insertion site should be identified, such as the left upper quadrant. Immediately after successful entry into the peritoneal cavity, the site of injury can be identified. Defects must be repaired immediately by laparoscopy or laparotomy.

Trocar Injuries

Damage caused by a sharp trocar is usually more serious than needle injury. Inadvertent gastric entry usually results from stomach distention because of aerophagia, difficult or improper intubation, or mask induction with inhalation anesthetic. Most often, the injury is created by the primary trocar. Ancillary cannulas may also result in visceral injury,

although placement of these cannulas under direct vision helps to reduce the risk of injury. **The risk of gastric perforation can be minimized with the selective use of preoperative nasogastric or oral gastric suction when left upper-quadrant entries are used or when the intubation was difficult.** Open laparoscopy likely has little impact on the risk for gastrointestinal complications, particularly those related to adhesions to the anterior abdominal wall from previous surgery. For high-risk patients, left upper quadrant needle and trocar insertion with a properly decompressed stomach may be preferable (82,83,84).

If the trocar of a primary cannula penetrates the bowel, the condition is usually diagnosed when the mucosal lining of the gastrointestinal tract is visualized. If the large bowel is entered, a feculent odor may be noted. However, the injury may not be immediately recognized because the cannula may not stay within the bowel or may pass through the lumen. Such injuries usually occur when a single loop of bowel is adherent to the anterior abdominal wall. The injury may not be recognized until peritonitis, abscess,

P.784

enterocutaneous fistula, or death occurs (85,86). Therefore, at the end of the procedure, the removal of the primary cannula must be viewed either through the cannula or an ancillary port, a process facilitated by routine direct visualization of closure of the incision of the primary port.

Trocar injuries to the stomach and bowel require repair as soon as they are recognized.

If the injury is small, a trained operator can repair the defect by laparoscopy using a double layer of running 2-0 or 3-0 absorbable sutures. Extensive lesions may require resection and reanastomosis, which in most instances requires laparotomy. The preoperative use of mechanical bowel preparation in selected high-risk cases minimizes the need for laparotomy or colostomy.

Dissection and Thermal Injury

When mechanical bowel trauma is recognized during the dissection, treatment is the same as that described for trocar injury. **Should the injury involve radiofrequency electrical energy, it is important to recognize that the zone of desiccation may exceed the area of visual damage.** This is especially true if the exact mechanism of the thermal injury is unknown or if injury results from contact with a relatively large surface area electrode that would be more likely to create a large coagulation injury. Conversely, **bowel injury created under direct vision with a radiofrequency needle or blade electrode is associated with little collateral coagulation effect and, therefore, can be managed similar to a mechanically induced lesion.** Consequently, surgical repair should be implemented considering these factors, and should include, if necessary, resection of ample margins around the injury. **Thermal injury may be handled expectantly if the lesion seems superficial and confined,** such as is the case when fulguration (noncontact arcing of high-voltage current) involves bowel. In such instances, the depth of injury is generally less than half a millimeter. In a study of 33 women with such injuries who were managed expectantly in the hospital, only 2 required laparotomy for repair of perforation (87).

Urologic Injury

Damage to the bladder or ureter may occur secondary to mechanical or thermal trauma during laparoscopic procedures. Ideally, such injury should be prevented; otherwise, as is the case for most complications, it is preferable to identify the trauma intraoperatively.

Bladder Injury

Bladder injury can result from the perforation of the undrained bladder by a trocar, but it also

may occur while the bladder is being dissected from adherent structures or from the anterior uterus (88,89). The injury may be readily apparent by direct visualization. If an indwelling catheter is in place, hematuria or pneumaturia (CO₂ in the catheter drainage system) may be noticed. A bladder laceration can be confirmed by injecting sterile milk or a diluted methylene blue solution through a transurethral catheter. Thermal injury to the bladder, however, may not be apparent initially and, if missed, can present as peritonitis or a fistula.

Routine preoperative bladder drainage usually prevents trocar-related cystotomies. Separation of the bladder from the uterus or other adherent structures requires good visualization, appropriate retraction, and excellent surgical technique. Sharp mechanical dissection is preferred, particularly when relatively dense adhesions are present.

Very small-caliber injuries to the bladder (1-2 mm) may be treated with bladder catheterization for 3 to 7 days. If repair is undertaken immediately, catheterization is unnecessary. **When a larger injury is identified, it can be repaired laparoscopically**

P.785

(88,89,90). **If the laceration is near the trigone or involves the trigone, however, an open procedure should be used.** The mechanism of injury should be taken into consideration in making this evaluation because electrical injuries often extend beyond the visible limits of the apparent defect.

For small lesions, closure may be performed with layers of absorbable 2-0 to 3-0 sutures. If thermal injury occurred, the coagulated portion should be excised. Postoperative catheterization with either a transurethral or suprapubic catheter should be maintained for 2 to 5 days for small fundal lacerations and for 10 to 14 days for injuries to the trigone. Cystography should be considered before the urinary catheter is removed.

Ureteral Injury

The most common cause of ureteral injury during laparoscopy is electrosurgical trauma (76,91). However, ureteral injury also can occur after mechanical dissection including linear cutting and stapling devices (92,93). **Although intraoperative recognition of ureteral injury is possible, the diagnosis is usually delayed** (91). Ureteral lacerations may be confirmed intraoperatively visually or with the intravenous injection of indigo carmine. Thermal injury presents up to 14 days after surgery with fever, abdominal or flank pain, and peritonitis. Leukocytosis may be present, and intravenous pyelography shows extravasation of urine or urinoma. Mechanical obstruction from staples or a suture may be recognized intraoperatively by direct visualization. **Cystoscopy following the intravenous injection of indigo carmine may be used to confirm failure of the dye to pass through the ureter.** Abdominal ultrasound may be helpful, but a CT urogram can more precisely identify the site and degree of the obstruction. Unrecognized ureteral obstruction may present a few days to 1 week after surgery with flank pain and often fever (93).

Discharge or continuous incontinence is a delayed sign of ureterovaginal or vesicovaginal fistulas. **A bladder fistula can be confirmed by detecting dye on a tampon previously placed in the vagina after filling the bladder with methylene blue. With a ureterovaginal fistula, the methylene blue will not pass into the vagina, but it can be detected with the intravenous injection of indigo carmine.**

Knowledge of the course of the ureter through the pelvis is a prerequisite to reducing the risk of injury. The ureter can usually be seen through the peritoneum of the pelvic sidewall between the pelvic brim and the attachment of the broad ligament. Because of variation from one patient to another or the presence of disease, however, the location of the ureter can become obscured, making it necessary to enter the retroperitoneal space. The

techniques used for retroperitoneal dissection are also important factors in reducing the risk of ureteric injury. Blunt and sharp dissection with scissors is preferred, although hydrodissection can be used (94). The selective placement of ureteral stents may also be helpful in preventing injury.

Ureteral injury can be treated immediately if it is diagnosed intraoperatively.

Although limited damage may heal over a ureteral stent left in place for 10 to 21 days, repair is indicated in most patients. Although laparoscopic repair of ureteric lacerations and transections has been performed, most injuries require laparotomy (91,95).

When the diagnosis of ureteral injury is delayed, the bladder should be drained with a catheter. Incomplete or small obstructions or lacerations may be treated successfully with either a retrograde or antegrade ureteral stent. Urinomas may be drained percutaneously. If a stent cannot be placed successfully, a percutaneous nephrostomy should be performed before operative repair is undertaken.

P.786

Neurologic Injury

Peripheral nerve injury is usually related either to poor positioning of the patient or to excessive pressure exerted by the surgeons. Nerve injury may also occur as a result of the surgical dissection.

In the extremities, the trauma may be direct, such as when the common peroneal nerve is compressed against the stirrups. **The femoral nerve or the sciatic nerve or its branches may be overstretched and damaged by excessive flexion or external rotation of the hips. The peroneal nerve may be injured by compression if the lateral head of the fibula rests against the stirrups (96,97,98). Brachial plexus injuries may occur secondary to the surgeon or assistants leaning against the abducted arm during the procedure.** If the patient is placed in a steep Trendelenburg position, the brachial plexus may be damaged because of the pressure exerted on the shoulder joint. In most cases, sensory or motor deficits are found as the patient emerges from anesthesia. The likelihood of brachial plexus injury can be reduced with adequate padding and support of the arms and shoulders or by placing the patient's arms in an adducted position.

Most injuries to peripheral nerves resolve spontaneously. The time to recovery depends on the site and severity of the lesion. For most peripheral injuries, full sensory nerve recovery occurs in 3 to 6 months. Recovery may be hastened by the use of physical therapy, appropriate braces, and electrical stimulation of the affected muscles. Open microsurgery should be performed for transection of major intrapelvic nerves.

Incisional Hernia and Wound Dehiscence

Incisional hernia after laparoscopy has been reported in more than 900 cases (66,99). The most common defect is dehiscence that develops in the immediate postoperative period. Hernias may be asymptomatic or may cause pain, fever, periumbilical mass, obvious evisceration, and the symptoms and signs of mechanical bowel obstruction. **Although no incision is immune to the risk, defects that are larger than 10 mm in diameter are particularly vulnerable (99,100,101).**

Richter's hernias contain only a portion of the intestine in the defect, and the diagnosis is often delayed because the typical symptoms and findings of mechanical bowel obstruction may be absent. The initial symptom is usually pain. These hernias most often occur in incisions lateral to the midline where there is a greater amount of preperitoneal fat creating a potential space for incarceration. Fever can be present if incarceration occurs, and peritonitis may result

from subsequent perforation. The condition is difficult to diagnose, requires a high index of suspicion, and may be confirmed with ultrasonography or computed tomography (102).

In most cases, these occurrences can be prevented by using small-caliber cannulas, where possible, and with routine fascial and peritoneal closure of defects made by peritoneal access. The risk of inadvertent incorporation of the intestine into the wound can be reduced by viewing the closure with the laparoscope. A small-diameter laparoscope should be used through a narrow cannula to facilitate incisional closure. All ancillary cannulas should be removed under direct vision to ensure that bowel is not drawn into the incision and that no active bleeding is present in the incision.

The management of laparoscopic incisional defects depends on the time of presentation and the presence and condition of entrapped bowel. Evisceration always requires surgical intervention. If the condition is diagnosed immediately, the intestine is replaced into the peritoneal cavity (if there is no evidence of necrosis or intestinal defect), and the incision is repaired, usually with laparoscopic guidance. If the diagnosis is delayed or the bowel is incarcerated or at risk of perforation, laparotomy is necessary to repair or resect the intestine.

P.787

Infection

Wound infections after laparoscopy are uncommon; most are minor skin infections that can be treated successfully with expectant management, drainage, or antibiotics (103). Severe necrotizing fasciitis can occur rarely (103). Bladder infection, pelvic cellulitis, and pelvic abscess have been reported (104).

Laparoscopy is associated with a much lower risk of infection than open abdominal or vaginal surgery. Prophylactic antibiotics should be offered to selected patients (e.g., those with enhanced risk for bacterial endocarditis and those for whom hysterectomy is planned). Patients should be instructed to monitor their body temperature after discharge and to report immediately a temperature higher than 38°C.

Hysteroscopy

The hysteroscope can be used to aid diagnosis or to direct the performance of a variety of intrauterine procedures. Hysteroscopic lysis of intrauterine adhesions was first described in 1973 (105). The technique of endoscopically guided electrosurgical resection was adapted from urology to gynecology for the removal of uterine leiomyomas (106). Hysteroscopic division of uterine septa was originally developed using a mechanical technique with specially designed scissors (107). Hysteroscopic destruction of the endometrium has been reported using Nd:YAG laser vaporization, and using electrosurgical desiccation or resection, and vaporization. More recently, hysteroscopically guided thermal ablation with heated fluid has been described (108,109,110).

Developments in the design of endoscopes have resulted in smaller-diameter instruments that retain the ability to provide a high-quality image. Such developments further facilitate the use of hysteroscopy in an office or procedure room setting.

Diagnostic Hysteroscopy

The goal of evaluation of the uterine cavity is either to obtain a sample of the endometrium, usually for the detection of hyperplasia or neoplasia, or to identify structural abnormalities such as polyps, myomas, or a uterine septum.

Blind endometrial sampling has been the diagnostic mainstay for the detection of endometrial hyperplasia, whereas transvaginal ultrasonography, hystero­graphy, and hysteroscopy are options in the detection and characterization of structural anomalies. **Hysteroscopic examination is probably superior to hystero­graphy in the evaluation of the endometrial cavity (111,112), but the diagnostic accuracy of transvaginal ultrasonography is similar, especially when intrauterine saline is used as a contrast medium, a procedure called sonohystero­graphy or saline infusion sonography (SIS) (113).** Ultrasound-based techniques have the advantage of allowing evaluation of the myometrium, whereas office-based hysteroscopy allows simultaneous removal of small polyps and even some myomas. Diagnostic hysteroscopy provides information not obtained by blind endometrial sampling (114,115,116,117,118,119,120), such as detection of endometrial polyps or submucous leiomyomas (117,118,120,121). Malignant or hyperplastic polyps or other localized lesions can be identified with hysteroscopy and removed via directed biopsy (119). However, blind curettage remains an effective approach for the identification of endometrial histopathology (115,118,120,122). **Following are potential indications for diagnostic hysteroscopy.**

- Unexplained abnormal uterine bleeding
 - Premenopausal
 - Postmenopausal

- Selected infertility cases
 - Abnormal hystero­graphy or transvaginal ultrasonography
 - Unexplained infertility
- Recurrent spontaneous abortion

For most patients, diagnostic hysteroscopy can be performed in an office or clinic with minimal discomfort and at a much lower cost than in an operating room. For some, concerns about patient comfort or a pre-existing medical condition may preclude office hysteroscopy. Although hysteroscopy can, in many patients, provide more information than blind curettage, it should still be used prudently. For most patients, other diagnostic or therapeutic measures can be undertaken before, or instead of, diagnostic hysteroscopy. For example, in women with perimenopausal and postmenopausal bleeding, office endometrial biopsy or curettage should be the initial method of assessment. If a satisfactory diagnosis cannot be established, or if bleeding continues without explanation, further investigation with ultrasound, SIS, or office hysteroscopy is appropriate. For women in their reproductive years who have abnormal uterine bleeding, medical or expectant management may be used initially, depending on the severity and inconvenience of the bleeding. For those who do not respond to medical treatments such as oral contraceptives, transvaginal ultrasonography, SIS, or hysteroscopy with biopsy, if appropriate, can be performed

for diagnosis (123).

For women with infertility, hysterosalpingography is the best initial imaging step because it provides information about the patency of the oviducts. In the presence of a suspicious or identified abnormality in the endometrial cavity, hysteroscopy can be performed to confirm the diagnosis, to define the abnormality, and perhaps to direct the removal of the lesion. Some experts consider hysteroscopy mandatory for such patients because of the high occurrence of false-negative radiologic images in those with intrauterine anomalies. However, there has been no evidence that identification and treatment of these "missed" anomalies improves pregnancy rates. Confirmation of patency of the oviduct is unnecessary in women who have recurrent abortions; therefore, these patients can be evaluated primarily with hysteroscopy.

Operative Hysteroscopy

A number of intrauterine procedures can be performed under endoscopic direction, including adhesiolysis, sterilization, division of a uterine septum, resection of myomas, and endometrial destruction through Nd:YAG laser vaporization or radiofrequency resection, desiccation, or vaporization. Hysteroscopy may also be used to direct the removal of foreign bodies or to position occluding devices in the fallopian tube for sterilization.

Foreign Body

If the string of an intrauterine device is absent, the device usually can be removed with a specially designed hook or a toothed curette (e.g., Novak). When removal is difficult or impossible, the location of the device may be confirmed by hysteroscopy, allowing removal with a grasping forceps.

Septum

When recurrent pregnancy loss is associated with a single corpus containing a uterine septum, hysteroscopic division of the septum improves reproductive outcome at a rate comparable to abdominal metroplasty, with reduced morbidity and cost (see Chapter 31) (124,125,126,127,128). The procedure may be performed mechanically with scissors or with energy-based techniques such as the Nd:YAG laser or an electrosurgical knife or loop. Because most septa have few vessels, scissors can be used easily, and the minimal risk for thermal damage is avoided.

P.789

Endometrial Polyps

Although endometrial polyps can be removed with blind curettage, many are missed (117,118,120,121). Therefore, known or suspected endometrial polyps are more successfully treated with hysteroscopic guidance, which can often be performed in a clinic or office using local anesthesia. Hysteroscopy may be used either to evaluate the result of blind curettage or use of grasping forceps, or preferably, with appropriate operating sheaths, to guide directed removal with small-caliber scissors or grasping forceps. Alternatively, for larger polyps, a uterine resectoscope may be used to sever the stalk or morcellate the lesion.

Leiomyomas

Hysteroscopy may be used to remove selected leiomyomas that involve the uterine cavity in women with heavy menstrual bleeding or infertility (113,129,130,131,132,133,134,135).

However, this approach is limited based on the location, size, and number of the lesions. Preoperative administration of gonadotropin-releasing hormone (GnRH) agonists may help shrink submucous myomas, facilitating their complete removal. Perhaps more importantly, they reduce operating time and systemic absorption of distension media (136,137,138).

To help document and evaluate the results of hysteroscopically directed myoma surgery, a classification system has been developed that is based on the proportion of the myoma that is in the uterine cavity. **In patients with myomas that are 5 cm or less in diameter and entirely intracavitary (Type 0), excision is feasible and in many instances relatively easy, whereas in large type 2 lesions an abdominal approach with laparoscopy or laparotomy will be necessary.** Small type 0 leiomyomas may be removed following transection of the stalk with scissors or an electrode attached to a uterine resectoscope. For larger type 0 lesions, or for type 1 myomas, electrosurgical morcellation with a resectoscope is necessary before removal. For a limited number of type 2 myomas, careful myometrial dissection may be attempted provided that ultrasonography or magnetic resonance imaging has demonstrated an adequate margin of myometrium between the deepest aspect of the lesion and the serosa. It may be preferable to undertake such procedures with laparoscopic monitoring to ensure that bowel is not adjacent to the zone of dissection. Patients should be counseled that for some type 1 and 2 myomas, it may take more than one procedure to complete excision (134). Alternatively, the Nd:YAG laser or radiofrequency electrodesiccation can be used to destroy the remaining portion of the leiomyoma, although the efficacy of this approach is unclear (130). The use of intrauterine prostaglandin F_{2α} has also been described to facilitate extrusion of type 2 myomas (139).

Endometrial Ablation

Heavy Menstrual Bleeding

Heavy menstrual bleeding that does not respond to oral medical therapy may be managed by endometrial ablation or resection, provided the patient is willing to forego future fertility (108,109,110,132,138,140,141,142,143,144,145,146,147).

Alternatively, or if future fertility is desired, a levonorgestrel—releasing intrauterine contraceptive device can provide virtually equal clinical outcomes (148,149). Ablation may be performed with the laser (108,139,140) by radiofrequency electrosurgical desiccation, resection, or vaporization using a uterine resectoscope (110,150) or by any of a number of nonresectoscopic techniques, including those employing thermal balloons, bipolar radiofrequency, cryonics, heated free fluid, or microwaves (151,152,153,154,155).

Endometrial resection is performed with an electrosurgical loop electrode that can shave the endometrium and superficial myometrium (109,142,143). Vaporization utilizes specially designed electrodes that are attached to standard resectoscopes but which are capable of removing large volumes of tissue without morcellation (156). Ablation is achieved using ball or barrel—shaped electrodes that coagulate the endometrial surface

P.790

(110). Complications of these procedures include fluid overload, electrolyte imbalances (if nonelectrolytic media are used), uterine perforation, bleeding, and intestinal and urinary tract injury (140,145). The risk of uterine perforation may be reduced by using a combination of resection or vaporization and electrosurgical ablation; the latter is most suitable for the thinner areas of the myometrium in the cornu (132). The preoperative use of GnRH analogues or *danazol* may reduce operating time, and GnRH may reduce bleeding and the amount of fluid absorbed into the systemic circulation (157,158).

For many women, these procedures are successful in reducing or eliminating menses without hysterectomy or long-term medical therapy (129,159,160). Success rates vary and depend on the duration of follow-up and the definition of success. For many patients, amenorrhea is the goal, whereas for others, it is normalization of menses. About 75% to 95% of patients are satisfied with the surgical procedure after 1 year, and 30% to 90% of patients have amenorrhea. In comparative studies, there is no advantage of laser over electrosurgical techniques (140,145). The nonresectoscopic techniques have similar clinical outcomes, thus reducing the need for resectoscopic ablation. However, the nonresectoscopic approaches all have limitations defined by the size or configuration of the endometrial cavity. Consequently, for those women with heavy menstrual bleeding who are not suitable for nonresectoscopic techniques because of large uteri (>12 cm sounded length), resectoscopic endometrial ablation remains a viable option (161).

The long-term efficacy and impact of ablation or resection on women with adenomyosis is unknown. Because some endometrium inevitably cannot be ablated, there is the potential for endometrial cancer; therefore, postmenopausal women who have undergone ablation or resection should take progestin as a part of hormonal therapy (159).

Sterilization

Sterilization can be performed under hysteroscopic guidance, an approach that eliminates the disadvantages and risks associated with abdominal or laparoscopic techniques (162,163). One such technique is currently available, and others are currently under development. The Essure system comprises a nickel-titanium coil with a Dacron filament that can be inserted relatively quickly in an office or procedure room setting (see Chapter 10). Current protocols require that hysterosalpingography be performed 3 months after the procedure to ensure that bilateral tubal occlusion has taken place.

Synechiae

Asherman's syndrome is the presence of adhesions in the endometrial cavity resulting in infertility or recurrent spontaneous abortion with or without amenorrhea. These synechiae may be detected on a hystrogram but are best shown with diagnostic hysteroscopy. Relatively thin, fragile synechiae may be divided with the tip of a rigid diagnostic hysteroscope (164). Thicker lesions may require division by semirigid or rigid scissors or energy-based instruments such as a resectoscope or an operative hysteroscope with an Nd:YAG laser. Reproductive outcome depends on the extent of the preoperative endometrial damage (125,165,166).

Patient Preparation and Communication

Most diagnostic hysteroscopy procedures are performed in the office or clinic, whereas operative hysteroscopy is usually performed in an operating room or hospital surgicenter. The patient should understand the rationale for either procedure, as well as the anticipated discomfort, the potential risks, and the expectant, medical, and surgical alternatives. The nature of the procedure and the chance of therapeutic success should be explained to the patient, and she should be given a realistic estimate of success based on the operator's experience.

Diagnostic Hysteroscopy: Risks

The risks of diagnostic hysteroscopy are few, and those complications that occur rarely have severe consequences. However, those risks related to anesthesia, perforation, bleeding,

and the distention media should be discussed. After diagnostic hysteroscopy, most patients have slight vaginal bleeding and occasionally, lower abdominal cramps. Severe cramps, dyspnea, and upper abdominal and right shoulder pain can develop if CO₂ passes into the peritoneal cavity. Consequently, the patient should be accompanied by a friend or relative to escort her home.

Operative Hysteroscopy: Risks

Counseling before operative hysteroscopy varies depending on the planned procedure and the type of anesthesia used. **The risks of operative hysteroscopy are higher and potentially more dangerous than those of diagnostic hysteroscopy.** These risks include those associated with anesthesia, intrinsic to all hysteroscopic procedures, and related to the specific surgical procedure to be performed. **With any hysteroscopic procedure, air embolus is a possibility, as are complications associated with the gaseous or fluid distention media used.** Hypotonic distention media may not be tolerated in some patients if there is significant intravascular absorption, especially in patients with underlying cardiovascular disease. The patient must also be aware of the risks associated with uterine perforation, which range from failure to complete the procedure to hemorrhage or damage to the intestines or to the urinary tract. If such complications occur, laparotomy may be necessary to repair the injury.

Equipment and Technique

The equipment required for hysteroscopy depends on the reason for the procedure. The surgeon must be knowledgeable about the equipment, its mechanisms, and the technical specifications to facilitate efficiency, optimal clinical outcome, and a decreased probability of complications. A typical hysteroscopy setup for diagnostic and minor operative procedures is shown in Figures 21.24 and 21.25. Core competencies required for hysteroscopy are as follows:

- Patient positioning and cervical exposure
- Anesthesia
- Cervical dilation
- Uterine distention
- Imaging
- Intrauterine manipulation

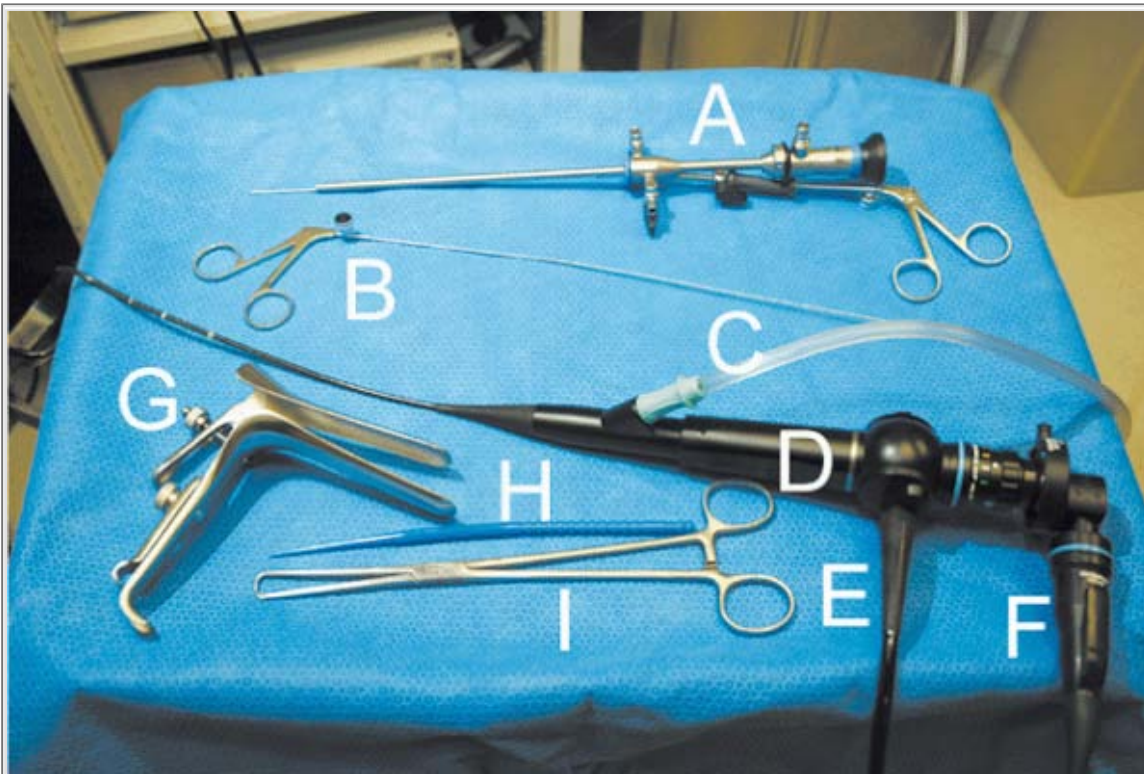

Figure 21.25 Office Hysteroscopy Instruments. An assembled continuous flow operating hysteroscope with a 5.5-mm diameter external sheath is shown in **A**. A 5 French semirigid scissors occupies the working channel. An additional biopsy forceps is shown in **B**. Tubing transporting media to the system is shown in **C** going into a 3-mm external diameter flexible and steerable hysteroscope (**D**). A medical video camera is attached to the hysteroscope (**F**) and the light source is attached at (**E**). An open speculum (**G**) facilitates removal with instruments in place. A small dilator (**H**) or series of dilators will be necessary for a large number of patients. A tenaculum (**I**) attached to the cervix frequently facilitates both dilation and entry of the hysteroscope into the endometrial cavity.

Patient Positioning and Exposure

Hysteroscopy is performed in a modified dorsal lithotomy position; the patient is supine, and the legs are held in stirrups. For hysteroscopic procedures performed while the patient is conscious, comfort must be considered in conjunction with the need to gain good exposure of the perineum. Stirrups that hold and support the knees, calves, and ankles permit prolonged procedures. "Candy cane" stirrups should be avoided for hysteroscopic surgery on conscious patients.

The smallest speculum possible should be used to expose the cervix. A bivalve speculum hinged on only one side allows its removal without disturbing the position of the tenaculum and hysteroscope. The use of weighted specula should be avoided in conscious patients because of the discomfort involved.

Anesthesia

The anesthetic requirements for hysteroscopy vary greatly, depending on the patient's level of anxiety, the status of her cervical canal, the procedure, and the outside diameter of the hysteroscope or sheath. **In some patients, diagnostic hysteroscopy is possible without**

anesthesia, especially if the patient is parous or if narrow—caliber (<3 mm in outside diameter) hysteroscopes and sheaths are used. The pain of cervical dilation also is avoided or minimized by inserting a laminaria tent in the cervix 3 to 8 hours before the procedure. However, if laminaria are left in place too long (e.g., longer than 24 hours), the cervix may overdilate, which is counterproductive for CO₂ insufflation.

P.793

For most diagnostic procedures, effective cervical anesthesia is obtained with an intracervical block. A spinal needle can be used to instill about 3 mL of 0.5% to 1% lidocaine into the anterior lip of the cervix. A tenaculum is used to grasp the cervix. An intracervical block is administered evenly around the circumference of the internal os. A paracervical block may also be injected into the uterosacral ligaments at the 4- and 8-o'clock positions, if necessary (167). Care must be taken to avoid intravascular injection. Additional topical anesthesia may be given by injecting 5 mL of 2% *mepivacaine* into the endometrial cavity with a syringe. Many operative procedures can be performed with this technique combined with intravenous use of anxiolytics or analgesics, as necessary. Alternatively, regional or general anesthesia may be used.

Cervical Dilation

Dilation of the cervix, although apparently simple, can be incorrectly performed in a way that compromises the whole procedure. If the objective lens of the hysteroscope cannot be placed in the endometrial cavity, the hysteroscopy cannot be done. Although findings have been inconsistent, preoperative administration of prostaglandin E₁ (*misoprostol*) to ripen the cervix 12 hours before the procedure (400 µg orally or 200 µg vaginally) may facilitate cervical dilation (168,169). Alternatively, there is evidence that intracervical injection of *vasopressin* (0.05 U/mL, 4 cc at 4 and 8 o'clock) also substantially reduces the force required for cervical dilation (170). The cervix should be dilated as atraumatically as possible. It is best to avoid using a uterine sound because it can traumatize the canal or the endometrium, causing unnecessary bleeding and uterine perforation.

P.794

Uterine Distention

Distention of the endometrial cavity is necessary to create a viewing space. The choices include CO₂ gas, high-viscosity 32% *dextran 70*, and a number of low-viscosity fluids, including glycine, sorbitol, saline, and dextrose in water. **A pressure of 45 mm Hg or higher is generally required for adequate distention of the uterine cavity. To minimize extravasation, this pressure should not exceed the mean arterial pressure.** For each of the fluids, there are several methods used to create this pressure by infusion into the endometrial cavity.

Sheaths

A rigid hysteroscope is passed into the endometrial cavity through an external sheath. The design and diameter of the sheath reflect both the dimensions of the endoscope and the purpose of the instrument. Diagnostic hysteroscopes have a sheath slightly wider than the telescope, allowing infusion of the distention media. Sheaths for operative hysteroscopes have one or two additional channels that permit the passage or efflux of distention media or the insertion of semirigid instruments or laser fibers. These sheaths are usually 5 to 8 mm in

diameter, and some allow continuous flow of distention media in and out of the endometrial cavity (Figs. 21.25,21.26).

Figure 21.26 Hysteroscope optics. Panoramic (0°) and oblique (15° and 30°) viewing angles.

Media

CO₂ provides an excellent view for diagnostic purposes, but it is unsuitable for operative hysteroscopy and for diagnostic procedures when the patient is bleeding because there is no effective way to remove blood and other debris from the endometrial cavity. To prevent CO₂ embolus, the gas must be instilled by an insufflator that is specially designed for the procedure—the intrauterine pressure is kept below 100 mm Hg, and the flow rate is maintained at less than 100 mL/min.

Normal saline is a useful and safe medium for procedures that do not require radiofrequency electricity from standard monopolar resectoscopes. Even if there is absorption of a substantial volume of solution, saline does not cause electrolyte imbalance. Therefore, saline is a good fluid for minor procedures performed in the office. The development of bipolar radiofrequency instrumentation for hysteroscopic surgery has allowed the application of saline as a distending medium in even more advanced and complex procedures.

P.795

Dextran 70 is useful for patients who are bleeding, because it does not mix with blood. However, it is expensive and tends to “caramelize” on instruments, which must be disassembled and thoroughly cleaned in warm water immediately after each use. Anaphylactic reactions, fluid overload, and electrolyte disturbances can occur.

For standard operative hysteroscopy with monopolar radiofrequency resectoscopes, low-viscosity, nonconductive fluids such as 1.5% glycine, 3% sorbitol, and 5.0% mannitol are used most often. These solutions can be used with standard, monopolar radiofrequency instrumentation because there are no electrolytes to disperse the current and impede the electrosurgical effect. Each of these media is inexpensive and readily available, usually in 3-L bags suitable for continuous-flow hysteroscopy. Because each fluid is electrolyte-free, extravasation into the systemic circulation can be associated with electrolyte disturbances. Compared with 1.5% glycine or 3.0% sorbitol,

5% mannitol is isosmolar, and it functions as a diuretic, both advantages when performing resectoscopic surgery. **Regardless of the electrolyte content of the fluid distending media, systemic "absorption" must be monitored continuously or at least frequently (every 5 minutes) by collecting outflow from the sheath and subtracting it from the total infused volume.** There exist a number of machines designed to provide continuous feedback to the surgeon regarding the degree of negative fluid balance. Absorbed volumes greater than 1L mandate the measurement of electrolyte levels. The administration of an appropriate dose of furosemide should be considered, and the surgeon should plan for the expeditious completion of the procedure. If there is more than a preset limit (1.5–2 L of extravasated fluid), the procedure should be stopped. Excessive circulating sorbitol may cause hyperglycemia, and large volumes of glycine may elevate levels of ammonia in the blood (171).

Media Delivery Systems

Syringes can be used for office diagnostic procedures and are especially good for infusing *dextran* solution. The syringe can be operated by the surgeon and is either connected directly to the sheath or attached by connecting tubing. Because this technique is so tedious, it is suited only for simple operations.

Continuous hydrostatic pressure is effectively achieved by elevating the vehicle containing the distention media above the level of the patient's uterus. The achieved pressure is the product of the width of the connecting tubing and the elevation—for operative hysteroscopy with 10–mm tubing, intrauterine pressure ranges from 70 to 100 mm Hg when the bag is between 1 to 1.5 m above the uterine cavity.

A pressure cuff may be placed around the infusion bag to elevate the pressure in the system. Caution must be exercised, however, because this technique causes increasing extravasation if intrauterine pressure rises above the mean arterial pressure.

A variety of infusion pumps are available, ranging from simple devices to instruments that maintain a preset intrauterine pressure. Simple pump devices continue to press fluid into the uterine cavity regardless of resistance, whereas the pressure-sensitive pumps reduce the flow rate when the preset level is reached, thereby impeding the efflux of blood and debris and compromising the view.

Imaging

Endoscopes

Hysteroscopes are available in two basic types—flexible and rigid. Flexible hysteroscopes have lower resolution than rigid instruments of a similar diameter and are most useful for cannulation of the fallopian tube. For other uses, rigid hysteroscopes are more durable and provide a superior image. The most commonly used hysteroscopes are 3 to 4 mm in

P.796

diameter, although those smaller than 2 mm in diameter are available. Small-diameter endoscopes have a somewhat lower resolution but are easier to pass through the cervix.

Endoscopes with angled (foreoblique) lenses are useful for hysteroscopy and are available in 0-degree, 12- to 15-degree, and 25- to 30-degree models (Fig. 21.26). The 0-degree telescope provides a panoramic view and is best for diagnostic procedures. Hysteroscopes with 25- to 30-degree angles are most often used for cannulation of the fallopian tubes or placement of sterilization devices, whereas 12- to 15-degree designs are a suitable compromise useful

for diagnosis and ablation or resection.

Light Sources and Cables

Adequate illumination of the endometrial cavity is essential. Because it runs from a standard 110- or 220-volt wall outlet, the light source requires no special electrical connections. For most cameras and endoscopes, the element must have at least 150 watts of power for direct viewing and preferably 250 watts or more for video and operative procedures (172).

Video Imaging

Although diagnostic hysteroscopy may be performed with direct visualization, it is best to use video guidance for prolonged operations. Video imaging is important for teaching and recording pathology and procedures. The camera must be sensitive because of the narrow diameter of the endoscope and the frequently dark background of the endometrial cavity, particularly when it is enlarged (Fig. 21.25).

Image Documentation

A small video camera can be used to teach and to coordinate the procedure with the operating room team. It also allows the acquisition of still or video images for future reference or teaching. When a video recorder is used, the camera should be attached directly to the recorder to preserve the image quality. A number of video recording formats are available, each with inherent advantages and disadvantages. Some video printers provide images suitable for a medical record. Newer digital cameras provide video still images, slides, or prints that are suitable for publication or teaching.

Intrauterine Surgery

The instruments available for use through operative hysteroscopes include grasping, cutting, and punch-biopsy devices. These tools are narrow and flexible enough to navigate the 1- to 2-mm diameter operating channel (Fig. 21.25). Their value is limited by their small size and flimsy construction; however, the scissors can be used to divide adhesions, the biopsy forceps can be used to sample targeted lesions, and the grasping forceps can be used to remove small polyps or intrauterine devices. Some operative hysteroscopes are designed to allow passage of fibers for the conduction of Nd:YAG laser.

The uterine resectoscope is similar to the one used in urology and is designed to apply radiofrequency electrical energy in the endometrial cavity (Fig. 21.27). An understanding of the principles of electrosurgery is mandatory for safe and effective use of this instrument. By sliding the "working element," one of a variety of electrode tips can be manipulated back and forth within the cavity. Tissue can be divided with a pointed electrode, excised with a loop, or desiccated with a rolling ball or bar. An electrode with multiple tips or edges can be used to vaporize tissue, provided high generator outputs are used. A clear operative field is maintained by the continuous flow of nonconductive distending media in and out of the cavity. Although basic design modifications have made the resectoscope more useful in gynecology, extraction of resected fragments is time consuming. The most effective approach is the periodic use of a uterine curette or polyp forceps inserted after

P.797

removal of the hysteroscope. Alternatively, much of the myoma or endometrium can be vaporized, thereby minimizing the need for periodic but time-consuming removal of tissue "chips." If vaporization is used, it is still important to obtain representative samples of the endometrium

or myoma for pathological analysis.

Figure 21.27 Resectoscope. The assembled resectoscope is shown, with two electrodes in the foreground. Manipulation of the electrode is via the white handle in the proximal portion of the device.

Other Instruments

For any hysteroscopic procedure, it is necessary to have available a cervical tenaculum, dilators, uterine curette, and appropriate-sized vaginal specula. When using the resecto scope, it is helpful to have a modern, solid-state, isolated circuit electrosurgical generator capable of delivering both modulated and nonmodulated radiofrequency current. Laparoscopy or laparotomy may be necessary for emergencies secondary to uterine perforation.

Complications

The potential risks of diagnostic hysteroscopy include uterine perforation, infection, excessive bleeding, and complications related to the distention media (145). The latter include CO₂ embolus and pulmonary edema secondary to overinfusion of 32% *dextran 70* (*Hyskon*) or low-viscosity fluids. Diagnostic hysteroscopy performed in the office has a low rate of complications (0%–1%) (114,115,116). **The risks of operative hysteroscopy are related to one of five aspects of the procedure performed: (i) anesthesia, (ii) the distention media, (iii) perforation, (iv) bleeding, and (v) the use of energy.**

Anesthesia

Local anesthesia is provided by the intracervical or paracervical injection of 0.5% to 2% *lidocaine* or *mepivacaine* solution, with or without a local vasoconstrictor such as adrenaline. Overdosage is prevented by ensuring that intravascular injection is avoided and by not exceeding the maximum recommended doses (*lidocaine*, 4 mg/kg; *mepivacaine*, 3 mg/kg). The use of a vasoconstrictor reduces the amount of systemic absorption of the agent, doubling the maximum dose that can be used.

Complications of intravascular injection or anesthetic overdose include allergy, neurologic effects, and impaired myocardial conduction. Allergy is characterized by the typical symptoms of agitation, palpitations, pruritus, coughing, shortness of breath, urticaria, bronchospasm, shock, and convulsions. Treatment measures include administration of oxygen, isotonic intravenous fluids, intramuscular or subcutaneous adrenaline, and intravenous prednisolone

and aminophylline. Cardiac effects related to impaired myocardial conduction include bradycardia, cardiac arrest, shock, and convulsions. Emergency treatment measures

include the administration of oxygen, intravenous *atropine* (0.5 mg), and intravenous *adrenaline*, and the initiation of appropriate cardiac resuscitation. The most common central nervous system manifestations are paresthesia of the tongue, drowsiness, tremor, and convulsions. Options for therapy include intravenous *diazepam* and respiratory support.

Distention Media

Carbon Dioxide

Carbon dioxide is highly soluble in blood; consequently, even if emboli occur, they are rarely clinically significant. However, rarely, CO₂ emboli may result in

serious intraoperative morbidity and even death (173,174,175). These risks can be eliminated by not using CO₂ with operative procedures, and by ensuring that the insufflation pressure is always lower than 100 mm Hg and that the flow rate is lower than 100 mL/min. The insufflator used must be especially designed for hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL/min.

Dextran 70

Dextran 70 is a hyperosmolar medium that can induce an allergic response, coagulopathy, and, if sufficient volumes are infused, vascular overload and heart failure (176,177). Because dextran is hydrophilic, it can draw 6 times its own volume into the systemic circulation. Consequently, the volume of this agent should be limited to less than 300 mL, particularly for office use.

Low-Viscosity Fluids

The low-viscosity fluids—1.5% glycine, 3% sorbitol, and 5.0% mannitol—are most often used, largely because of their low cost, compatibility with standard electrosurgery, and availability in large-volume bags. However, the use of a continuous-flow system with hypotonic media can create fluid and electrolyte disturbances.

- **Before undertaking a procedure using the resectoscope, baseline serum electrolyte levels should be measured.** Women with cardiopulmonary disease should be evaluated carefully. The selective preoperative use of agents such as GnRH agonists may reduce operating time and media absorption. Intracervical injection of 8 mL dilute intracervical vasopressin (0.01 U/mL) has been shown effective at reducing the amount of systemic absorption of distending media (178).

- **In the operating room, media infusion and collection should take place in a closed system to allow accurate measurement of the “absorbed” volume.** The volume should be measured continuously with a device specifically designed for the purpose or calculated every 5 to 10 minutes.

- **The lowest intrauterine pressure necessary for adequate distention should be used to complete the operation, usually at a level that is below the mean arterial pressure.**

A good range is 70 to 80 mm Hg, which can be achieved with a specially designed pump or by maintaining the meniscus of the infusion bag 1 m above the level of the patient's uterus.

Deficits of more than 1 L require measurement of electrolyte levels and may require an appropriate dose of intravenous furosemide. The procedure should be completed expeditiously. If the deficit is more than a preset limit (1.5–2 L), the procedure should be terminated, and a diuretic such as *mannitol* or *furosemide* should be used as needed. In patients with cardiovascular compromise, deficits must be avoided (179).

P.799

Perforation

Perforation may occur during dilation of the cervix or during the hysteroscopic procedure. With perforation, the endometrial cavity does not distend, and the visual field is lost.

When perforation occurs during dilation of the cervix, the procedure must be terminated, but usually there are no other injuries. If the uterus is perforated by a hysteroscopic instrument, the tip of a laser, or an activated electrode, there is a risk for bleeding or injury to the adjacent viscera. Therefore, the operation must be stopped and the instruments withdrawn under hysteroscopic guidance.

If there is evidence of bleeding or presumed visceral injury, laparoscopy or laparotomy should be performed. Injury to the uterus is relatively easy to detect with a laparoscope. However, mechanical or thermal injury to the bowel, ureter, or bladder is more difficult and may require laparotomy. If the patient's condition is managed expectantly, she should be advised of the situation and asked to report any symptoms of bleeding or visceral trauma such as fever, increasing pain, nausea, and vomiting.

Bleeding

Bleeding that occurs during or after hysteroscopy results from trauma to the vessels in the myometrium or injury to other vessels in the pelvis. Myometrial vessels can be lacerated during the resectoscopic procedures.

In planning operations that involve deep resection, autologous blood can be obtained before surgery. The risk for bleeding may be reduced by the preoperative injection of diluted vasopressin into the cervical stroma (178). The risk of injury to branches of the uterine artery can be lowered by limiting the depth of resection in the lateral endometrial cavity near the uterine isthmus, where ablative techniques should be considered. When bleeding is encountered during resectoscopic procedures, the ball electrode can be used to desiccate the vessel electrosurgically. Intractable bleeding may respond to the injection of diluted vasopressin or to the inflation of a 30-mL Foley catheter balloon or similar device in the endometrial cavity (132).

Thermal Trauma

Thermal injury to the intestine or ureter may be difficult to diagnose, and symptoms may not occur for several days to 2 weeks. Therefore, the patient should be advised of the symptoms that could indicate peritonitis.

Hysterectomy

Thomas G. Stovall

- **Hysterectomy is one of the most commonly performed surgical procedures in the United States.**
- **Vaginal hysterectomy continues to be the procedure of choice unless this route is contraindicated.**
- **There appears to be no advantage to the routine use of supracervical hysterectomy when compared with total hysterectomy.**
- **Oophorectomy at the time of hysterectomy is associated with an increase in patient mortality, and it is currently recommended that ovarian conservation be considered until at least age 65 years.**
- **A number of concurrent surgical procedure may be performed safely at the time of hysterectomy.**

Hysterectomy is one of the most common surgical procedures performed. After cesarean delivery, it is the second most frequently performed major surgical procedure

in the United States (1). In 1965, there were 426,000 hysterectomies performed in the United States, with an average length of hospital stay of 12.2 days. This number reached its peak in 1985, when 724,000 procedures were reported, with the length of stay decreasing to 9.4 days. The number of hysterectomies performed in the United States declined to 544,000 in 1991, with an average length of stay of 4.5 days. Of these 544,000 hysterectomies, 408,000 (75%) were performed abdominally, and 136,000 (25%) were performed vaginally (2,3). However, by 1998, the number of hysterectomies performed had increased to more than 600,000 (4). Using 1987 age-specific hysterectomy rates and the population projections supplied by the U.S. Census Bureau, it is projected that there will be 824,000 hysterectomies in the year 2005 (5).

The rate of hysterectomy has varied between 6.1 and 8.6 per 1,000 women of all ages. A woman's chance of having a hysterectomy is dependent on a variety of factors, including her age, race, and where she lives, and the sex of her physician. Women between the ages of 20 and 49 years constituted the largest segment of women undergoing the procedure. **The average age of a woman undergoing hysterectomy is 42.7 years and the median age is 40.9 years, which has remained constant since the**

P.806

1980s. About 75% of all hysterectomies are performed in women between the ages of 20 and 49 years. The rates of hysterectomy vary by region of the country. The highest overall rate is in the southern states, where the rate tends to be higher for women aged 15 to 44 years. The lowest rates have consistently been in the northeastern portion of the United States. Hysterectomy is more often performed in African American than in white women and is performed more frequently by male gynecologists than by female gynecologists (6,7,8,9).

Indications

The indications for hysterectomy are listed in Table 22.1. **In virtually all studies, uterine leiomyomas are consistently the leading indication for hysterectomy. As expected, the indications differ with the patient's age** (10). For instance, whereas pelvic support defects account for 16% of all hysterectomies, this diagnosis is responsible for more than 33% of hysterectomies in women older than 55 years of age. More complete discussions of these indications are presented in the specific chapters indicated.

Leiomyomas

Uterine leiomyomas are the most common pelvic tumors in women; therefore, this condition is responsible for a large number of hysterectomies (10). Hysterectomy for uterine leiomyomas should be considered only in patients who do not desire future fertility. Otherwise, fertility-preserving surgical management (myomectomy) is possible in most patients with leiomyomas. **The decision to perform a hysterectomy for leiomyomas is usually based on the need to treat symptoms**—abnormal uterine bleeding, pelvic pain, or pelvic pressure. Other indications for intervention have included “rapid” uterine enlargement (although this finding is poorly defined), ureteral compression, or uterine growth after menopause. **The concept of rapid growth has been challenged** (11) **because such patients have not been shown clearly to have malignant conditions.** Furthermore, there is no clearly reproducible definition of rapid growth. The removal of the uterus because it reaches a certain size is widely debated. In the past, surgeons removed the uterus if its size reached that approximating 12 weeks of gestation or greater, even if it was asymptomatic. The reasons given for such an intervention include the inability to palpate the ovaries on bimanual examination and the assumption that, as the uterus enlarges, the morbidity for hysterectomy increases. Malignancy is uncommon in premenopausal patients, however, and adnexal palpation is not possible in many patients whose ovaries are of normal size. If

the procedures are performed abdominally, there is no difference in surgical morbidity between patients with a 12-week-sized uterus and those with a 20-week-sized uterus (12). **Therefore, hysterectomy for leiomyomas should be considered only in symptomatic patients who do not desire future fertility (12).**

To reduce uterine size before hysterectomy, patients with large leiomyomas may be pretreated with a gonadotropin-releasing hormone (GnRH) agonist (13,14,15). In many cases, the reduction of uterine size is sufficient to permit vaginal hysterectomy when otherwise an abdominal hysterectomy would have been necessary. In one prospective trial, premenopausal patients with leiomyomas the size of 14 to 18 weeks of gestation were randomized to receive either 2 months of preoperative depot GnRH agonist or no GnRH agonist (15). Treatment with a short course (8 weeks) of *leuprolide acetate* before surgery enabled the procedures to be converted safely from an abdominal hysterectomy to a vaginal hysterectomy. This preoperative regimen was associated with a rise in hematocrit before surgery and, because patients were more likely to have vaginal than abdominal hysterectomy, a shorter hospital stay and convalescent period.

P.807

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding is the indication for about 20% of hysterectomies.

Because dysfunctional uterine bleeding usually is the result of anovulation, the bleeding can be controlled by medical interventions with *progestin*, *estrogen*, a combination of *progestin* and *estrogen*, oral contraceptives, or nonsteroidal anti-inflammatory agents (see Chapter 14). In most patients, the bleeding requires no therapy unless anemia is present or bleeding is excessive and interferes with the patient's quality of life. In patients older than 35 years of age, endometrial sampling should be performed before hysterectomy. **Dilation and curettage is not an effective means of controlling bleeding and is not necessary before hysterectomy** (16). Therefore, **hysterectomy should be reserved for patients**

P.808

who do not respond to or who cannot tolerate medical therapy. Alternatives to hysterectomy (eg, endometrial ablation or resection) should be considered in selected patients because these operations may be cost-effective and have a lower morbidity rate (see Chapter 21).

Intractable Dysmenorrhea

About 10% of adult women are incapacitated for up to 3 days per month as a result of dysmenorrhea (see Chapter 15) (17). Dysmenorrhea can be treated with nonsteroidal anti-inflammatory agents used alone or in combination with oral contraceptives or other hormone agents to reduce or ablate menstrual flow (18,19). Hysterectomy is rarely required for the treatment of primary dysmenorrhea. In patients with secondary dysmenorrhea, the underlying condition (e.g., leiomyomas, endometriosis) should be treated primarily.

Hysterectomy should be considered only if medical therapy fails or if the patient does not want to preserve fertility (20,21,22).

Pelvic Pain

In a review of 418 women in whom hysterectomy was performed for a variety of nonmalignant conditions, 18% had chronic pelvic pain. Preoperative laparoscopy was performed in only 66% of these patients. After hysterectomy, there was a significant reduction in symptoms associated with an improvement in the patient's quality of life (23). In a review of 104 patients who underwent hysterectomy for chronic pelvic pain that was believed to be of uterine origin, 78% experienced improvement in their pain after follow-up for a mean of 21.6 months (24). However, 22% of patients had no improvement in or exacerbation of their pain. **Hysterectomy should be performed only in those patients whose pain is of uterine origin and does not respond to nonsurgical treatments** (18) (see Chapter 15).

Cervical Intraepithelial Neoplasia

In the past, hysterectomy was performed as primary treatment of cervical intraepithelial neoplasia. However, the maximum depth of dysplasia at the squamocolumnar junction is 5.2 mm; 99.7% of dysplasias (including carcinoma *in situ*) are located within 3.8 mm of the epithelial surface (25). Therefore, **more conservative treatments such as cryotherapy, laser, or a loop electrosurgical excision procedure can be effective in treating the disease, making hysterectomy unnecessary in most women with these conditions** (see Chapter 17). For patients with recurrent high-grade dysplasia who do not desire to preserve fertility, hysterectomy is an appropriate treatment option. Even after hysterectomy, however, patients are at increased risk for vaginal intraepithelial neoplasia.

Genital Prolapse

Hysterectomy for symptomatic genital prolapse accounts for about 15% of hysterectomies performed in the United States (7). **Unless there is an associated condition requiring an abdominal incision, vaginal hysterectomy is the preferred approach for genital prolapse.** Uterine prolapse typically is not an isolated event and most often is associated with a variety of pelvic support defects (see Chapter 24). Each defect must be corrected to optimize the surgical outcome and decrease the risk of future development of pelvic support defects.

Obstetric Emergency

Most emergency hysterectomies are performed because of postpartum hemorrhage resulting from uterine atony. Other indications include uterine rupture that cannot be repaired or a pelvic abscess that does not respond to medical therapy. Hysterectomy may be required for patients with placenta accreta or placenta increta.

P.809

Pelvic Inflammatory Disease

Pelvic inflammatory disease can generally be treated successfully with antibiotics. The uterus, tubes, and ovaries should not be removed in a patient with pelvic inflammatory disease unless the patient has not responded to intravenous antibiotic therapy (see Chapter 16). Whether one proceeds with conservative surgical management, abscess drainage, or organ removal is a subjective decision that must be based on the individual. If accessible, some pelvic abscesses may be drained successfully by percutaneous catheter drainage guided by ultrasonography or computed tomography (CT) scanning. Surgical intervention also is necessary if the patient has acute abdominal findings associated with peritonitis and signs of sepsis in the presence of a ruptured tubo-ovarian abscess. **For the patient who desires future fertility, consideration should be given to unilateral adnexectomy or partial bilateral adnexectomy without hysterectomy.** For the patient in whom bilateral adnexectomy is required, the uterus can be left in place for possible ovum donation and *in vitro* fertilization (see Chapter 30).

Endometriosis

Medical and conservative surgical procedures generally are successful for treatment of endometriosis (see Chapter 29). Therefore, **adnexectomy, with or without hysterectomy, should be performed only in patients who do not respond to conservative surgical** (resection or ablation of endometriotic implants) or medical therapy. Most patients with endometriosis who require hysterectomy have unrelenting pelvic pain

or dysmenorrhea. Other less common situations include patients who do not desire future fertility and who have endometriosis involving other pelvic organs, such as the ureter or colon.

Cancer

Metastases from nongynecologic sites may cause symptoms requiring hysterectomy. As a primary procedure, hysterectomy with bilateral salpingo-oophorectomy should be considered for patients with colorectal carcinoma because these patients are at risk for either synchronous pelvic cancers or occult metastases (26,27).

Benign Ovarian Tumor

Benign ovarian tumors that are persistent or symptomatic require surgical treatment. Obviously, if the patient desires fertility, the uterus should be conserved. If fertility is not an issue, however, or if the patient is perimenopausal or postmenopausal, a decision must be made regarding whether the uterus should be removed. In a one study, 100 patients who underwent adnexectomy plus hysterectomy for benign adnexal disease were compared with a group of risk-matched women who underwent adnexectomy without hysterectomy for the same indication (28). There was a significant increase in operative morbidity, estimated blood loss, and the length of hospital stay for patients in whom hysterectomy was performed.

Vaginal versus Abdominal Hysterectomy

The proportion of abdominal versus vaginal hysterectomies has not changed significantly since the 1980s—about 75% of hysterectomies are abdominal (2,3,7,29,30,31,32). There are no specific criteria that can be used to determine the route of hysterectomy. The route chosen should be based on the individual patient. Absolute and relative contraindications have been proposed (27,28,29). In a large, multicenter retrospective study conducted by the U.S. Centers for Disease Control and Prevention between 1978 and 1981, the risks and outcome of abdominal and vaginal hysterectomy were compared (32). The study included 1,851 patients aged 15 to 44 years in whom hysterectomy was performed for

P.810

benign gynecologic disorders (568 vaginal, 1,283 abdominal). Surgical complications were classified into six categories. The overall complication rate was 24.5 per 100 for vaginal hysterectomy compared with 42.8 per 100 women for abdominal hysterectomy. **The risk for one or more complications after abdominal hysterectomy was 1.7 times the risk after vaginal hysterectomy.** The two major categories of complications were febrile morbidity and hemorrhage requiring transfusion. **The risk for febrile morbidity was 2.1 times higher for abdominal hysterectomy than for vaginal hysterectomy, and the risk for transfusion was 1.9 times higher for abdominal surgery.** Since the collection of these data, transfusion practices within the United States have changed as a result of increased awareness of the human immunodeficiency virus. Although only one fourth of hysterectomies are performed vaginally, this proportion could probably be increased substantially. In a study of 617 hysterectomies, 548 were performed vaginally; laparoscopic assistance was used in 63 patients, and an abdominal approach was required in only 6 patients (33). If feasible, vaginal hysterectomy is the preferred approach.

Supracervical Hysterectomy

The indications for supracervical hysterectomy are somewhat vague. Potential indications include endometriosis with obliteration of the anterior and posterior cul-de-sac, cesarean hysterectomy when the cervix is fully dilated and difficult to identify, and concern

for sexual function. During a technically difficult surgical procedure (e.g., obliteration of the cul-de-sac), there may be concern about the potential morbidity associated with the removal of the cervix. However, **the cervix can almost always be removed**. Some women desire to conserve the cervix because they believe that it is important for sexual satisfaction, although there are no sound scientific data to prove this perception. Some authors (currently representing the minority view) believe that the cervix should not be removed unless there is a specific reason. They suggest that removal of the cervix leads to a decrease in sexual pleasure, increased operative and postoperative morbidity, vaginal shortening, vault prolapse, abnormal cuff granulations, and the potential for oviductal prolapse (34,35).

There is a debate about the effects of leaving the cervix *in situ*. In a study of a group of 210 patients who underwent hysterectomy, one half had total abdominal hysterectomies and one half had supracervical hysterectomies (36). Studies of the same population disclosed an increase in psychiatric symptoms in both groups (34,35,36). Sexual desire and functioning was unchanged, although both groups experienced a decrease in dyspareunia. Patients undergoing supracervical hysterectomy were reported to have increased orgasmic frequency when compared with patients in whom the cervix was left intact (36,37,38,39). **In a clinical trial, 135 women were randomized to undergo total abdominal hysterectomy or supracervical hysterectomy. After 2-year follow-up, both groups had similar sexual functioning and health-related quality of life** (40). Regardless of the reason for leaving the cervix at the time of hysterectomy, preoperative Papanicolaou (Pap) test results must be normal, and appropriate consent must be obtained from the patient.

Laparoscopically Assisted Hysterectomy

Laparoscopy has been used diagnostically before hysterectomy (see Chapter 21). In a study of laparoscopy performed in 46 patients who had been advised to have abdominal hysterectomies, the findings suggested that the referring physicians had overestimated uterine size and underestimated uterine mobility (33). All 14 patients who were referred for assessment of adnexal pathology had none. In 91% (42 of 46) of the patients, vaginal hysterectomy was performed. Another study evaluated seven patients who, aside from their histories suggestive of adhesions, were candidates for vaginal hysterectomy (41). Six

P.811

of the patients underwent laparoscopy, which did not reveal any adhesive disease, and were able to undergo vaginal hysterectomy. These findings are consistent with the other data demonstrating that the **presence of pelvic adhesions cannot be predicted based on either history or physical examination** (42). If laparoscopy is performed on patients with risk factors for adhesions or endometriosis, however, many patients will undergo the procedure needlessly, and about one half of those with adhesions or endometriosis will be overlooked. Thus, the role of diagnostic laparoscopy immediately before hysterectomy seems limited.

The use of operative laparoscopy to complete some or all of the hysterectomy has been widely reported (43,44,45,46,47,48,49,50,51,52,53) (see Chapter 21). However, in most of these studies, the patient population was neither randomized nor defined. Furthermore, the reasons the patient would require an abdominal approach are unclear. **The criteria for selection of patients for laparoscopically assisted vaginal hysterectomy (LAVH) versus abdominal hysterectomy have not been clearly established.**

In a prospective, controlled trial, patients who were candidates for vaginal hysterectomy were randomized to either LAVH or a standard vaginal approach (47). All procedures were performed on an outpatient basis; included were patients who had uterine leiomyomas up to the size of 16 weeks of gestation. There was no difference between the groups in terms of

uterine weight, febrile morbidity, or the need for transfusion. Patients undergoing LAVH had a lower hematocrit value on the first and second postoperative days and required more pain medication on the second postoperative day. Although these findings are not clinically significant, they suggest that, when compared with a vaginal approach, LAVH does not reduce perioperative morbidity. The cost of LAVH is significantly higher than that of vaginal hysterectomy; the largest component of this cost differential resulted from the use of disposable equipment. **This study demonstrates that there is no advantage of LAVH over traditional vaginal hysterectomy.**

It has been suggested that LAVH may be helpful in treating patients with documented endometriosis, known pelvic adhesive disease, an adnexal mass that requires hysterectomy, and lack of uterine mobility (see Chapter 21). Depending on the circumstances, LAVH may be appropriate in some patients with stage I endometrial cancer or previous episodes of multiple major pelvic surgery. For example, if the patient has had endometriosis that has been treated previously or adhesions that have been lysed previously and now require hysterectomy, a vaginal approach can most likely be taken. In a study of a group of patients with stage III or IV endometriosis, the procedure was successful in 40 of 46 patients (54). Even in the hands of expert laparoscopic surgeons, however, the rate of complications was high.

Mild pelvic adhesions do not preclude vaginal hysterectomy. If the patient has intensive adhesions that involve the adnexa, bowel, and uterus, however, an abdominal approach usually is needed (55). In such patients, laparoscopy may be a better alternative than hysterectomy.

It is uncertain whether LAVH is preferable in patients with limited uterine mobility, and there is no standard method to assess the best approach. The major supporting structures of the uterus are the uterosacral ligaments and lower cardinal complex (56), which are not generally transected with a laparoscopic approach. Transection of the utero-ovarian ligament, round ligament, and broad ligament does not improve mobility.

Both LAVH and pelvic lymphadenectomy may be useful in selected patients with endometrial carcinoma (57). The data suggest that a lymphadenectomy can be performed successfully and that hospital stay and morbidity are decreased when compared with the standard transabdominal approach. Long-term prospective studies are needed to address these questions.

Concurrent Surgical Procedures

Oophorectomy

A laparoscopic approach should not be used in conjunction with hysterectomy solely for the purpose of accomplishing ovarian removal. Although not every ovary can be removed through the vagina, it has been shown clearly that most can be removed in this manner (58).

Prophylactic oophorectomy is the most common surgical procedure performed concurrently with hysterectomy. Oophorectomy is performed prophylactically to prevent ovarian cancer and to eliminate the potential need for further surgery for either benign or malignant disease. However, the optimal age for this prophylactic oophorectomy in women who have increased risk as well as those who do not have increased risk has not been determined. **Arguments against prophylactic oophorectomy center on the need for earlier and more prolonged hormone therapy and the potential increase risk of cardiovascular disease** (59,60). Although hormone therapy generally is well tolerated and provides

good symptomatic relief, it may not be as effective as normal ovarian function, and the implications of long-term hormone therapy are not fully known. Therefore, the decision to proceed with oophorectomy should be considered carefully after the patient has been informed of the risks and benefits.

The risk for developing ovarian cancer after hysterectomy for benign disease is lower than would be expected based on its prevalence. Of those women who have no history of ovarian tumors and normal-appearing ovaries at the time of abdominal hysterectomy, 0.14 to 0.47% subsequently develop ovarian cancer in their conserved ovaries (59,60). Considering that as many as 1.4% of women are expected to get ovarian cancer, this is about one tenth to one third the expected rate. Presumably, this lower rate occurs because the cohort of women with normal-appearing ovaries in whom hysterectomy is performed for benign disease is a "selected" population, and because it excludes patients at high-risk for developing ovarian cancer. In women who do not have ovarian disease at the time of hysterectomy, the risk for developing benign ovarian tumors is less than 5% (61). The risk for ovarian cancer in women with a strong family history is 3% to 50%, depending on the pedigree (62,63) (see Chapter 35).

Long-term compliance with posthysterectomy estrogen therapy is low (64). Only 20% to 40% of women who initiate treatment after hysterectomy and bilateral oophorectomy continue to take estrogen for more than 5 years. Therefore, it should not be assumed that patients will receive adequate estrogen after oophorectomy. Women who subsequently develop breast cancer may be advised not to take estrogen.

A Markov decision analysis model has been used to estimate the best strategy for maximizing a woman's survival when oophorectomy is considered in low-risk women undergoing hysterectomy for benign disease. Researchers found that women who had oophorectomy before age 55 years had an 8.58% excess mortality by age 80, and those with oophorectomy before age 59 have a 3.92% excess mortality. By age 75 years, this excess mortality is less than 1%.

The conclusion was that ovarian conservation until at least age 65 years confers long-term survival benefits for those women at average risk for ovarian cancer undergoing hysterectomy for benign disease (60).

Appendectomy

Appendectomy may be performed concurrently with hysterectomy to prevent appendicitis and to remove disease that may be present. The former use is of limited value, however, because the peak incidence of appendicitis is between 20 and 40 years of age, whereas the peak age for hysterectomy is 10 to 20 years later (65). Appendectomy is effective in removing previously undetected disease, but the likelihood that these

P.813

abnormalities would cause any clinical problems is uncertain. In one study, histologic abnormalities were found in 71% (32 of 45) of appendices removed at the time of hysterectomy, and two had asymptomatic carcinoid tumors (66). In another study, 22% of appendices removed at the time of hysterectomy showed evidence of pathologic alterations, and five carcinoid tumors were identified (67).

There is no increase in morbidity associated with appendectomy performed at the time of hysterectomy (67,68,69), **although it does require an average of 10 minutes additional operating time** (60). Thus it is felt that incidental appendectomies in all abdominal hysterectomies could reduce the morbidity of appendicitis at a later time (70). Appendectomy has also been performed with vaginal hysterectomy without

additional intraoperative or postoperative morbidity (71,72,73,74).

Cholecystectomy

Gallbladder disease is about four times more common in women than men, and its highest incidence occurs between 50 and 70 years of age, when hysterectomy is most often performed. Thus, women may require both procedures. A combined procedure does not appear to result in increased febrile morbidity or length of hospital stay (75,76).

Abdominoplasty

Abdominoplasty performed at the time of hysterectomy is associated with a shorter hospital stay, a shorter operating time, and a lower intraoperative blood loss than when the two operations are performed separately (77,78). Liposuction also can be performed safely at the time of vaginal hysterectomy (79).

Technique

Negative results of a Pap test done within the year should be obtained before performing a hysterectomy for benign disease. If the patient is 40 years of age or older and has not recently had a mammography, this examination should be performed. Endometrial sampling is recommended if the patient has reported abnormal uterine bleeding. In patients older than 40 years of age, a stool guaiac test should be performed. Other preoperative testing should be dictated by the patient's specific medical conditions.

Abdominal Hysterectomy

Preoperative Preparation

Although not mandatory, a cleansing tap water or soap enema given on the evening before or the morning of the scheduled hysterectomy is preferred by some surgeons. To reduce the colony count of skin bacteria, the patient is asked to shower. Hair surrounding the incision area may be removed at the time of surgery or before surgery using a depilatory agent. Hair clipping is preferable to shaving because it decreases the incidence of incisional infection (80).

Patient Positioning

The patient is placed in the dorsal supine position for the procedure. After the patient is anesthetized adequately, her legs are placed in the stirrups and a pelvic examination is performed to validate the in-office pelvic examination findings. A Foley catheter is placed in the bladder, and the vagina is cleansed with an iodine solution. The patient's legs are then straightened.

Skin Preparation

Several methods for skin cleaning can be recommended, including a 5-minute iodine solution

scrub followed by application of iodine solution, iodine solution scrub followed by alcohol with application of an iodine-impregnated occlusive drape, or an iodine-alcohol combination with or without application of an iodine-impregnated occlusive drape.

Surgical Technique

Incision

The choice of incision should be determined by the following considerations:

- **Simplicity of the incision**
- **The need for exposure**
- **The potential need for enlarging the incision**
- **The strength of the healed wound**
- **Cosmesis of the healed incision**
- **The location of previous surgical scars**

The skin is opened with a scalpel, and the incision is carried down through the subcutaneous tissue and fascia. With traction applied to the lateral edges of the incision, the fascia is divided. The peritoneum is opened similarly. This technique minimizes the possibility of inadvertent enterotomy, entering the abdominal cavity.

Abdominal Exploration

After entering the peritoneal cavity, the upper abdomen and the pelvis are explored systematically. The liver, gallbladder, stomach, kidneys, para-aortic lymph nodes, and large and small bowel should be examined and palpated. Cytologic sampling of the peritoneal cavity, if needed, should be performed before abdominal exploration.

Retractor Choice and Placement

A variety of retractors have been designed for pelvic surgery. The Balfour and the O'Connor-O'Sullivan retractors are used most often. The Bookwalter retractor has a variety of adjustable blades that can be helpful, particularly in obese patients.

Elevation of the Uterus

The uterus is elevated by placing broad ligament clamps at each cornu so that it crosses the round ligament. The clamp tip may be placed close to the internal os. This placement provides uterine traction and prevents backbleeding (Fig. 22.1).

Round Ligament Ligation or Transection

The uterus is deviated to the patient's left side, stretching the right round ligament. With the proximal portion held by the broad ligament clamp, the distal portion of the round ligament is ligated with a suture ligature or simply transected with Bovie cautery (Fig. 22.2). The

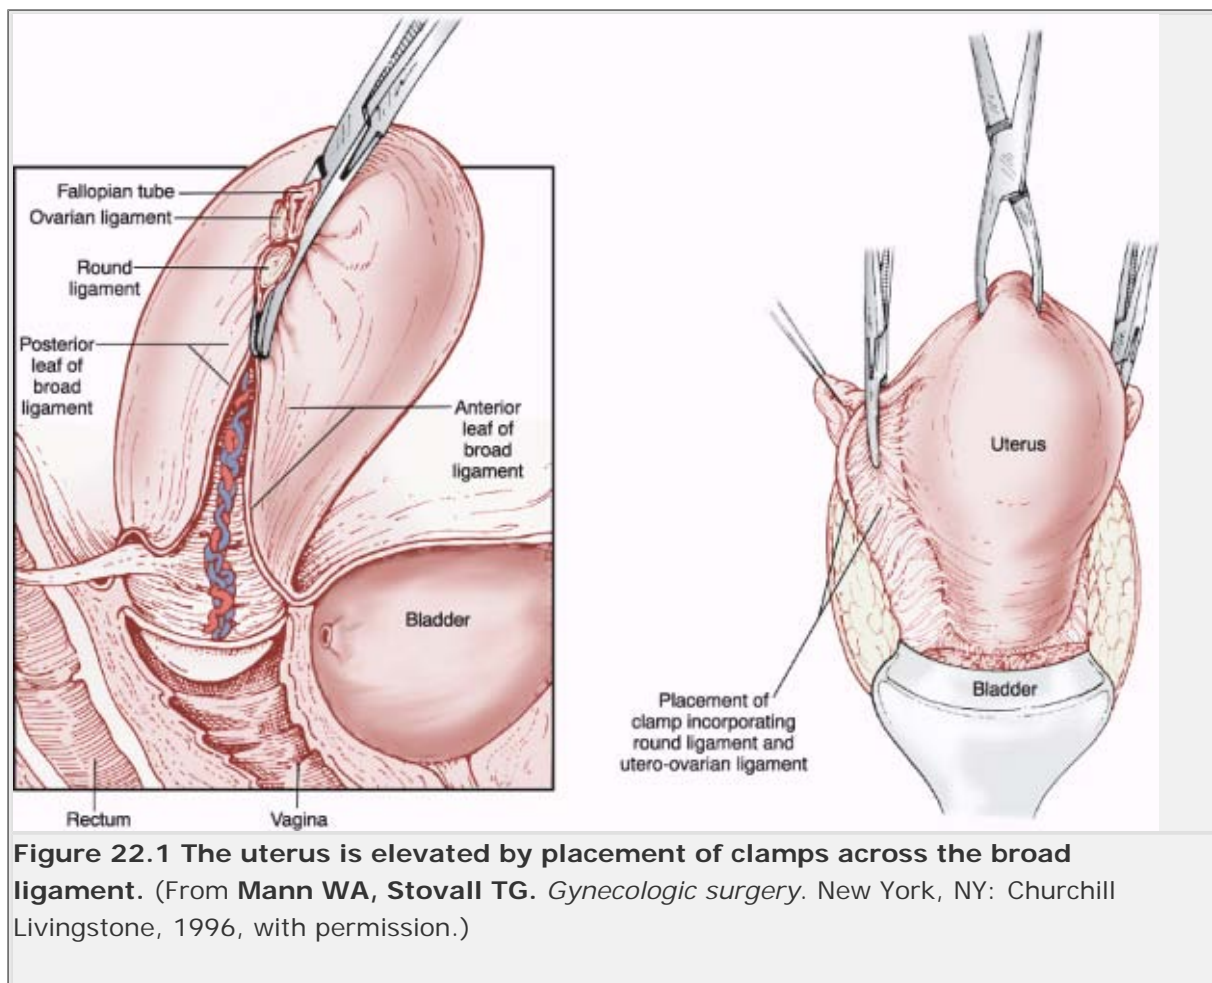

distal portion can be grasped with forceps, and the round ligament is cut to separate the anterior and posterior leaves of the broad ligament. The anterior leaf of the broad ligament is incised with Metzenbaum scissors or electrocautery along the vesicouterine fold, separating the peritoneal reflection of the bladder from the lower uterine segment (Fig. 22.3).

Ureter Identification

The retroperitoneum is entered by extending the incision cephalad on the posterior leaf of the broad ligament. Care must be taken to remain lateral to both the infundibulopelvic ligament and iliac vessels. The external iliac artery courses along the medial aspect of the psoas muscle and is identified by bluntly dissecting the loose alveolar tissue overlying it. **By following the artery cephalad to the bifurcation of the common iliac**

artery, the ureter is identified crossing the common iliac artery. The ureter should be left attached to the medial leaf of the broad ligament to protect its blood supply (Fig. 22.4).

P.815

Utero-ovarian or Infundibulopelvic Ligament Ligation

If the ovaries are to be preserved, the uterus is retracted toward the pubic symphysis and deviated to one side, placing tension on the contralateral infundibulopelvic ligament, the tube, and the ovary. **With the ureter under direct visualization, a window is created in the peritoneum of the posterior leaf of the broad ligament under the utero-ovarian ligament and fallo-pian tube.** The tube and utero-ovarian ligament are clamped on each side with a curved Heaney or Ballentine clamp, cut, and ligated with both a free-tie and a suture ligature. The medial clamp at the uterine cornu should control backbleeding; if it does

not, the clamp should be repositioned to do so (Fig. 22.5).

If the ovaries are to be removed, the peritoneal opening is enlarged and extended cephalad to the infundibulopelvic ligament and caudad to the uterine artery. This opening allows proper exposure of the uterine artery, the infundibulopelvic ligament, **and the ureter.** In this manner, the ureter is released from its proximity to the uterine vessels and the infundibulopelvic ligament.

A curved Heaney or Ballentine clamp is placed lateral to the ovary (Fig. 22.6); care is taken to ensure that the entire ovary is included in the surgical specimen. The infundibulopelvic ligament on each side is cut and doubly ligated (Fig. 22.7). Alternatively, free ties

P.816

can be passed around the infundibulopelvic ligament, two cephalad and one caudad, before the ligament is cut.

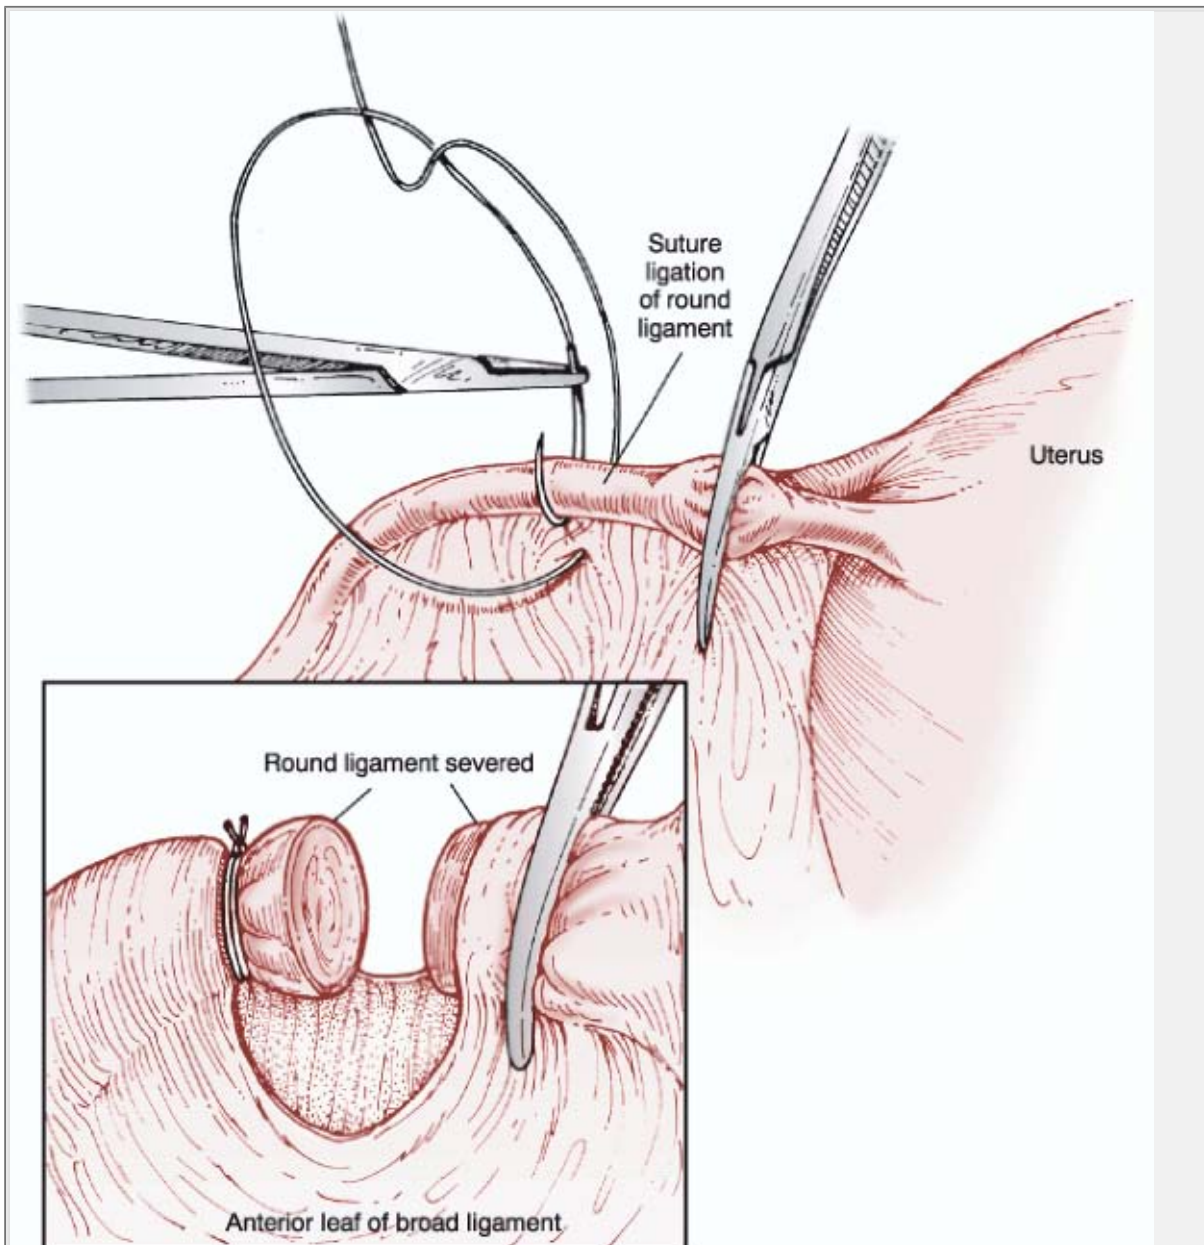

Figure 22.2 The round ligament is transected and the broad ligament is incised and opened. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Bladder Mobilization

Using Metzenbaum scissors, with the tips pointed toward the uterus, the bladder is sharply dissected from the lower uterine segment and cervix. Alternatively, Bovie electrocautery can be used. An avascular plane, which exists between the lower uterine segment and the bladder, allows for this mobilization. Tonsil clamps may be placed on the bladder edge to provide countertraction and easier dissection (Fig. 22.8).

Uterine Vessel Ligation

The uterus is retracted cephalad and deviated to one side of the pelvis, stretching the lower ligaments. The uterine vasculature is dissected or "skeletonized" from any remaining areolar tissue, and a curved Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of the uterus. Care is taken to place the tip of the clamp adjacent to the uterus at this anatomic narrowing. The vessels are cut, and the suture is ligated. The same procedure is repeated on the opposite side (Fig. 22.9).

Incision of Posterior Peritoneum

If the rectum is to be mobilized from the posterior cervix, the posterior peritoneum between the uterosacral ligaments just beneath the cervix

P.817

and rectum may be incised (Fig. 22.10). A relatively avascular tissue plane exists in this area, allowing mobilization of the rectum inferiorly out of the operative field. A sponge may be placed to control the venous oozing that often occurs.

Figure 22.3 The incision in the anterior broad ligament is extended along the vesicouterine fold. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Cardinal Ligament Ligation

The cardinal ligament is divided by placing a straight Heaney clamp medial to the uterine vessel pedicle for a distance of 2 to 3 cm parallel to the uterus. The ligament is then cut, and the pedicle suture is ligated. This step is repeated on each side until the junction of the cervix and vagina is reached (Fig. 22.11).

Removal of the Uterus

The uterus is placed on traction cephalad, and the tip of the cervix is palpated. Curved Heaney clamps are placed bilaterally, incorporating the uterosacral ligament and upper vagina just below the cervix. **Care should be taken to avoid foreshortening the vagina.** The uterus is then removed with heavy, curved scissors (Fig. 22.12).

Vaginal Cuff Closure

Several techniques of vaginal cuff closure have been described. A figure-of-eight suture of 0-0 braided absorbable material is placed between the tips of the two clamps. The suture is used for both traction and hemostasis. Sutures are also placed at the tip of each clamp, and the pedicles are sutured with a Heaney stitch, thereby incorporating the uterosacral and cardinal ligament at the angle of the vagina (Fig. 22.13). Alternatively, the vaginal cuff can be left open to heal secondarily. If this method is used, a running-locked suture is used for hemostasis along the cuff edge (Fig. 22.14).

Irrigation and Hemostasis

The pelvis is thoroughly irrigated with saline or lactated Ringer's solution. Meticulous care is taken to ensure hemostasis throughout the pelvis, particularly of the vascular pedicles. Ureteral position and integrity are checked again to ensure that they are intact and do not appear dilated.

Figure 22.4 Identification of the ureter in the retroperitoneal space on the medial leaf of the broad ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

P.818

Peritoneal Closure

The pelvic peritoneum is not reapproximated. Research using animal models suggests that reapproximation may increase tissue trauma and promote adhesion formation (80). If the ovaries have been retained, they may be suspended to the pelvic sidewall to minimize the risk of becoming retroperitoneal or adherent to the vaginal cuff.

Incision Closure

The parietal peritoneum is not reapproximated as a separate layer. Fascia can be closed with an interrupted or a continuous 0-0 or 1-0 monofilament absorbable suture. A continuous suture may reduce the risk for necrosis, which may occur when interrupted sutures are tied too tightly (80). As with interrupted sutures, bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Skin Closure

The subcutaneous tissue should be irrigated, with careful attention given to maintaining hemostasis. Subcutaneous sutures are not used because they may increase the incidence of wound infection (80). Skin staples or subcuticular sutures are used to reapproximate the skin edges. A bandage is applied and left in place for about 24 hours.

Intraoperative Complications

Most intraoperative injuries during abdominal hysterectomy can be traced to poor

lighting, unsatisfactory assistance, undue haste, anatomic variants, or involvement of the injured organ in the disease process (81). Some of these factors can be eliminated with careful attention to detail and use of proper surgical technique. However, some operative injuries

P.819

P.820

cannot be avoided by even the most skilled surgeons. The surgeon, therefore, must be prepared to recognize and repair these injuries. Even with a high level of attention to detail, injuries and complications, recognized and unrecognized, can still occur.

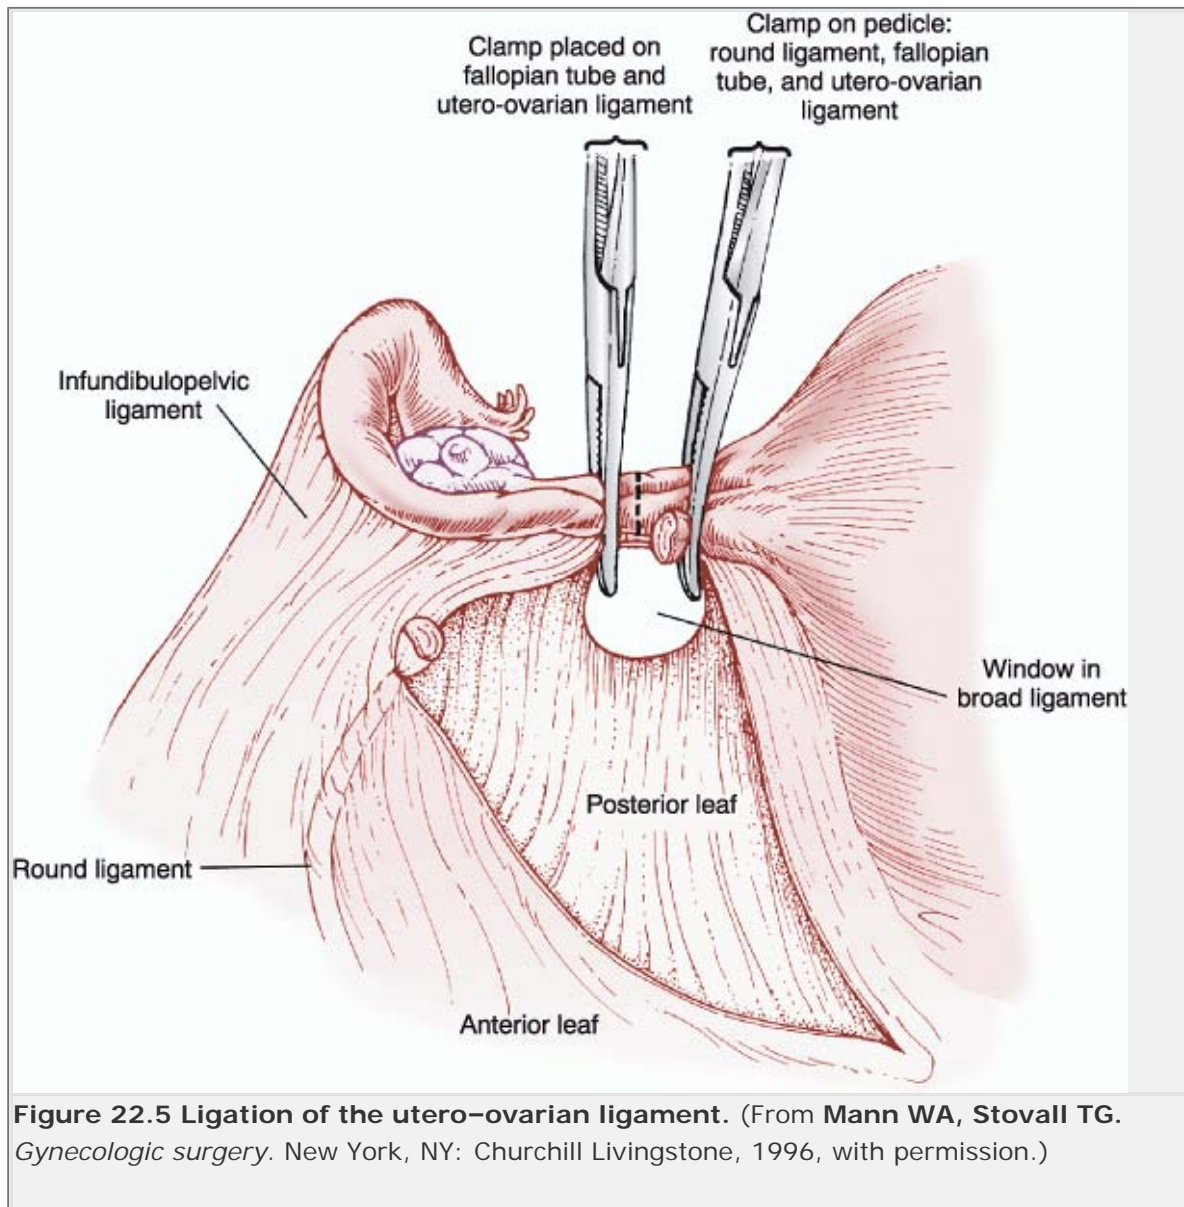

Figure 22.5 Ligation of the utero-ovarian ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

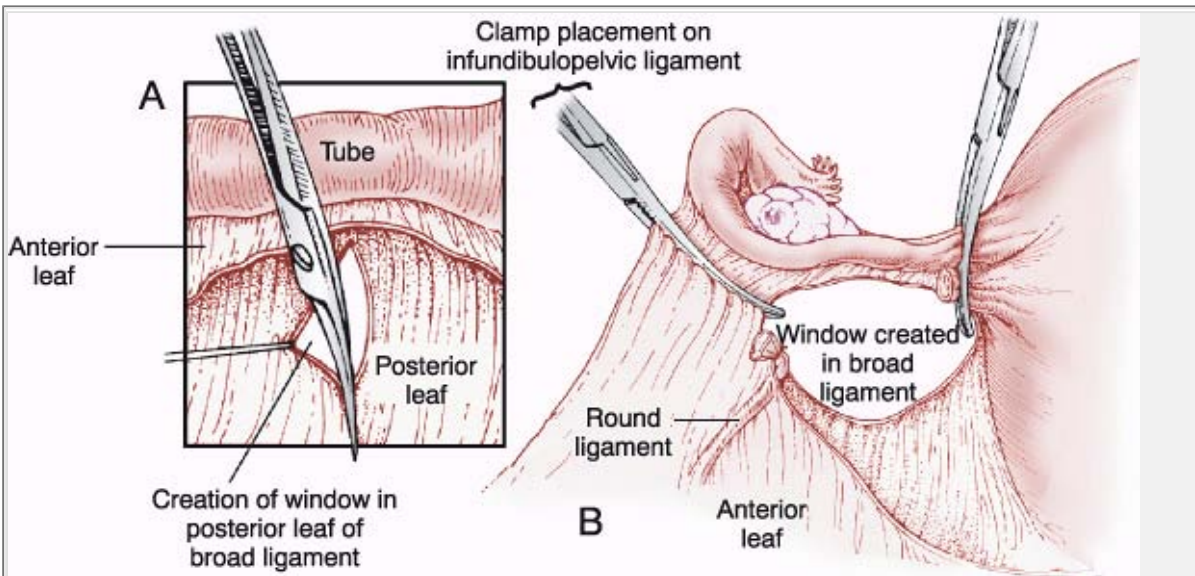

Figure 22.6 Ligation of the infundibulopelvic ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Figure 22.7 Transection of the infundibulopelvic ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Ureteral Injuries

Injury to the pelvic ureter is one of the most formidable complications of hysterectomy (82,83,84). Because of the risk for subsequent renal impairment, injury to the ureter is far more serious than injury to the bladder or bowel (85,86).

It is essential to be aware of the proximity of the ureter to the other pelvic structures at all times. **Most ureteral injuries can be avoided by opening the retroperitoneum and directly identifying the ureter.** The use of ureteral catheters as a substitute for direct visualization is often of little help in patients with extensive fibrosis or scarring resulting from endometriosis, pelvic inflammatory disease, or ovarian cancer. In these instances, a false sense of security may actually increase an already high risk for ureteral injury (87). The use of ureteral catheters can also be associated with hematuria and acute urinary retention. Their complications are usually transitory in nature.

Direct visualization is accomplished by opening the retroperitoneum lateral to the external iliac artery. Blunt dissection of the loose areolar tissue is performed to visualize the artery directly. The artery may then be traced cephalad to the bifurcation of the internal and external iliac arteries. The ureter crosses the common iliac artery at its bifurcation and may be followed throughout its course in the pelvis.

Despite these precautions, ureteral injuries may occur. Prompt consultation is necessary if the surgeon has not been trained in ureteral repair. If a ureteral obstruction is suspected, confirmation may be obtained by intravenous injection of 1 ampule of *indigo carmine* dye,

P.821

opening the dome of the bladder, and observing the presence or absence of bilateral spill of tinted urine. Alternatively, ureteral patency may be established by opening the dome of the bladder and positioning retrograde ureteral stents. Cystoscopic evaluation may replace opening the bladder to evaluate the spill of tinted urine (82,83,84,85,86,87).

Figure 22.8 Dissection of the vesicouterine plane to mobilize the bladder. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Bladder Injury

Because of the close anatomic relationship of the bladder, uterus, and upper vagina, the bladder is the segment of the lower urinary tract that is most vulnerable to injury (85,87). **Bladder injury may occur on opening the peritoneum or, more frequently, during the dissection of the bladder off the cervix and upper vagina** (88). Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired. In the nonirradiated bladder, a one- or two-layer closure with a small-caliber braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is controversial. If the bladder is not compromised, drainage should be continued at least until gross

P.822

hematuria clears, which may occur as soon as 48 hours postoperatively. A more conservative practice is to continue drainage until the patient is ready for discharge, usually a total of 3 to 4 days. Elective incision into the dome of the bladder is performed similarly (88). If the trigone is involved, a surgeon trained in complicated urologic repair should be consulted.

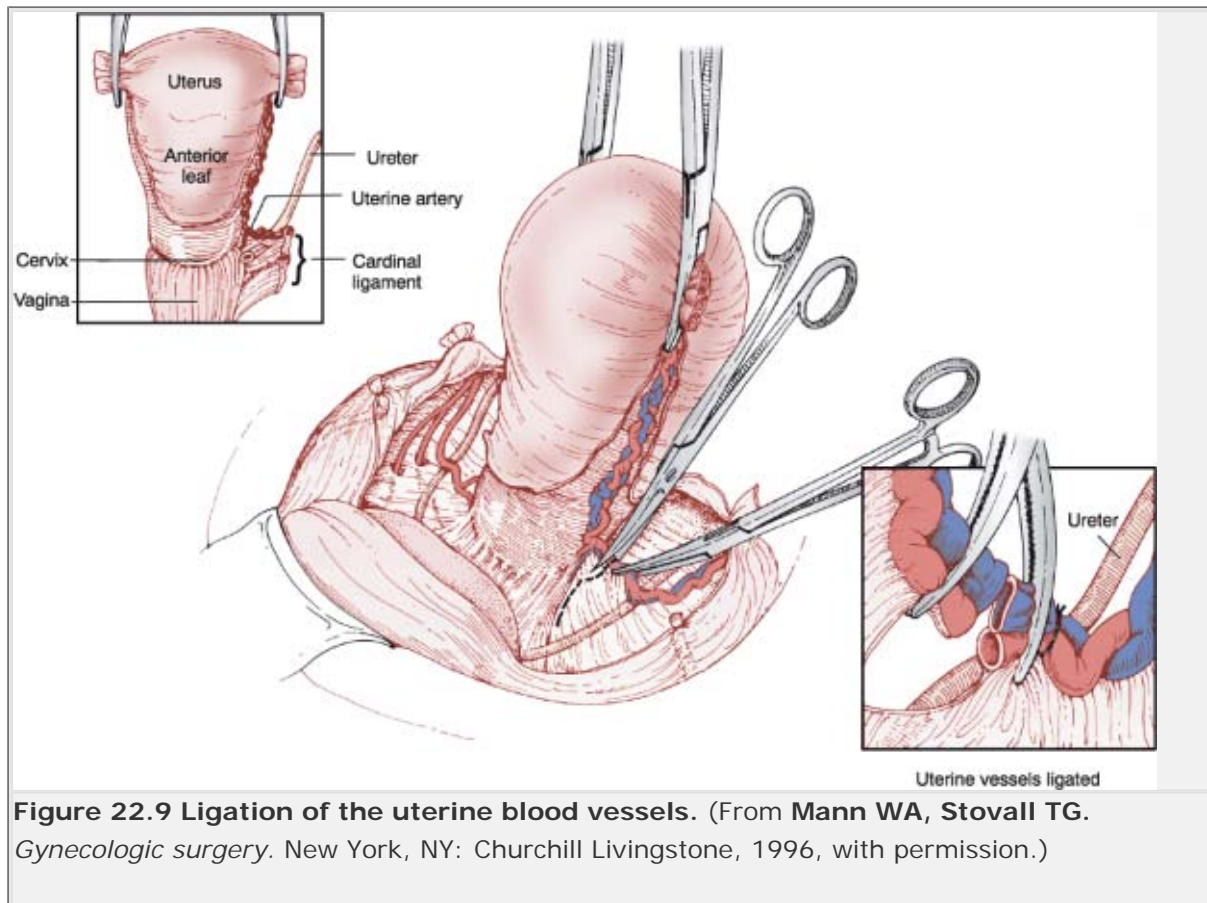

Figure 22.9 Ligation of the uterine blood vessels. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

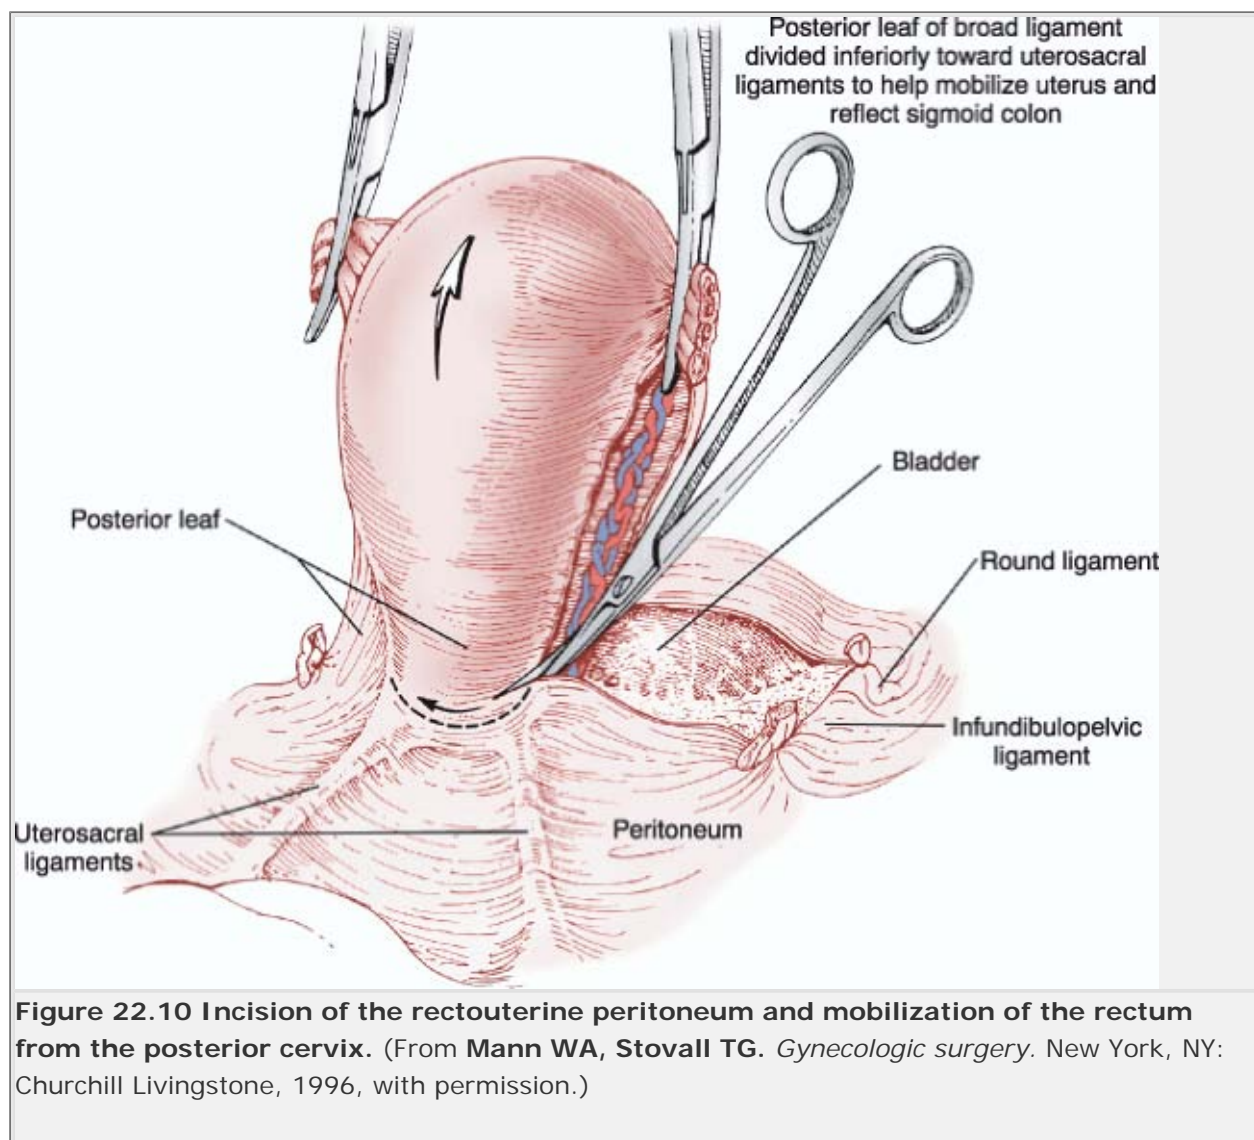

Bowel Injury

Small bowel injuries are the most common intestinal injuries in gynecologic surgery (89). Small defects of the serosa or muscularis may be repaired using a single layer of continuous

or interrupted 3–0 braided absorbable suture. Although single-layer closure of the small bowel has proved adequate, it is safer to close defects involving the lumen in two layers using a 3–0 braided absorbable suture. **The defect should be closed in a direction perpendicular to the intestinal lumen.** If a large area has been injured, resection with reanastomosis may be necessary (88,90). Because the bacterial flora of the ascending colon is similar to that of the small bowel, injuries can be repaired in a similar manner. The transverse colon rarely is injured in normal gynecologic procedures because it is well outside the operative field. However, the descending colon and the rectosigmoid colon are intimately involved with the pelvic structures and are at significant risk for injury during gynecologic surgery. Injuries not involving the

P.823

mucosa may be repaired with a single running layer of 2–0 or 3–0 braided absorbable suture. If the laceration involves the mucosa, it may be closed as with small bowel injuries if the colon has been prepared adequately. Otherwise, diverting colostomy may be necessary in some patients to protect the repair site from fecal contamination, especially if the defect is larger than 5 cm or if there is spillage of the bowel contents (88,90).

Hemorrhage

Significant arterial bleeding usually arises from the uterine arteries or the ovarian vessels near the insertion of the infundibulopelvic ligaments (91). Blind clamping of

these vessels presents a risk for ureteral injury; therefore, the ureters should be identified in the retroperitoneal space and traced to the area of bleeding to avoid inadvertent ligation. **It is best to apply a pressure pack to tamponade the bleeding and then slowly remove the pack in an effort to visualize, isolate, and individually clamp the bleeding vessels.** Mass ligatures should be avoided. The use of surgical clips may be helpful. Venous bleeding is less dramatic but often is more difficult to manage, particularly in the presence of extensive adhesions and fibroids. This type of bleeding can be controlled with pressure alone or with suture ligation. Bleeding from peritoneal edges or denuded surfaces may be controlled with pressure, application of topical agents such as thrombin or collagen, or Bovie cautery. A variety of laser techniques have been used to control bleeding.

P.825

Postoperative Management

Bladder Drainage

Overdistention of the bladder resulting from bladder trauma or the patient's reluctance to initiate the voluntary phase of voiding is one of the most common complications after abdominal hysterectomy (92). For this reason, an indwelling bladder catheter should be used for the first few postoperative hours until the patient is able to ambulate and urinate.

Figure 22.14 A: Vaginal cuff left open with a running suture along the cuff. B: Peritoneum closed. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

P.826

If retropubic urethropexy has been performed, consideration should be given to using a suprapubic catheter, which allows postvoid residual levels to be checked without repetitive catheterizations. This catheter may be removed when satisfactory postvoid residual levels of less than 100 mL have been obtained.

Diet

In anticipation of the rare case in which the patient must be returned to the operating room, the patient is allowed only ice chips and liquids on the day of surgery. On the first postoperative day, assuming bowel sounds are present, diet is resumed, advancing to solid foods as tolerated. This dietary regimen assumes minimal intraoperative bowel manipulation and dissection.

Early postoperative feeding has been shown not only to be safe but also to speed return of bowel function and recovery. In patients who have undergone pelvic and para-aortic lymphadenectomy, bowel surgery, or other extensive dissections, a slower return to normal bowel function may occur, so care should be taken to advance the diet only as tolerated.

Activity

Early ambulation decreases the incidence of thrombophlebitis and pneumonia. Patients are encouraged to begin ambulation on their first postoperative day if possible and to increase their time out of bed progressively as their strength improves. **On discharge, the patient is instructed to avoid lifting more than 20 pounds for 6 weeks, thereby minimizing stress on fascia to allow full healing. Sexual intercourse is not recommended until 6 weeks after surgery, when the vaginal cuff is fully healed.** Patients are instructed to avoid driving until full mobility returns because postoperative pain and tenderness may hinder sudden braking or steering maneuvers in emergency situations. With these exceptions, the patient is encouraged to return to normal activities as soon as she feels comfortable doing so.

Wound Care

The abdominal incision normally requires little attention, except for ordinary hygienic measures. The wound is kept covered with a sterile bandage for the first 24 hours after surgery, by which time the incision has sealed. After the bandage has been removed, the incision should be cleaned daily with mild soap and water and kept dry.

Vaginal Hysterectomy

Preoperative Evaluation

Evaluation of Pelvic Support

The most important observation in determining the feasibility of a vaginal hysterectomy is the demonstration of uterine mobility (92,93). A vaginal approach should not be chosen if the uterus is not freely mobile. Pelvic support structures are elevated at the initial pelvic examination. In patients with no apparent prolapse, poor pelvic support can often be demonstrated by observing descent of the uterus with a series of Valsalva maneuvers. Although vaginal hysterectomy is easier to perform when the uterine supporting ligaments are lax, it is not an absolute requirement. Some gynecologists advocate the application of a tenaculum to the anterior cervical lip, with subsequent traction applied as the patient bears down. Although this exercise may give some indication of uterine mobility, it is uncomfortable and not necessarily predictive of the success of vaginal hysterectomy. Therefore, **the practice of applying traction to the cervix with a tenaculum to demonstrate descent of an apparently well-supported uterus is not recommended.**

Evaluation of the Pelvis

After assessment of pelvic support, the bony pelvis should be evaluated. Ideally, the angle of the pubic arch should be 90 degrees or greater, the vaginal canal should be ample, and the posterior vaginal fornix should be wide and deep. The surgeon may use a closed fist to approximate the bituberous diameter, which should

exceed 10 cm. The size and shape of the female pelvis contributes to increased exposure. The importance of a wide pubic arch was underscored by the result of a study of 25 failed vaginal hysterectomies that were compared with 50 successful vaginal hysterectomies. Risk factors, such as age, parity, body weight, surgical indication, uterine size, presence of

leiomyomata in the anterior lower uterine segment, previous pelvic surgeries, adhesions, location and length of the cervix, and narrow pubic arch (less than 90 degrees), were examined. In the study, only the presence of a narrow pubic arch increased the risk of vaginal hysterectomy (94).

Surgical Considerations

Patient Positioning

Once the patient is in the dorsal lithotomy position, the buttocks should be positioned just over the table's edge. Several stirrup types are available, including those that support the entire leg and those that suspend the legs in straps. **To avoid nerve injury, adequate padding should be used; marked flexion of the thigh and pressure points should be avoided.**

Trendelenburg (10- to 15-degree) positioning aids in the intravaginal visualization needed during surgery.

Vaginal Preparation

A povidone-iodine solution is applied to the vagina, the bladder is drained, and the catheter is removed. Several methods for draping have been proposed, including individual or single-piece drapes; the method chosen is at the surgeon's discretion. There is usually no need to shave or clip the pubic hair. Individual drapes with an adhesive barrier should be used to hold the drapes in place and prevent the pubic hair from compromising the field.

Instruments

Instruments specific to and useful in performing a vaginal hysterectomy include right-angled retractors, narrow Deaver retractors, weighted specula, Heaney needle holders, and an assortment of Briesky-Navratil vaginal retractors. Heaney and Heaney-Ballentine hysterectomy clamps are preferable. Several other clamps also are commonly used, including the Masterson clamp.

Lighting

Overhead high-intensity lamps should be used and positioned to direct light over the operator's shoulder. In addition, the surgeon may prefer a headlight, which can be worn to provide direct horizontal lighting. Although not routinely used, a fiberoptic-lighted irrigating suction system can provide additional light and transilluminate tissue planes.

Suture Material

Various suture materials have been advocated for gynecologic surgery. The type of suture material chosen should be based on the surgeon's preference. A synthetic delayed absorbable polyglactin or polyglycolic acid suture and atraumatic needles are generally preferable.

Procedure

The patient is examined while anesthetized to confirm prior findings and to assess uterine mobility and descent. The decision is then made whether to proceed vaginally or abdominally.

Grasping and Circumscribing the Cervix

The anterior and posterior lips of the cervix are grasped with a single- or double-toothed tenaculum. With downward traction applied on the cervix, a circumferential incision is made in the vaginal epithelium at the junction of the cervix (Fig. 22.15).

Dissection of Vaginal Mucosa

After the initial incision is made, the vaginal epithelium may be dissected sharply from the underlying tissue or pushed bluntly with an open sponge (Fig. 22.16). **If the initial incision is made too close to the external cervical os,**

P.828

P.829

there is a greater amount of dissection required and associated bleeding. Therefore, this circumscribing incision should be made just below the bladder reflection. It is important to continue the dissection in the correct cleavage plane because dissection in the wrong plane will increase blood loss.

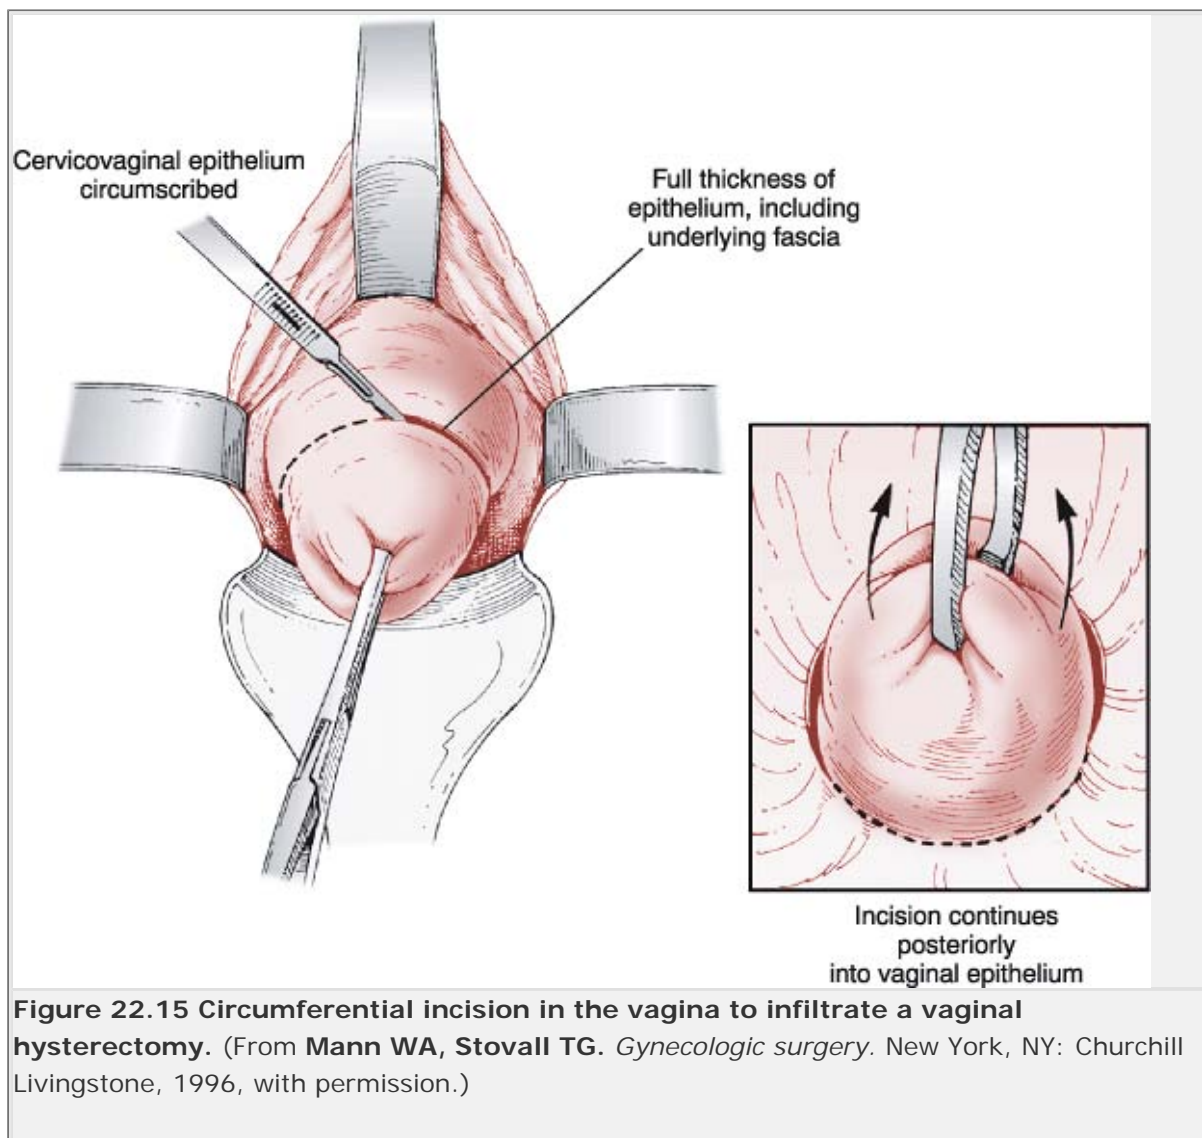

Figure 22.15 Circumferential incision in the vagina to infiltrate a vaginal hysterectomy. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

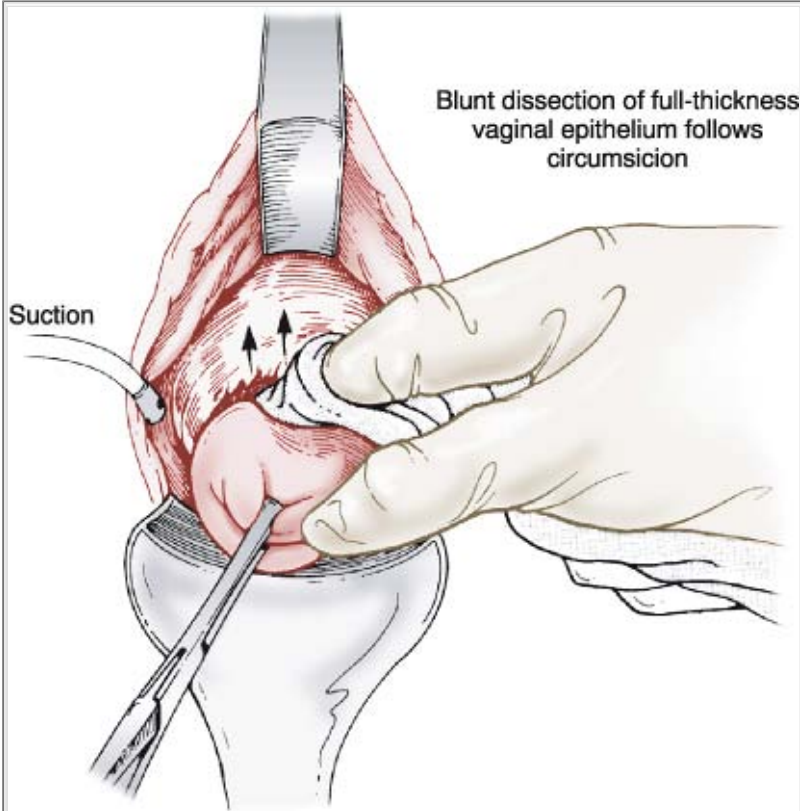

Figure 22.16 Dissection of the vaginal mucosa. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

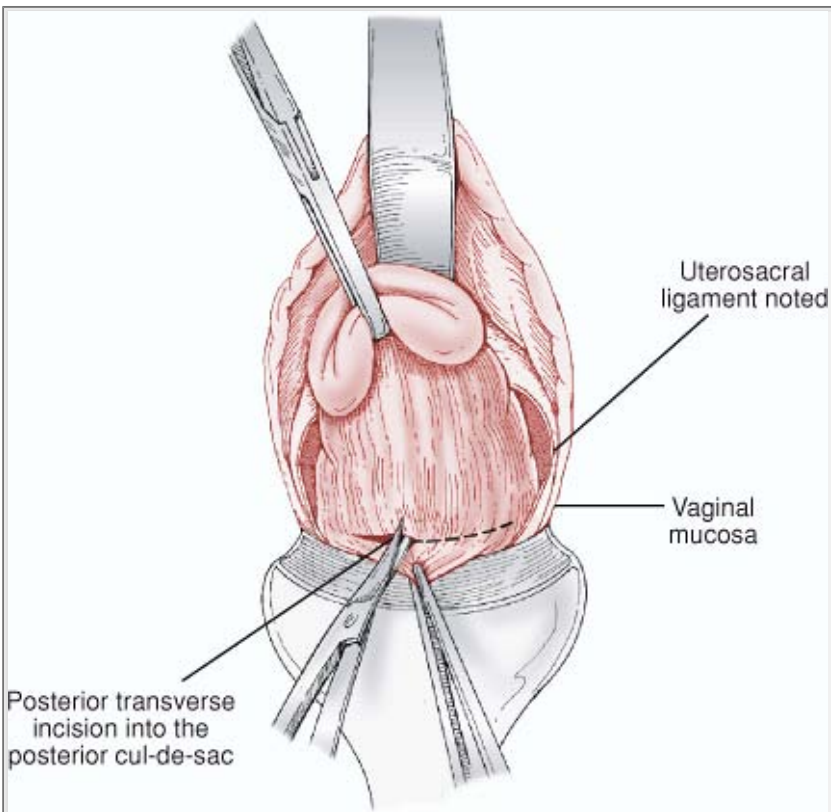

Figure 22.17 Entry into the posterior cul-de-sac. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Posterior Cul-de-Sac Entry

The peritoneal reflection of the posterior cul-de-sac (cul-de-sac of Douglas) can be identified by stretching the vaginal mucosa and underlying connective tissue with forceps (Fig. 22.17). If difficulty is encountered (e.g., if the cervix is elongated and the peritoneum is not evident), the vaginal mucosa may be incised vertically to the point at which the cul-de-sac becomes more apparent.

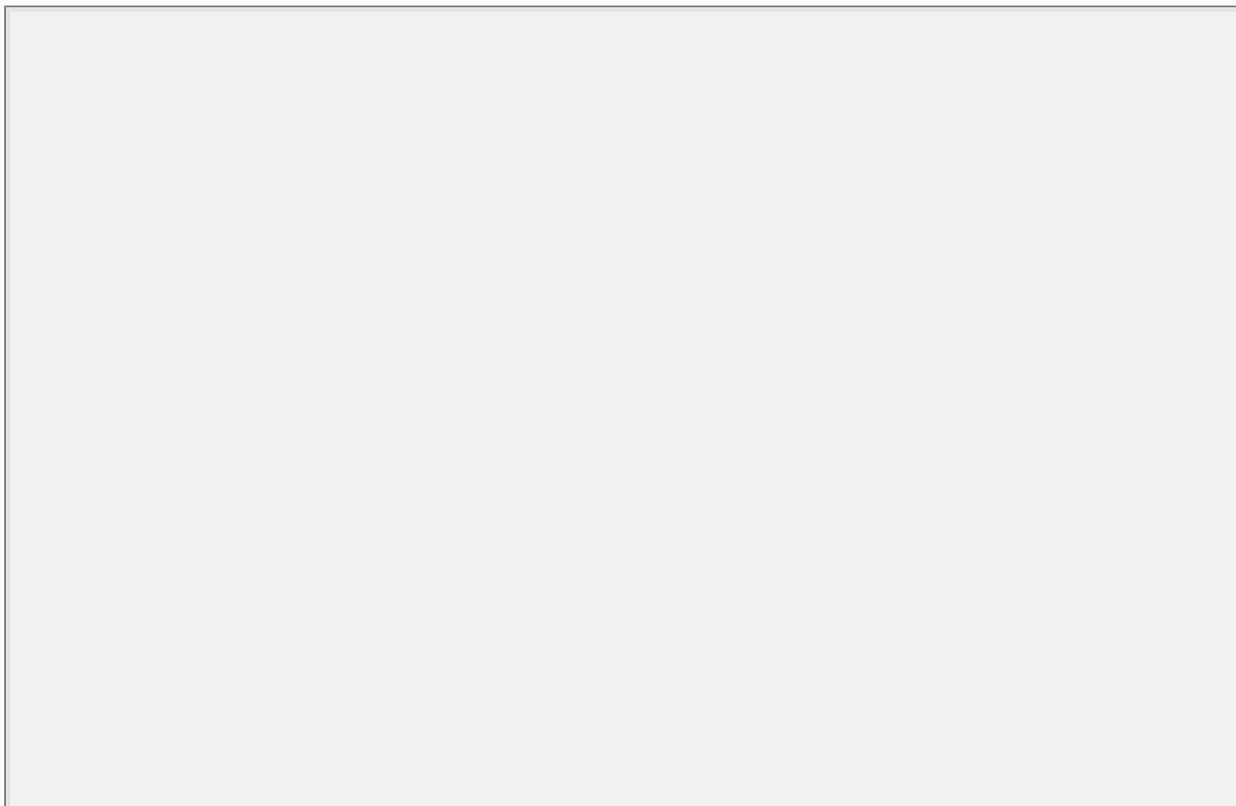

If the vaginal mucosa has been dissected in the wrong plane, the hysterectomy may be begun extraperitoneally by clamping and cutting the uterosacral and cardinal ligaments close to the cervix. The posterior cul-de-sac will then become readily identifiable. If the peritoneal reflection of the posterior cul-de-sac still cannot be identified, entry into the anterior peritoneum is attempted, and a finger is hooked into the posterior cul-de-sac to place tension on the peritoneum. The peritoneum is opened with Mayo scissors. An interrupted suture is placed to approximate the peritoneum and vaginal cuff and thus provide hemostasis (Fig. 22.18). The posterior pelvic cavity is examined for pathologic alterations of the uterus or adhesive disease of the cul-de-sac. The weighted speculum is placed into the posterior cul-de-sac.

Uterosacral Ligament Ligation

With retraction of the lateral vaginal wall and countertraction on the cervix, the uterosacral ligaments are clamped with the tip of the clamp incorporating the lower portion of the cardinal ligaments (Fig. 22.19). The clamp is placed perpendicular to the uterine axis, and the pedicle is cut close to the clamp and sutured. A small pedicle (0.5 cm) distal to the clamp is optimal because a larger pedicle becomes necrotic and the tissue sloughs, which may become culture medium for micro-organisms.

P.830

The pedicle should be incised no more than one half to three fourths of the way around the tip of the clamp. Limiting the incision prevents the next pedicle, which may be vascular, from being cut.

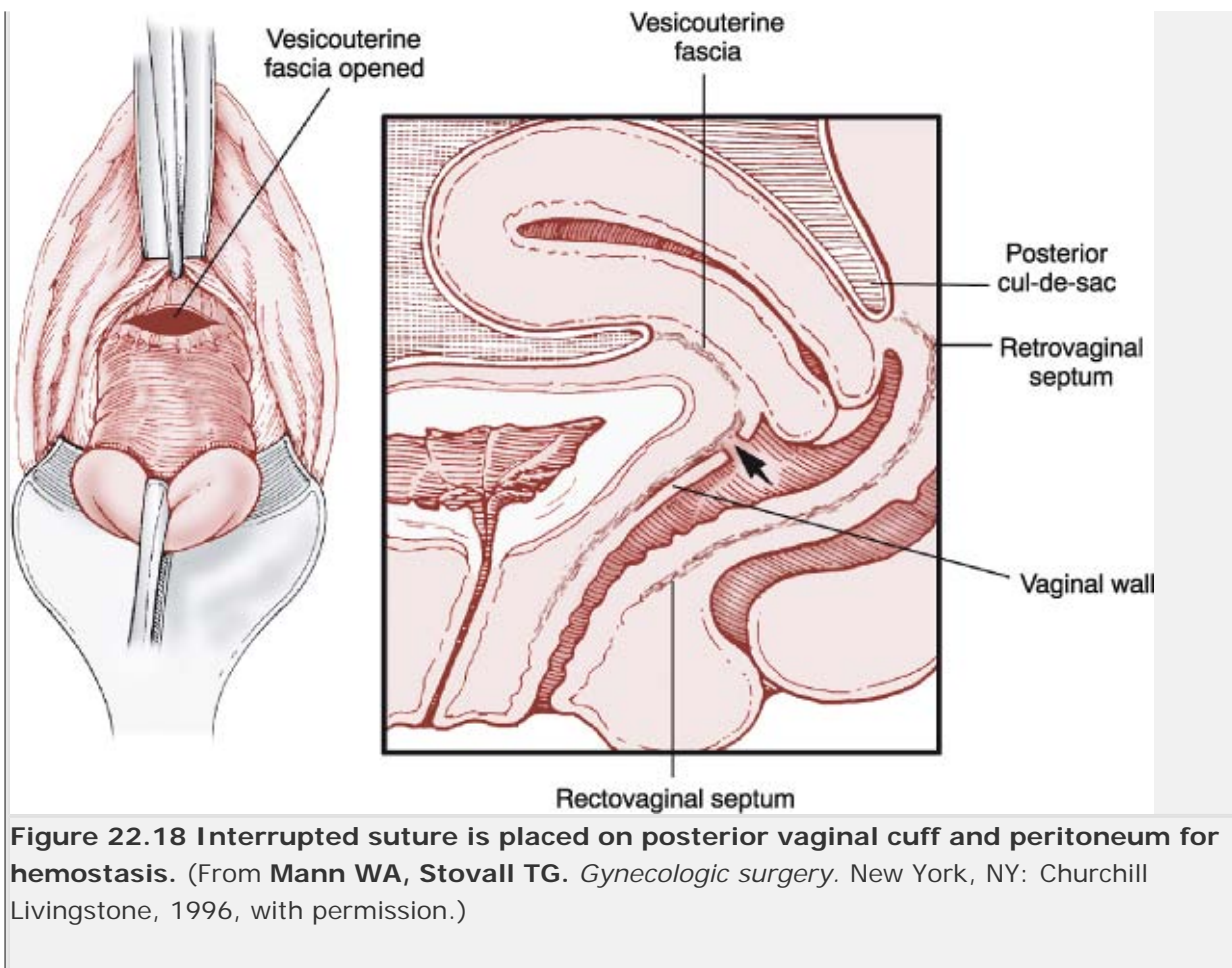

Figure 22.18 Interrupted suture is placed on posterior vaginal cuff and peritoneum for hemostasis. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

When suturing any pedicle, the needle point is placed at the tip of the clamp, and the needle is passed through the tissue by a rolling motion of the operator's wrist. Once

P.831

ligated, the uterosacral ligaments may be transfixed to the posterolateral vaginal mucosa (Fig. 22.20). This suture may lend additional support to the vagina and provides hemostasis at this point on the vaginal mucosa. This suture is held with a hemostat to facilitate location of any bleeding at the completion of the procedure and to aid in the closure of vaginal mucosa.

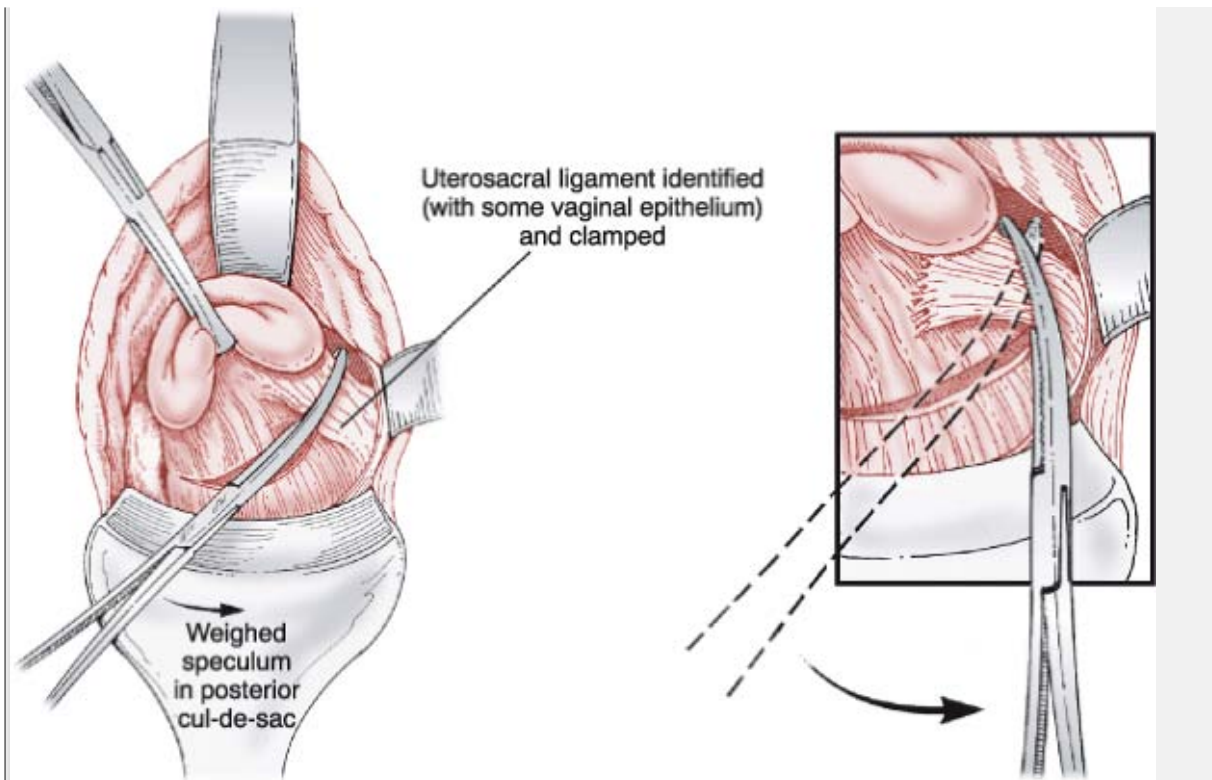

Figure 22.19 Ligation of the uterosacral ligaments. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Figure 22.20 Transfixion of the uterosacral ligament to the posterolateral vaginal mucosa. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Entry versus Nonentry into the Vesicovaginal Space (Cul-de-Sac)

Downward traction is placed on the cervix. Using either Mayo scissors, with the points directed toward the uterus, or an open moistened 4 × 4 gauze sponge, the bladder is advanced. If the vesico-vaginal peritoneal reflection is easily identified at this point, the vesicovaginal space may be entered. Otherwise, it may be preferable to delay entry. There is no danger in delaying entry so long as the operator has ascertained that the bladder has been advanced.

After the bladder has been advanced, a curved Deaver or Heaney retractor is placed in the midline, holding the bladder out of the operative field. This process precedes each step of the vaginal hysterectomy until the vesicovaginal space is entered.

Cardinal Ligament Ligation

With traction on the cervix continued, the cardinal ligaments are identified, clamped, and cut. The suture is ligated (Fig. 22.21).

Advancement of Bladder

The bladder again is advanced out of the operative field. A blunt dissection technique may be used; however, sharp dissection may be helpful if the patient has had previous surgery, such as cesarean delivery, which may have scarred the bladder reflection.

Figure 22.21 Ligation of the cardinal ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

P.832

Uterine Artery Ligation

Contralateral and downward traction is placed on the cervix. **With an effort to incorporate the anterior and posterior leaves of the visceral peritoneum, the uterine vessels are identified, clamped, and cut, and the suture is ligated** (Fig. 22.22). **A single suture and single clamp technique is adequate and decreases the potential risk for ureteral injury.** When the uterus is large or when a fibroid distorts the

P.833

anatomic relationships, a second suture may be required to ligate any remaining branches of the uterine artery.

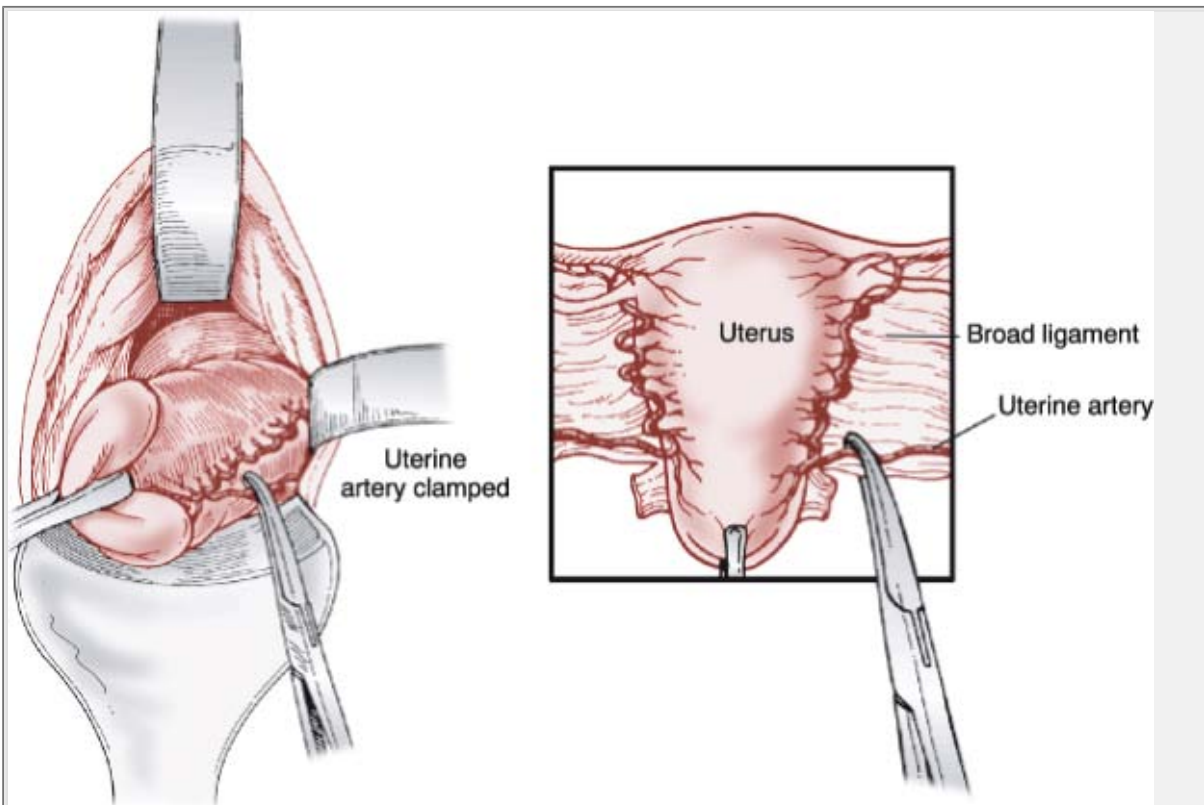

Figure 22.22 Ligation of the uterine artery. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996.)

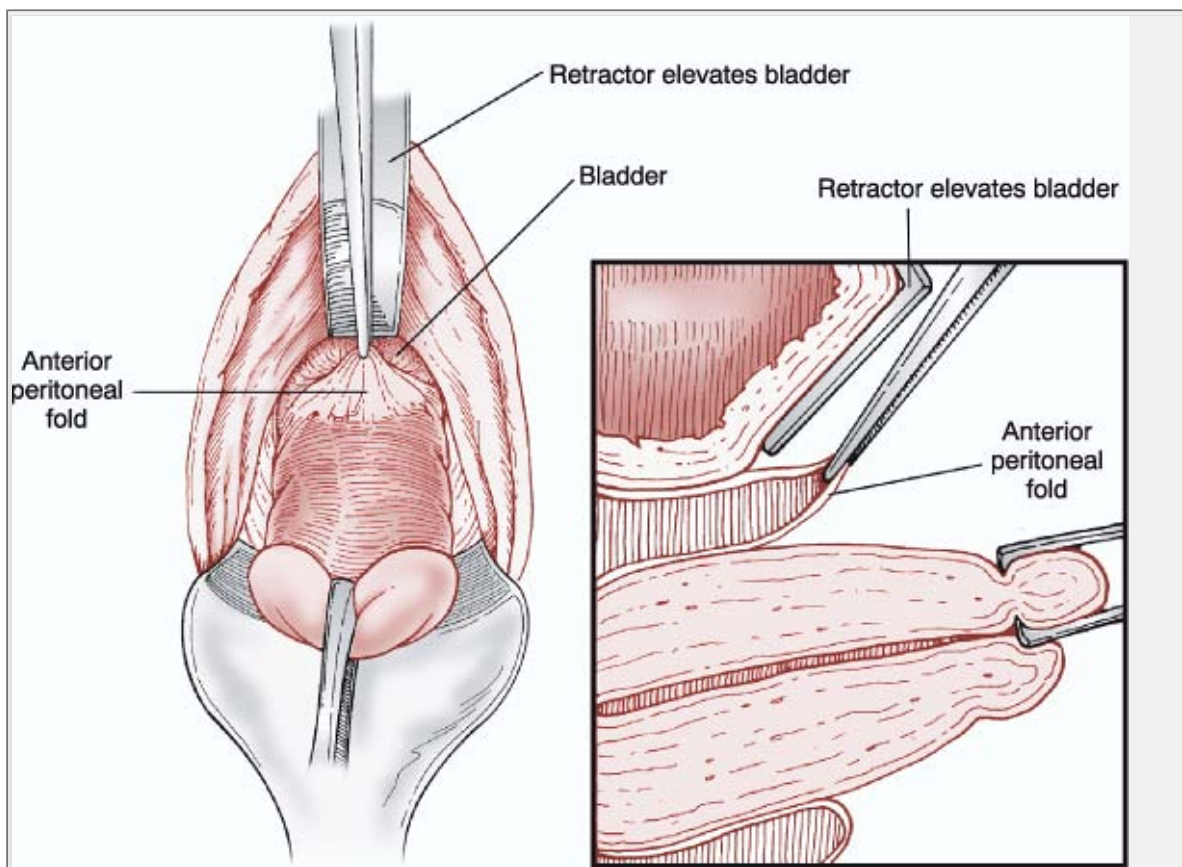

Figure 22.23 Entry into the vesicovaginal space. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Entry into the Vesicovaginal Space

The anterior peritoneal fold usually can be identified readily just before or after clamping and suture ligation of the uterine arteries. The anterior peritoneal cavity should not be opened blindly because of the increased risk of bladder injury (Fig. 22.23). The peritoneum is grasped with forceps, tented, and opened with scissors with the tips pointed toward the uterus. A Heaney or Deaver retractor is then placed, and the peritoneal contents are identified. This retractor serves to keep the bladder out of the operative field.

Delivery of the Uterus

A tenaculum is placed onto the uterine fundus in a successive fashion to deliver the fundus posteriorly (Fig. 22.24). The operator's index finger is used to identify the utero-ovarian ligament and aid in clamp placement.

Utero-ovarian and Round Ligament Ligation

With the posterior and anterior peritoneum opened, the remainder of the broad ligament and utero-ovarian ligaments are clamped, cut, and ligated (Fig. 22.25). The utero-ovarian and round ligament complexes are double ligated with a suture tie followed by a ligature medial to the first suture. A hemostat is placed on the second suture to aid in the identification of any bleeding and to assist with peritoneal closure. A hemostat should not be placed on the first suture or any other vascular pedicle to avoid the risk for loosening the tie.

Removal of the Ovaries

When the adnexa are removed, the round ligaments should be removed separately from the adnexal pedicles. Traction is placed on the utero-ovarian pedicle. The ovary is drawn into the operative field by grasping it with a Babcock clamp. A Heaney clamp is placed across the infundibulopelvic ligament, and the ovary and tube are excised (Fig. 22.26). A transfixion tie and suture ligation are placed on the infundibulopelvic ligament. The surgeon should not be reluctant to remove the fallopian

P.834

P.835

tube separately from the ovary if taking them together risks loss of the tissue pedicle or injury to the ureter or nearby blood vessels.

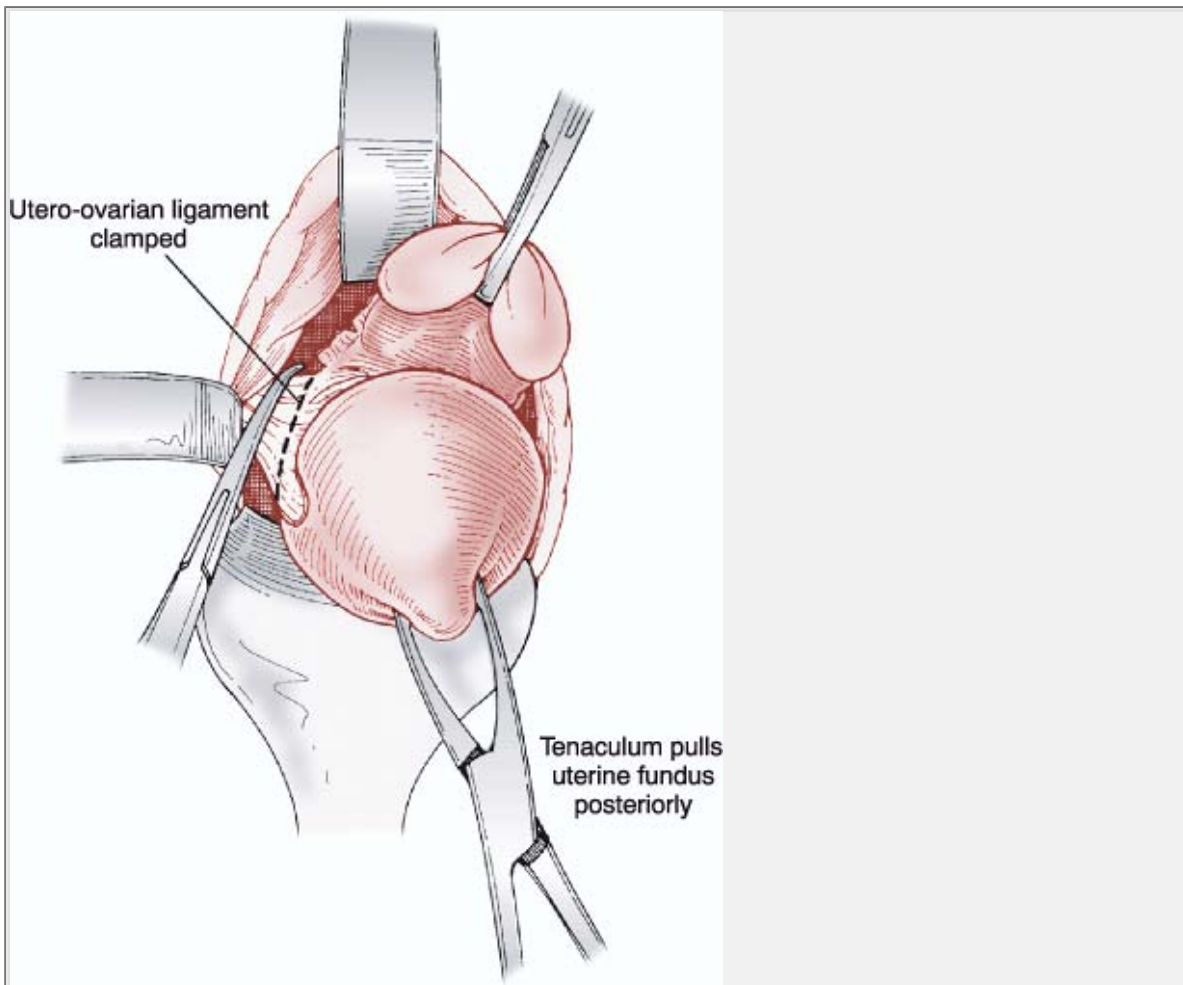

Figure 22.24 Delivery of the uterine fundus posteriorly. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

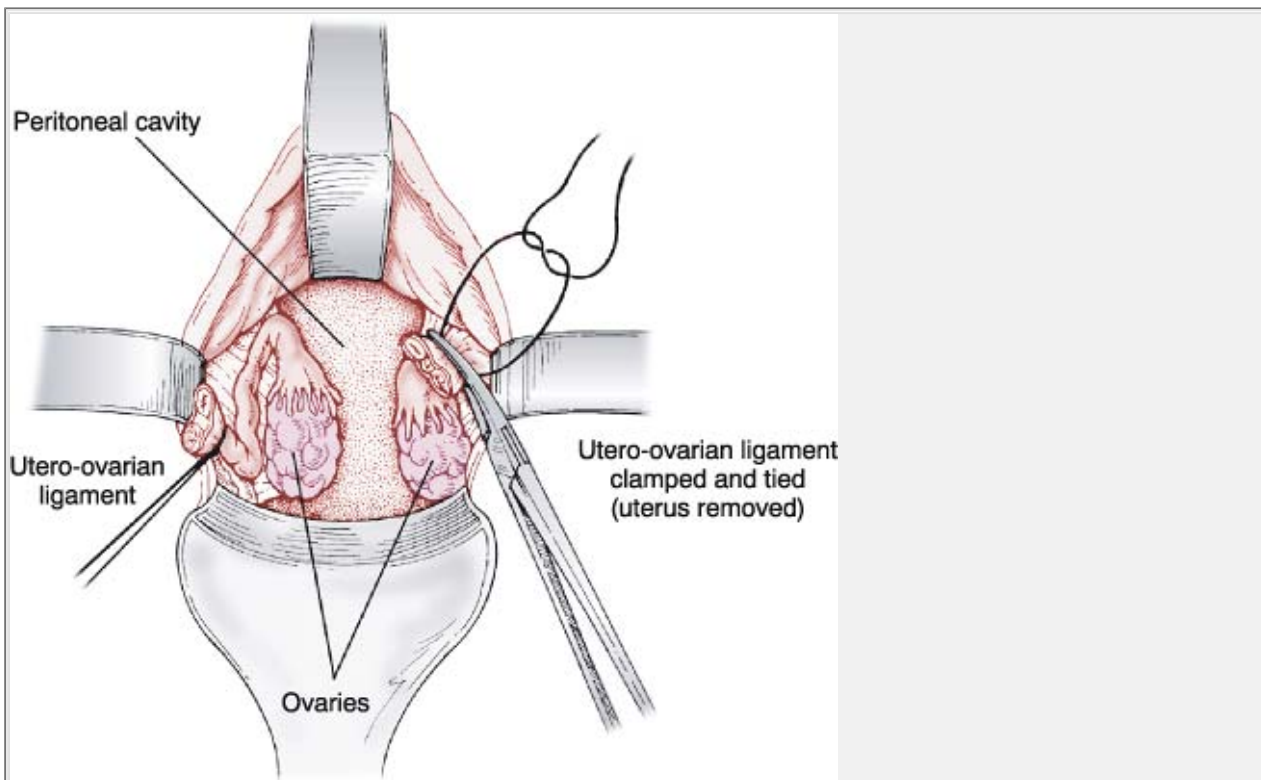

Figure 22.25 Ligation of the utero-ovarian and round ligaments. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

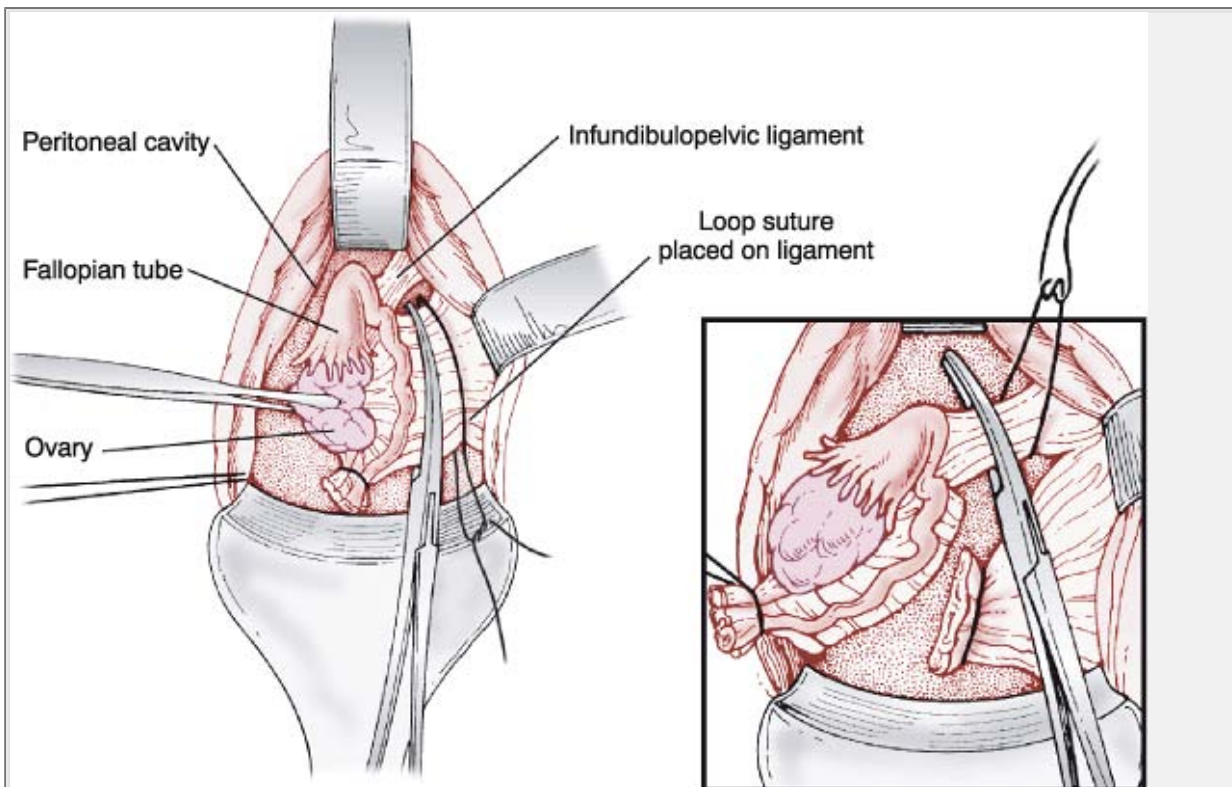

Figure 22.26 Removal of the ovaries and fallopian tubes by clamping across the infundibulopelvic ligament. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Hemostasis

A retractor or tagged sponge is placed into the peritoneal cavity, and each of the pedicles is visualized and inspected for hemostasis. If additional sutures are required, they should be placed precisely with care to avoid the ureter or bladder.

Peritoneal Closure

Because the pelvic peritoneum does not provide support and re-forms in 24 hours after surgery, the peritoneum need not be reapproximated routinely. If it is believed to be important, the anterior peritoneal edge is identified and grasped with forceps. A continuous absorbable 0-0 suture is begun at the 12-o'clock position. The suture is continued in a purse-string fashion and incorporates the distal portion of the left upper pedicle and the left uterosacral ligament (Fig. 22.27). Tension is applied to the suture placed at the beginning of the procedure that incorporates the posterior peritoneum and vaginal mucosa. This allows for high posterior reperitonealization, which shortens the cul-de-sac and thus helps to prevent future enterocele formation. The right uterosacral ligament and the distal portion of the right upper pedicle are incorporated, and this continuous suture ends at the point on the anterior peritoneum where it was begun.

The intra-abdominal tagged sponge is removed and inspected for the presence of blood at its distal end. The slack of the purse-string peritoneal suture is taken up by pulling the suture tight. Before tying the peritoneal suture, the surgeon should make certain that no prolapse of viscera has occurred.

Vaginal Mucosa Closure

The vaginal mucosa can be reapproximated in a vertical or horizontal manner, using either interrupted or continuous sutures (Fig. 22.28). The vaginal mucosa is, in this case, reapproximated horizontally with interrupted absorbable sutures. The sutures are placed through the entire thickness of the vaginal epithelium, with care taken to avoid entering the bladder anteriorly. These sutures will obliterate

P.836

the underlying dead space and produce an anatomic approximation of the vaginal epithelium, thereby decreasing the postoperative formation of granulation tissue.

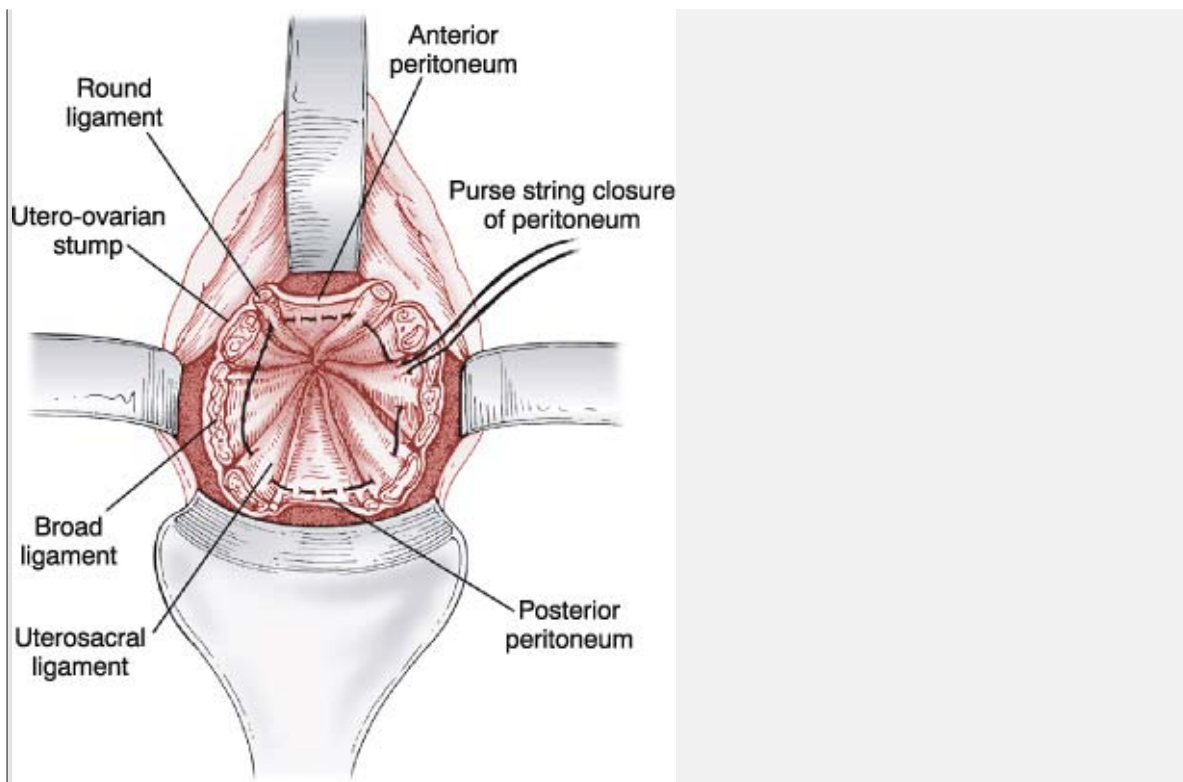

Figure 22.27 Closure of the peritoneum. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Bladder Drainage

After completion of the procedure, the bladder is drained. Unless an anterior or posterior colporrhaphy or other reconstructive procedure is performed, neither bladder catheter nor vaginal packing are mandatory.

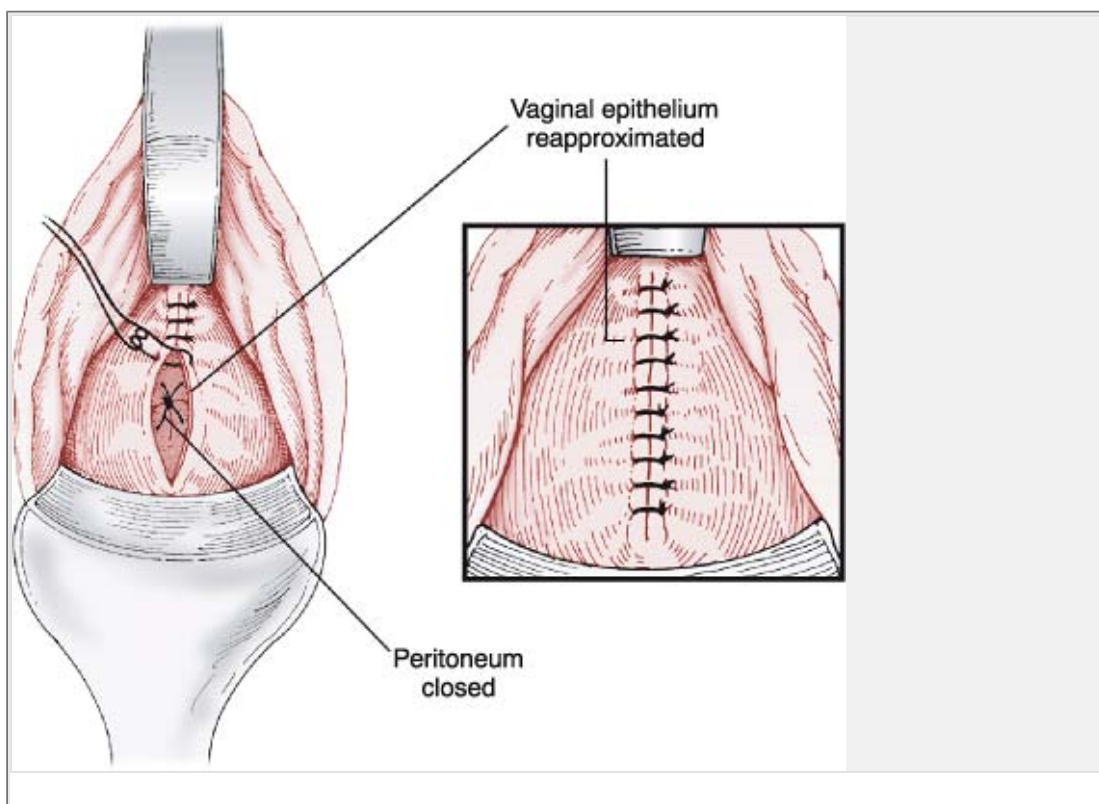

Figure 22.28 Closure of the vaginal mucosa. (From Mann WA, Stovall TG. *Gynecologic surgery*. New York, NY: Churchill Livingstone, 1996, with permission.)

Surgical Techniques for Selected Patients

Injection of Vaginal Mucosa

The use of paracervical and submucosal injection of 20 to 30 mL of 0.5% lidocaine with 1:200,000 epinephrine before incision of the vaginal mucosa is believed by some to decrease postoperative pain and facilitate identification of surgical planes. There is no need to inject the cervix. Areas to be injected include the bladder pillars, lower portion of the cardinal ligament, uterosacral ligaments, and paracervical tissue. However, it has been shown that the incidence of cuff cellulitis and cuff abscess formation is increased when *epinephrine* is injected into the cervicovaginal mucosa.

Morcellation of the Large Uterus

Uterine morcellation is a well known but often underutilized surgical procedure whereby the uterus is removed piecemeal. Several methods of uterine morcellation have been described (95), including hemisection or bivalving, wedge or "V" incisions, and intramyometrial coring. Before beginning any morcellation procedure, the uterine vessels must be ligated, and the peritoneal cavity must be entered. When uterine hemisection or bivalving is performed, the cervix is split at the midline, and the uterus is cut into halves, which are removed separately (96,97). This method seems best suited for fundal, midline leiomyomas.

Wedge morcellation is best suited for anterior or posterior fibroids or for fibroids in the other broad ligaments (i.e., when the fibroids are away from the midline) (97,98,99,100,101). The cervix is amputated, and the myometrium is grasped with clamps. Wedge-shaped portions of myometrium are removed from the anterior or posterior uterine wall. The apex of the wedge is kept in the midline, thereby reducing the bulk of the myometrium. This process is repeated until the uterus can be removed or until a pseudocapsule of a fibroid can be grasped with a Leahy clamp or towel clip. Traction is then applied, and a "myomectomy" is performed.

When the intramyometrial coring technique is used, the myometrium above the site of the ligated vessels is incised parallel to the axis of the uterine cavity and serosa of the uterus. This incision is continued around the full circumference of the myometrium in a symmetric fashion beneath the uterine serosa. Traction is maintained on the cervix, and the avascular myometrium is cut to allow the undisturbed endometrial cavity, with a thick layer of myometrium, to be delivered with the cervix. As a result, the inside of the uterus with its unopened endometrial cavity is brought closer to the operator. Incision of the lateral portions of the myometrium medial to the remaining attachment of the broad ligament results in considerable additional descent of the uterus and greatly increases the mobility of the uterine fundus. The uterus is converted from a globular to an elongated tissue mass. The cored uterus is removed by clamping the utero-ovarian pedicle and fallo-pian tubes.

In a retrospective comparison of 383 patients undergoing abdominal hysterectomy or vaginal hysterectomy with uterine morcellation, length of stay and perioperative complications were significantly increased with abdominal hysterectomy. Therefore, it appears that vaginal hysterectomy with uterine

morcellation is safe and allows for an increased number of women to undergo vaginal hysterectomy.

McCall Culdoplasty

Although McCall culdoplasty has been thought by some surgeons to help decrease future enterocele formation (100), whether this is accurate remains open to debate.

An absorbable suture is placed through the full thickness of the posterior vaginal wall at the point of the highest portion of the vaginal vault. The patient's left uterosacral ligament pedicle is grasped and sutured. The suture then incorporates the posterior peritoneum,

P.838

between the uterosacral ligaments and the right uterosacral ligament. The suture is completed by passing the needle from the inside to the outside at the same point at which it was begun. The suture is tied, thereby approximating the uterosacral ligaments and the posterior peritoneum.

Schuchardt Incision

When vaginal exposure is difficult, the Schuchardt incision may be used (100). If the surgeon is right-handed, the incision is made on the patient's left side. To decrease blood loss, the area can be infiltrated with lidocaine-containing epinephrine. The incision follows a curved line from the 4-o'clock position at the hymenal margin to a point halfway between the anus and the ischial tuberosity. The incision may be continued as high as necessary in the vaginal vault to gain exposure. The depth of the incision is the medial portion of the pubococcygeus muscle, which may be divided in extreme cases. The incision must be closed in layers at the completion of the procedure.

Intraoperative Complications

Bladder Injury

Injury to the urinary bladder is one of the most common intraoperative complications associated with hysterectomy. **If the bladder is inadvertently entered, repair generally should be performed when the injury is discovered and not delayed until completion of surgery (87).** When bladder injury is recognized, the edges of the wound should be mobilized to assess the full extent of the injury and to allow repair without tension. This assessment should include visualization of the trigone to exclude injury to that area. The bladder may then be repaired with a single- or double-layered closure with a small-caliber absorbable suture. *Methylene blue* or a dye of sterile milk formula can be instilled into the bladder to ensure that the repair is adequate.

Bowel Injury

Because patients with suspected pelvic adhesions or obvious pelvic disease are excluded as candidates for vaginal hysterectomy, bowel injuries do not occur often. Bowel injuries more often are associated with the performance of a posterior colporrhaphy and are usually confined to the rectum (87,100).

If the rectum is entered, the injury is repaired with a single- or double-layer closure using a small-caliber absorbable suture, followed by copious irrigation. Postoperatively, the patient should be given a stool softener and a low-residue diet.

Hemorrhage

Intraoperative hemorrhage invariably is the result of failure to ligate securely a significant blood vessel, bleeding from the vaginal cuff, slippage of a previously placed ligature, or avulsion of tissue before clamping (100). Most intraoperative bleeding can be avoided with adequate exposure and good surgical technique. Using square knots with attention to proper knot-tying mechanisms will prevent bleeding in most cases. Likewise, the use of Heaney-type sutures may minimize ligature slippage and subsequent bleeding from bulky pedicles. When bleeding does occur, blind clamping, which may endanger the ureter, should be avoided. The bleeding vessel should be identified and precisely ligated, with visualization of the ureter if necessary. **If the location of the ureter is in question, it should be visualized before suturing a bleeding vessel.** Although excessive blood loss occasionally occurs despite these precautions, it should be infrequent.

P.839

Perioperative Care

Bladder Drainage

Postoperative bladder drainage should be employed after any procedure in which spontaneous, complete voiding is not anticipated. Reasons to consider closed bladder drainage include significant local pain, additional vaginal reparative procedures, surgery for stress incontinence, the use of a vaginal pack, and patient anxiety.

After vaginal hysterectomy without additional repair, most patients can void spontaneously, and therefore, catheter drainage is not required. The relative amount of pain after a vaginal hysterectomy is less than with abdominal hysterectomy and, in the absence of additional repairs or a pack, no obstructive effect should be present.

If the patient does not tolerate pain well postoperatively or is extremely anxious, the transurethral insertion of a 16-Fr. catheter after completing surgery is warranted. This catheter may also be inserted postoperatively if the patient is unable to void spontaneously on two attempts. Closed-catheter drainage after vaginal hysterectomy usually is not necessary for longer than 24 hours. The catheter is removed without clamping, and there is no need to obtain a urine specimen for culture and sensitivity.

Diet

Although little manipulation of the bowel occurs during vaginal hysterectomy, there is some slowing of gastrointestinal motility. This slowing rarely occurs to a degree that limits some form of oral intake soon after surgery. Most patients experience some degree of nausea after surgery, which, combined with drowsiness from analgesics, usually makes them disinterested in food on the evening after surgery. A clear liquid diet is suitable during the first night after surgery. On the first full postoperative day, a regular diet can usually be consumed. **The patient is often the best judge of what she can tolerate.**

Perioperative Complications of Hysterectomy

A comprehensive discussion of postoperative complications after gynecologic surgery is presented in Chapter 20.

Wound Infections

Wound infections occur after 4% to 6% of abdominal hysterectomies (29).

Measures believed to reduce the incidence of wound infections include a preoperative shower, no removal of hair, or if hair removal is necessary, removal of hair with clippers in the operating room, use of adhesive drapes and prophylactic antibiotics, and delayed primary closure (see Chapter 20).

Hemorrhage

Immediately after hysterectomy, hemorrhage may become apparent in one of two ways (91). **First, bleeding from the vagina may be noted by the nursing staff or physician within the first few hours after surgery. Second, and less commonly, the patient may be noted to have little bleeding from the vagina but deteriorating vital signs manifested by low blood pressure and rapid pulse, falling hematocrit level, and flank or abdominal pain. The first presentation usually is in the form of bleeding from the vaginal cuff or one of the pedicles. The second presentation may be a retroperitoneal hemorrhage.** Each situation is approached differently in its evaluation and treatment, but both involve the same general principles of rapid diagnosis, stabilization of vital signs, appropriate fluid and blood replacement, and constant surveillance of the patient's overall condition.

After vital signs are assessed, attention should be directed to the amount of bleeding. A small amount of bleeding is expected after any vaginal hysterectomy. However, **steady**

P.840

bleeding 2 to 3 hours after surgery suggests lack of hemostasis. The patient should be taken promptly to the examining room, where the operative site is viewed using a large speculum and good lighting. If bleeding is not excessive, the vaginal cuff can be inspected, and in many instances, bleeding from the cuff edge will be found. Hemostasis can easily be achieved with one or two sutures placed through the mucosa.

If bleeding is excessive or appears to be coming from above the cuff, or if the patient is too uncomfortable to tolerate adequate examination, she should be taken to the operating room. General anesthesia should be administered and the vaginal operative site should be thoroughly explored. Any bleeding point may be sutured or ligated. However, bleeding that is coming from above the cuff or is extremely heavy usually cannot be controlled through the vaginal route. An exploratory laparotomy is necessary to examine the pelvic floor, identify and isolate the bleeding vessel, and achieve hemostasis. **The ovarian vessels and uterine arteries should be thoroughly inspected because they often are the source of excessive vaginal bleeding.** If it is difficult to localize bleeding to a specific pelvic vessel, or if these maneuvers do not work, ligation of the hypogastric artery may be performed.

In the patient with little vaginal bleeding in whom vital signs have deteriorated, retroperitoneal hemorrhage should be suspected. Input and output should be monitored. Hematocrit assessment, along with cross-matching, should be performed immediately. Examination may reveal tenderness and dullness in the flank. In cases of intraperitoneal bleeding, abdominal distention may occur. Diagnostic radiologic studies can be used to confirm the presence of retroperitoneal or intra-abdominal bleeding. Ultrasonography is one option for viewing low pelvic hematomas; CT provides better visualization of retroperitoneal spaces, however, and can delineate a hematoma.

If the patient's condition stabilizes rapidly with intravenous fluids, one of two approaches may be used for continued care. The first is to give the patient a transfusion and follow serial hematocrit assessments and vital signs. In many instances, retroperitoneal bleeding will tamponade and stop, forming a hematoma

that may eventually be resorbed. The risk with this approach is that the hematoma will later become infected, necessitating surgical drainage. In some instances when the patient's condition is stable, radiologic embolization may be considered.

Another option is to perform abdominal exploratory surgery while the patient's condition is stable. This approach adds the morbidity of a second procedure but avoids the possibility of the patient's condition deteriorating with continued delay or the formation of a pelvic abscess. Once adequate exposure is obtained, the peritoneum over the hematoma should be opened, and the blood should be evacuated. All bleeding vessels should be identified and ligated. Again, if bleeding is difficult to control, consideration should be given to unilateral or bilateral ligation of the anterior division of the internal iliac artery. Once hemostasis is achieved, the pelvis should be drained using a closed system.

Urinary Tract Complications

Urinary Retention

Urinary retention after hysterectomy is an uncommon occurrence (32). If the urethra is unobstructed and retention occurs, it is usually the result of either pain or bladder atony resulting from anesthesia. Both are temporary effects.

If a catheter was not placed after surgery, retention can be relieved initially with the insertion of a Foley catheter for 12 to 24 hours. Most patients are able to void after the catheter is removed 1 day later. If the patient still has trouble voiding and urethral spasm is suspected, success often can be achieved with a skeletal muscle relaxant such as

P.841

diazepam (2 mg twice a day). In most cases, waiting is the best course, and voiding usually occurs spontaneously.

Ureteral Injury

In patients who develop flank pain soon after vaginal hysterectomy, ureteral obstruction should be suspected. The incidence of ureteral injury is lower with vaginal hysterectomy than with abdominal hysterectomy (86). One risk factor for its occurrence is total uterine prolapse, in which the ureters are drawn outside the bony pelvis.

In a patient with flank pain in whom ureteral obstruction is suspected, a CT urogram and a urinalysis should be performed (83). If obstruction is noted on CT scan, it is usually present near the ureterovesical junction. The first immediate step should be attempted passage of a catheter through the ureter under cystoscopic guidance. If a catheter can be passed through the ureter, it should be left in place for at least 4 to 6 weeks, allowing sutures to absorb and the obstruction or kinking to release. If the catheter cannot be passed through the ureter, the best course is to perform abdominal exploratory surgery and repair the ureter at the site of obstruction (82,83,84,85,86,87).

Vesicovaginal Fistula

Vesicovaginal fistulas occur most often after total abdominal hysterectomy for benign gynecologic disease (86). Intraoperative steps to avoid the formation of a vesicovaginal fistula include correct identification of the proper plane between the bladder and cervix, sharp rather than blunt dissection of the bladder, and care in clamping and suturing the vaginal cuff. The development of a postoperative vesicovaginal fistula after hysterectomy is

rare; the incidence is as low as 0.2% (85,86).

Patients who have a postoperative vesicovaginal fistula develop a watery vaginal discharge 10 to 14 days after surgery. Some fistulas resulting from surgery are noted as early as the first 48 to 72 hours after surgery (87). After vaginal examination with a speculum, the diagnosis can usually be confirmed with the insertion of a cotton tampon into the vagina followed by the instillation of *methylene blue* or *indigo carmine* dye through a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, however, the presence of a ureterovaginal fistula must be ruled out by the intravenous injection of 5 mL of *indigo carmine* dye. Within 20 minutes, the tampon should stain blue if a ureterovaginal fistula is present. A CT urogram should also be performed to rule out ureteral obstruction.

If a vesicovaginal fistula is diagnosed, a Foley catheter should be inserted for prolonged drainage. Up to 15% of fistulas close spontaneously with 4 to 6 weeks of continuous bladder drainage. If closure has not occurred by 6 weeks, operative correction is necessary. Waiting 3 to 4 months from the time of diagnosis before operative repair is recommended to allow reduction of inflammation and to improve vascular supply. After vaginal hysterectomy, the fistula site is above the bladder trigone and away from the ureters. Vaginal repair can be anticipated in most patients. The surgical correction generally is undertaken in a four-layered closure: the bladder mucosa, the seromuscular layer, the endopelvic fascia, and the vaginal epithelium.

Incidental cystotomy at the time of hysterectomy is more common than vesicovaginal fistula. When repaired correctly, cystotomy rarely results in the development of a fistula (85).

Prolapse of the Fallopian Tube

Posthysterectomy prolapse of the fallopian tube is a rare event and often is confused with granulation tissue at the vaginal apex (32). Predisposing factors for the development of

P.842

fallopian tube prolapse include development of a hematoma and an abscess at the vaginal apex. Approximately one half of patients undergoing vaginal hysterectomy form some granulation tissue at the vaginal vault. **In patients in whom granulation tissue persists after attempts to cauterize it or pain is experienced with attempts to remove it, fallopian tube prolapse should be suspected.** A biopsy of the area is warranted and usually reveals tubal epithelium if a fallopian tube is present.

If fallopian tube prolapse is diagnosed, it should be repaired with surgery. In general, the surrounding vaginal mucosa should be opened and undermined widely. The tube is then ligated high and removed, followed by closure of the vaginal mucosa.

Discharge Instructions

Before discharging the patient, instructions should be reviewed. Printed postoperative instructions are helpful to the patient and should include the following information:

- Avoid strenuous activity for the first 2 weeks, and increase activity level gradually.
- Avoid heavy lifting, douching, or sexual intercourse until instructed by the physician.

Bathe as needed using shower or tub baths.

- Follow a regular diet.
- Avoid straining for a bowel movement or urination. For constipation, use *Milk of Magnesia* or *Metamucil* (1 tsp in juice).
- Call the physician if excessive vaginal bleeding or fever occurs.
- Schedule a return appointment at the time specified by the physician.

The physician should provide telephone numbers for emergencies both during and after office hours. Typically, the first postoperative visit is scheduled about 4 weeks after discharge from the hospital. At the time of that visit, the patient should be ambulating well, and vaginal discharge or bleeding should be minimal. Speculum examination of the cuff should be gentle and cursory, but the patient should be assured that the healing process is proceeding normally. Finally, the patient's questions should be answered, and advice should be given on increasing her activity level, including sexual activity, work, and normal household activity.

Psychosomatic Aspects

The decision to proceed with hysterectomy should be made jointly by the patient and her physician. Factors leading a patient or her physician to choose hysterectomy and reasons that patients with similar conditions choose different treatments are uncertain. For many patients, the decision to undergo hysterectomy may be sudden. They face the potential risks of anesthesia and surgery, and, if premenopausal, they must also cope with the loss of menstruation and the ability to procreate. Many women are concerned that the procedure will result in a loss of femininity, a decrease in sexual satisfaction, or an increase in interpersonal problems with their spouses. The concern over the loss of the reproductive tract is greater than that related to the loss of other intra-abdominal organs (102,103). To minimize the possibility that the patient has a poor outcome, preoperative counseling and preparation are essential.

P.843

In a study of 23 women who had hysterectomy, most regretted the loss of menstruation, even those who had experienced dysmenorrhea (104). Several of these women viewed the menstrual cycle as a way for the body to "rid itself of waste," and they felt better after the menstrual phase of their cycle.

Depression

There is wide variation in women's responses to hysterectomy. Most studies suggest that there is little evidence that hysterectomy increases the risk of depression. Some investigators have reported depression and an increased incidence of psychiatric symptoms after hysterectomy (105,106). One study concluded that almost twice as many women were admitted to a psychiatric hospital after pelvic operations compared with other types of surgery (107). However, others have not found such an association (108), and some report a decrease in symptoms after hysterectomy (109,110,111,112,113). **The impact of hysterectomy on the development of depression is unknown because most studies are retrospective**

and not well controlled for preoperative depression (see Chapter 12).

Patients who had a moderate amount of preoperative anxiety do much better postoperatively than patients with little or no anxiety or patients who had an exaggerated response (114). Both long delays before surgery and a very short time before surgery increase patients' anxiety. Thus, women should be scheduled for surgery several weeks in advance to avoid this problem (114). Women who planned to have children in the future had more problems during the immediate postoperative period. The patient's response to previous loss (eg, death of family members) predicted her response after hysterectomy (115).

Sexuality

The incidence of sexual dysfunction after hysterectomy ranges from 10% to 40%. Estimates vary based on study variations, cultural variations, and the definitions used to determine the diagnosis. Some report a decrease in libido after hysterectomy, whereas others suggest that libido is increased because of the reduced fear of unwanted pregnancy (106,116). Humphries found that most patients do not experience a change in their sexual practices after hysterectomy (117), whereas others report a deterioration of sexual relations (118). Preoperative anxiety about sexual functioning often is associated with an overall deterioration of sexual relations (119).

Hysterectomy does not cause psychiatric sequelae or diminished sexual functioning in most patients. The best predictor of satisfaction after hysterectomy is the patient's preoperative understanding of the procedure. **The best predictor of postoperative sexual functioning is the patient's preoperative sexual satisfaction.** Preoperatively, these issues should be discussed with the patient, and her questions and concerns should be addressed to decrease the fear and anxiety associated with surgery.

Lower Urinary Tract Disorders

Ingrid Nygaard

Shawn A. Menefee

L. Lewis Wall

- **Bladder storage and emptying depend on a complex interplay between the brain, spinal cord, bladder, urethra, and pelvic floor.**
- **Urinary incontinence is common in women and is generally treated successfully with a range of nonsurgical and surgical treatments.**
- **Stress urinary incontinence occurs with increases in abdominal pressure (such as coughing, running, lifting) and can be treated with pelvic muscle exercises, vaginal devices, lifestyle changes, and surgery.**
- **Urge urinary incontinence occurs with a sudden sense of urgency (such as on the way to the bathroom or when washing hands) and can be treated with bladder training, medications, lifestyle changes, and neuromodulation.**
- **Bladder pain remains a challenging and poorly understood entity.**

Physiology of Micturition

The bladder is a complex organ that has a relatively simple function: to store urine effortlessly, painlessly, and without leakage and to discharge urine voluntarily, effortlessly, completely, and painlessly. To meet these demands, the bladder must have normal anatomic support as well as normal neurophysiologic function.

Normal Urethral Closure

Normal urethral closure is maintained by a combination of intrinsic and extrinsic factors. The *extrinsic* factors include the levator ani muscles, the endopelvic fascia, and their attachments to the pelvic sidewalls and the urethra. This structure forms a hammock beneath the urethra that responds to increases in intra-abdominal pressure by tensing, allowing the urethra to be closed against the posterior supporting

P.850

shelf (Fig 23.1). When this supportive mechanism becomes faulty for some reason—the endopelvic fascia has detached from its normal points of fixation, muscular support has weakened, or a combination of these two processes—normal support is lost, and anatomic hypermobility of the urethra and bladder neck develops. For many women, this loss of support is severe enough to cause loss of closure during periods of increased intra-abdominal pressure, resulting in stress incontinence. However, many women remain continent in spite of loss of urethral support (1).

Figure 23.1 Lateral view of the pelvic floor drawn from a three-dimensional reconstruction with the urethra, vagina, and fascial tissues transected at the level of the vesical neck. Note how the urethra is compressed against the underlying supportive tissues by the downward force (arrow) generated by a cough or sneeze. (From Delancey J. Structural support of the urethra as it relates to stress urinary incontinence: the hammock hypothesis. *Am J Obstet Gynecol* 1994;170:1718, with permission.)

The *intrinsic* factors contributing to urethral closure include the striated muscle of the urethral wall, vascular congestion of the submucosal venous plexus, the smooth muscle of the urethral wall and associated blood vessels, the epithelial coaptation of the folds of the urethral lining, urethral elasticity, and the tone of the urethra as mediated by α -adrenergic receptors of the sympathetic nervous system.

Effective urethral closure is maintained by the interaction of extrinsic urethral support and intrinsic urethral integrity, each of which is influenced by several factors (muscle tone and strength, innervation, fascial integrity, urethral elasticity, coaptation of urothelial folds, urethral vascularity). In the clinical setting, damaged urethral support is manifested clinically by urethral hypermobility, which often results in incompetent urethral closure during physical activity and presents as stress urinary incontinence. Intrinsic urethral functioning is more complicated and is not nearly as well understood as incontinence related to loss of urethral support (2).

Clinical appreciation of the importance of extrinsic support and intrinsic urethral function led to the separation of stress incontinence into two broad types:

P.851

- **Incontinence caused by anatomic hypermobility of the urethra**
- **Incontinence caused by intrinsic sphincteric weakness or deficiency**

Surgical approaches have been based on this arbitrary distinction, with pubovaginal sling recommended for women with intrinsic sphincter deficiency and a colposuspension (also known as retropubic urethropexy) for those with hypermobility. This rationale was based initially on a small study in which women younger than age 50 years with urethral closure pressure less than 20 cm H₂O had a higher failure rate after a Burch colposuspension than did women with a closure pressure greater than 20 cm H₂O (3). No difference in outcome was seen in women older than 50 years. More recently, this dichotomy has been called into question, based on the observation that all women with stress incontinence have some degree of sphincter weakness, regardless of whether they have hypermobility. Currently, it is not known whether women with more severe sphincter weakness have improved success with a specific type of surgery or whether they are more likely to experience treatment failure with any surgery.

The Bladder

The bladder is a bag of smooth muscle that stores urine and contracts to expel urine under voluntary control. It is a low-pressure system that expands to accommodate increasing volumes of urine without an appreciable rise in pressure. This function appears to be mediated primarily by the sympathetic nervous system.

During bladder filling, there is an accompanying increase in outlet resistance. The bladder muscle (the detrusor) should remain inactive during bladder filling, without involuntary contractions. When the bladder has filled to a certain volume, fullness is registered by tension-stretch receptors, which signal the brain to initiate a micturition reflex. This reflex is permitted or not permitted by cortical control mechanisms, depending on the social circumstances and the state of the patient's nervous system. Normal voiding is accomplished by voluntary relaxation of the pelvic floor and urethra, accompanied by sustained contraction of the detrusor muscle, leading to complete bladder emptying.

Innervation

The lower urinary tract receives its innervation from three sources: (i) the sympathetic and (ii) parasympathetic divisions of the autonomic nervous system, and (iii) the neurons of the somatic nervous system (external urethral sphincter).

The *autonomic nervous system* consists of all efferent pathways with ganglionic synapses that lie outside the central nervous system. The sympathetic system primarily controls bladder storage, and the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

The sympathetic nervous system originates in the thoracolumbar spinal cord, principally T11 through L2 or L3 (see Chapter 6). The ganglia of the sympathetic nervous system are located close to the spinal cord and use acetylcholine as the preganglionic neurotransmitter. The postganglionic neurotransmitter in the sympathetic nervous system is norepinephrine, and it acts on **two types of receptors: α receptors, located principally in the urethra and bladder neck, and β receptors, located principally in the bladder body. Stimulation of α receptors increases urethral tone and thus promotes closure, whereas α -adrenergic receptor blockers have the opposite effect. Stimulation of β receptors decreases tone in the bladder body.**

The parasympathetic nervous system controls bladder motor function—bladder contraction and bladder emptying. The parasympathetic nervous system originates in the sacral spinal cord, primarily in S2 to S4, as does the somatic innervation of the pelvic

P.852

floor, urethra, and external anal sphincter. Sensation in the perineum is also controlled by sensory fibers that connect with the spinal cord at this level. For this reason, examination of perineal sensation, pelvic muscle reflexes, and pelvic muscle or anal sphincter tone is relevant to clinical evaluation of the lower urinary tract. The parasympathetic neurons have long preganglionic neurons and short postganglionic neurons, which are located in the end organ. Both the preganglionic and postganglionic synapses use acetylcholine as their neurotransmitter, acting on muscarinic receptors. **Because acetylcholine is the main neurotransmitter used in bladder muscle contraction, virtually all drugs used to control detrusor muscle overactivity have anticholinergic properties.**

Bladder storage and bladder emptying involve the interplay of the sympathetic and parasympathetic nervous systems. The modulation of these activities appears to be influenced by a variety of nonadrenergic, noncholinergic neurotransmitters and neuropeptides, which fine-tune the system at various facilitative and inhibitory levels in the spinal cord and higher areas of the central nervous system (4,5,6). Thus, neuropathology at almost any level of the neurourogenic axis can have an adverse effect on lower urinary tract function.

Micturition

Micturition is triggered by the peripheral nervous system under the control of the central nervous system. It is useful to consider this event as occurring at a micturition threshold, a bladder volume at which reflex detrusor contractions occur. The threshold volume is not fixed; rather, it is variable and can be altered depending on the contributions made by sensory afferents from the perineum, bladder, colon, and rectum as well as input from the higher centers of the nervous system. The micturition threshold is, therefore, a floating threshold that can be altered or reset by various influences.

The spinal cord and higher centers of the nervous system have complex patterns

of inhibition and facilitation. The most important facilitative center above the spinal cord is the pontine–mesencephalic gray matter of the brain stem, often called the *pontine micturition center*, which serves as the final common pathway for all bladder motor neurons. Transection of the tracts below this level leads to disturbed bladder emptying, whereas destruction of tracts above this level leads to detrusor overactivity. The cerebellum serves as a major center for coordinating pelvic floor relaxation and the rate, force, and range of detrusor contractions, and there are multiple interconnections between the cerebellum and the brain–stem reflex centers. Above this level, the cerebral cortex and related structures exert inhibitory influences on the micturition reflex. Thus, the upper cortex exerts facilitative influences that release inhibition, permitting the anterior pontine micturition center to send efferent impulses down the complex pathways of the spinal cord, where a reflex contraction in the sacral micturition center generates a detrusor contraction that causes bladder emptying.

A normal lower urinary tract is one in which the bladder and urethra store urine without pain until a socially acceptable time and place arises, at which point voiding occurs in a coordinated and complete fashion. Lower urinary tract disorders include disorders of storage (such as urinary incontinence), emptying (such as urinary hesitancy and retention), and sensation (such as urgency or pain).

Current definitions for these disorders are depicted in Table 23.1.

Urinary Incontinence

Definitions

Defining urinary incontinence would seem an easy task: women that leak urine must be “incontinent.” **The International Continence Society, an organization charged with defining the various disorders of pelvic floor dysfunction, recently defined incontinence**

P.853

as “the complaint of any involuntary leakage of urine” (7). Unfortunately, this definition does not take into account the wide variation in this symptom and the disruption it causes. For example, half of young nulliparous women report occasional minor urine leakage; for most this is not neither a bother nor a symptom for which they would seek treatment. At the other extreme, 5% to 10% of adult women have severe leakage daily. These women often dramatically alter their lives because of leakage, curtailing activities, social outings, and intimacy. Many suffer marked deterioration in self–esteem. In between these two extremes lies another one–third of adult women who report leakage at least weekly, but without the same degree of life–altering severity as the women previously noted.

Table 23.1 Classification and Definition of Lower Urinary Symptoms in Women

I. Abnormal Storage	
<i>Incontinence (symptom)</i>	The complaint of any involuntary leakage of urine
<i>Stress urinary incontinence (symptom)</i>	The complaint of involuntary leakage on effort or exertion, or on sneezing or coughing
<i>Stress urinary incontinence (sign)</i>	Observation of involuntary leakage from the urethra, synchronous with exertion/effort, or sneezing or coughing
<i>Urge urinary incontinence (symptom)</i>	The complaint of involuntary leakage accompanied by or immediately preceded by urgency
<i>Mixed incontinence</i>	Complaints of both stress and urge incontinence
<i>Continuous urinary incontinence</i>	Complaint of continuous leakage.

Frequency The number of voids per day, from waking in the morning until falling asleep at night

Increased daytime frequency Complaint by the patient that she voids too often

Nocturia Complaint that the individual has to wake at night one or more time to void (each void is preceded and followed by sleep)

Nocturnal enuresis Complaint of loss of urine during sleep

Extraurethral incontinence The observation of urine leakage through channels other than the urethra

Uncategorized incontinence The observation of involuntary leakage that cannot be classified into one of the above categories based on signs and symptoms

Overactive bladder syndrome (OAB), urge syndrome, urgency–frequency syndrome Can all be used to describe urgency, with or without urge incontinence, usually with frequency and nocturia

II. Abnormal Emptying

Hesitancy Trouble initiating voiding

Straining to void Voiding accompanied by abdominal straining

Poor stream Decreased force of flow of the urinary stream

Intermittent stream A stop–and–start pattern of urination

Incomplete emptying A persistent feeling of bladder fullness after voiding

Postmicturition dribble Urine loss occurring just after normal voiding has been completed

Acute urinary retention Sudden inability to void, resulting in painful bladder overdistention and the need for catheterization to obtain relief

Abrams P, Cardozo L, Fall M, et al. The standardization of terminology of lower urinary tract function: report from the Standardization Sub-committee of the International Continence Society. *Neurourol Urodyn* 2002;21:167–178.

Collectively, these women assume a substantial cost burden. The total annual cost to care for patients with incontinence in the United States is estimated at \$11.2 billion in the community and \$5.2 billion in nursing homes (8). In the United States, much of this cost is borne directly by women in the form of incontinence pads and excess laundry costs. Despite the burden imposed by leakage, many women do not discuss this symptom with a

P.854

health care professional. For some women, this is because the leakage does not bother them, whereas others are embarrassed and suffer in silence. Still others do not raise this issue because they mistakenly believe the only treatment option is surgical. Thus, it is incumbent on the provider to ask women about leakage.

Studies have shown that there is little relationship between the volume of urine lost and the distress that it causes a patient (9). The degree to which women are bothered by leakage is influenced by various factors, including cultural values and expectations regarding urinary continence and incontinence. **If the leakage is distressing to the patient, evaluation and treatment should be offered. Incontinence can almost always be improved and frequently can be cured, often using relatively simple, nonsurgical interventions.**

Types of Disorders

Stress Urinary Incontinence

Stress urinary incontinence occurs during periods of increased intra-abdominal pressure (e.g., sneezing, coughing, or exercise) when the intravesical pressure rises higher than the pressure that the urethral closure mechanism can withstand.

Stress urinary incontinence is the most common form of urinary incontinence in women and is particularly common in younger women. Active women are more likely to notice symptoms of stress urinary incontinence. In a survey of 144 collegiate female varsity athletes, 27% reported stress incontinence while participating in their sport (10). The activities most likely to produce urinary loss were jumping, high-impact landings, and running.

Stress incontinence is an interesting "disease" as the same symptoms have varying effects on different women. This condition is best thought of by a biobehavioral model that examines the interaction of three variables: (i) the biologic strength of the urethral sphincteric mechanism, (ii) the level of physical stress placed on the closure mechanism, and (iii) the woman's expectations about urinary control. This model explains the enormous variation that exists among the symptoms, the degree of demonstrable leakage, and a patient's response to her stress incontinence. Modification of any one of these factors may influence the patient's clinical status; for example, many patients give up certain physical activities (e.g., running, dancing, aerobics) when they experience stress incontinence. Limiting their activities may eliminate the incontinence problem, but it does so at a certain cost to their quality of life. Other women learn to cope with stress incontinence by adopting new body postures during physical activities that prevent them from leaking or by strengthening their pelvic muscles to compensate for increased exertion. Other women may be profoundly relieved to find out that the small amount of leakage they experience from time to time is not abnormal. In any case, the interaction of these three biopsychosocial factors opens up a variety of strategies for the management of stress incontinence. Surgical intervention is only one strategy, and it addresses only the biologic competence of the sphincteric mechanism rather than either of the other factors that interact to produce the clinical problem.

Urge Urinary Incontinence and Overactive Bladder

Although stress incontinence is the most common type of urinary continence in women, urge incontinence is the most common form of incontinence in older women (11). Urge urinary incontinence is the involuntary leakage of urine accompanied by or immediately preceded by urgency. This is a symptom-based diagnosis and may or may not be caused by detrusor overactivity, which is a urodynamic observation characterized by involuntary detrusor contractions during the filling phase.

Women may also have related problems such as urgency, nocturia, and increased daytime frequency. The definition of nocturia is quantifiable: The woman wakes one or more times a night to void (7). The other symptoms are more subjective. Increased

P.855

daytime frequency occurs when the patient considers that she voids too often. (Note that the term *pollakisuria* is used to describe this condition in many countries.)

Urgency is the sudden compelling desire to pass urine that is difficult to defer. Most women have experienced these symptoms during times of voluntary delays in voiding or increased fluid intake. However, urinary urgency implies more than just the feeling that all normal women have if they voluntarily delay voiding beyond a reasonable time (12). When a woman presents for treatment, she generally reports an intrusive, bothersome, persistent need to urinate that takes her attention away from other activities. Increased daytime frequency is often brought up as an issue when a woman experiences a change in her own voiding pattern.

There is very little information about what is "normal" in terms of voiding frequency.

Overactive bladder (OAB) is frequently defined in studies of pharmacologic agents as more than eight voids per 24 hours, a definition that was based on the 95th percentile of voids in a small sample of Scandinavian women (13). **More recent data from a broader sample of women in the United States suggests that the median number of voids per day is eight, and 95% of so-called normal women void 12 or fewer times per day (14).**

Detrusor overactivity is qualified, when possible, by cause and is termed *neurogenic detrusor overactivity* (formerly called *detrusor hyperreflexia*) when a neurological condition may account for the finding, and *idiopathic detrusor overactivity* (formerly called *detrusor instability*) when there is no defined cause.

The term *overactive bladder syndrome* also describes women with symptoms of urgency, frequency, and urge incontinence. It is referred to as *OAB-dry* when women with these symptoms do not leak urine, and *OAB-wet* when it is accompany by incontinence. It is important to note that a woman with severe urgency and a sense of impending leakage who remains dry may have the exact same bladder pathology as one with severe urgency and concomitant leakage. A woman with a strong urethral sphincteric mechanism may be able to avoid leakage during uninhibited bladder contractions, whereas one with a strong sphincter may remain dry but be disturbed by the urgency and impending sense of leakage.

Mixed Incontinence

As implied by the name, women with mixed incontinence have symptoms of both stress and urge urinary incontinence. Younger women are more likely to have stress incontinence alone, whereas in older women mixed and urge incontinence predominate. In a review of 15 population-based studies of women of all ages with urinary incontinence, a median of 49% (range 24%–75%) had stress urinary incontinence, 21% (range 7%–49%) had urge urinary incontinence, and 29% (range 11%–61%) had mixed urinary incontinence (15).

Functional and Transient Incontinence

Functional incontinence is more common in elderly women and refers to incontinence that occurs because of factors unrelated to the physiologic voiding mechanism. A woman who can't get to the bathroom quickly may often become incontinent.

Functional incontinence can be related to such factors as decreased mobility, musculoskeletal pain, or poor vision. Factors leading to transient urinary incontinence are, as the name implies, medically reversible conditions. **A useful mnemonic to help remember these factors is DIAPPERS (16,17) (Table 23.2).** These factors argue strongly for the inclusion of a thorough medical evaluation as part of the workup of any patient with urinary incontinence.

Extraurethral Incontinence

While most urinary incontinence represents unwanted urine loss through the urethra (transurethral incontinence), urine loss can also occur through abnormal openings. These

openings can be created by congenital causes or some form of trauma. The congenital causes of urinary incontinence are not common and usually are easy to diagnose. The most extreme cases are caused by **bladder exstrophy**, in which there is a congenital absence of the lower anterior abdominal wall and anterior portion of the bladder, resulting in the entire bladder opening directly to the outside (18). Such cases are diagnosed at birth. Before the advent

of modern reconstructive surgery, these infants usually died very early in life from sepsis.

Table 23.2 Reversible Causes of Incontinence

D	Delirium
I	Infection
A	Atrophic urethritis and vaginitis
P	Pharmacologic causes
P	Psychological causes
E	Excessive urine production
R	Restricted mobility
S	Stool impaction

Resnick NM, Yalla SV. Management of urinary incontinence in the elderly. *N Engl J Med* 1985; 313:800–805.

Ectopic ureter, a subtle congenital anomaly causing extraurethral urine loss, generally is detected early in life, but occasionally one may escape detection until adolescence or early adulthood (19). In infancy, an ectopic ureter should be suspected when a mother seeks care for her baby, whom she says is never dry. Normally, infants have periods of dryness interspersed with periods of wetness. Most commonly, the ectopic ureter drains into the vagina, but occasionally, it may drain into the urethra distal to the point of continence. This condition can be diagnosed by excretory urography.

A traumatic opening between the urinary tract and the outside is called a fistula. Vesicovaginal fistulas, located between the bladder and urethra, are most common, but fistulas may also occur between the vagina, uterus, or bowel, and the urethra, ureter, or bladder.

Worldwide, the most common cause of vesicovaginal fistulas is obstructed labor. This also was true in the Western world 150 years ago, but advances in the provision of basic obstetric services and advanced obstetric intervention have virtually eliminated this problem in developed countries. The rest of the world is not so fortunate.

Obstructed labor often occurs in rural areas where girls are married young (sometimes as early as 9 to 10 years of age) and where transportation is poor and access to medical services is limited. In such circumstances, pregnancy often occurs shortly after menstruation begins and before maternal skeletal growth is complete. When labor begins, cephalopelvic disproportion is common, and little can be done to correct fetal malpresentations. Women may be in labor as long as 5 to 6 days without intervention, and if they survive, they usually give birth to a stillborn infant. In such cases, the soft tissues of the pelvis have been crushed by constant pressure from the fetal head, leading to an ischemic vascular injury and subsequent tissue necrosis. When this tissue sloughs, a genitourinary or rectovaginal fistula develops. Many of these patients have complex or multiple fistulas, involving total destruction of the urethra and sloughing of the entire bladder base (Fig 23.2). Obstetric fistulas are frequently as large as 5 to 6 cm in diameter.

After such fistulas develop, the lives of these young women (most of whom are younger than 20 years of age) are ruined unless they can gain access to curative surgical services.

P.857

The constant, uncontrolled dribble of urine makes them offensive to their husbands and family members. They can no longer live with their families. Most of them eventually become destitute social outcasts—and yet these are otherwise healthy functional young women.

The social and economic costs of this problem are enormous, yet it largely has been neglected by the world medical community. The morbidity associated with obstetric fistulas remains, along with the related maternal mortality, one of the single most neglected issues in international women's health care (20).

Figure 23.2 Moderate-sized obstetric vesicovaginal fistula. A metal probe has been placed through the urethra and is clearly visible through the bladder base. Copyright Worldwide Fistula Fund, used by permission.

Figure 23.3 Posthysterectomy fistulas. Note three small fistulas in a row.

In the industrialized world, **the most common causes of genitourinary fistulas are surgery, malignancy, and radiation therapy, alone or in combination. Most often, a vesicovaginal fistula develops after an otherwise uncomplicated vaginal or abdominal hysterectomy in which a small portion of the bladder was inadvertently trapped in a surgical clamp or was transfixated by a suture.** These fistulas most often occur at the vaginal apex and are no larger than 1 to 2 mm. The amount of urine that can leak through a fistula of any size, however, is enormous. Figure 23.3 shows a cystoscopic view of three small vesicovaginal fistulae, lined up where the cuff suture line would have been.

Although rare, vesicouterine fistulas are increasing in incidence as the rate of cesarean deliveries increases. Such fistulas are almost always associated with repeat cesarean deliveries. **The classic triad of vaginal urinary leakage, cyclic hematuria, and amenorrhea is known as Yousef's syndrome (21).**

Nocturia

Nocturia is the number of voids recorded during a night's sleep; each void is preceded and followed by sleep. To sort out whether nocturia is due to heightened urine production at night, the nocturnal urinary volume can be assessed from a bladder chart. Nocturnal urinary volume is defined as the total volume of urine passed between the time the woman goes to bed with the intention of sleeping and the time of waking with the intention of rising. Thus, it excludes the last void before going to bed but includes the first void after rising in the morning. Nocturnal polyuria is present when an increased proportion of the 24-hour output occurs at night.

Risk Factors for Urinary Incontinence

Most of the data about risk factors for urinary incontinence come from clinical trials or cross-sectional studies using survey design. Some risk factors have been more rigorously studied than others. Thus, the information available is limited in its general applicability and one cannot infer causality from it. Despite these limitations, **there is some evidence that age, pregnancy, childbirth, obesity, functional impairment, and cognitive impairment are associated with increased rates of incontinence or incontinence severity (15,22).** Some factors pertain more to certain age groups than others. For example, in studies of older women, childbirth no longer increases the risk of incontinence, possibly because of the presence of comorbidities and other factors that promote incontinence. Medical diagnoses that generally have been associated with urinary incontinence include diabetes, strokes, and spinal cord injuries. Other factors about which less is known or findings are contradictory include hysterectomy, constipation, occupational stressors, smoking, and genetics.

Pregnancy and delivery predispose women to stress urinary incontinence, at least during their younger years. Of women who have not borne children, those who are pregnant leak more often than their nonpregnant counterparts; about half of women report symptoms of stress urinary incontinence during pregnancy, but in most, the symptom resolves after delivery. In a prospective study, 32% of 305 primiparas developed stress urinary incontinence during pregnancy and 7% after delivery. By 1 year, only 3% reported stress urinary incontinence (23). However, 5 years later, 19% of women with no symptoms after the first delivery had stress urinary incontinence. Of women reporting stress urinary incontinence 3 months postpartum (in most of whom it had resolved by 1 year), 92% had such leakage 5 years later. Thus, transient postpartum leakage may be a marker for future incontinence.

Various changes happen after delivery that may predispose women to stress

urinary incontinence. Levator ani muscle strength decreases (24). About 20% of women develop a visible defect in the levator ani muscles after vaginal delivery (25). The bladder neck descends (26), and the pelvic muscles undergo partial denervation with

P.859

pubdental neuropathy (27). In most studies, parity is strongly associated with urinary incontinence in younger women (28). However, in studies of women 60 years and older, parity is generally no longer an independent risk factor for incontinence (29). The reason for this is not well elucidated, but it may be because the changes in muscle, nerve, connective tissue, and hormonal function that occur with aging make other women "catch up" to those that developed incontinence at a younger age because of delivery trauma. Alternately, it may be that medical problems more common in older women account for a larger proportion of incontinence risk as women age.

Obesity deserves special mention for its role in causing or exacerbating stress incontinence. Many researchers have reported an association (that remains after adjusting for age and parity) between increased weight and body mass index (BMI), and urinary incontinence. For example, a dose-response relationship between BMI and severe urinary incontinence has been described (30). Compared with women with a BMI less than 25 kg/m², odds ratios (OR) for the following BMI groups were: 25-29, OR 2.0 (1.7-2.3); 30-34, OR 3.1 (2.6-3.7); 35-39, OR 4.2 (3.3-5.3); 40+, 5.0 (3.4-7.3).

Initial Evaluation

The initial evaluation of patients with incontinence requires a systematic approach to consider possible causes. The basic evaluation should include the following items: history (including assessment of quality of life and degree of bother from symptoms), physical examination, and simple primary care level tests. Most women can begin nonsurgical treatment after this basic evaluation.

History

A thorough medical history should be obtained from every incontinent patient. The history should include a review of symptoms, general medical history, review of past surgery, and current medications. The woman's most troubling symptoms must be ascertained—how often she leaks urine, how much urine she leaks, what provokes urine loss, what improves or worsens the problem, and what treatment (if any) she has had in the past. It is essential to keep the patient's chief symptom at the forefront to avoid inappropriate management. Consider, for example, a woman whose chief concern is that once a month, while leading a business seminar, she has a sudden, overwhelming urge to void following by precipitant emptying of her entire bladder content. She finds this leakage devastating, and is considering quitting her job because of her acute embarrassment. On occasion, she also leaks a few drops of urine during exercise, but this minor leakage does not bother her. During the evaluation, urodynamics reveal minimal stress urinary incontinence at capacity during strong coughing. No detrusor overactivity is seen. The patient is offered, and undergoes, a surgical procedure for her documented urodynamic stress incontinence. Not surprisingly, her chief symptom is not improved and she is devastated.

The general medical history may reveal systemic illnesses that have a direct bearing on urinary incontinence, such as diabetes mellitus (which produces osmotic diuresis if glucose control is poor), vascular insufficiency (which can lead to incontinence at night when peripheral edema is mobilized into the vascular system, resulting in increased diuresis), chronic pulmonary disease (which can lead to stress incontinence from chronic coughing), or a wide variety of neurologic conditions that

can affect the neurourologic axis at any point from the cerebral cortex to the peripheral nervous system. Medications that may affect the lower urinary tract are summarized in Table 23.3 (31,32,33,34).

Quality-of-life Measures

Physicians caring for incontinent women should ask them about how the incontinence specifically affects their lives and to what degree the incontinence bothers them. There often is discord between the objective symptom severity and subjective bother. Only by understanding each woman's situation can treatment be appropriately

P.860

planned and response evaluated. Some women may be completely satisfied if they are able to sit through a movie without running to the bathroom, even if they leak urine at other times. Others may be satisfied only if they are 100% dry. Given that the latter is likely an unrealistic goal, knowing that the patient feels this way gives the provider the opportunity to educate her about the likely outcome of treatment.

Table 23.3 Medications that May Affect the Urinary Tract

1.	Sedatives such as the benzodiazepines may cause confusion and secondary incontinence, particularly for elderly patients.
2.	Alcohol may have similar effects to benzodiazepines and also impairs mobility and causes diuresis.
3.	Anticholinergic drugs may impair detrusor contractility and may lead to voiding difficulty and overflow incontinence. Drugs with anticholinergic properties are widespread and include antihistamines, antidepressants, antipsychotics, opiates, antispasmodics, and drugs used to treat Parkinson's disease.
4.	α -Agonists, which are often found in over-the-counter cold remedies, increase outlet resistance and may lead to voiding difficulty.
5.	α -Blockers, sometimes used to treat hypertension (e.g., prazosin, terazosin), may decrease urethral closure pressure and lead to stress incontinence.
6.	Calcium-channel blockers may reduce bladder smooth muscle contractility and lead to voiding problems or incontinence; they may also cause peripheral edema, which may lead to nocturia or nighttime urine loss.
7.	Angiotensin-converting enzyme inhibitors may result in a chronic and bothersome cough that can result in increasing stress urinary incontinence in an otherwise asymptomatic patient.

Physicians who have a large number of incontinence patients or who wish to evaluate patients in a more standardized fashion before and after treatment may choose to use one of several well-designed, validated quality-of-life measures available. An expert summary of the literature in this area conducted for the International Consultation on Incontinence recommended the instruments summarized in Table 23.4. These instruments were found to be valid, reliable, and responsive to change following standard psychometric testing.

Physical Examination

The physical examination of the patient with incontinence should focus on both general medical conditions that may affect the lower urinary tract as well as problems related to urinary incontinence. Such conditions include cardiovascular insufficiency, pulmonary disease, occult neurologic processes (e.g., multiple sclerosis, stroke, Parkinson's disease, and anomalies

of the spine and lower back), abdominal masses, and mobility. Key factors to assess during the physical examination are summarized in Table 23.5. **A Q-tip test has poor predictive value for determining either stress urinary incontinence diagnosis or predicting treatment success** (35). It is used by some clinicians to determine movement of the anterior vaginal wall with Valsalva. A woman with a fixed nonmobile urethra is a poor candidate for a surgery (such as a Burch colposuspension) designed to elevate the urethra. It is not possible to support an already well-supported urethra.

Table 23.4 Questionnaires to Assess Urinary Incontinence

The following questionnaires have been recommended by the International Consultation on Incontinence to assess symptoms of incontinence and impact of incontinence on quality of life in women.^a

Symptoms

Urogenital Distress Inventory. Shumaker SA, Wyman JF, Uebersax JS, et al.

Health-related quality of life measures for women with urinary incontinence: the Incontinence Impact Questionnaire and the Urogenital Distress Inventory. *Qual Life Res* 1994;3:291-306.

Urogenital Distress Inventory (UDI)-6 (short form). Uebersax JS, Wyman JF, Shumaker SA, et al. Short forms to assess life quality and symptom distress for urinary incontinence in women: the incontinence impact questionnaire and the urogenital distress inventory. *Neurourol Urodyn* 1995;14:131-139.

Urge-UDI. Lubeck DP, Prebil LA, Peebles P, et al. A health related quality of life measure for use in patient with urge urinary incontinence: a validation study. *Qual Life Res* 1999;1999:337-344.

King's Health Questionnaire. Kelleher CJ, Cardozo LD, Khullar V, et al. A new questionnaire to assess the quality of life of urinary incontinent women. *Br J Obstet Gynaecol* 1997;104:1374-1379.

Incontinence Severity Index. Sandvik H, Hunskaar S, Seim A, et al. Validation of a severity index in female urinary incontinence and its implementation in an epidemiological survey. *J Epidemiol Community Health* 1993;47:497-499

Quality of Life

Quality of life in persons with urinary incontinence (I-QOL). Wagner TH, Patrick DL, Bavendam TG, et al. Quality of life of persons with urinary incontinence: development of a new measure. *Urology* 1996;47:67-72.

Incontinence Impact Questionnaire. Wyman JF, Harkins SW, Taylor JR, et al. Psychosocial impact of urinary incontinence in women. *Obstet Gynecol* 1987;70:378-381.

Incontinence Impact Questionnaire (IIQ)-7 (short form). Uebersax JS, Wyman JF, Shumaker SA, et al. Short forms to assess life quality and symptom distress for urinary incontinence in women. The incontinence impact questionnaire and the urogenital distress inventory. *Neurourol Urodyn* 1995;14:131-139.

Urge-IIQ. Lubeck DP, Prebil LA, Peebles P, et al. A health related quality of life measure for use in patient with urge urinary incontinence: a validation study. *Qual Life Res* 1999;1999:337-344.

^a**Donovan JL, Badia X, Corcos J, et al.** Symptom and quality of life assessment. In: **Abrams P, Cardozo L, Khoury J, et al.**, eds. *Incontinence*. Plymouth, UK: Plymbridge Distributors Ltd, 2002.

Simple (Primary Care Level) Tests

It is important to realize that formal urodynamics tests are neither the only, nor the most important, tests of bladder function. Other simple tests that can easily be performed in the primary care setting provide useful information to guide patient care.

P.861

Voiding Diary

A frequency/volume bladder chart (often termed a "bladder diary") is an invaluable aid in the evaluation of patients with urinary incontinence. A frequency/volume chart is a voiding record kept by the patient for several days. Patients are instructed to write down the time of every void on the chart and measure the amount of urine voided. The time of any incontinent episodes, as well as the specific activities associated with urine loss, should be recorded. If desired, the patient can also be instructed to keep a record of fluid intake. Although the type of intake may guide management suggestions, in most cases volume of intake can be estimated with some accuracy from the amount of urine produced.

A frequency/volume bladder chart provides vital information about bladder function that is not provided by formal urodynamics studies: 24-hour urinary output, the total number of daily voids, number of nighttime voids, the average voided volume, and

P.862

the functional bladder capacity (largest volume voided in normal daily life). This information allows the clinician to confirm reports of urinary frequency with objective data and to determine whether part of the patient's problem is an abnormally high (or low) urinary output. The chart can also be used to calculate the volume of urine generated in nighttime hours versus daytime hours. Nighttime volume is calculated by adding output from voids that occur after the woman has fallen asleep for the night as well as the first morning void on awakening for the day. Older women sometimes have a marked shift in urine production, with more than half of their urine output generated during sleeping hours (Fig. 23.4). Demonstrating this on the voiding diary may lead to further treatment options.

Table 23.5 Physical Examination of a Woman with Lower Urinary Tract Dysfunction

Prolapse
Atrophy
Levator muscle palpation (symmetry, ability to squeeze)
Anal sphincter function
Test of urethral mobility (e.g., Q-tip test)

Urinalysis

Examination of the urine by dipstick testing and microscopy is done to exclude infection, hematuria, and metabolic abnormalities. **Hematuria cannot be diagnosed on the results of a dipstick test alone; confirmation by microscopic evaluation is mandatory.**

If a urinary tract infection is documented by microscopy or culture, it is reasonable to see whether urinary tract symptoms improved with eradication of bacteriuria. Occasionally, a simple urinary tract infection causes the onset or exacerbation of urinary incontinence. However, **some women, particularly older ones, have asymptomatic bacteriuria that truly is asymptomatic; thus, if attempted treatment of a woman with bacteriuria but without classic urinary tract infection symptoms (such as dysuria, urgency, frequency) does not improve incontinence, further antibacterial treatment is generally unnecessary.**

If hematuria as well as bacteriuria is found, the urine should be rechecked after eradication of the bacteriuria. **Hematuria found in the absence of bacteriuria may need further evaluation to rule out kidney or bladder tumors;** the necessity for and extent of the evaluation depends on concomitant risk factors and the clinical presentation. If

P.863

malignancy is suspected, bladder biopsy should be performed by the surgeon who would treat the patient in the event a malignancy is discovered.

Number of pads changed today 1
 Type of pad used Maxi pad

	Urinate in toilet (time and amount)	Accident (time)	Activity during accident	Fluid intake (time, type, amount)
To Bed	2200 240 cc			1 glass water
	0300 660 cc	0300	Leak on way to bathroom	
	0500 540 cc	0500	Preparing to urinate	
Up For Day	0700 150 cc			16 oz coffee 1 cup water
	0845 35 cc			
	1145 160 cc			
	1200			16 oz lemonade
	1540 60 cc			
	1800 100 cc			2 glasses wine 2 cups water
	1940 60 cc			16 oz diet coke 1 glass water

Figure 23.4 Voiding diary (also called bladder chart). Daytime frequency is seven. The patient has nocturia (gets up to void two times during sleeping hours) and also has nocturnal polyuria (an increased proportion of the 24-hour output occurs at night; note that nighttime urine output excludes the last void before sleep but includes the first void of the morning). She has urge incontinence, likely caused by the relatively larger bladder volumes voided at night, which in turn may be related to her greater fluid, caffeine, and alcohol consumption in the evening.

Routine urinary cytology is not helpful, but testing may be of value in women older than 50 years with irritative urinary tract symptoms, particularly if those symptoms are of sudden onset.

Postvoid Residual Volume

Incomplete bladder emptying may cause incontinence. Patients with a large postvoid residual urine volume (PVR) have a diminished functional bladder capacity because of the dead space occupied in the bladder by retained urine. This stagnant pool of urine also is a source of urinary tract infections because the major defense of the bladder against infection is frequent, nearly complete emptying.

A large PVR can contribute to urinary incontinence in two ways. If the bladder is overdistended, increases in intra-abdominal pressure can force urine past the urethral sphincter, causing stress incontinence. In some cases, bladder overdistention may provoke an uninhibited contraction of the detrusor muscle, leading to incontinence. These conditions may coexist, further complicating the problem.

The PVR can be assessed by either direct catheterization or ultrasonography. Although sufficiently accurate for clinical purposes, ultrasonography measurements of PVR have a standard error of 15% to 20%. Thus, assessment of the catheterized volume is preferred (36). It is important to perform this test within 10 minutes of a void to avoid an artificially

P.864

elevated result because of diuresis. It is generally agreed that a PVR level less than 50 mL is normal and greater than 200 mL is abnormal, but there is much debate about values in the midrange. Because many women are unable to void well during an anxiety-ridden first visit, it is helpful to recheck the PVR at a future visit before embarking on further diagnostic tests. The value of assessing bladder emptying in neurologically normal women who do not have pelvic organ prolapse or symptoms of voiding dysfunction has not been demonstrated.

Cough Stress Test

Patients should be examined with a full bladder, particularly if stress incontinence is a consideration. Urine egress from the urethra at the time of a cough documents stress incontinence. If leakage is not observed when the woman is supine, she should stand with her feet separated to shoulder width and cough several times. **Many women with urge incontinence caused by detrusor overactivity may experience urine loss during a cough stress test, but this finding may not be relevant to their real symptom.** The physical findings must be set within the context of the patient's history to be relevant.

Pad Tests

Pad tests are widely used in patient-oriented research as an objective way of assessing treatment effectiveness, but rarely are they used in clinical practice. Pad tests, usually performed in women with a full bladder, quantify the volume of urine lost by weighing a perineal pad

before and after specified activities. Pad tests can be divided into short-term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24–48 hours. Pad tests are generally performed with a symptomatically full bladder or with a certain volume of saline instilled into the bladder before beginning the series of exercises. A pad weight gain of 1 or more grams is considered positive for a 1-hour test, and a pad weight gain greater than 4 grams is positive for a 24-hour test.

Advanced Testing

Urodynamics

At its most basic level, a urodynamic study is anything that provides objective evidence about lower urinary tract function (37). In this sense, measurement of a patient's voided urine volume and catheterization to determine her PVR are urodynamic studies. A frequency/volume chart is also a valuable urodynamic study. **Obtaining clinically valuable information does not always require the use of expensive, complex technology. After basic testing, further testing is recommended in the following circumstances: the diagnosis is uncertain (for example, because of major discrepancies between the history, the voiding diary, and symptom scales); surgery is being considered; or the patient has hematuria in the absence of an infection, an elevated PVR, a neurologic condition that may complicate treatment (such as multiple sclerosis), marked pelvic organ prolapse, or numerous prior surgical attempts at correction.** Current urodynamic definitions are summarized in Table 23.6.

Uroflowmetry

To assess voiding function, urodynamic testing usually begins with uroflowmetry, a study in which the volume of urine voided is plotted over time. Flow time, peak flow rate, and time to peak flow usually increase as the voided volume increases.

Filling Cystometry

Cystometrography (also termed *cystometry*) is done to assess bladder and urethral function during bladder filling. Simple (or single-channel) cystometry is performed

P.865

P.866

when bladder pressure only is measured during filling. Because the bladder is an intra-abdominal organ, the pressure recorded in the bladder is a combination of several other pressures, most notably the pressure created by the activity of the detrusor muscle itself and the pressure exerted on the bladder by the weight of the surrounding intra-abdominal contents (e.g., uterus, intestines, straining, or exertion). For this reason, **the technique of complex (also called multichannel or subtracted) cystometry is generally used to try to approximate the actual pressure exerted in the bladder by the activity of the detrusor muscle alone. The detrusor pressure (P_{det}) is obtained by measuring total intravesical pressure (P_{ves}) with a bladder pressure catheter, approximating intra-abdominal pressure (P_{abd}) with a rectal or vaginal catheter, and then electronically subtracting the latter from the former:**

$$P_{det} = P_{ves} - P_{abd}$$

Measurements can be obtained using electronic microtip transducer pressure catheters, fluid-filled pressure lines, fiberoptic catheters, or air-charged catheters. All are acceptable for clinical use, but it is important to realize that when different types of catheters are used, the correlation between numbers is imperfect. Other technical factors that influence

P.867

cystometry results include the choice of distending medium, filling rate, and patient position.

The steps involved in a multichannel urodynamic study are outlined in Table 23.7.

Normal cystometric values for women are shown in Table 23.8.

Table 23.6 Urodynamic Definitions

I. Bladder sensation	
A. First sensation	First becomes aware of bladder filling
B. First desire to void	Feeling that would lead the person to void at next convenient moment, but voiding can be delayed if necessary
C. Strong desire to void	Persistent desire to void without the fear of leakage
D. Sensation	classified as:
1.	Increased
2.	Reduced
3.	Absent
4.	Nonspecific bladder sensations (other symptoms make person aware of bladder filling, like abdominal fullness)
5.	Bladder pain (is abnormal)
6.	Urgency (sudden compelling desire to void)
II. Detrusor function	
A. Normal	Allows bladder filling with little or no change in pressure; no involuntary phasic contractions
B. Detrusor overactivity	Involuntary detrusor contractions during filling
1.	<i>Phasic</i> Characteristic wave form; may or may not lead to incontinence
2.	<i>Terminal</i> Single involuntary detrusor contractions occurring at cystometric capacity, which cannot be suppressed, and results in incontinence usually resulting in bladder emptying
3.	<i>Detrusor overactivity incontinence</i> Incontinence that is due to an involuntary leakage episode
4.	<i>Neurogenic detrusor overactivity</i> There is a relevant neurologic condition (replaces term <i>detrusor hyperreflexia</i>)
5.	<i>Idiopathic detrusor overactivity</i> No definite cause (replaces term <i>detrusor instability</i>)
C. Bladder compliance	Fill volume/change in detrusor pressure (P_{det})
1.	Calculate at start of bladder filling (usually 0)
2.	At cystometric capacity (excluding any detrusor contraction)
D. Bladder capacity	
1.	<i>Cystometric capacity</i> Volume at end of cystometrogram; capacity is volume voided together with any residual urine
2.	<i>Maximum cystometric capacity</i> Volume at which person feels she can no longer delay voiding

III. Urethral function

A. Normal urethral closure mechanism Maintains a positive urethral closure pressure during bladder filling

B. Incompetent urethral closure mechanism Allows leakage of urine in the absence of a detrusor contraction

C. Urethral relaxation incontinence Leakage that is due to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity

D. Urodynamic stress incontinence Involuntary leakage of urine during increased abdominal pressure, in the absence of detrusor contraction (replaces term *genuine stress incontinence*)

E. Urethral pressure (P_{ura}) Fluid pressure needed to open closed urethra

1. Pressure profile Pressure along length of urethra

2. Urethral closure pressure $P_{ura} - P_{ves}$

3. Maximum urethral closure pressure (MUCP) Maximum difference between P_{ura} and P_{ves}

4. Pressure transmission ratio Increment in urethral pressure on stress as percentage of simultaneously recorded increment in intravesical pressure

F. Abdominal leak point pressure Intravesical pressure at which urine leakage occurs because of increased abdominal pressure

IV. Pressure flow studies

A. Urine flow is defined as

1. Continuous

2. Intermittent

a. Flow rate Volume voided/unit time

b. Voided volume Total volume voided

c. Maximum flow rate

d. Voiding time Includes interruptions

e. Flow time Time over which measurable flow actually occurs

f. Average flow rate Voided volume/flow time

g. Closing pressure Pressure measured at end of measured flow

h. Detrusor function during voiding can be classified as:

1. Normal

2. Detrusor underactivity Contraction of reduced strength resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying

3. Acontractile Cannot be demonstrated to contract

i. Urethral function during voiding can be classified as:

1. Normal Continuously relaxed

2. Dysfunctional voiding Intermittent and/or fluctuating flow rate that is due to involuntary intermittent contractions of the periurethral striated muscle during voiding in neurologically normal people

3. Detrusor sphincter dyssynergia Detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle

4. Nonrelaxing urethral sphincter obstruction Usually occurs in people with a neurologic lesion

Abrams P, Cardozo L, Fall M, et al. The standardization of terminology of lower urinary tract function: report from the Standardization Sub-committee of the International Continence Society. *Neurourol Urodyn* 2002;21: 167–178.

Table 23.7 Steps in Conducting a Multichannel Urodynamic Study

1. **Insert pressure and filling catheter into bladder** (may be two catheters or dual catheter) to measure intravesical pressure and to fill bladder. Insert pressure catheter into upper vagina or rectum to approximate abdominal pressure.
2. **Infuse fluid (usually sterile water or saline, sometimes radiographic contrast dye) at a rate of 50 to 100 mL/min.** Record the volume infused and the pressure measurements continuously. The patient's bladder may be filled with her lying supine, in a modified lithotomy position, sitting, or standing. When possible, do cystometry in the standing position as most patients with incontinence report this problem more when they are erect.
3. **Note the point at which any leakage occurs.**
4. **During filling, record the first desire to void (that is, the feeling that would lead her to void at the next convenient moment, but voiding can be delayed if necessary) and the strong desire to void (that is, the persistent desire to void without the fear of leakage).** The maximum cystometric capacity, in women with normal sensation, is the volume at which the woman can no longer delay micturition; filling should not be continued to the point of pain or severe discomfort.
5. **If no detrusor overactivity is noted during filling, have the patient do provocative maneuvers at maximum capacity, such as coughing, heel-bouncing, and listening to the sound of running water to provoke uninhibited detrusor contractions,** which may be the cause of the patient's symptoms.

An example of detrusor overactivity seen during complex cystometry is shown in Figure 23.5. Surface or needle electromyography may be performed during filling and voiding to assess muscle activity of the urethral sphincter or pelvic floor. Electromyography as generally performed has not been proved useful in neurologically intact women with symptoms of only stress urinary incontinence, and thus is not required in this patient population.

Both false-positive and false-negative results can occur with urodynamic studies.

False-positive results occur in patients with asymptomatic detrusor overactivity, detrusor overactivity that is irrelevant to the symptom, or detrusor overactivity that is situational (e.g., caused by test anxiety). False-negative results can occur with 20-minute cystometrography

P.868

because this test is not always an accurate measure of daily bladder activity. Looking for detrusor instability with such a test is like looking for an episodic cardiac arrhythmia using 12-lead electrocardiography, as opposed to looking for the arrhythmia using a 24-hour Holter monitor. The sensitivity of the latter test is far greater than that of the former. Ambulatory urodynamics can be performed and are more likely to detect detrusor overactivity than office-based studies.

Table 23.8 Approximate Normal Values of Female Bladder Function

- Residual urine <50 mL
- First desire to void occurs between 150 and 250 mL infused
- Strong desire to void does not occur until after 250 mL
- Cystometric capacity between 400 and 600 mL
- Bladder compliance between 20 and 100 mL/cm H₂O measured 60 sec after reaching cystometric capacity
- No uninhibited detrusor contractions during filling, despite provocation
- No stress or urge incontinence demonstrated, despite provocation
- Voiding occurs as a result of a voluntarily initiated and sustained detrusor contraction
- Flow rate during voiding is >15 mL/sec with a detrusor pressure of <50 cm H₂O

From **Wall LL, Norton P, Delancey J.** *Practical urogynecology*. Baltimore, MD: Williams & Wilkins, 1993, with permission.

Figure 23.5 Detrusor overactivity on filling cystometrography. The patient begins to sense urgency, accompanied by an unstable bladder contraction, when 88 mL of water are instilled into the bladder. The detrusor pressure rises, and when 96 mL of water are instilled, she leaks. (P_{abd}, abdominal pressure; P_{ves}, vesical pressure; P_{det}, detrusor pressure)

Tests of Urethral Function

Several tests of urethral function, including urethral pressure profilometry, Valsalva leak-point pressures, and the fluoroscopic and cystoscopic assessment of the bladder neck, have been used to guide therapy in women with stress urinary incontinence. **Women with poor urethral function, evidenced by low Valsalva leak-point pressures, low maximal**

urethral closure pressures, or a visualized open bladder neck (Fig. 23.6), are thought to be at higher risk of treatment failure using standard retropubic urethropexy. Cutoff values for these tests are poorly defined and remain controversial. Although women with stress urinary incontinence have, on average, significantly lower maximal urethral closure pressures than those without incontinence, there is wide overlap in the values between such women, and no lower limit of urethral closure pressure has been established that predisposes women to stress urinary incontinence.

The urethral pressure profile is a test designed to measure urethral closure. Because continence requires the pressure in the urethra to be higher than the pressure in the bladder, it

P.869

was believed that measuring the pressure differential between the two would provide useful clinical information. The urethral pressure profile is determined by slowly pulling a pressure-sensitive catheter through the urethra from the bladder.

Figure 23.6 Open and scarred bladder neck in an elderly woman who has undergone three anterior colporrhaphies for stress urinary incontinence in the past.

The urethral closure pressure (P_{close}) is the difference between the urethral pressure (P_{ure}) and the bladder pressure (P_{ves}): $P_{\text{close}} = P_{\text{ure}} - P_{\text{ves}}$.

Although this pressure can be used to differentiate groups of normal women from groups of those with stress incontinence (women with stress incontinence tend to have higher urethral pressure levels than those who do not), there is considerable overlap between the

two groups. It has also been suggested that women with stress incontinence with low urethral closure pressure (<20 cm H₂O) have a poorer prognosis for surgical outcome than women who do not have this condition; however, this area has been the subject of considerable debate (3,38,39). Because stress incontinence, by definition, occurs during increases in intra-abdominal pressure that are generated by some kind of physical activity, it is not obvious why measurement of resting urethral pressure should be relevant to stress-related leakage, which is a dynamic event. One review concluded that urethral pressure profilometry is not a useful diagnostic test for stress incontinence in women and that its use in clinical management is unsupported by current evidence (40).

Leak-point pressure (LPP) is a urodynamic measure of the minimum intra-abdominal or intravesical pressure required to cause incontinence during abdominal strain or cough. There is no consensus about whether it should be measured from the resting supine baseline (generally near 0) or from the standing resting baseline (which increases

P.870

depending on body mass). Other factors that may affect the results include the catheter's type, caliber, and placement (vaginal, rectal, or intravesical), the bladder volume at which the measurement is obtained, the mechanism by which intra-abdominal pressure is increased (coughing versus straining), and patient position (41).

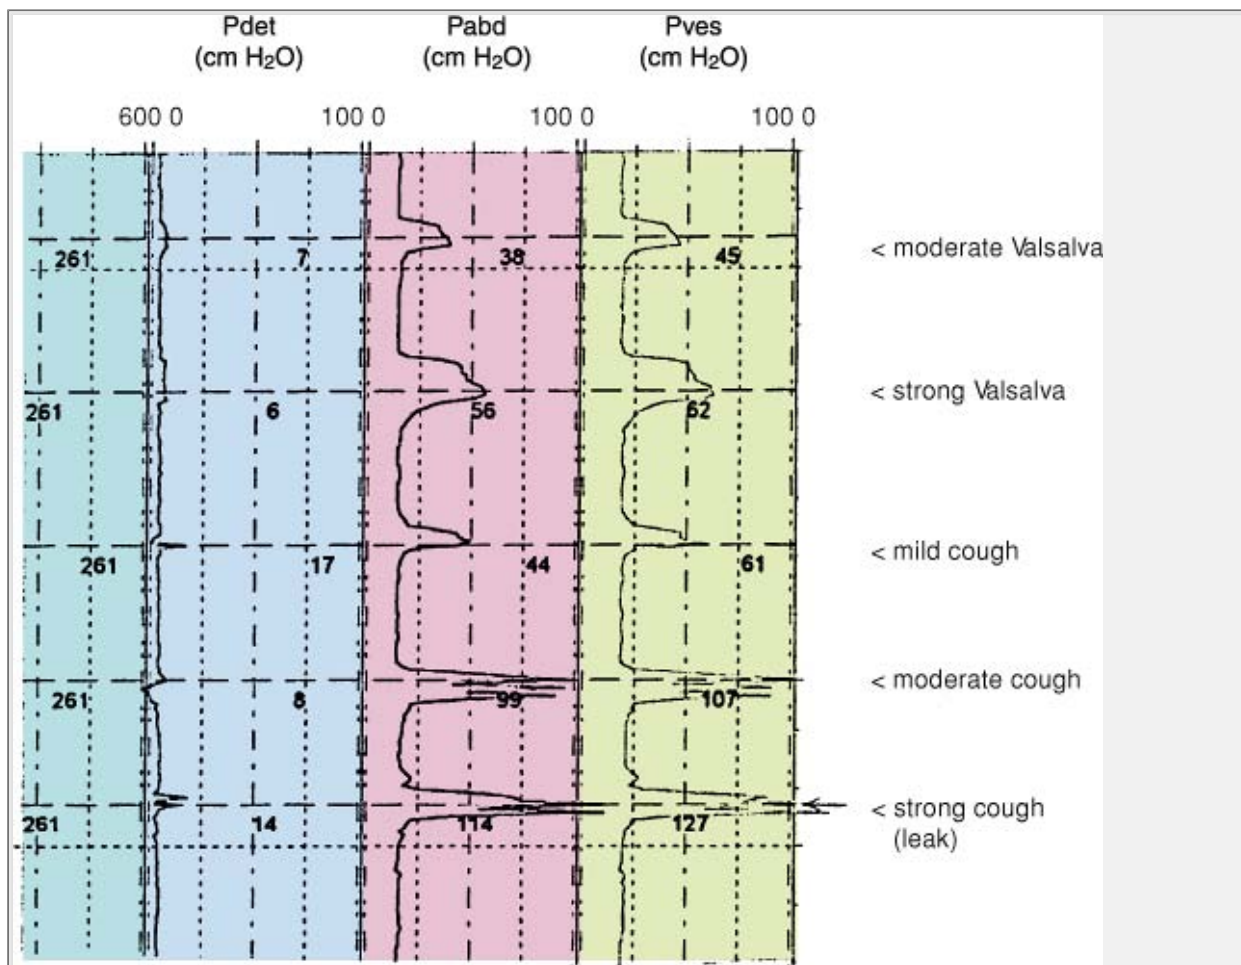

Figure 23.7 Leak point pressure. The abdominal leak point pressure (LPP) is 114 cm H₂O (the abdominal pressure at which the patient leaked urine).

Leak point pressure measurements often are performed at a bladder volume of 200 or 300 mL. Patients are asked to cough with gradually increasing force (cough leak-

point pressure) and finally to strain slowly (Valsalva) to increase intravesical pressure gradually. The lowest pressure at which leakage occurs is recorded as the cough or the Valsalva leak-point pressure (Fig. 23.7). If leakage is not demonstrated, the highest pressure that has been obtained can be recorded with the notation "no leakage" to the specified pressure as measured in cm H₂O. Currently, many clinicians use a cutoff point of 60 cm water pressure to separate women who have intrinsic sphincter deficiency from those who do not. This is problematic for two reasons: (i) the marked variability of results that depend on all the aforementioned factors, and (ii) the lack of prospective studies that demonstrate the predictive value of leak point pressure values on surgical outcomes. Results from this and other urodynamics tests must be evaluated as one piece of the patient's puzzle, along with the history, physical examination, voiding diary and other tests. Current Medicare guidelines require that when bulking agents, such as collagen, are considered to treat stress incontinence, the intra-abdominal leak point pressure when the bladder has been filled with at least 150 mL of fluid must be less than 100 cm H₂O.

Fluoroscopy and cystourethroscopy have both been used to visualize the bladder neck because many clinicians and investigators believe that a closed bladder neck is important in maintaining continence. However, studies of continent women reveal that many individuals with normal urethral function show evidence of bladder neck opening with physical stress

P.871

(42). Neither test is recommended in the routine evaluation of women with straightforward incontinence.

Figure 23.8 Voiding cystometrogram. This patient voids in an uninterrupted flow pattern by means of a prolonged bladder contraction. She does not strain to void, with the exception of minimal straining toward the end of the flow.

Voiding Cystometrography

Urodynamic testing usually concludes with an instrumented voiding study (also known as a pressure–flow study or voiding cystometrography), in which the vesical, abdominal, and urethral pressures are measured simultaneously during bladder emptying (Fig. 23.8). Various studies have identified Valsalva voiding, low preoperative flow rate, and high preoperative detrusor pressures during voiding as risk factors for postoperative voiding dysfunction; however, findings often are contradictory.

Imaging Tests

The role of imaging techniques in studying female urinary incontinence has not yet been established. Researchers are evaluating the potential roles of ultrasonography, fluoroscopy, functional neuroimaging, and magnetic resonance imaging (MRI). These tests should not be done routinely but are useful in certain conditions. If the patient's symptoms (easily remembered by the 3 Ds: dysuria, dribbling, and dyspareunia) or examination suggest a urethral diverticulum, MRI is the test of choice (43).

Neurophysiologic Tests

The neuromuscular function of the pelvic floor is dependent on the integrity of the nervous system. Injury can theoretically occur anywhere along these nerves, from the cell

P.872

body located in Onuf's nucleus in the ventral part of the spinal cord, along its axon, to the neuromuscular junction. Pelvic floor neurophysiology utilizes techniques applied to nerves and skeletal muscles elsewhere in the body to document neuromuscular integrity or evidence of injury. Currently, these tests are not routinely used in the clinical evaluation of most incontinent women.

Pudendal Nerve Terminal Motor Latency

The pudendal nerve terminal motor latency (PNTML) indirectly assesses the integrity and patency of the terminal portion of the pudendal nerve, its neuromuscular junction, and the muscle it serves. Using a specialized electrode affixed over the index finger, the pudendal nerve is electrically stimulated near the ischial spine (either transrectally or transvaginally), and the resulting muscular response is measured. The response, termed a *compound muscle action potential (CMAP)*, is detected at the anal sphincter. The interval between the stimulation and the onset of the CMAP is measured. A prolonged latency is noted with injury to large and heavily myelinated axons. The latency time may be within the normal range when only smaller nerve fibers have been affected; thus, neurological dysfunction may exist in the presence of a normal latency time.

Sacral Reflexes

Only the distal efferent arm of the pudendal nerve is analyzed in the PNTML. Similar to the clinically obtained anal wink or bulbocavernosus reflex, electrically induced sacral reflexes can

gather information about both the afferent and efferent arc in the pelvic nerves. A short train of dual impulses delivered next to the clitoris and measured at the anal sphincter is termed the clitoroanal reflex and provides information about the integrity of the afferent and efferent arm of the somatic pudendal nerve. A stimulating electrode placed in the bladder sends these signals along the visceral, autonomic fibers to the spinal cord, and a reflex signal will return along the pudendal nerve to the anal sphincter.

Somatosensory Evoked Potentials

Normal pelvic floor and pelvic organ function ultimately is controlled by higher centers in the central nervous system, including the cerebral cortex. Recording electrodes located on the scalp near the motor cortex allow the signal transmission speed between a skeletal muscle and the brain to be measured. Repeated electrical stimuli, called *somatosensory evoked potentials*, at a muscle of interest are used to assess the integrity of the central afferent limb. In a reverse fashion, electrical or magnetically induced stimuli can be delivered at the motor cortex (or along the spine), and the induced muscle action potentials can be detected. Prolonged latencies not attributable to the peripherally studied nerves (such as with a PNTML or sacral reflex) are evidence of a central nervous system conduction flaw.

Electromyography

Electromyography (EMG) assesses the inherent electrical potentials generated during neuronal activation of skeletal muscle. It can be performed using surface electrodes or needle electrodes. Surface EMG measures the summation of muscle activity in the general area of the applied electrode. It is best used for simply describing the pattern and coordination of muscle activity, but is less useful in providing more specific assessments. Needle EMG of the pelvic floor can "map" the anatomic location of muscles but has largely been replaced by ultrasonography. The major value of needle EMG is its ability to assess nerve injury and determine whether the injury is acute and ongoing or chronic. Single-fiber EMG can quantify the ratio of muscle fibers to nerve fibers (the so-called fiber density). An increase in fiber density is evidence of previous nerve injury with successful reinnervation. Concentric needle EMG is more widely available and allows for further neurophysiologic evaluation. Abnormal electrical activity associated with acute injury may be seen, and

P.873

motor unit action potentials (MUAPs) can be assessed and quantified. Following nerve injury and reinnervation, MUAP parameters—such as duration, amplitude, number of phases, and turns—are typically larger. Finally, the ability of a muscle to increase the firing frequency of motor neurons and the ability to recruit more motor neurons can also be assessed using this needle.

Nonsurgical Treatment

Treatment of urinary incontinence can be either nonsurgical or surgical. The approach to treatment is based on the clinical findings and the degree of discomfort experienced by the patient, who should be fully informed of the risks and expected outcome.

Lifestyle Changes

Lifestyle interventions can decrease stress urinary incontinence in many women (44). Weight loss in both morbidly and moderately obese women decreases leakage, and ways to incorporate this intervention in a management plan are being investigated. Postural changes (such as crossing the legs during periods of increased intra-abdominal pressure) often prevent stress urinary incontinence. There is some evidence that decreasing caffeine

intake improves continence; however, fluid intake in general seems to play a minor role in the pathogenesis of incontinence. Although smokers are at greater risk for incontinence, no data have been reported on whether smoking cessation resolves incontinence.

Physical Therapy

Medical evidence from well-designed randomized clinical trials shows that supervised pelvic floor muscle training (Kegel exercises) is an effective treatment for stress urinary incontinence.

The Cochrane Incontinence Group concluded that pelvic floor muscle training is consistently better than no treatment or placebo treatment for stress incontinence and should be offered as first-line conservative management to women. Intensive training sessions that include personal contact with a health care professional to teach and supervise pelvic floor muscle training may be more beneficial than standard care.

Biofeedback provides no added benefit over pelvic floor muscle training alone in women with stress urinary incontinence (45).

Several factors improve the likelihood that pelvic muscle training will relieve stress urinary incontinence. The woman must do the exercises correctly, regularly, and for an adequate duration. Based on exercise training of skeletal muscles elsewhere in the body, many physical therapists recommend training sessions three to four times per week, with three repetitions of eight to ten sustained contractions each time.

Electrical stimulation therapy has been used to treat incontinence by delivering low levels of current via a probe placed in the vagina or rectum. When compared with sham devices and pelvic floor exercises, electrostimulation has produced mixed results in the treatment of stress urinary incontinence (46,47) but may be more helpful in women with overactive bladders (48,49). Further research is needed to determine what niche this treatment may fill for women with urinary incontinence.

Behavioral Therapy and Bladder Training

Bladder training focuses on modifying bladder function by changing voiding habits. Behavioral therapy focuses on improving voluntary control rather than bladder function (50). The key component to bladder training is a scheduled toileting program. After reviewing the patient's voiding diary, an initial voiding interval is chosen that represents the longest interval between voiding that is comfortable. She is then instructed to empty her bladder when she awakes, and then every time during the day that the interval is reached (for example, every 30 to 60 minutes). When patients feel the urge to void during that interval, they are instructed to use urge-suppression strategies, such as distraction or

P.874

relaxation techniques, until they get to the stated interval. Effective distraction strategies include mental exercises (such as mathematical problems), deep breathing, or "singing" the words to a song silently. The main goal is to avoid running to the bathroom at the moment of severe urgency. Another strategy is to quickly contract the pelvic muscle several times in a row ("freeze and squeeze"), which often lessens urgency. Gradually, the interval is increased (usually weekly), until the patient voids every 2 to 3 hours. Bladder training is most effective when women record every void and check in (by telephone or in person) with a health care provider weekly. Generally this program lasts for about 6 weeks. Bladder training is effective; in a trial in which bladder training was compared with treatment with *oxybutynin*, 73% of women in the bladder training group were clinically cured (51).

The primary technique of behavioral training is pelvic floor muscle training, as

described previously, but with a focus on urge inhibition. Mastering voluntary pelvic floor muscle contractions helps to strengthen the outlet (decreasing leakage) and inhibit detrusor contractions. Other components of therapy may include voiding schedules, urge-inhibitions strategies, and fluid management.

Patients with neurogenic detrusor overactivity, rather than idiopathic detrusor overactivity, do not respond as well to behavioral therapy because the problem is actually one of neural pathway destruction rather than the need to re-establish cortical control mechanisms. Frequently, these patients have a trigger volume of urine that sets off a contraction that they cannot control voluntarily. They may benefit from a timed schedule in which they void at regular intervals (such as every 2 hours) to keep their bladder volume below the trigger point. Attempting to lengthen the interval between voids does not often work well.

Less-intensive treatments also decrease incontinence episodes. In a randomized trial, a simple self-help booklet was only somewhat less effective in reducing leakage (mean reduction in leakage episodes 43%) than behavioral training (mean reduction 69%) or behavioral training plus electrical stimulation (mean reduction 72%) (52).

Vaginal and Urethral Devices

Vaginal devices (pessaries) and urethral inserts are available for treating stress urinary incontinence. There are no long-term randomized trials comparing devices and other treatments, but devices appear to be an acceptable treatment for some women. In a tertiary care population, approximately two thirds of women with stress urinary incontinence offered a trial of vaginal devices chose to undergo pessary fitting (53). Most (89%) achieved a successful fit. Of those that took a pessary home to manage their stress urinary incontinence, approximately one half used it for more than 6 months. Women who stopped using the pessary generally did so within the first month. Some women are pleased to be able to avoid surgery, or to use a "crutch" while waiting for the effect of pelvic muscle training; others prefer a treatment option (like surgery) that doesn't require daily intervention. Examples of some vaginal devices are shown in Figure 23.9.

Urethral inserts are sterile inserts placed into the urethra by the patient and removed before a void, after which a new sterile insert is reinserted. Such inserts are appropriate for women with relatively pure stress incontinence, no history of recurrent urinary tract infections, and no serious contraindications to bacteriuria (e.g., artificial heart valves).

Devices that were once marketed in the United States and may be available again include a single-use triangularly shaped foam device with an adhesive hydrogel (54) that adheres to the perimeatal area to keep urine from exiting the urethral meatus, and a hat-shaped silicone patch (55) that adheres by applying an adhesive gel to the edge of the device, squeezing the central dome, and creating a vacuum. The patch can be reapplied after voids and reused for up to 1 week.

P.875

Medications

Stress Incontinence

The tone of the urethra and bladder neck is maintained in large part by α -adrenergic activity from the sympathetic nervous system. For this reason, many pharmacologic agents have been used with varying degrees of success to treat stress incontinence. These drugs include *imipramine* (which has a concomitant relaxing effect on the detrusor), *ephedrine*, *pseudoephedrine*, *phenylpropanolamine*, and *norepinephrine*. Unfortunately, many of these compounds also increase vascular tone and may, therefore, lead to problems with hypertension, a condition that afflicts many postmenopausal women with stress incontinence. These effects may preclude the use of α -agonists in such patients. A recent U.S. Food and Drug Administration (FDA) statement urged caution in the use of *phenylpropanolamine*, an α -agonist, in women because of an apparent increased epidemiologic risk for hemorrhagic cerebral vascular accidents. Although the risk remains very low, it is not possible to predict who is at risk for this complication (56). The use of these agents in the treatment of stress urinary incontinence appears to be more limited than originally thought (57).

Based on a biologic rationale, it was thought that estrogen could effectively treat

urinary incontinence given the presence of estrogen receptors in the bladder, urethra, and levator muscles. In early uncontrolled case series, women using various estrogen preparations experienced less incontinence. However, more recently, in several large randomized trials,

women assigned to receive estrogen and progesterone not only did not have less leakage, but in fact were more likely to experience the onset of incontinence or worsening of baseline symptoms (58). In 23,296 women enrolled in the Women's Health Initiative double-blind, placebo-controlled, randomized clinical trial, use of menopausal hormone therapy (*conjugated estrogen* alone in women with a prior hysterectomy, *conjugated estrogen* and *medroxyprogesterone acetate* in women with a uterus) increased the incidence of all types of urinary incontinence at 1 year among women who were continent at baseline (59). Among women who reported urinary incontinence at baseline, both frequency and severity of incontinence worsened at 1 year in women taking either hormone preparation compared with those in the placebo group. Thus, **conjugated estrogen with or without progestin should not be prescribed for the prevention or relief of urinary incontinence.**

Serotonin and norepinephrine reuptake inhibitors (SSRIs) are being investigated for their role in treating stress urinary incontinence but currently are not available for this indication. In a multicenter, double-blind, placebo-controlled randomized trial, there was an 18% to 23% net difference in the percent reduction in incontinence episode frequency comparing *duloxetine chloride* 40 mg/day (59% reduction) and 80 mg/day (64% reduction) with placebo (40% reduction) after a 12-week treatment period (60). Other investigators have also found a high response rate in women assigned to placebo. This is partly due to the intensity of research protocols (which require paying more attention to one's bladder than usual) but also speaks to the potential therapeutic role of simply completing the voiding diary.

Urge Incontinence and Overactive Bladder

The drugs used for treating detrusor overactivity can be grouped into different categories according to their pharmacologic characteristics; however, for all practical purposes, **these drugs are anticholinergic agents that exert their effects on the bladder by blocking the activity of acetylcholine at muscarinic receptor sites.** All of these drugs have side effects, the most common of which are dry mouth resulting from decreased saliva production, increased heart rate because of vagal blockade, feelings of constipation resulting from decreased gastrointestinal motility, and occasionally, blurred vision caused by blockade of the sphincter of the iris and the ciliary muscle of the lens of the eye. Other drugs, such as *imipramine*, may produce orthostatic hypotension and cardiac arrhythmias.

Current medications commonly used to treat these conditions are listed in Table 23.9. The introduction of several new drugs for overactive bladder has resulted in significant attention being given to urinary incontinence in the media (61,62,63,64,65,66,67,68).

The newer drugs have some advantages over *oxybutynin*, which has been available for decades. These advantages include once- (or sometimes twice-) daily dosing, rather than three to four times per day and, to some degree, a less severe side-effect profile. The latter is due to changes in the delivery system and to more selectivity of muscarinic receptors (so that, for example, the bladder may be targeted more than the salivary glands). In addition, quaternary amines (such as trospium chloride) are not distributed into the central nervous system because of their large molecular size and hydrophilicity. The primary disadvantage of the newer agents is cost. Head-to-head trials of many of these newer drugs (sponsored by the drug manufacturers) have been carried out and generally show favorable results for the newer preparations with respect to the comparison drugs. **In general, in these large**

randomized trials, the drug reduces incontinence episodes by 50% to 70%, whereas placebo reduces incontinence episodes by 40% to 60%. Clinicians must carefully assess whether statistically significant changes in incontinence episodes or frequency translate into clinically significant ones. **A review of one newly**

P.877

released agent concluded that, "None of these drugs are as effective as advertisements to the public have suggested" (69).

Table 23.9 Commonly Used Medications for Urge Incontinence	
Drug	Oral Dose Range
Generic and Brand Names	
Oxybutynin	
<i>Ditropan</i> ^a	2.5–5 mg tid–qid
<i>Ditropan syrup</i>	1 tsp (5 mg)
<i>Ditropan XL</i> ^b	5, 10, or 15 mg qd
<i>Oxytrol patch</i> ^c	1 patch 2 times per week
Hyoscyamine	
<i>Levsin</i> ^d	0.125–0.25 mg qid
<i>Levbid, Levsinex</i>	1 tab bid
<i>Levsin elixir</i>	1 tsp (0.25 mg qid)
<i>Levsin/SL</i>	sublingual pill
<i>Cystospaz</i> ^e	0.15–0.3 mg qid
<i>Cystospaz-M</i>	1 tab bid
Dicyclomine	
<i>Bentyl</i> ^a	20 mg qid
Probantheline	
<i>ProBanthine</i> ^f	15–30 mg qid
Tolteridene	
<i>Detrol</i>	1–2 mg bid (immediate release)
<i>Detrol LA</i> ^g	4 mg qd (extended release)
Tropium chloride ^h	
<i>Sanctura</i>	20 mg bid
Solifenacin succinate ⁱ	
<i>Vesicare</i>	5–20 mg qd (one daily dose; usual dosing is 5–10 mg qd)

tid, three times a day; qid, four times a day; qd, every day; bid, twice a day.

When initiating therapy with generic oxybutynin, it is best to start with a lower dose (particularly for elderly patients) and increase it as needed to a higher, more frequent dosage. Patients should be encouraged to titrate their medication to their symptoms and to vary the dosage (within acceptable limits) according to their needs. If this is not effective, the next step is to move to one of the other anticholinergic agents. Some women may respond better to one agent than another. A 2-week trial is sufficient to determine effectiveness. It is helpful to ask patients to record daily episodes of incontinence or urgency before and during therapy so effectiveness can be more accurately determined.

Patients should be warned of the side effects of anticholinergic agents. Patients should be particularly advised about the symptom of a dry mouth and told that this is not due to thirst. Some patients increase their fluid intake to combat this problem, with a subsequent worsening of their incontinence. If dry mouth is a problem, patients should relieve it by chewing gum, sucking on a piece of hard candy, or eating a piece of moist fruit.

Nocturia and Nocturnal Enuresis

Medications that treat nocturia and nocturnal enuresis generally have one of three aims: to reduce urine output, to increase bladder capacity and reduce unstable bladder contractions, and to act centrally on sleep and micturition centers.

An analog of arginine vasopressin, DDAVP, has been used extensively to treat children with nocturnal enuresis. Some studies suggest that it may also be useful in adults (70,71). It is available both as a nasal spray and as an oral preparation. When taken orally, the dose required is approximately 10 times greater because of the increased availability of the nasal preparation. Complications associated with the DDAVP include hyponatremia, particularly in patients with excessive fluid intake; therefore, it is essential in higher-risk patients to measure serum sodium levels periodically.

There are few clinical trials that specifically investigate the use of anticholinergic medications to treat nocturia or nocturnal enuresis. Anecdotal evidence supports a trial of a long-acting or extended-release form of an anticholinergic, taken approximately 1 hour before bedtime.

The most extensively studied medications for the treatment of nocturnal enuresis are tricyclic antidepressants, particularly imipramine. These agents may work by altering sleep mechanism, by providing anticholinergic or antidepressant effects, or by affecting antidiuretic hormone excretion. The typical starting dose of *imipramine* is 25 mg at bedtime, which may be increased to as high as 75 mg. In the elderly, *imipramine* should be used cautiously because it increases the risk of hip fracture, presumably related to the potential side effect of orthostatic hypertension (72).

In a randomized, placebo-controlled study comparing nighttime doses of placebo and 1 mg of *bumetanide* (a loop diuretic), *bumetanide* decreased nocturia episodes by 25% compared with placebo (73). Patients who produce half of their total urine at night often benefit from the use of a diuretic (e.g., 20 mg *furosemide*) in the late afternoon to move fluid through the system and decrease their nighttime urine production.

Surgical Treatment for Stress Incontinence

In a systematic review of 943 citations, only 76 (11 randomized trials, 20 prospective cohort studies, and 45 retrospective cohort studies) met minimum criteria that the investigators set for reporting results of surgical trials or series (74). The median follow-up interval was short: 1 year for prospective studies and 2 years for retrospective studies. None of the studies at that time described quality-of-life considerations, and few studies obtained the patient's perception on outcome in a standardized fashion. Of the 31 prospective studies, 28 were single center, and 29 were limited to teaching hospitals. As a result, the ability to generalize the findings was questionable. Although current studies generally do include instruments for measuring the impact of the surgery on the patient's quality of life, most published studies continue to represent the short-term experience of surgeons from one site.

In 1997, the American Urological Association convened a clinical guidelines panel to analyze published outcomes data on surgical procedures to treat female stress urinary incontinence and to produce practice recommendations to guide surgical decision-making (56,75). **The panel concluded that colposuspensions (e.g., Burch, Marshall-Marchetti-Krantz [MMK]) and slings were more effective than transvaginal needle suspensions or anterior repairs for long-term success (48 month cure/dry rates). The median probability estimates for cure/dry rates at 48 months and longer were 84% (95% CI, 79%–88%) for colposuspensions and 83% (95% CI, 75%–88%) for sling procedures, compared with 67% (95% CI, 53%–79%) for transvaginal needle suspensions and 61% (95% CI, 47%–72%) for anterior repairs.**

Historical Perspective

Anterior vaginal repair (also termed *anterior colporrhaphy*) was described by Howard Kelly in 1914, and this operation remained the standard first approach to stress incontinence until the middle of the twentieth century (76). Many different operations have been lumped together under the term *anterior colporrhaphy*, including simple plication of the bladder neck, elevation of the bladder neck by plicating the fascia under the urethra, and elevation and fixation of the bladder neck by passing sutures lateral to the urethra and driving the needles anteriorly into the back of the pubic symphysis for fixation. As noted previously, the problem with most techniques of anterior colporrhaphy is that they do not hold up well over time (77,78,79). In essence, this operation attempts to take weak support from below and to push it back up from below, with hope that these structures will maintain their strength and position over time. Although there have been excellent long-term results shown with anterior colporrhaphy, most of these cases involve specific techniques requiring skillful dissection of the endopelvic fascia, deep bold bites of suture, and fixation of permanent sutures to the pubic bone from below: in essence, a transvaginal retropubic bladder neck suspension (80,81). Most surgical series that have evaluated techniques of anterior colporrhaphy for stress incontinence show long-term success rates of only 35% to 65%, a figure that most would regard as unacceptably low. **Anterior colporrhaphy should be reserved primarily for patients requiring cystocele repair who do not have significant stress incontinence.**

Needle suspension procedures are so named because they suspend the urethra and bladder neck through a technique that involves passage of sutures between the vagina and anterior abdominal wall using a specially designed long needle carrier. To perform these operations, a vaginal incision is typically made at the level of the bladder neck, the endopelvic fascia is perforated, the space of Retzius is entered from below, and a permanent suture is passed down through a low abdominal incision through the retropubic space, where it is fixed to the endopelvic fascia at the level of the bladder neck. The long needle is then passed back up through the retropubic space to the abdominal incision, where it is tied in place. The first needle suspensions were performed by a gynecologist, Dr. Armand Pereyra, in the 1950s, but many urologic surgeons have since modified the technique (82,83,84,85,86,87). These procedures are relatively simple and take less time to perform than open procedures, but this advantage is offset by the fact that they are not as effective in curing stress incontinence. **Although initial cure rates are between 70% to 90%, rates decrease significantly over time in many series, with 5-year success rates of 50% or less (88,89,90,91,92,93). Therefore, these operations are also falling out of favor.**

Retropubic Urethropexy (Colposuspension)

The modern era of retropubic surgery for stress incontinence began in 1949, when

Marshall, Marchetti, and Krantz described their technique for urethral suspension in a man with post prostatectomy incontinence (94). Since that time, a variety of modifications of this operation have been described, all of which share at least two characteristics: They are performed through an open low abdominal incision or with laparoscopically assisted exposure of the space of Retzius, and they all involve attachment of the periurethral or perivesical endopelvic fascia to some other supporting structure in the anterior pelvis (Fig 23.10). In the MMK operation, the periurethral fascia is attached to the back of the pubic symphysis. Another approach, the Burch colposuspension, involves the attachment of the fascia at the level of the bladder neck to the iliopectineal ligament (Cooper's ligament) (95,96). With the paravaginal repair, the lateral endopelvic fascia along the urethra and bladder is reattached to the arcus tendineus fascia pelvis (97,98). In the Turner–Warwick vagino–obturator shelf procedure, the endopelvic fascia, vagina, or both are attached to the fascia of the obturator internus muscle (99,100). All of these operations aim to correct anatomic hypermobility of the urethra and bladder neck. **The long-term success rate for patients undergoing these operations as primary procedures for stress incontinence is in the range of 70% to 90% (88,101,102,103,104).**

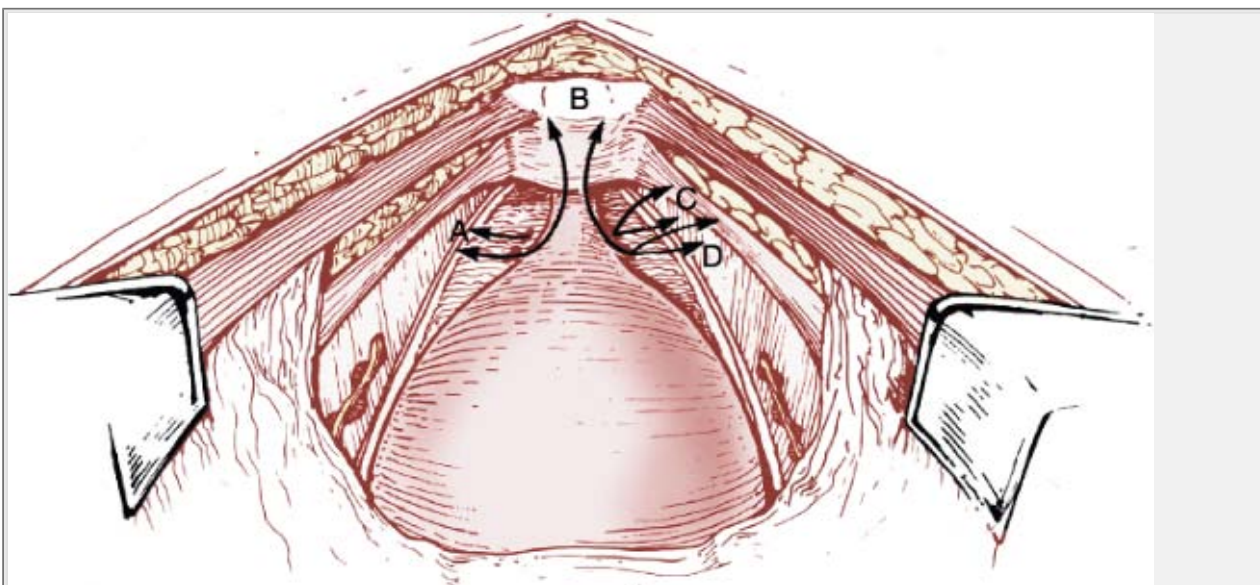

Figure 23.10 Points of reattachment of the endopelvic fascia during retropubic bladder neck suspensions. **A:** Arcus tendineus fascia pelvis (for paravaginal repair). **B:** Periosteum of pubic symphysis (for Marshall–Marchetti–Krantz procedure). **C:** Iliopectineal, or Cooper's, ligament (for Burch colposuspension). **D:** Obturator internus fascia (also used for paravaginal, or obturator shelf, repair).

In 1991, Vancaille introduced the laparoscopic colposuspension to meet the growing demand for a minimally invasive surgical approach to stress urinary incontinence. In a summary of randomized comparisons between laparoscopic and open colposuspensions, the Cochrane Incontinence Group concluded that laparoscopic colposuspension may have short-term benefits, such as quicker recovery, but may have more complications and be more costly because it takes longer to perform than other surgical procedures for stress urinary incontinence. The long-term success of laparoscopic colposuspension is unclear, but there is limited evidence to suggest the results are less favorable than with open colposuspension, although this may reflect a learning effect and is unreliable in isolation (105).

Traditional Pubovaginal Sling

Sling operations have traditionally been performed using a combined vaginal and abdominal approach (Fig. 23.11). The anterior vagina is opened, the space of Retzius is dissected on each side of the bladder neck, and a sling is passed around the bladder neck and urethra and then attached to the anterior rectus fascia or some other structure to cradle the urethra in a supporting hammock. This both supports the urethra and allows it to be compressed during periods of increased intra-abdominal pressure (106,107,108,109,110,111,112,113,114,115,116). The sling can be made of organic or inorganic materials. Organic materials can be autologous tissues harvested from the patient (e.g., fascia lata, rectus fascia, tendon, round ligament, rectus muscle, vagina), processed allografts from human donors (e.g., fascia lata, dermis), or heterologous tissues harvested from another species and processed for surgical use (e.g., ox dura mater, porcine dermis). Synthetic materials (e.g., Silastic, Gore-Tex, Marlex) are popular because of their consistent strength and availability, but historically these substances have been plagued by problems with erosion and infection when used around the urethra (75,117,118).

Minimally Invasive Sling

In the 1990s, various orthopedic bone anchors were marketed to implant into the pubic bone to suspend the urethra with sutures or slings. Despite a lack of medical evidence to support either the bone anchor or the allograft use, bone anchor systems became the quick and minimally invasive method to suspend allograft slings (119). Although bone anchors have not been shown to be superior to standard fixation techniques, their use has led to increased complications in several series.

Figure 23.11 A completed traditional suburethral sling procedure with the fascia located at the bladder neck with the ends of the sling tied to or above the rectus fascia. The classic procedure uses autologous fascia; however, some surgeons use allograft or xenograft tissue performed in a similar fashion. Redrawn from original by Jasmine Tan.

P.881

In 1996, Falconer et al. described the tension-free vaginal tape (TVT) for correcting stress urinary incontinence (120). In this technique, polypropylene mesh is placed under the midurethra with minimal tension (Fig. 23.12, A and B). To perform this operation, a small midurethral incision is made in the vaginal epithelium mucosa. A 40 × 1-cm mesh tape covered by a plastic sheath and attached to two 5-mm curved trocars is passed lateral to the urethra and through the endopelvic fascia into the retropubic space. The trocar is then passed along the back of the pubic bone, through the rectus fascia, into two small suprapubic skin incisions. The tension on the tape is adjusted, the sheath is removed, and the remaining tape is cut off at the level of the skin. This technique has the advantage of being performed quickly using limited anesthesia (fewer than 30 minutes in experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

Since its introduction, there have been scores of articles published suggesting that TVT is generally effective and safe and similar in effectiveness to colposuspension. Larger, multicenter trials provide the most realistic look at outcomes of a surgical procedure by many surgeons with varying experience on a wide array of patients. **A report of the 2-year follow-up of 344 women with urodynamic stress incontinence enrolled from 14 centers in a multicenter randomized clinical trial compared TVT and open Burch colposuspension. The objective cure rates (defined as a negative 1-hour pad test) ranged from 63% to 85% for the TVT procedure and 51% to 87% for open colposuspension, depending on how missing data were handled, leading the authors to conclude that "TVT may be better, worse, or the same as open colposuspension in the**

P.882

cure of stress incontinence." Subjectively, only 43% of women in the TVT group and 37% of women in the open colposuspension group reported cure of their stress leakage. Women undergoing the TVT were more likely to have a cystocele after surgery, whereas those undergoing the Burch colposuspension were more likely to have apical prolapse. Two years after the index procedure, seven women (4.8%) in the Burch colposuspension group underwent surgery for pelvic organ prolapse, compared with no women in the TVT group. There was no difference in the number of women that underwent repeat surgery for stress incontinence (1.8% in the TVT group and 3.4% in the Burch group). Women who underwent TVT were less likely to have voiding disorders requiring intermittent self-catheterization than those who underwent colposuspension (0% vs. 2.7%) (121).

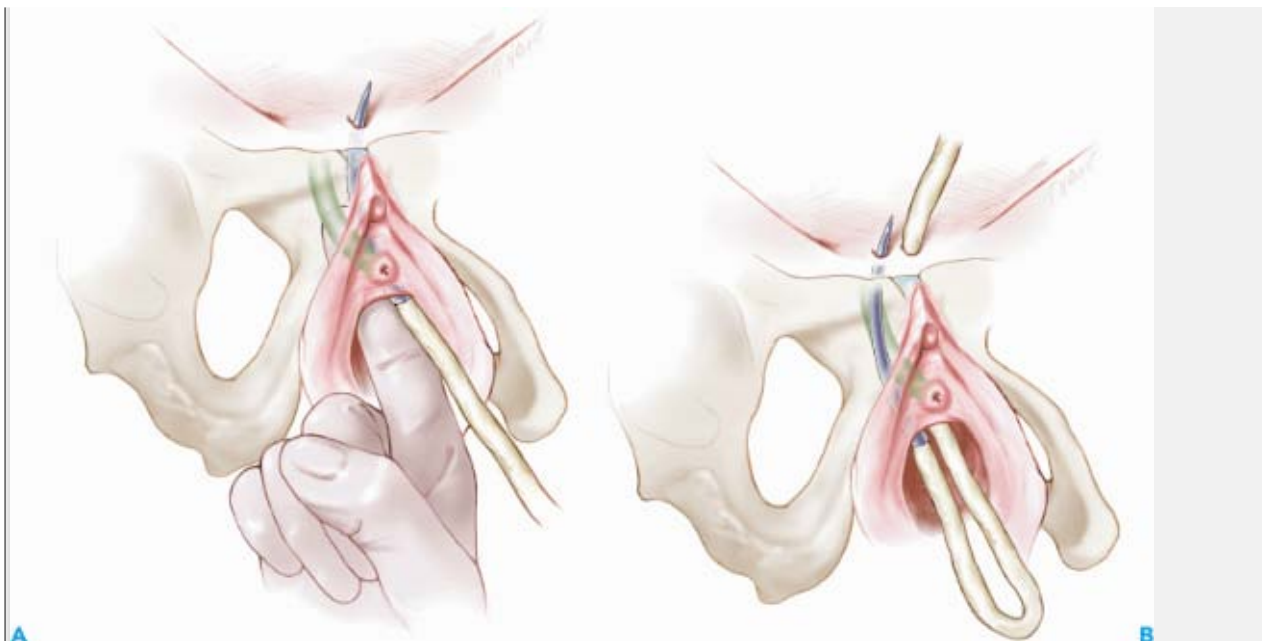

Figure 23.12 Midurethral synthetic slings involve the use of large pore, monofilament polypropylene mesh placed after minimal dissection at the midurethra followed by placement of a trocar through the retropubic route. Some surgeons prefer placing the trocar by a suprapubic route beginning with a small abdominal incision. A: The trocar is guided into the previously performed midurethral incision with care to place the trocar against the pubic bone to avoid entry into the peritoneal cavity. The trocar handle has been removed in this view after perforation through the abdominal incision. B: The synthetic sling should rest in the midurethra location and is brought through two stab incisions above the pubic symphysis. Redrawn from original by Jasmine Tan.

Over the past 5 years, numerous modifications of the TVT have been proposed and marketed. Such devices generally circumvent the stringent regulatory control provided by the U.S. FDA by gaining approval through a Premarket Notification 510(k). This mechanism is a submission to the FDA demonstrating that a new device is substantially equivalent either to a legally marketed or "predicate" device introduced before 1976 in the United States or to one approved by the FDA through the 510(k) process itself. Substantial equivalence means the new device has the same intended use as the "predicate" device *and* has the same technological characteristics *or* different technological characteristics, but it is as safe and effective as the "predicate" device. **Surgeons should be aware that most new devices for urinary incontinence are not tested in clinical trials before they are marketed.**

One modification gaining favor is the transobturator tape procedure (also known as a TOT, transobturator suburethral tape, subfascial hammock, and TOMUS—transobturator

midurethral sling). This modification was designed to reduce complications associated with retropubic needle passage. Inserting the trocar through the obturator space theoretically lessens the risk of bladder, bowel, or vascular injury because the procedure involves passing the polypropylene midurethral sling through the obturator membrane along its ischioanal fossa path, bypassing the pelvic cavity altogether.

Currently, data on this technique are limited. One report showed no bladder perforations in the first 71 transobturator tape procedures performed and, in 68 patients examined 6 to 12 weeks postoperatively, 64 were cured and 2 improved (122). Another report indicated a 90.6% cure rate in 32 patients who were followed for a minimum of 1 year. Five patients had voiding disorders suggestive of bladder outflow obstruction, but only one required self-catheterization for 1 month. No problems with urethral erosion, residual pain, or

functional impairment were reported (123). In a multicenter trial, 183 women from seven sites underwent a transobturator tape procedure for stress and mixed urinary incontinence. At one year follow up 80.5% patients were cured. (defined as absence of subjective report of stress urine leakage and negative cough stress test). Perioperative complications included one bladder perforation, two urethral perforations, and one lateral vaginal perforation. Tape erosion necessitating removal occurred in five cases (three vaginal and two urethral). Cystoscopy was not routinely performed (124).

Bulking Agents

Injectable (so-called bulking) agents are less invasive than surgery, and although they are less likely to result in cure than surgery, they relieve symptoms in many women. In the United States, glutaraldehyde cross-linked bovine collagen (*Contigen*) and carbon beads (*Durasphere*) are approved for use to treat stress urinary incontinence and can be injected either peri- or transurethrally. Injecting a material around the periurethral tissues facilitates coaptation of the urethra under conditions of increased intra-abdominal pressure (125,126,127,128,129,130). In a 15-article review, the short-term cure or improvement rate was 75% (131). *Contigen* can be passed easily through small-bore needles under local anesthesia but requires preoperative skin testing to check for possible allergic reactions (3%). *Durasphere* is nonantigenic (thus no skin testing is required) and does not migrate. As compared with collagen, *Durasphere* appears to have similar reduction in leakage episodes and is more likely to require only a single injection (132). This bulking agent does require a larger-gauge needle for injection and is somewhat more difficult to inject than collagen. These techniques may require several injections to achieve continence, and the long-term success of these operations remains poorly studied. It is known, however, that success declines with time, and patients often need additional procedures every 1 to 2 years. New, longer-acting agents are in development and potentially will decrease the interval between injections.

Complications

In choosing surgical management, surgeons must weigh the chance of cure against the chance of severe complications. In the aforementioned randomized trial comparing TVT and Burch, **women undergoing TVT were more likely to experience a bladder perforation than those undergoing the Burch procedure (9% versus 2%, respectively) but less likely to have a fever (1% versus 5%) or prolonged catheterization more than 29 days (3% versus 13%)** (133). Less common complications require a large sample size to detect differences. In the randomized trial, 2% of women in the TVT group had a retropubic hematoma and 1% a vascular injury, compared with no women in the Burch group. Given the small numbers, it is not clear whether the rate of vascular injuries differs. In a report to the FDA in which worldwide safety data from more than 500,000 procedures were summarized, there were seven deaths reported after TVT, six associated with bowel perforation and one from vascular injury. No such data are available for Burch urethropexy.

In a nationwide analysis of 367 complications associated with 1,455 TVT procedures performed in Finland, there was a 1.9% rate (95% CI, 1.2–2.7) of blood loss over 200 mL, a 1.9% rate (95% CI, 1.2–2.7) of retropubic hematoma, a 0.5% rate (95% CI, 0.2–1.0) of

hematoma outside the retropubic area, a 0.1% rate (95% CI, 0.0–0.4) of injury to the epigastric vessel, a 0.1% rate (95% CI, 0.0–0.4) of injury to the obturator nerve, and a 3.8% rate (95% CI, 2.9–5.0) of bladder perforation (134).

Erosion is unique to surgeries in which a graft is placed, and the rate depends largely on the type of graft used. Rates from one type of material cannot be extrapolated to another. Tension-free vaginal tape is associated with a low rate of graft erosion, compared with a much higher rate of erosion with certain synthetics used for pubovaginal slings in the past. In the randomized trial comparing Burch and TVT described previously, of the 170 women who underwent a TVT procedure, one woman had a graft erosion in the first 6 months, and two others had graft erosion or extrusion between 6 and 24 months postoperatively (121).

The most common adverse events (generally 5%–10% rate for each) after all surgeries for stress urinary incontinence include urinary tract infection, failure to cure, new onset detrusor overactivity, voiding dysfunction, genital prolapse, and bladder perforation. When new onset detrusor overactivity occurs after surgery for incontinence, cystoscopy should be considered to rule out a foreign body in the bladder (Fig. 23.13). Less common events (generally 2%–5% for each) include excessive blood loss, wound infection, pain, nerve injury, or incisional hernia. Events such as sinus tracts and fistulae are rare. Erosion rates depend on the material implanted and, as noted previously, are rare for the newer midurethral slings. In addition, medical events, such as thromboembolic, cardiac, or pulmonary events, are rare.

Surgical Treatment for Detrusor Overactivity

Neuromodulation

Even with the development of newer anticholinergic medications with fewer side effects, there continues to be a select group of patients with overactive bladders who remain refractory to standard medical and behavioral treatment. Surgical treatment of this condition has traditionally involved substantial morbidity and major urinary denervation, reconstruction, or both to achieve therapeutic benefits. The development of implantable sacral nerve root stimulators led to FDA approval of sacral root neuromodulation in patients with refractory urinary urgency and frequency, urge incontinence, and voiding dysfunction. This therapy offers patients with severe symptoms an alternative to urinary augmentation or diversion. **Sacral nerve stimulation therapy** is performed in two phases. In the first phase, a **percutaneous nerve evaluation test** is performed to determine which patients respond to this type of therapy. **Those who respond are then implanted with a permanent electrode lead adjacent to the third sacral nerve root connected to a pulse generator.**

A multicenter prospective study demonstrated that 63% of test patients responded to the initial procedure. After implantation, 47% of patients became completely dry, and 77% were successful in eliminating "heavy" leakage episodes. **Despite substantial success in nearly 80% of patients who received implants, 30% of patients required further surgical revision because of pain or other complications at the generator or implant site.** No permanent injuries or nerve damage was reported in the initial trials (135,136).

In a group of 96 patients with implants (who responded favorably during the test stimulation period), reductions in urge incontinence episodes and severity were still seen at an average of 31 months after implantation. The device was removed in 11 of the 96 patients because of lack of efficacy, pain, or bowel dysfunction. There were no permanent injuries (137). The technique for this procedure has evolved over the last several years to include the location of a generation implant site on the back and the performance of the procedure in two stages with initial percutaneous implantation of a quadpolar instead of a unipolar stimulator. These modifications may improve success rates and decrease the morbidity associated with these procedures.

Figure 23.13 Cystoscopic view of encrusted suture penetrating bladder wall following sling urethropexy.

Botox Injections

Botulinum toxin A (BtxA), a neurotoxin produced by the anaerobic bacteria *Clostridium botulinum*, acts on peripheral cholinergic nerve endings to inhibit calcium-mediated release of acetylcholine vesicles at the presynaptic neuromuscular junctions. Researchers describing the use of BtxA for detrusor overactivity in spinal cord injury patients reported that 17 of 19 were completely dry 6 weeks after treatment (138). In a report from a multicenter study, a 73% continence rate occurred in 180 patients with neurogenic detrusor overactivity incontinence who underwent cystoscopic Botox injections (139).

The procedure is done via cystoscopy and involves injecting 15 to 30 different detrusor muscle sites under direct visualization, sparing the bladder trigone and ureteral orifices. The off-label use of Botox A cystoscopic detrusor injections to treat refractory detrusor overactivity (in women with and without neurologic impairment) is gaining popularity. Clinical trials assessing effectiveness and side effects are ongoing.

Augmentation Cystoplasty and Urinary Diversion

Surgery to replace the function of a diseased bladder has been done for more than a century and Urinary Diversion and, over the past several decades, gained some popularity in treating people with intractable detrusor overactivity not responsive to any other form of management. **These surgical options include (i) conduit diversion (creation of various intestinal conduits to the skin) or continent diversion (which includes a rectal reservoir or continent cutaneous diversion), (ii) bladder reconstruction, or**

(iii) replacement of the bladder with various intestinal segments. These techniques, both historical and current, are beyond the scope of this chapter; the interested reader is referred to a review by Greenwell et al. (140). In a Cochrane review, the reviewers found only two randomized trials that were of sufficient quality to include and concluded that there were no major differences in outcomes between the techniques and that higher quality research was needed (141). With the advent of sacral neuromodulation, these procedures are done much less often to treat women with detrusor overactivity.

Surgical Treatment of Fistulae

A wide variety of techniques are available for fistula repair (142,143). Traditionally, fistula repair has been performed after a waiting period to allow the resolution of inflammation and formation of scar tissue. This is particularly important in the case of obstetric fistulas, in which the extent of the vascular injury to the soft tissues of the pelvis may not be apparent for many weeks. However, there has been a recent trend toward early closure of small gynecologic fistulas (144). The keys to closure of a vesicovaginal fistula include wide mobilization of tissue planes so that the fistula edges can be approximated without any tension, close approximation of tissue edges, closure of the fistula in several layers, and meticulous attention to postoperative bladder drainage for 10 to 14 days. The closure of large fistulas will be enhanced by the use of tissue grafts (e.g., Martius labial fat-pad grafts, gracilis muscle flaps) that provide an additional blood supply to nourish an area that has sustained vascular injury. The Latzko procedure used to close a vesicovaginal fistula is shown in Figure 23.14.

Cystoscopy

Scientific evidence does not support routine cystoscopy in women with stress urinary incontinence in the absence of other pathologies (145). Cystoscopy cannot be used to predict intrinsic sphincteric deficiency, stress incontinence, or detrusor overactivity. Cystoscopy can be considered in the following circumstances: (i) in women with urge incontinence to rule out other disorders, especially in women with microscopic hematuria, (ii) in the evaluation of vesicovaginal fistulae, and (iii) intraoperatively to evaluate possible ureteral or vesical injury.

Urologists often use flexible cystoscopy in men; however, women tolerate a rigid cystoscope well, given their short urethras and absence of prostate glands. The view afforded by a rigid cystoscope is clearer than that obtained with a flexible scope, and less technical skill is required to view the entire bladder using a rigid scope. **Cystoscopes are available with several viewing angles: 0° (straight), 30° (forward-oblique), 70° (lateral), and 120° (retroview).** The last scope is rarely used in women. Zero-degree lenses are essential for viewing the urethra, whereas a 30° lens provides the best view of the bladder base and posterior wall, and the 70° lens generally provides the best view of the anterior and lateral walls. For diagnostic cystoscopy, sterile water is an ideal medium because it is readily available and inexpensive.

To evaluate the urethra, the cystoscope should be advanced with distension medium flowing, keeping the center of the urethral lumen in the center of the visual field. The mucosa is normally pink and smooth and the urethral folds close.

To examine the bladder, the cystoscope should be inserted into the bladder with both the light cord and the camera cord oriented toward the floor. When using a 70° lens, this will show the bladder dome, which is easily identified by an air bubble anteriorly. The remainder of the bladder is then systematically examined by making a series of sweeps, slowly rotating

the cystoscope between the dome and urethrovesical junction. To view the trigone, the light cord should be oriented toward the ceiling (keeping the camera cord toward the floor). The scope is pulled back until it is almost in the urethra, and the base of the bladder is then viewed. Because the trigone is a zone of metaplasia, it generally looks different from the rest of the urothelium (Fig. 23.15).

Vaginal and abdominal hysterectomies are associated with a 0.02% to 0.85% incidence of ureteral injury (146). However, the injury rate increases in reconstructive pelvic surgeries, reaching as high as 11% after uterosacral ligament suspension (147). In a study of 46 women that underwent proximal uterosacral ligament vaginal vault suspension, three of the five women with cystoscopic evidence of obstruction were treated

P.887

P.888

by simply removing and replacing the sutures. This finding emphasizes the importance of confirming ureteral integrity at surgery.

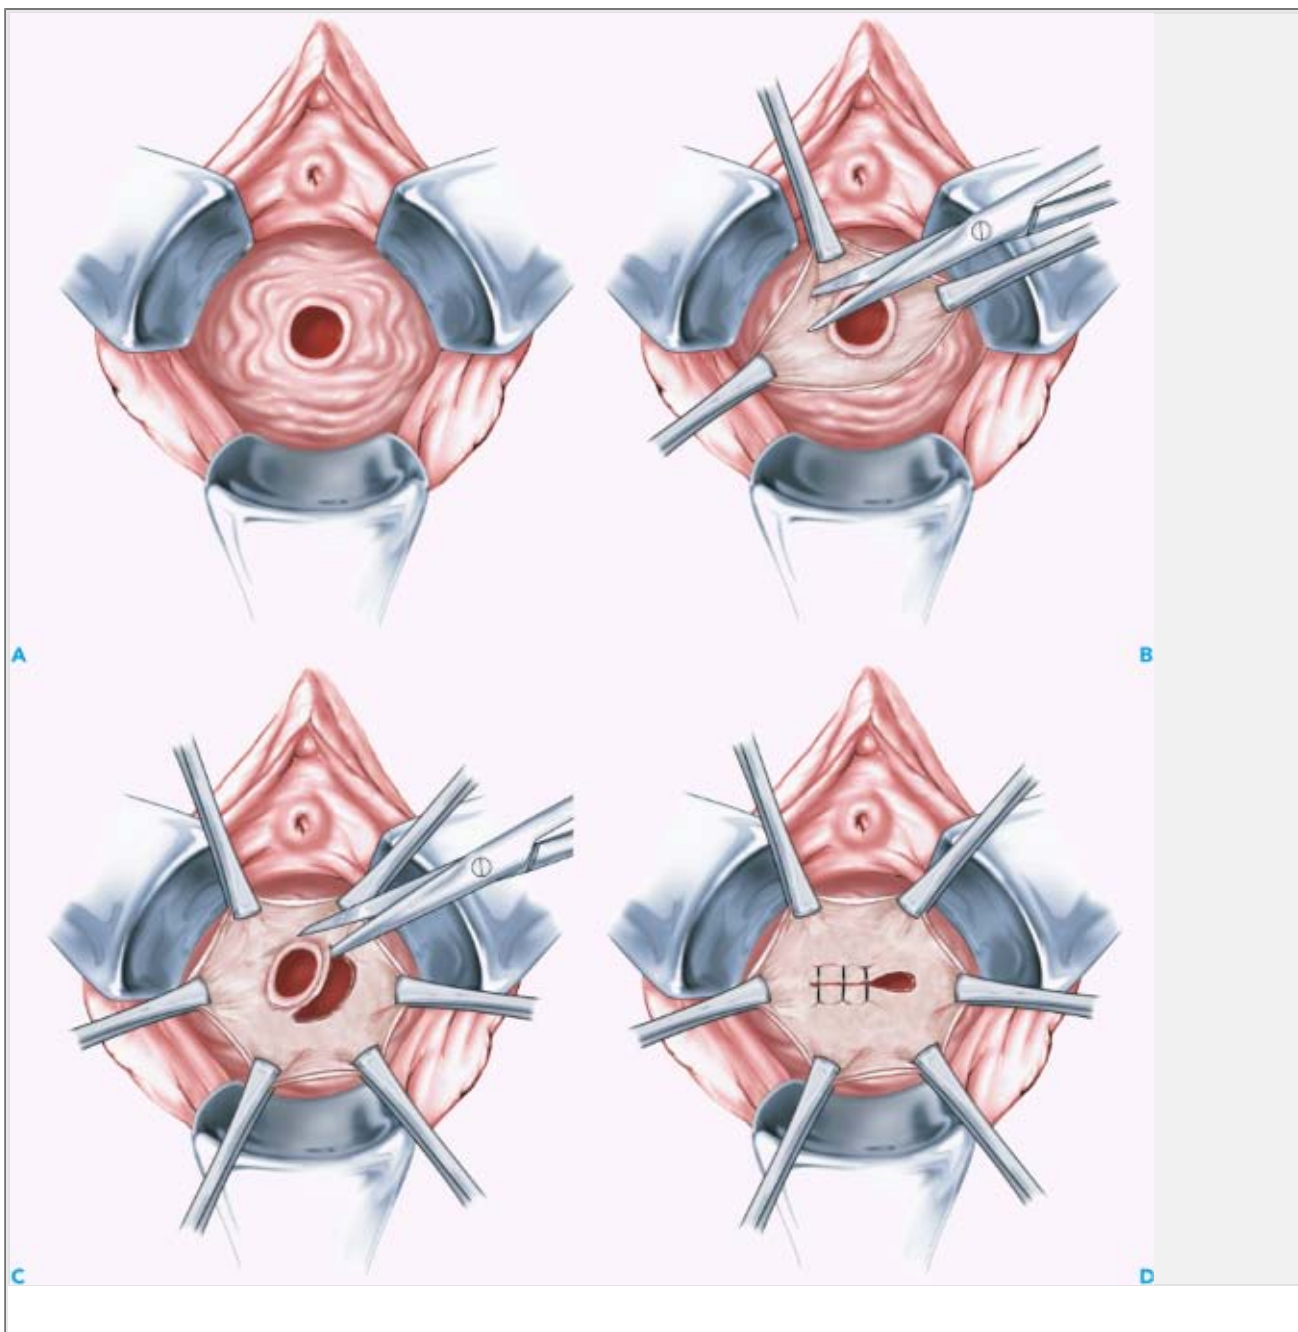

Figure 23.14 Repair of apical vesicovaginal fistula. A: The fistula at the vaginal apex is exposed with adequate retraction. A pediatric foley B: The vaginal epithelium is dissected from the fistula to mobilize the tissue to allow for tension-free closure. In the classic Latzko procedure, the vaginal epithelium 2 cm around the opening of the fistula is removed. C: The fistula tract may either be completely excised, or in the Latzko procedure, the fistula edge may freshened up slightly but is not excised. D: Interrupted absorbable sutures are placed in an extramucosal location in an interrupted fashion. An additional layer of interrupted sutures is often placed to invert the initial suture line. The vaginal epithelium is then closed over the repair. In the classic Latzko procedure, the initial layer involves closure of the vagina over the fistula tract, then two additional layers with the vaginal epithelium result in an apical colpocleisis. Redrawn from original by Jasmine Tan.

Figure 23.15 Cystoscopic view of normal-appearing trigone with left ureteral orifice visible.

Administering indigo carmine dye intravenously 5 minutes before cystoscopy aids in the assessment of ureteral patency. Quick efflux of stained urine should be seen bilaterally. Sluggish efflux should prompt further investigation. However, pre-existing ureteral obstruction may also be responsible for lack of flow. In 157 women who underwent complex urogynecologic procedures, 5 (3.2%) cases of unsuspected ureteral obstruction were identified with intraoperative cystoscopy (148). One was due to ureteral ligation, and the remaining four represented chronic ureteral obstruction resulting from pelvic organ prolapse (two cases), ureteropelvic junction obstruction (one case), and ureterovesical junction stenosis after prior transurethral resection of bladder cancer (one case).

Voiding Dysfunction and Bladder Pain Syndromes

Voiding Dysfunction

Women are afflicted less commonly than men with voiding difficulties, but these disorders do occur in women and can be defined as emptying dysfunction resulting from relaxation of the pelvic floor musculature or failure of the detrusor muscle to contract appropriately. **True outflow obstruction (defined as a detrusor pressure of more than 50 cm H₂O in association with a urine flow rate of less than 15 mL/sec) is rare in women and, when seen, is usually found in those who have undergone obstructive bladder neck surgery for stress incontinence (149,150). For normal voiding to occur, the pelvic floor and urethral sphincter must relax, which should occur in conjunction with a coordinated contraction of the detrusor muscle that leads to complete bladder emptying.** The bladder may also be emptied by other mechanisms, such as by abdominal straining in the absence of a detrusor contraction, or simply by relaxation of the pelvic floor. Complete bladder emptying is not the same as normal voiding. Some women may empty their bladders

P.889

completely but only by expending great effort over several minutes. In such cases, voiding is clearly abnormal, even though the bladder is empty when voiding ceases. In the worst cases, voiding is both difficult and incomplete.

Causes

Neurologic diseases, such as multiple sclerosis, may cause voiding difficulty as a result of *detrusor-sphincter dyssynergia* (151,152), in which the urethral sphincter contracts at the same time as the detrusor. Great effort is required to overcome urethral resistance; the patient voids with an interrupted stop-and-start stream and usually has a significant amount of residual urine.

Other causes of voiding difficulty include medications (such as antihistamines and anticholinergic agents), infections (in particular, herpes simplex virus and urinary tract infections), obstruction (following bladder neck surgery, or in women with advanced pelvic organ prolapse), overdistension, severe constipation (particularly in elderly), and, rarely, psychogenic factors. Fowler's syndrome refers to unexplained urinary retention occurring as an isolated phenomenon (153). Generally such women are between 20 and 35 years of age. Commonly the first retention episode will be triggered by an event such as surgery or childbirth. Retention rarely resolves but is not associated with the development of other disorders.

Evaluation

Evaluation of a woman with voiding difficulty begins with a careful physical examination. **Advanced pelvic organ prolapse may contribute to urinary retention, but it is unlikely that prolapse above the level of the vaginal introitus will be the sole cause of retention.** When in doubt, the woman can wear a pessary for a week to see whether elevating the prolapse reduces the voiding difficulty. Occasionally pelvic masses—in particular, low anterior myomas—may cause urinary retention. Abnormal findings detected during neurologic examination of the perineum and lower extremities may suggest the need to focus on the spine. Urodynamics evaluation will help determine whether the woman has an obstruction (manifested by high detrusor pressures during voiding or by no urethral relaxation during voiding) or whether the detrusor muscle is not contracting. The latter is not necessarily indicative of a neurogenic disorder in women, as a large minority of normal healthy women void by urethral and pelvic floor muscle relaxation alone, with no

detrusor contraction. Cystourethroscopy may reveal an obstructing lesion, such as a polyp, tumor, ureterocele, or ball-valve stone. Usually, the evaluation reveals no obvious source, and treatment can commence.

Treatment

The mainstay in the treatment of voiding difficulty is clean, intermittent self-catheterization (154). The most important protection against urinary tract infection is frequent and complete bladder emptying rather than avoiding the introduction of a foreign body into the bladder. Self-catheterization allows the patient to accomplish this task using a small (14-Fr.) plastic catheter that she inserts through the urethra into the bladder, draining its contents. The catheter is then removed, washed with soap and water, dried, and stored in a clean, dry place. Elaborate sterile procedures are not necessary. Bacteria are introduced into the bladder in this process, and the urine of women after self-catheterization regimens will always be colonized with bacteria; however, this condition should not be treated unless symptomatic infection occurs.

In addition to decreasing urinary urgency and incontinence caused by detrusor overactivity, neuromodulation of the sacral nerve roots also may help women with nonobstructive urinary retention (136). In a trial of 177 patients with idiopathic urinary retention, those who had greater than 50% improvement in baseline voiding symptoms during a test stimulation period qualified for surgical implantation of InterStim. Of these, 37 were randomly assigned to early implantation, whereas 31 in the control group delayed implantation for

P.890

6 months. Improved voiding occurred in 83% of the implant group compared with 9% of the control group at 6 months (155). Although this technology requires a major surgical procedure, many women favor this therapy over lifelong self-catheterization.

Mild sedatives are sometimes helpful in this process, as are α -blockers (e.g., *prazosin*, *phenoxybenzamine*), which reduce urethral tone. For patients who are unable to generate a detrusor contraction, attempts have been made to enhance detrusor contractility using a cholinergic agonist such as *bethanechol chloride*. Although cholinergic medications are successful in making strips of bladder muscle contract in a laboratory, there is little evidence that such drugs are helpful clinically (156).

Bladder Pain Syndromes

Most patients with disorders of bladder sensation experience pain rather than lack of bladder sensation. As with the treatment of most chronic pain disorders, the cause of most painful bladder conditions is unknown, and the therapies currently used are only partially successful. As a result, disorders of bladder sensation are among the most frustrating urogynecologic conditions to manage.

Terminology and Prevalence

Painful bladder syndrome, often termed *interstitial cystitis*, is a poorly defined heterogeneous syndrome, and diagnostic criteria are changing continuously. **The latest International Continence Society standardization report recommends adapting the term *painful bladder syndrome*, rather than *interstitial cystitis* and defines painful bladder syndrome as the "suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and nighttime frequency, in the absence of proven urinary infection or other obvious pathology" (7). Urgency and pain are the defining characteristics of painful bladder syndrome** (157). Several

factors have inhibited advances in the understanding of interstitial cystitis, including the lack of specific diagnostic criteria, the lack of specific histopathologic changes, the unpredictable fluctuation in symptoms, and the marked variability among patients in terms of symptoms, objective findings, and treatment responses (158).

The National Institute of Diabetes, Digestive, and Kidney Diseases (NIDDK) developed a research definition for interstitial cystitis that requires objective findings of glomerulations or a classic Hunner's ulcer during hydrodistention of the bladder and subjective symptoms of bladder pain or urinary urgency in the absence of other urogenital pathology (159). Strict application of NIDDK criteria in one study would have misdiagnosed more than 60% of patients thought to definitely or possibly have interstitial cystitis (160). Many clinicians have challenged the clinical utility of the NIDDK research criteria, and most conceptualize interstitial cystitis as the end point on the spectrum of painful bladder disorders (162).

The prevalence of painful bladder syndrome varies widely depending on the diagnostic criteria utilized. When mild and moderately severe cases are considered, the syndrome is not rare (162). Estimates of prevalence in the United States range from 52 per 100,000 women in the population-based Nurses Health Study to as high as 1 in 4.5 women "with accurate diagnostic records" (163,164). The prevalence appears to be 6 to 15 times more common among women than men (163,165). The identification of risk factors for painful bladder syndrome is particularly challenging because of the typically long delay in diagnosis (163). The recently completed Interstitial Cystitis Database study confirms many of the previous epidemiologic observations: Affected individuals are predominately female (92%), white (91%), and report an average age of symptom onset of 32.2 years (158,163).

Diagnosis

A careful history should be obtained, along with a sterile urine specimen for analysis and culture. Many women treated repetitively for chronic cystitis have taken multiple courses

P.891

of antibiotics on the basis of symptoms without ever having the presence of an infection confirmed by cultures. Detrusor overactivity may be the cause of frequency, urgency, and urge incontinence but is not usually a factor in dysuria or painful urination. **Women older than 50 years (particularly those who smoke or are exposed to chemicals at work) are at risk for bladder cancer, and this possibility must be considered, especially if hematuria is present.** Urinary cytologic assessment is sometimes helpful in detecting early tumors of the urinary tract, and cystoscopy and intravenous urography are mandatory in the evaluation of patients with hematuria.

Other possible causes for painful voiding must be considered in the differential diagnosis, including urethral diverticula; vulvar disease; endometriosis; chemical irritation from soaps, bubble bath, or feminine hygiene products; urinary stones; urogenital atrophy from estrogen deprivation; and sexually transmitted disease (165).

The diagnosis of interstitial cystitis is largely one of exclusion. The ideal diagnostic test for interstitial cystitis has not been determined, and there are myriad proposed tests.

Treatment

Typically, the evaluation of painful bladder syndrome results in no definitive diagnosis, and management focuses on the treatment of symptoms.

Frequency-urgency syndromes should be managed with a careful voiding regimen

(similar to that used in the treatment of detrusor overactivity) and local care.

The use of urinary tract analgesics such as *Urised* may be helpful in reducing urethral irritation. *Urised* is a polypharmaceutical agent containing a mixture of *methenamine*, *methylene blue*, *phenyl salicylate*, *benzoic acid*, *atropine sulfate*, and *hyoscyamine* that has a soothing effect on many irritative urethral symptoms.

There is no scientific evidence linking diet to painful bladder syndrome, but many doctors and patients find that alcohol, tomatoes, spices, chocolate, caffeinated and citrus beverages, and high-acid foods may contribute to bladder irritation and inflammation. Some patients also note that their symptoms worsen after eating or drinking products containing artificial sweeteners. Patients may try eliminating various items from their diet and reintroducing them one at a time to determine which, if any, affect their symptoms. Instruction in the basics of vulvar and perineal hygiene is important (thorough drying; avoidance of most body powders, perfumes, or colored irritating soaps; avoidance of tight-fitting undergarments) to avoid other factors that may contribute to painful voiding.

Hydrodistention of the bladder (usually under anesthesia) has been recommended as a treatment option and can result in clinical improvement in some patients. Some patients benefit from the instillation of 50 mL of a 50% solution of *dimethylsulfoxide* (DMSO) for 20 to 30 minutes every other week for four or five sessions.

Pentosan polysulfate (*Elmiron*) is an FDA-approved oral agent with heparinlike activity that attempts to replace the glycoaminoglycan sulfate layer that is believed deficient in these patients. In clinical trials, the drug improved symptoms in 38% of patients treated. The FDA-recommended oral dosage of *Elmiron* is 100 mg, three times a day. Patients may not feel relief from pain for the first 2 to 4 months, and it may take up to 6 months for a decrease in urinary frequency to occur.

Because it has been theorized that bladder pain may result from increased histamine release, some patients benefit from medications that block these inflammatory mediators, such as *diphenhydramine hydrochloride*, 25 to 50 mg orally three times per day, in combination with 300 mg of *cimetidine* three times per day. Tricyclic antidepressants help some women by modulating sensory nerve pain.

P.892

Transcutaneous electrical nerve stimulation (TENS), through wires placed on the lower back or just above the symphysis, may help some women, though the mechanism of action is unclear. Ongoing preliminary research suggests that some women with severe bladder pain syndrome may find relief following sacral neuromodulation (*InterStim*) or acupuncture.

In 1998, NIDDK initiated the Interstitial Cystitis Clinical Trials Group, a multicenter group charged with developing and testing new treatment strategies for patients with this disorder. It is hoped that research such as this will ease the great suffering by women with painful bladder syndrome and improve their quality of life.

Pelvic Organ Prolapse

Holly E. Richter

R. Edward Varner

- **With the aging of the population, pelvic organ prolapse is an increasingly common condition seen in women.**
- **Causes of pelvic organ prolapse are multifactorial and result in weakening of the pelvic support connective tissue and muscles as well as nerve damage.**
- **Patients may be asymptomatic or have significant symptoms such as those relating to the lower urinary tract, pelvic pain, defecatory problems, fecal incontinence, back pain, and dyspareunia.**
- **Physical examination includes thoughtful attention to all parts of the vagina, including the anterior, apical, and posterior compartments, levator muscle, and anal sphincter complex.**
- **Nonsurgical treatment options include pelvic floor muscle training and the use of intravaginal devices.**
-

Surgical treatment involves an individualized, multicompartamental approach consistent with the patient's previous treatment attempts, activity level, and health status.

- **Studies are needed to determine the characteristics of those patients who would benefit long-term from vaginal versus abdominal approaches to the surgical repair of pelvic organ prolapse.**

Pelvic organ prolapse (POP) is a bulge or protrusion of pelvic organs and their associated vaginal segments into or through the vagina (1). It is a common and costly affliction of older women (2,3). **It has been estimated that over the next 30 years, the demand for treatment of POP will increase 45%, commensurate with an increase in the population of women older than 50 years of age (4,5).** As this problem grows in significance, it becomes increasingly important to work toward an understanding of the pathophysiology and risk factors associated with pelvic organ prolapse to try to prevent its occurrence. Furthermore, continued efforts are needed to understand factors that result in long-lasting, robust repair of pelvic organ prolapse for those patients undergoing surgical management.

P.898

Despite extensive anecdotal experience, the optimal surgical approach to apical and other compartment prolapse remains elusive (6).

In the United States, 11% of women up to the age of 80 years have surgery for pelvic organ prolapse or urinary incontinence, and nearly one third of procedures are repeat surgery (3). Data from the Women's Health Initiative revealed anterior pelvic organ prolapse in 34.3%, posterior wall prolapse in 18.6%, and uterine prolapse in 14.3% of women in the study (7). In this study, a significant risk factor associated with prolapse was vaginal delivery. After adjusting for age, ethnicity, and body mass index, women with at least one vaginal delivery were twice as likely as nulliparous women to have pelvic organ prolapse. Causes of pelvic support disorders are most likely multifactorial, however; factors other than vaginal delivery also are associated with the development of these disorders. One study found that the incidence of prolapse doubled with each decade of life between the ages of 20 and 59 years (8). In another study, each year of increasing age was associated with a 12% increase in the risk of developing prolapse (9). Other associated risk factors for the development of POP include history of hysterectomy (8), obesity (7,10,11), history of previous prolapse operations, and race (11).

Pathophysiology

Pelvic organ prolapse results from attenuation of the supportive structures, whether by actual tears or "breaks" or by neuromuscular dysfunction or both. Support of the vaginal canal is provided by the enveloping endopelvic connective tissue and its condensations at the vaginal apex, which form the cardinal uterosacral ligament complex. The endopelvic connective tissue is the first line of support buttressed intimately with the pelvic diaphragm, composed of the levator ani and coccygeus muscles. These muscles provide a supportive diaphragm through which the urethra, vagina, and rectum egress (Fig. 24.1). The muscular support provides basal tonicity and support of the pelvic structures; when contracted as in the setting of increased abdominal pressure, the rectum, vagina and urethra are pulled anteriorly toward the pubis.

Definitions

The more common pelvic support disorders include **rectoceles** and **cystoceles** (Fig. 24.2), **enteroceles** (Fig. 24.3), and **uterine prolapse** (Fig. 24.4), reflecting displacement of the rectum, small bowel, bladder, and uterus, respectively, resulting from failure of the endopelvic connective tissue, levator ani muscular support, or both.

A **rectocele** is a protrusion of the rectum into the vaginal lumen resulting from weakness in the muscular wall of the rectum and the paravaginal musculoconnective tissue, which holds the rectum in place posteriorly.

An **enterocele** is a herniation of the peritoneum and small bowel and is the only true hernia among the pelvic support disorders. Most enteroceles occur downward between the uterosacral ligaments and the rectovaginal space, but they may also occur primarily apically, especially in the setting of a previous hysterectomy.

A **cystocele** is a herniation of the urinary bladder through the anterior vaginal wall. Cystoceles usually occur when the pubocervical musculoconnective tissue weakens midline or detaches from its lateral or superior connecting points.

Uterine prolapse is generally the result of poor cardinal or uterosacral ligament apical support, which allows downward protrusion of the cervix and uterus toward the introitus.

Figure 24.1 A sagittal view of the female pelvis with bladder and uterus removed (ureters, trigone, and cervix intact) illustrating anterior and posterior vaginal fibromuscular planes, their endopelvic fascial attachments, and a functional pelvic floor. (Redrawn by J. Taylor from Skandalakis JE et al., eds. *Hernia: Surgical Anatomy and Technique*, 244–250.)

Procidentia, which involves prolapse of the uterus and vagina, and *total vaginal vault prolapse*, which can occur after hysterectomy, represent eversion of the entire vagina (Fig. 24.5).

These descriptive terms are somewhat inaccurate and misleading, focusing on the bladder, rectum, small bowel, or uterus rather than the specific defects responsible for the alterations in vaginal support. Specific defect support issues will be discussed in the setting of the surgical management section.

Evaluation

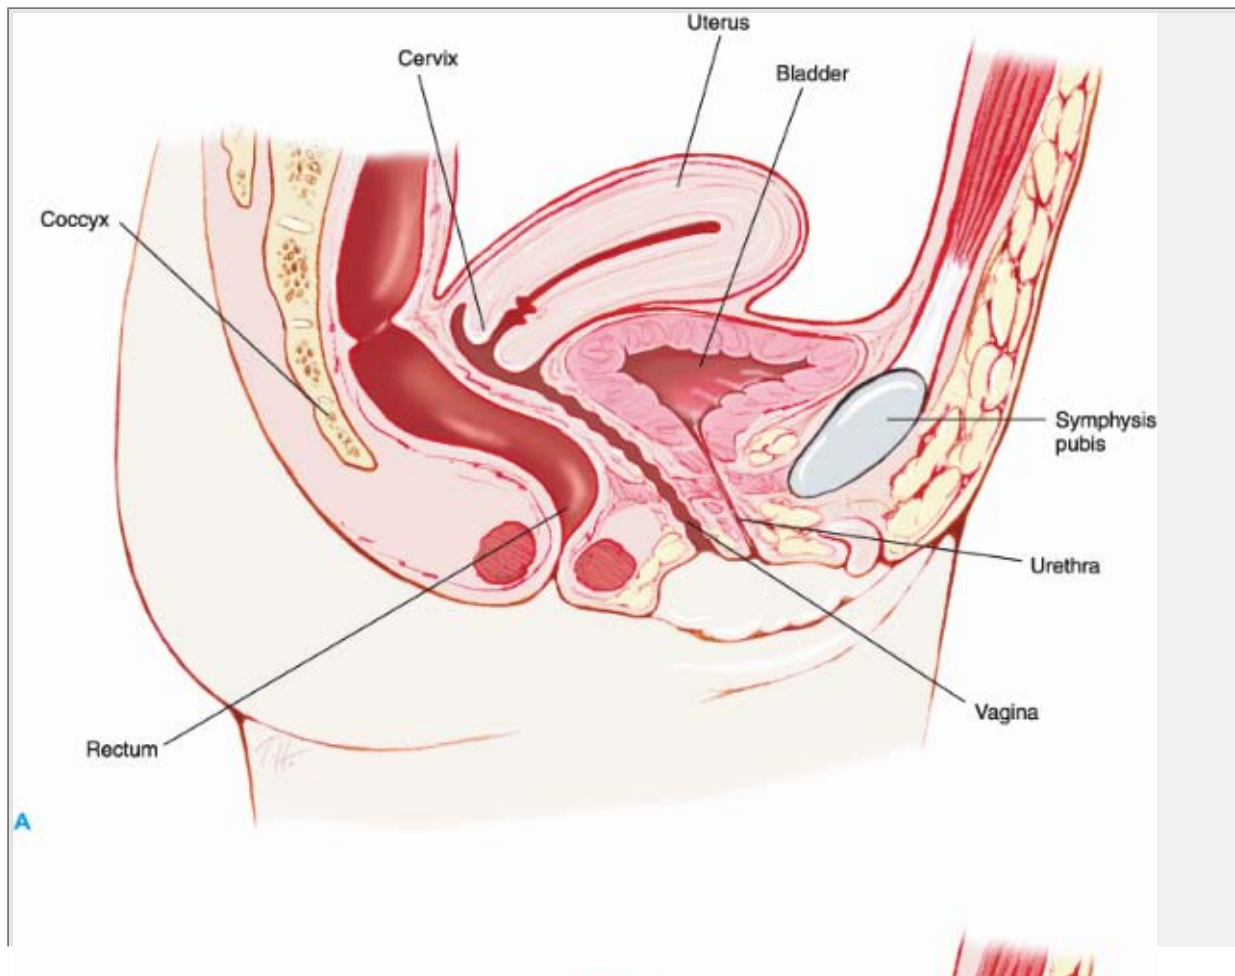

Although as many as 50% of women older than age 50 have some degree of pelvic organ prolapse (12), fewer than 20% seek treatment (13). This may be due to a number of reasons, including lack of symptoms, embarrassment, or misperceptions

P.900

P.901

P.902

about available treatment options. Although pelvic organ prolapse is not life threatening, it can impose a significant burden of social and physical restrictions of activities, impact on psychological well-being, and overall quality of life.

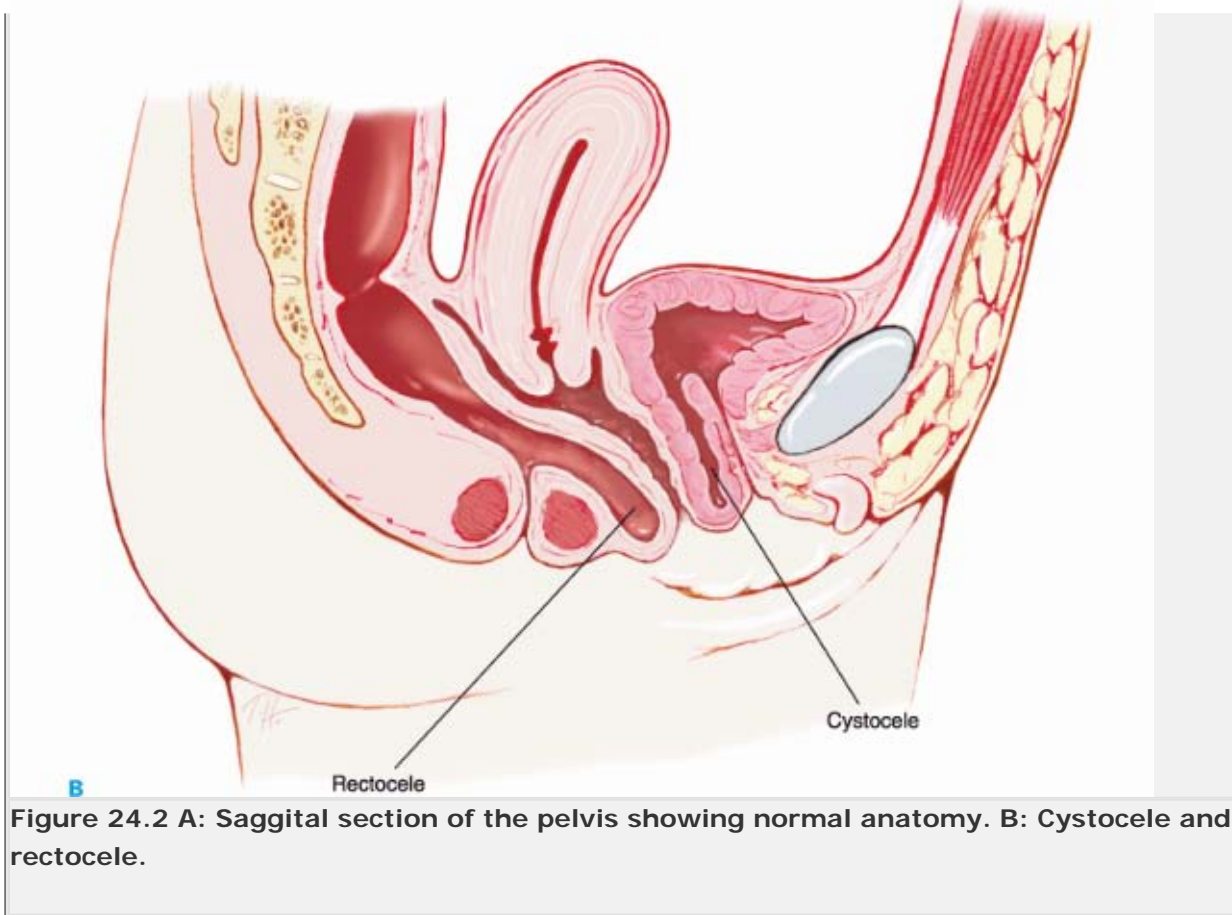

Figure 24.2 A: Saggital section of the pelvis showing normal anatomy. B: Cystocele and rectocele.

Figure 24.3 A: Posterior enterocele without eversion. B: Enterocele with eversion.

Figure 24.4 Uterine prolapse with apical detachment from the uterosacral ligament complex and lateral wall detachment from the endopelvic connective tissue.

Symptoms

Pelvic organ prolapse often is accompanied by symptoms of voiding dysfunction, including urinary incontinence, obstructive voiding symptoms, urinary urgency and frequency, and, at the extreme, urinary retention and upper renal compromise with resultant pain or anuria. Other symptoms often associated with POP include pelvic pain, defecatory problems (e. g., constipation, diarrhea, tenesmus, fecal incontinence), back and flank pain, overall pelvic discomfort, and dyspareunia. Patients seeking care for prolapse may have one or several of these symptoms involving the lower pelvic floor. **Choice of treatment usually depends on severity of the symptoms and the degree of prolapse consistent with the patient's general health and level of activity.**

Data relating pelvic floor symptoms to the extent and location of prolapse are weak (14,15,16). Any symptoms associated with physical findings of lower stage prolapse require careful evaluation, especially if surgery is being considered. A recent retrospective study of 330 patients reported that women with more advanced prolapse were less likely to have symptoms of stress incontinence and more likely to use manual reduction of the prolapse to void. Therefore, careful consideration of lower urinary tract symptoms

P.903

is important. Prolapse severity was not associated with bowel or sexual problems in this study (17).

Figure 24.5 Procidentia of the uterus and vagina.

Physical Examination

In evaluating patients with pelvic organ prolapse, it is particularly useful to divide the pelvis into compartments, each of which may exhibit specific defects. The use of a Graves speculum or Baden retractor can help to evaluate the apical compartment of the vagina. The anterior and posterior compartments are best examined with the use of a univalve or Sims' speculum. The speculum is placed posteriorly to retract the posterior wall downward when examining the anterior compartment and placed anteriorly to retract the anterior wall

upward when examining the posterior compartment. A rectovaginal examination may be useful in evaluating the posterior compartment to distinguish a posterior vaginal wall defect from a dissecting apical enterocele or a combination of both.

If an anterior lateral detachment defect is suspected, an open ring forceps (or a Baden retractor) may be placed in the vagina at a 45-degree angle posteriorly cephalad to hold the lateral fornices adjacent to the pelvic sidewall.

During the evaluation of each compartment, the patient is encouraged to perform Valsalva so the full extent of the prolapse can be ascertained. If the findings determined with Valsalva are inconsistent with the patient's description of her symptoms, it may be helpful to perform a standing straining examination with the bladder empty (18).

Pelvic Organ Prolapse Quantitation System

Many systems for staging prolapse have been described. Typically it is graded on a scale of 0 to 3 or 0 to 4, with the grade increasing with the severity of prolapse (19,20). **Currently the system approved by the International Continence Society is the Pelvic Organ Prolapse Quantification system, or POP-Q (21).** This standardized quantification system facilitates communication between physicians in practice and research and enables progression of these conditions to be followed accurately. In this system, anatomic descriptions of

P.904

specific sites in the vagina are used in place of traditional terms. The system identifies nine locations in the vagina and vulva in centimeters relative to the hymen, which are used to assign a stage (from 0 to IV) of prolapse at its most advanced site (Fig. 24.6). Although probably more detailed than necessary for general practice, clinicians should be familiar with the POP-Q system because most published studies use it to describe research results. Its two most important advantages over previous grading systems are (i) it allows the use of a standardized technique with quantitative measurements at straining relative to a constant reference point (i.e., the hymen), and (ii) its ability to assess prolapse at multiple vaginal sites.

Figure 24.6 Standardization of terminology for female pelvic organ prolapse (POP-Q classification). This diagram demonstrates the anatomic position of the POP-Q sites, including six sites involving the anterior (Aa, Ba), middle (C, D), and posterior (Ap, Bp) compartments with the genital hiatus (gh), perineal body (pb), and total vaginal length (tvl). (From **Bump RC, Mattiason A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996; 175: 12, with permission.)

The classification uses six points along the vagina (two points on the anterior, middle, and posterior compartments) measured in relation to the hymen. The anatomic position of the six defined points should be measured in centimeters proximal to the hymen (negative number) or distal to the hymen (positive number), with the plane of the hymen representing zero. Three other measurements in the POP-Q examination include the genital hiatus, perineal body, and the total vaginal length.

The genital hiatus is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length is the greatest depth of the vagina in centimeters when the vaginal apex is reduced to its full normal position. All measurements except the total vaginal length are measured during maximal straining.

The anterior vaginal wall measurements are termed Aa and Ba, with the Ba point moving depending on the amount of anterior compartment prolapse. Point Aa

P.905

represents a point on the anterior vagina 3 cm proximal to the external urethral meatus, which corresponds to the bladder neck. By definition, the range of position of this point is -3 to +3. Point Ba represents the most distal or dependent point of any portion of the anterior vaginal wall from point Aa to just anterior to the vaginal cuff or anterior lip of the cervix. This point can vary depending on the nature of the patient's support defect. For example, point Ba is -3 in the absence of any prolapse (it is never less than -3) to a positive value equal to the total

vaginal length in a patient with total eversion of the vagina.

Table 24.1 Possible Ranges of the Six Site-specific Pelvic Organ Prolapse Quantitative Examination Measurements

<i>Points</i>	<i>Description</i>	<i>Range</i>
Aa	Anterior wall 3 cm from hymen	-3 cm to +3 cm
Ba	Most dependent portion of rest of anterior wall	-3 cm to +TVL
C	Cervix or vaginal cuff	±TVL
D	Posterior fornix (if no prior hysterectomy)	±TVL or omitted
Ap	Posterior wall 3 cm from hymen	-3 cm to +3 cm
Bp	Most dependent portion of rest of posterior wall	-3 cm to +TVL

TVL, total vaginal length.

Adapted from **Bump RC, Mattiasson A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:11–12, with permission.

The middle compartment consists of points C and D. Point C represents the most dependant edge of the cervix or vaginal cuff after hysterectomy. Point D is the location of the posterior fornix; it is omitted if the cervix is absent. This point represents the level of the attachment of the uterosacral ligament to the posterior cervix. It is intended to differentiate suspensory failure from cervical elongation.

The posterior compartment is measured similarly to the anterior compartment: the corresponding terms are Ap and Bp. The nine measurements can be recorded as a simple line of numbers (i.e., -3, -3, -8, -10, -3, -3, 11, 4, 3 for points Aa, Ba, C, D, Ap, Bp, total vagina length, genital hiatus, and perineal body). The six vaginal sites have possible ranges that depend on the total vaginal length (Table 24.1). After collection of the site-specific measurements, stages are assigned according to the most dependent portion of the prolapse (Table 24.2). The POP-Q examination often appears confusing on initial review; however, a measuring device (i.e., a marked ring forceps or marked cotton-tip applicator) can assist

P.906

in instructing those unfamiliar with this staging system. The POP-Q examination provides a standardized measurement system to allow for more accurate assessments of postoperative outcome and to ensure uniform, reliable, and site-specific descriptions of pelvic organ prolapse. A videotape describing the system and showing its use in several patients is available from the American Urogynecology Society.

Table 24.2. Stages of Pelvic Organ Prolapse

Stage 0	No prolapse is demonstrated. Points Aa, Ap, Ba, Bp are all at -3 cm, and point C is between total vaginal length (TVL) and -(TVL -2 cm).
Stage I	The most distal portion of the prolapse is >1 cm above the level of the hymen.
Stage II	The most distal portion of the prolapse is <1 cm proximal or distal to the plane of the hymen.
Stage III	The most distal portion of the prolapse is <1 cm below the plane of the hymen but no further than 2 cm less than the total vaginal length.
Stage IV	Complete to nearly complete eversion of the vagina. The most distal portion of the prolapse protrudes to > + (TVL -2) cm.

From **Bump RC, Mattiassion A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:13, with permission.

In a clinical setting, at least three measurements should be obtained: the most advanced extent of the prolapse in centimeters relative to the hymen that affects the anterior vagina, the posterior vagina, and the cervix or vaginal apex.

As noted previously, whether the older staging systems or the POP-Q system is used, **it is important to document the most pertinent findings on examination. This will help in documenting the baseline extent of prolapse and the results of treatment.**

Pelvic Muscle Function Assessment

Pelvic muscle function should be assessed during the pelvic examination. Following bimanual examination with the patient in lithotomy position, the examiner can palpate the puborectalis muscle inside the hymen along the pelvic sidewalls at approximately the 4 and 8 o'clock positions. One can appreciate basal muscle tone and whether there is increased tone with contraction as well as strength, duration, and symmetry of contraction (22). **A rectovaginal examination should also be performed to assess basal and contraction muscle tone of the anal sphincter complex.**

As a part of the pelvic organ prolapse examination, urethral mobility often is measured. Many women with prolapse will have urethral hypermobility (defined as a resting urethral angle greater than 30 degrees or a maximal strain angle greater than 30 degrees). The presence of urethral mobility in combination with symptoms of stress incontinence may help determine whether an incontinence procedure should be performed. During pelvic examination, the urethra is typically swabbed with Betadine, and lidocaine jelly is placed in the urethra or on a cotton tip swab. The swab is placed in the urethra at the urethrovesical junction and with the use of a goniometer (Fig. 24.7), and the baseline urethral angle from the horizontal and maximal strain angles are measured.

Figure 24.7 Goniometer, which is used to measure baseline urethral angle and maximal strain angle of the urethra with a Q-tip in place.

Bladder Evaluation

Patients with prolapse exhibit the full range of lower urinary tract symptoms. Despite the fact that some patients may not have significant symptoms, it is important to obtain objective information about bladder and urethral function. With severe POP, the urethral kinking effect of the prolapse may mask a potential urine leakage problem; therefore, basic office bladder testing with prolapse reduction should be performed to mimic bladder and urethral function if the prolapse were treated. At a minimum, the following assessments should be performed: a clean catch or catheterized urine sample to test for infection, a postvoid residual (PVR) volume, and assessment of bladder sensation, which can be performed as a part of office cystometrics. Although there is no consensus on what constitutes an abnormal PVR volume, provided the patient has voided 150 mL or more, a PVR less than or equal to 100 mL is acceptable. Reduction stress testing at the time of simple office cystometrics can be performed with the use of a pessary, large cotton swab, ring forceps, or the posterior blade of a speculum. Care should be taken that the urethra not be overly straightened (with a resultant false-positive test result) or obstructed (with a resultant false-negative test result), or that tension is not placed on the puborectalis muscles by excessive posterior retraction. These risks can be minimized by orienting the vaginal apex toward the sacrum.

Imaging

Diagnostic imaging of the pelvis in women with pelvic organ prolapse is not routinely performed. However, if clinically indicated, tests that may be performed include fluoroscopic evaluation of bladder function, ultrasound of the pelvis, and defecography for patients in whom intussusception or rectal mucosal prolapse are suspected. Magnetic resonance imaging is increasingly being used for the evaluation of pelvic pathology such as mullerian anomalies and pelvic pain, however, generalized use in women with prolapse is not currently clinically indicated and is used primarily for research purposes.

Treatment

Nonsurgical Therapy

Nonsurgical therapy of pelvic organ prolapse includes conservative behavioral management and the use of mechanical devices. **A nonsurgical treatment approach usually is considered in women with mild to moderate prolapse, those who desire preservation of future childbearing, those in whom surgery may not be an option, or those who do not desire surgical intervention.**

Conservative Management

Conservative management approaches include alteration of lifestyle or physical intervention such as **pelvic floor muscle training (PFMT)**. These approaches are used mainly in cases of mild to moderate prolapse; however, their true role in managing prolapse and associated symptoms is unclear (23,24). The goals of a conservative therapy approach to the treatment of prolapse are as follows (25):

- Prevent worsening prolapse
- Decrease the severity of symptoms
- Increase the strength, endurance, and support of the pelvic floor musculature
- Avoid or delay surgical intervention

Lifestyle intervention includes such activities as weight loss and reduction of those activities that increase intra-abdominal pressure. This interaction is typically anecdotal in practice. No case series, prospective studies, or randomized control trials exist that have examined the effectiveness of this approach to the treatment of prolapse.

P. 908

Pelvic floor muscle exercises may limit the progression of mild prolapse and related symptoms (26,27); however, a lower response rate has been noted when prolapse extends beyond the vaginal introitus (28).

The efficacy of biofeedback therapy in the treatment of impaired defecation associated with a rectocele has been determined (29). Thirty-two female patients, median age 52 years (range, 34–77 years), experiencing impaired rectal evacuation with a rectocele greater than 2 cm at proctography underwent a structured behavioral retraining. Immediate and medium-term follow-up results were reported (median 10 months; range 2–30 months). Fifty-six percent of patients ($n = 14$) felt a little and 16% ($n = 4$) felt major improvement in symptoms, including 3 (12%) with complete symptom relief. Immediately after biofeedback there was a modest reduction in need to strain (72; 50%), feeling of incomplete evacuation (78; 59%), and need to assist defecation digitally (84; 63%) that was maintained at follow-up. Bowel movement frequency was significantly normalized at follow-up ($p = 0.02$). These investigators concluded that **behavioral retraining, including biofeedback therapy, may be an effective primary therapy for some patients with a rectocele associated with impaired defecation.**

Mechanical Devices

The use of mechanical devices such as pessaries is usually considered in women who for medical reasons cannot undergo surgery, desire to avoid surgery, or have a significant degree of prolapse that makes other nonsurgical approaches unfeasible.

Some practitioners extend indications to include pregnancy-related prolapse as well as prolapse and incontinence in elderly women. Reports have shown that age older than 65 years, the presence of severe medical comorbidity (30), and sexual activity (31) were associated with successful pessary use. Unsuccessful use or a desire for surgery has been associated with a shortened vaginal length (≤ 6 cm), a wide vaginal introitus (32), sexual activity, stress incontinence, stage III–IV posterior compartment prolapse, and desire for surgery at a first office visit. Few literature-based reviews and reports recommend pessaries as first-line treatment for women with POP, and there is little consensus regarding choice of pessary and management of pessary usage (33). Most of the information on pessary use is derived primarily from descriptive and retrospective studies, relatively small prospective series, manufacturer's recommendations, and anecdotal experience.

Pessaries provide pelvic organ support within the vaginal vault. **Two categories of pessaries—support and space filling—exist for prolapse (33). The ring pessary (with diaphragm) is a commonly used support pessary, and the Gelhorn pessary is a commonly used space-filling pessary. The ring and other support pessaries are recommended for stage I and II prolapse, whereas the space-filling pessaries are used for stage III and IV prolapse (34).** It is unclear whether pessaries with regular use can prevent the progression of POP. A prospective cohort study addressed this issue in a series of 56 women who were fit with a pessary, of which 33.9% (n = 19) continued use for at least 1 year (35). Baseline and follow-up pelvic examinations were performed using the POP-Q system (21). The women removed the pessary 48 hours before one visit, but there was no information to ascertain adherence to pessary use. No woman had worsening of the prolapse, and four women (21.1%, 95% CI 0.2, 43.7%) had an improvement. Improvement overall was noted in women with anterior compartment prolapse.

There are no randomized controlled trials of pessary use in women with POP (36). Likewise, there are no consensus guidelines on the care of pessaries (i.e., intervals between changes), the role of local estrogens, or the type of pessary indicated for specific types of POP (36). Manufacturers recommendations and different pessary types can be seen in Figure 24.8. Effective and satisfactory outcomes have been reported for stage II or greater prolapse using the Gelhorn and ring diaphragm pessary (30). After 2 to 6 months, 77% to 92% of women with a successful pessary fitting were satisfied and, using intention-to-treat analysis, 44% to 67% of all women who were treated initially with a pessary for prolapse

P.909

were satisfied. There are few other series describing pessary use for prolapse with greater than 4 weeks follow-up (37,38,39,40,41).

V Incontinence Dish (Silicone) **W** Inflatoball (Latex) **X** Donut (Silicone)

Figure 24.8 Pessaries used to treat the various degrees of prolapse (Milex Company, a Division of Cooper Surgical).

Possible complications associated with pessary use include vaginal discharge and odor. Failure to retain the pessary may occur or, conversely, the pessary may be too large, which could lead to excoriation or irritation. With reduction of vaginal prolapse, *de novo* or increased stress incontinence may occur (42), and in rare instances, more severe complications, including vesicovaginal fistula, small bowel entrapment, hydronephrosis, and urosepsis, have been described (43,44).

Placement and Management

Pessary placement involves consideration of a number of issues, primarily the patient's desire and motivation to use this type of device. Typically, if she has had previous surgery or strongly desires to avoid surgery, she may be motivated enough for a primary attempt at pessary placement. Other issues include current sexual function status, type and duration of exercise in which the patient engages, and the status of the vaginal walls and cervix.

P.910

In hypoestrogenic women, treatment of the vagina with estrogen and maintenance of intravaginal estrogen treatment is recommended.

Fitting a Pessary

The patient should be examined in the lithotomy position after emptying her bladder. The clinician should use a dry glove to better grasp the pessary and water-soluble lubricants as needed. The size of the pessary is estimated after a digital examination and use of ring forceps to reduce the prolapse or bladder neck. Once the approximate size is determined, the appropriate type is selected based on the patient's needs and activity level. **When fitted, the patient is asked to stand, perform Valsalva, and cough to ensure the pessary is retained.** The pessary should be assessed to ensure it is providing the desired support and leakage control. The patient should be able to void with the pessary in place before leaving the office. Proper size is assured by the ability to sweep the index finger between the pessary and the vaginal wall. The patient should feel comfortable with the pessary in place.

Insertion of the pessary is eased by using a water-soluble lubricant for insertion, folding or collapsing the pessary to reduce its size, and when it is inside the vagina, pushing it high to an area behind the symphysis pubis and inserting the device more posteriorly to avoid the urethra. Instructing the patient how to insert and remove the pessary may be done with the patient in a standing or supine position, depending on her dexterity (41,45).

Ring pessaries, with or without support, are the most commonly used type. They are the easiest to fold, insert, and remove. **Gellhorn** and **cube** pessaries are typically more difficult to insert and remove by the patient. They are held in place by significant space occupation and suction and offer strong support. The suction of the cube pessary needs to be broken, facilitating removal. Cube pessaries should be removed daily; Gelhorns can stay in longer (up to 6–8 weeks). **Donut pessaries**, which are very popular, are considered a space-fitting pessary for large vaginal vault prolapse, complete procidentia with decreased perineal support, and good introital integrity. **The patient should be questioned about a latex allergy and instructed to remove and clean the device every 2 to 3 days.** Continence pessaries, rings,

and dishes with support typically also are easy to fold, insert, and remove (46).

Follow-Up Recommendations

After the initial fitting, the patient should return in 1 to 2 weeks and then at 4 to 6 weeks, depending on her independence with the pessary, her proficiency in placement and removal, and her cognitive and motor abilities (38). After this initial follow-up, continued follow-up should continue at 6- to 12-month intervals at the discretion of the provider and depending on the patient's ability to insert and remove the pessary effectively. If the patient needs to return to the provider for removal and cleaning of the pessary, 4- 12-week intervals are more appropriate.

On follow-up visits, proper placement of the pessary and support of the prolapse as well as continence efficacy should be assured. Because pessaries are fit by a process of trial and error, it is not uncommon to change the size or type at least once after the initial fitting. The pessary's integrity should be checked, and the tissue for evaluated for irritation, pressure sores, ulceration, and lubrication.

Surgical Management

The primary aims of surgery are to relieve symptoms, which may be caused by prolapse, and, in most cases, to restore vaginal anatomy so that sexual function may be maintained or improved without significant adverse effects or complications. Occasionally, when sexual function is not desired, obliterative or constrictive surgery is more appropriate and also may relieve symptoms. There is no steadfast rule as to when

P.911

surgery is indicated. Many patients with more advanced prolapse have few or no symptoms, whereas some with lesser degrees of prolapse have what they term *severe symptoms*. This is confounded by the observation that many of the "symptoms" may not be specifically related to the anatomic defect or may be worsened by anxiety. In general, surgery should be offered to patients who have tried conservative therapy and were not satisfied with the results or who do not desire conservative therapy. The prolapse should be symptomatic or should be greater than or equal to stage II with apparent progression. All patients should be given the alternative of trying conservative treatments when applicable.

Approaches to surgery include vaginal, abdominal, and laparoscopic routes, or a combination of approaches. Depending on the extent and location of prolapse, surgery may involve a combination of repairs directed to the anterior vagina, vaginal apex, posterior vagina, and perineum. Concomitant surgery may be planned for urinary or fecal incontinence. The surgical route is chosen based on the type and severity of prolapse, the surgeon's training and experience, the patient's preference, and the expected or desired surgical outcome.

Procedures for prolapse can be broadly categorized into three groups: (i) restorative, which use the patient's endogenous support structures; (ii) compensatory, which attempt to replace deficient support with permanent graft material; and (iii) obliterative, which close or partially close the vagina.

These groupings are somewhat arbitrary and not entirely exclusive. For example, grafts may be used to reinforce repairs such as colporrhaphy, or to replace support that is deficient or lacking. Graft use in sacrocolpopexy substitutes for the connective tissues attachments (cardinal and uterosacral ligaments) that would normally support the vaginal apex. In addition to the primary goal of relieving symptoms related to prolapse, urinary, defecatory, and sexual function must be considered in choosing the appropriate procedures. The following section includes

a review of (i) the anatomy of pelvic support structures, (ii) the defects related to these structures, and (iii) some of the most commonly used surgical procedures to correct these defects.

Basic Anatomy of Support Structures

Pelvic support structures include:

- The muscles and connective tissue of the pelvic floor
- The fibromuscular tissue of the vaginal wall
- The endopelvic connective tissue

The endopelvic connective tissue includes:

- The cardinal/uterosacral complex, which attaches the upper vagina and cervix posteriorly
- Lateral connective tissue attachments of the anterior vaginal wall to the arcus tendineus pelvis and of the posterior vaginal wall to the fascia of the levator ani and to the posterior arcus tendineus near the ischial spine
- Less dense areolar connective tissue surrounding retroperineal portion of the pelvic organs

The orientation of these structures is noted in Figure 24.1. In general, an intact pelvic floor, including a functional puborectalis muscle and an intact cardinal/uterosacral complex, should prevent pelvic organ prolapse by allowing posterior deflection of the rectum and

P.912

vagina, and compression of these structures against the pelvic floor in the upright position (Fig. 24.9). The fibromuscular layer of the vaginal wall and the other endopelvic connective tissue attachments augment the support structure and are particularly important when pelvic floor function is compromised.

Figure 24.9 Vaginograms from the same patient at rest (A) and during Valsalva maneuver (B). Illustrates posterior vaginal deflection maintained by apical cardinal/uterosacral posterior suspension and the anterior sling effect of the puborectalis muscle and more distal perineal structures. (From **Nichols DH, Randall CL.** *Vaginal surgery.* 4th ed. Baltimore, MD: Williams & Wilkins, 1996: 4–5.)

Whether to repair all defects is controversial. Restorative repairs may be less successful than compensatory repairs in patients with generally “poor tissue,” and at times one defect repair may exert more tension on the repair of another defect. Management should be based on the patient's presentation, expectations, the specific anatomical defects noted (preoperatively and, at times, intraoperatively), and on the presence or absence of lower urinary and bowel dysfunction.

The Anterior Compartment

The anterior vaginal compartment includes the anterior vaginal wall, its attachments, the urethra, and the bladder. The support structure for the bladder is the rhomboid-shaped anterior vaginal wall (specifically its fibromuscular layer), which is attached laterally to the arcus tendineus fascia (Fig. 24.10). Inferiorly, the fibromuscular layer blends in with the connective tissue, which spans the two bands of puborectalis and pubococcygeus muscles and the pubic rami. The urethra appears to be preferentially supported by these connective tissues as well as by the pubourethral ligaments, which have debatable function. In the apical area, the vaginal fibromuscular layer blends in with the precervical fascia and the connective tissue of the cardinal ligament complex. In the upright position, the rhomboid-shaped anterior vaginal wall is oriented approximately

30 degrees from the horizon (from pubis to ischial spines). There is some downward bulge of the central area of the rhomboid plate, which should be minimized by the back-stop effect of the posterior vagina and rectum if the pelvic floor anatomy and function are normal.

Figure 24.10 View of the pelvic cavity with bladder, upper vagina, and sigmoid colon removed. The fibromuscular wall of the anterior vagina is attached to the arcus tendineus fascia pelvis by endopelvic connective tissue and supports the bladder. The pararectal fascia (Denonvillier's fascia) includes the fibromuscular tissue of the posterior vagina and its lateral attachment to the fascia levator ani.

Defects of this support structure may include tears or attenuation of the vaginal fibromuscular wall, or detachment from the pelvic sidewalls, the cervix or cardinal ligament complex, or from the pubis. Specific sites of fibromuscular tears are frequently difficult to recognize.

Physical examination may reveal the following findings:

- The presence of a central ballooning-type defect
- Descent of the area of the vaginal wall below the bladder neck
- Descent of the cervix or apical vaginal area
- The presence or absence of sulci extending lateroanteriorly, which would indicate that lateral detachment to the arcus is maintained or lost.

Anterior Vaginal Colporrhaphy

Anatomic correction of an anterior defect or cystocele will generally relieve symptoms of protrusion and pressure, and usually will improve micturition function when abnormal micturition is associated temporally with the defect and if there is no associated neuropathy. If a single, well-defined midline defect is recognized, excision of the weak vaginal wall and an imbricating closure of the defect may be performed. Most central

anterior defects require a more extensive dissection of the vesicovaginal space. Following this dissection, many surgeons then separate the vaginal mucosa and submucosal layers from the fibromuscular layer out to a point lateral to the defect, followed by midline plication of this tissue, then excision of excess epithelium, and closure. **It appears of great importance to maintain the continuum of repaired fibromuscular tissue to a well-supported vaginal apex.** A high central defect may also be corrected via a transabdominal approach by dissecting between the base of the bladder and the upper one third of the anterior vaginal wall. The defective tissue may then be wedged out and the defect closed with running or interrupted sutures. This approach may be of use when performing transabdominal procedures for apical suspension.

If the patient has significant stress incontinence (based on report or the presence of occult or potential incontinence), an appropriate bladder neck suspension may be performed simultaneously with the anterior repair (see Chapter 23). When performing midurethral sling procedures, it may be preferable not to extend the repair procedure below the urethra, but instead to make a separate incision for the sling. Maintaining some degree of the urethrovesical angle may improve the results of any incontinence procedure. If the patient has voiding dysfunction (reports of incomplete emptying and a high residual urine) and stress incontinence, appropriate urodynamic evaluation should be performed before a procedure is selected, and the patient should be made aware of the potential for continued problems after surgery.

Recurrence rates of traditional "fibromuscular plication" anterior repairs vary from 3% to 92% (47,48,49,50,51,52,53,54,55,56); however, studies define recurrence in numerous ways, from minimal prolapse to stage III descent. The clinical significance of recurrent mild cystoceles (stage I) that are asymptomatic is debatable because many of these defects do not progress to larger ones. When traditional anterior repairs are performed in patients with POP-Q stage II or greater cystoceles (frequently concurrently with other procedures), a 20% recurrence rate of stage II or greater prolapse is not uncommon, although overall recurrence rates as low as 3% have been reported (50). Many studies do not define how the subjects were evaluated postoperatively and vary with respect to patient populations, type of and severity of defects, presence of concurrent defects, surgical technique, and follow-up time and length. Some studies have suggested higher recurrence rates when these repairs are performed concurrently with sacrospinous suspensions and hypothesize that this type of apical suspension may predispose the repair anterior wall to greater pressure transmission (51,57,58). These studies may show higher failure rates because patients having such concurrent repairs may be more likely to have more complicated forms of prolapse or more extensive pelvic floor defects than other patients.

The addition of adjunctive graft materials empirically should improve success rates. Two randomized trials (55,56) suggest modest improvement in success, with an additional 12% to 18% to the "cure" rates after 1 year when polyglactin mesh (Vicryl) was placed over the midline plication compared with standard repair. However, most surgeons have abandoned this type of mesh because of subsequent failures. Other graft materials appear to have more promise. Fascial autologous grafts, allografts, xenografts, and newer synthetics are presently used by many surgeons with variable short-term success. Thus far, there are little data on adverse effects and success rates after 3 years. These materials have been used in several ways in the anterior compartment, including placement of smaller grafts to bolster suture lines and larger grafts to provide complete substitution of the entire anterior support plate from the pubis to the arcus to the vaginal apex (59,60,61,62,63,64).

Paravaginal Repair

The paravaginal or "lateral defect" repair involves reattachment of the anterior lateral vaginal sulcus to the obturator internus fascia and, in some cases, muscle at the level of the arcus tendineus pelvis ("white line") (65,66). It is usually performed as

P.915

a bilateral procedure via transvaginal or retropubic (abdominal or laparoscopic) access. The procedure essentially restores normal anatomy; however, as it is not practical to rebuild the defective endopelvic–fascial bridge to the pelvic sidewall, it attaches the vaginal wall itself. Observational studies have reported good success with this procedure (80%–95%) (67,68,69,70,71,72); however, long-term data on durability and function are lacking. **Most women with anteriolateral detachments usually have separation of the upper vaginal fornices from the arcus tendineus immediately adjacent to the ischial spine (Fig. 24.11) (73). Thus, it is important to resuspend those specific areas.**

It is difficult to achieve optimal results when the paravaginal repair is used in combination with traditional central repairs because of the creation of tension on opposing suture lines. A repair that removes a weakened central vaginal wall may decrease the side-to-side dimensions of the anterior vaginal wall, making it difficult to suspend its lateral points more laterally. When large central defects coexist with lateral defects, one option is an extensive central repair accompanied by a good apical support procedure. This changes the shape of the vagina to a more cylindrical structure. Another choice is placement of a graft

P.916

to span the entire anterior rhomboid-shaped plate, thus augmenting anterior paravaginal tissue strength. The graft with tension adjusted may be anchored to the arcus tendineus along with the adjacent vaginal wall from the level of the pubic rami to the ischial spine.

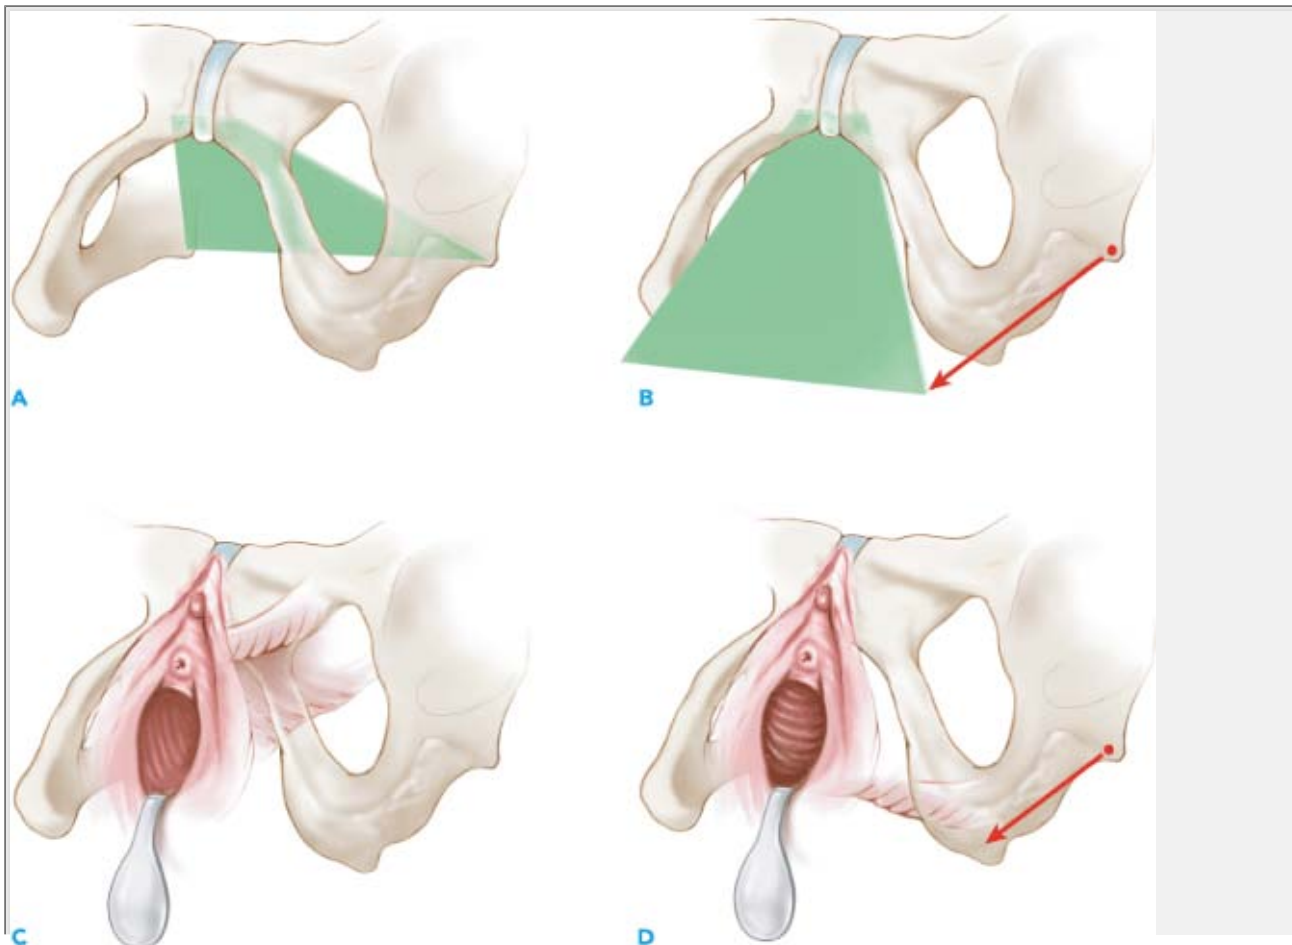

Figure 24.11 Schematics illustrating normal attachments of the anterior fibromuscular vaginal plane (A and C) and bilateral detachments of that plane from the arcus tendineus up to the level of the ischial spines (B and D). Note: For B and D to occur, there will either be concurrent apical descent or a detachment of the upper fibromuscular plane from the apical structures. (From Delancey JO. Fascial and muscular abnormalities in women with urethral hypermobility and anterior vaginal wall prolapse. *Am J Obstet Gynecol* 2002;187(1):93–98.)

Although most reports indicate that repair of anterior defects with all of these procedures relieves symptoms directly related to prolapse, there are very little data on patient satisfaction and quality-of-life improvement over time.

The Posterior Compartment

The support of the rectum and posterior vagina includes the pelvic floor musculature and connective tissue posteriorly and Denonvillier's (pararectal) fascia, which is the fibromuscular layer of the posterior vaginal wall and its lateral attachments to the lateral pelvic floor (levator) musculature and its fascia (Fig. 24.12). This lateral attachment site, the fascia levator ani, fuses with the arcus tendineus fascia pelvis at the mid- to upper level of the vagina and continues to the level of the ischial spine. Less dense, areolar, connective tissue surrounds the rectum and vagina and may supply some support to these structures as well.

Three levels of vaginal attachment have been described (74):

- Level 1 includes the upper vagina, which has cardinal/uterosacral attachments.
- Level 2 is the midvagina and its attachments laterally.
- Level 3 is the vagina between the puborectalis muscle, bulbocavernosus muscle, and perineal membrane.

The fibromuscular layer at the upper vagina fuses with the paracervical fascia and the fan-shaped cardinal ligament structure. The integrity of the attachment of this posterior vaginal layer to the anterior rectal wall just below the rectal sigmoid junction

P.917

prevents enterocele formation. In the distal vagina, the fibromuscular layer fuses laterally with the fascia of the puborectalis and then the bulbocavernosus muscle and centrally with the perineal connective tissue. Thus, normal posterior support includes a plate of connective tissue that is attached laterally as noted, posteriorly toward sacral segments 2–4, and inferiorly to the perineum. This fibromuscular plane not only holds the rectum in place posteriorly, but also aids in preventing perineal descent by suspending the perineum to the sacrum. The constant resting tone of the pelvic floor muscles, particularly the puborectalis, serve to close the genital hiatus pulling the distal vagina and anorectal junction toward the pubic symphysis, creating an anorectal angle and a posterior deflection of the rectum, vagina, and bladder base.

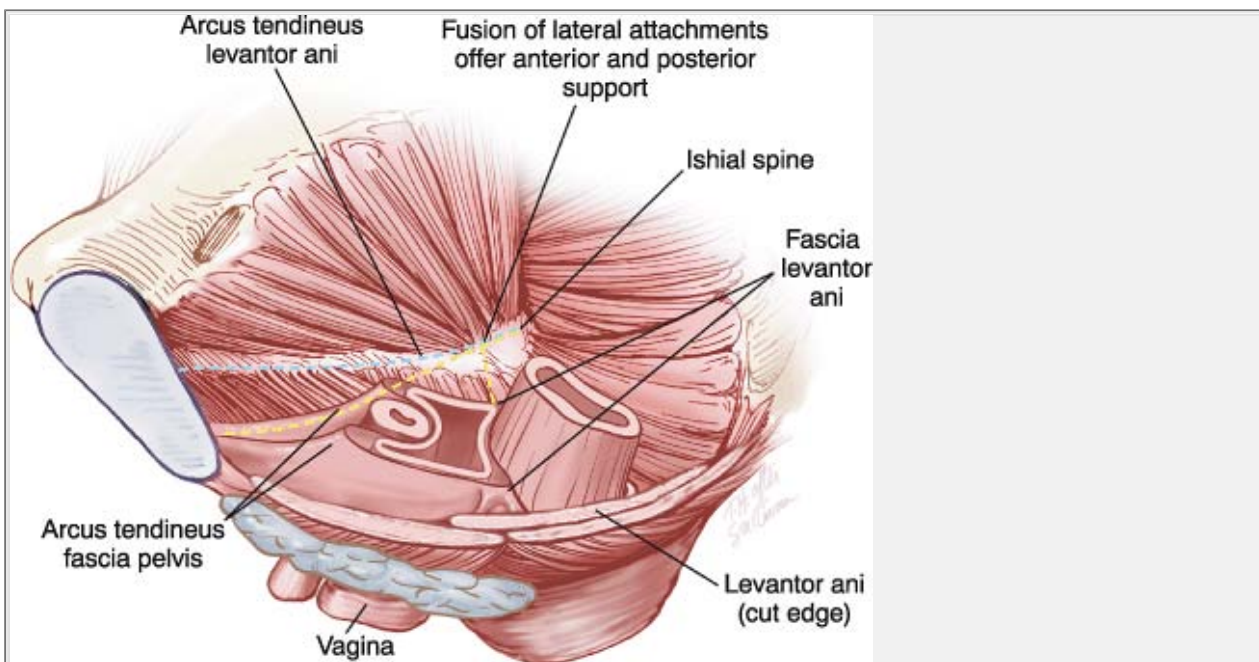

Figure 24.12 Saggital oblique view of the distal midvagina illustrating lateral connection of the posterior musculoconnective tissue wall to the fascia levator ani and anterior wall to the arcus tendineus pelvis. The attachment sites fuse together at a point closer to the ischial spine where the vagina assumes a more oval shape. (Modified by J. Taylor from illustration by Lianne Krueger Sullivan. From **Cundiff GW, Fenner D.** Evaluation and treatment of women with rectocele: focus on associated defecatory and sexual dysfunction. *Obstet Gynecol* 2004; 104:1403–1421, erratum in *Obstet Gynecol* 2005; 105:222.)

It has been hypothesized, based on careful cadaveric dissections, that most rectoceles were due to discrete tears in the Denonvillier's fascia at its lateral, apical, and perineal attachments and centrally within the fascia itself (75). Perineal detachment, along with a defect in the perineal membrane, has been described as a perineal rectocele, which is most commonly associated with reports of difficulty with defecation. Apical attachment defects are generally associated with enteroceles and occasionally sigmoidoceles.

Once a decision is made to perform surgical repair of the posterior compartment based on symptoms, type, and location of defects, an appropriate approach should be determined and the patient should be made aware of the expected outcomes and potential adverse effects such as pain and sexual dysfunction. **If the patient has defecatory dysfunction with a rectocele and symptoms of constipation, pain with defecation, fecal or flatal incontinence, or any signs of levator spasm or anal sphincter spasm, appropriate evaluation and conservative management of concurrent problems should be initiated before repair of the rectocele.** Specific types of repairs include the traditional posterior colporrhaphy, the defect-directed repair, replacement of fascia with graft materials, transanal repairs, and abdominal approaches by laparotomy or laparoscopy.

Traditional Posterior Colporrhaphy

The first description of the **posterior colporrhaphy** involved plication of the pubococcygeus muscles across the anterior rectum as well as perineal body reconstruction (76). The technique has subsequently been modified in attempts to preserve sexual function. Typically a midline incision is extended from the perineal body to the vaginal apex or to the cephalad border of a small or distal rectocele. **The Denonvillier's fascia is mobilized from the vaginal epithelium, leaving as much of this tissue as possible attached laterally to the levator fascia. After obvious defects in the rectal muscularis are repaired, the fascia**

is then plicated in the midline with interrupted or continuous sutures. The authors prefer delayed absorbable for this plication. Permanent nonbraided suture material also can be used. Braided permanent suture material is associated with a greater incidence of stitch infection and formation of granulation tissue (77). The vaginal epithelium is trimmed and closed with absorbable sutures.

When a defective perineal body or perineal membrane is present, reconstruction is performed after accompanying posterior colporrhaphy. The superficial muscles of the perineum and bulbocavernosus fascia are plicated in the midline and the skin closed as in an episiotomy repair. Detachments of the inferior portion of the Denonvillier's fascia from the perineal body are also corrected. The puborectalis muscles are plicated concurrently with these procedures by some surgeons, but this approach is associated with a high incidence of sexual dysfunction and thus is not recommended routinely. It may be worth consideration in patients who have severe prolapse accompanied by a large genital hiatus with palpable levator weakness or who are unable to contract their pelvic floor muscles. Sutures should be placed carefully through the puborectalis muscles at least 3 cm or greater posterior to their insertion on the pubic rami, thereby decreasing the tension of the plication. For those women with an enlarged hiatus and weakened puborectalis muscles

P.918

who desire sexual function, an attempt can be made to plicate the muscles far enough posteriorly to allow two fingers to easily pass through the vaginal introitus and to reconstruct the distal posterior vagina and perineum, whereby there will not be a ledge at the site of the puborectalis plication. Outcome data on such procedures are inadequate to make conclusions regarding its efficacy; however, it is reasonable to postulate that **pelvic floor defects producing an enlarged genital hiatus are common reasons for failure of support procedures and that puborectalis plication may decrease the incidence of such failures.**

A complete review of rectocele, anorectal functional disorders, and various repairs can be found elsewhere (78). Reported anatomic cure rates for traditional posterior colporrhaphy have ranged from 76% to 90% with variable follow-up intervals (79,80,81,82,83). Most studies show a benefit in ease of defecation if patients are using splinting preoperatively; however, overall defecatory dysfunction (defined as constipation) was not relieved in most of the subjects and increased (approximately 30%) after the procedure in one study (81). These repairs appear to have little to no benefit in the treatment of fecal incontinence. It is not surprising that the repairs are not particularly effective for defecatory dysfunction related to disorders of constipation or for fecal incontinence because these problems have multifactorial causes. **De novo dyspareunia is reported to occur in 8% to 26% of sexually active patients who have traditional posterior colporrhaphy** (79,80,81,82,84) and is not always associated with levator plication procedures (85). Potential causes for dyspareunia, other than vaginal strictures or introital tightness, include scarring with immobility of the vaginal wall, levator spasm, and neuralgia associated with sutures or dissection. Dyspareunia also may occur when a Burch procedure or other procedures that displace the vaginal canal anteriorly are combined with a posterior repair (82). Careful surgical technique and appropriate choice of procedure should decrease the incidence of postoperative dyspareunia.

Defect Specific Posterior Repair

Defect or site-specific posterior repairs are restorative procedures by which posterior defects are corrected. These repairs begin with midline posterior vaginal incision through the epithelium, then continue with separation of the epithelium from the fibromuscular wall. After irrigation to provide better exposure, a finger is inserted in the rectum to help define defects

of the rectal wall and the fibromuscular layer that has been dissected from the vaginal wall submucosa. The specific defects are closed with either interrupted or running sutures (preferably the delayed absorbable type). Defect closure is accomplished in such a way to minimize tension on the surrounding tissue and may involve vertical, horizontal, or oblique approximation. When fibromuscular tissue has separated from the perineum, the upper anterior rectum, or a well-supported cervix or vaginal cuff, it is important to reapproximate these connections. Repairs of coexistent perineal and apical support defects are important. **The object of the surgery is to re-establish an intact plane of connective tissue that positions the rectum against the pelvic floor and obliterates any potential space between a well-supported cervix or vaginal cuff and the cephalad edge of the tissue plane and upper rectum.** The technique should minimize tension and potential strictures, which may be more likely to occur with traditional posterior colporrhaphy.

Initial case series reveal anatomical cure rates with mean follow-up times less than 18 months from 82% to 100% (85,86,87,88,89) and *de novo* dyspareunia rates of 2% to 7% (85), which are much lower than those seen with traditional repairs. Symptom relief appears to be as good or better than that seen with traditional repairs. The greatest concern with these and other procedures has been durability. A recent report (83) indicates that the recurrence rate of rectocele beyond the midvaginal plane was higher with defect-specific posterior repairs than with side-to-side plication procedures using laterally attached fascia pulled to the midline (33% versus 14%) and beyond the hymenal ring (11% versus 4%). The study was not randomized; however, the procedures were performed during the same period with

P.919

consistent follow-up evaluations 1 year after surgery. Symptoms (dyspareunia, constipation, and fecal incontinence) after surgery did not differ between the two groups. Long-term follow-up of previously reported case series that had good short-term success or prospective randomized trials looking at modifications of traditional repairs versus defect-specific repairs should clearly delineate durability of these procedures.

As with anterior compartment procedures, graft materials have been used to improve the success of posterior compartment repairs. The use of a dermal allograft to augment defect-directed repairs has been described (90). The graft is sutured to the levator fascia on both sides of the defect to cover the rectovaginal plane. One concern about this technique is that, in patients with relatively thin vaginal walls, removal of the fibromuscular tissue may devascularize the mucosa and make it more subject to erosion over the graft material. The following technique may allow better healing of the vaginal epithelium anterior to the graft: **Vaginal estrogen is administered for 4 to 8 weeks preoperatively to improve the quality of vaginal mucosa in women with vaginal atrophy.** The initial surgical dissection is deep to the fibromuscular layer. Access to the lateral levator fascia is generally easily accomplished with a division of the Denonvillier's fascia at its incorporation into the posterior vaginal wall or, if the lateral attachment is not present, with combined sharp and blunt dissection to expose the paralevator fascia. This levator fascia on each side, as well as any remaining lateral Denonvillier's fascia and occasionally muscle, is incorporated into the edge of the graft with sutures. The cephalad edge of the graft is attached posteriorly to the anterior rectum at its sigmoid junction and anteriorly to a well-suspended vaginal cuff. The caudad edge is incorporated in an appropriate repair of the perineal area. With short-term, mean followup of 12 to 30 months, overall results reveal good anatomic cure rates of 89% to 100% with cadaveric dermis (90), autologous dermis (91), polyglactin mesh (56), and polypropylene mesh (92,93,94). Improvement in obstipation has also been reported. Although the numbers of subjects assessed have been relatively low, *de novo* dyspareunia rates have been between 0 and 7%, which are less than those reported for traditional posterior repairs (78).

Abdominal Approach to Posterior Repair

When abdominal sacrocolpopexy is planned for apical vaginal prolapse and concomitant rectocele is present, some have advocated extending the posterior graft down the posterior vaginal wall to correct the defect. The technique of sacral colpoperineopexy is used to replace the normal vaginal suspensory ligaments and to augment or replace the posterior fibromuscular plane with graft material that runs from the sacrum to the perineal body (95). Its purpose is to correct the posterior compartment defects and to suspend the perineal body, thus preventing descent and opening of the genital hiatus. It has been performed transabdominally or as a combined abdominal and vaginal procedure (95,96) with both Mersilene mesh and dermal allografts. Mesh erosion occurred frequently when the vagina was open: 16% for vaginal placed sutures and 40% for transvaginally placed mesh (96). The use of dermal allografts results in an anatomical cure rate of 82% with short-term follow-up and a mean of 12 months following surgery (95,96). Significant improvements also were seen in bowel symptoms. One author (97) reported results on 205 of 236 subjects who underwent an abdominal sacral colpoperineopexy with polypropylene mesh (Marlex) without opening the vagina. This procedure included two straps of mesh attached from the lateral anterior vagina to Cooper's ligament. Ten-year satisfaction rates were 68%, and erosion rates were 5%.

Laparoscopic Approach to Posterior Repair

Laparoscopic rectocele repair involves the dissection of the rectovaginal space to the perineal body with either plication of levator fascia or suturing absorbable or permanent mesh in place (98,99). A few small case series have been reported with variable results.

P.920

Transanal Posterior Repair

The aim of transanal rectocele repair, usually performed by colorectal surgeons rather than gynecologists, is to remove or plicate redundant rectal mucosa, to decrease the size of the rectal vault, and to plicate the rectal muscularis. The rectovaginal adventitia and septum are plicated as well, probably along with the posterior vaginal muscularis. The vaginal epithelium is not incised or excised with this procedure, which probably accounts for the reported lack of adverse effects on sexual function in contrast to the vaginal approach to posterior repair. Two randomized trials (100,101) and several case series (102,103,104) from transanal repairs with mean follow-up intervals of 12 to 52 months report anatomic cure rates of 70% to 98%, improved constipation and fecal incontinence, and less need for vaginal digitation to expel stool. Complications included infections and rectovaginal fistulas, which are surprisingly rare in the reported series. From the gynecologic perspective, transanal posterior repair is an option only when the procedure is performed for defecatory dysfunction and not for prolapse of the posterior vaginal wall. The question remains whether the transanal approach with defect excision and repair improves defecatory dysfunction better than a defect-specific transperineal or transvaginal approach with imbrication of tissues to correct palpable weakness in the rectal wall and its adjacent connective tissues.

The Apical Compartment

Normal apical support includes the integrity of the cardinal/uterosacral ligaments, the upper paravaginal fibromuscular connective tissue, and, when the uterus is present, the paracervical fascia. The fibromuscular tissue of the upper vagina blends in with the paracervical fascia. Both of these are attached laterally and posterior laterally to the cardinal ligaments and uterosacral ligaments (see Fig. 24.1). The

vaginal fibromuscular tissue is also attached to the upper anterior rectum at its sigmoid junction and forms the inferior border of the cul-de-sac of Douglas. The cardinal and uterosacral ligaments are condensations of areolar connective tissue. Their origin is at the lateral borders of sacral vertebra 2–4, and they travel retroperitoneally to their insertion at the upper vagina and cervix (Fig. 24.1). They serve as the anterior and lateral borders of the cul-de-sac and cross at or just anterior to the ischial spines. The ureter is closest to the uterosacral ligament at or just posterior to its insertion on the posterior lateral cervix. If anterior cephalad traction is placed on the ureter or cervix, frequently the cardinal uterosacral ligaments will stand out as ridges lateral to the cul-de-sac; however, peritoneal folds may have similar appearance. Therefore, placement of sutures in such structures based on visual appearance alone does not always guarantee inclusion of the ligament.

Defects in apical support include:

- The loss of cardinal/uterosacral support with resultant cervical/uterine or vaginal cuff descent
- The detachment of the fibromuscular vagina from the anterior rectum with resultant enterocele or, at times, sigmoidocele into the rectovaginal space
- Tears or attenuation of the upper fibromuscular tissue, usually after hysterectomy, leading to a central apical descent that frequently presents as a ballooning defect

Often, these defects occur concurrently. Defects in cardinal/uterosacral attachment are at sites close to their insertion where breaks or tears occur; in subjects with apical descent, condensations of cardinal/uterosacral tissue can be found adjacent to the peritoneum just cephalad to the ischial spines (105).

Examination for apical defects is at times difficult. Such defects may easily be missed when large anterior or posterior defects are present. In cases when apical defects are

P.921

suspected but not confirmed, surgeons should evaluate the apical support intraoperatively and plan for management of these defects when they are found. Traction on the cervix with a tenaculum or on the vaginal cuff both centrally and laterally with Allis clamps may reveal otherwise unrecognized defects.

Repairs of apical defects may be performed transvaginally or transabdominally, with laparotomy or laparoscopy. **Transvaginal repairs include extraperitoneal procedures such as sacrospinous suspensions, iliococcygeal suspensions, and high paravaginal suspensions** of the apical vaginal fornices to the arcus tendineus at the level of the ischial spine or to the endopelvic fascia, and intraperitoneal suspensions such as uterosacral suspensions and McCall culdoplasties (106). It is generally agreed that the vaginal apex should be resuspended in a posterior cephalad direction to a site or sites posterior and caudad to the sacral promontory. Anterior apical suspensions change the direction of the vaginal axis and may be fraught with a greater incidence of posterior compartment defects, including rectoceles, enteroceles, and sigmoidoceles.

The general principles of the repair should include management of the specific apical defects:

-

If present, the attenuated part of the upper vaginal wall (fibromuscular defect) should be repaired or covered by graft material.

- The vaginal cuff or, in some instances, the cervix should be suspended without excessive tension.
- Any defect in the attachment of the upper vagina to the rectum at or below its sigmoid junction should be corrected.

Enterocoele repairs may include:

- Removal of the peritoneal sac with closure of the peritoneal defect, followed by closure of the fascial or fibromuscular defect or both below it
- Dissection and reduction of the peritoneal sac and closure of the defect
- Obliteration of the peritoneal sac from within with transabdominal Halban or Moschowitz type procedures or transvaginal McCall or Halban procedures (107).

Historically, the treatment for symptomatic uterine prolapse has been hysterectomy, which is performed vaginally or abdominally in combination with an apical suspension procedure, and repair of coexisting defects. Apical support procedures that have been described for use when the uterus or cervix is to be kept in place include Manchester and Gilliam procedures and fixation of the cervix to the sacrospinous ligament (108). The other procedures described in this section may also be used in women who desire uterine conservation. Adequate outcome data on such uterine sparing procedures are not yet available. When the cervix is absent, in addition to repair of fibromuscular defects, both fibromuscular planes anterior and posterior to the vaginal cuff should be attached to whatever suspension is employed.

Sacrospinous Ligament Fixation

The fixation of the vaginal apex to the sacrospinous ligament, the tendinous component of the coccygeus muscle, was first described in 1958 (109) and subsequently was modified in Europe and the United States (110,111,112). **Access is traditionally extraperitoneal via the rectovaginal space with penetration of the pararectal (Denonvillier's fascia) at the level of the ischial spine to expose the muscle and ligament. Variations to this approach to the**

P.922

ligament include approaches through an anterior lateral approach, an apical approach posterior to the uterosacral ligament, and a laparoscopic approach (113,114,115). Bilateral sacrospinous ligament suspensions (116,117) have also been advocated; however, these techniques may impose a greater degree of tension on the sutures and, at times, create a band of apical vagina across the rectum at the level of the suspension. Whether this can cause defecatory dysfunction is debatable. The advantages of the sacrospinous fixation procedure include (i) its transvaginal extraperitoneal approach, (ii) resultant posterior vaginal deflection, and (iii) the fact that it is a relatively durable repair if performed correctly. Reported success for apical support has been good—approximately 97%—with follow-up times ranging from 1 month to 11 years (106). However, there have

been subsequent reports of high rates of anterior vaginal prolapse (51,57,58). It is not clear whether this observation is related to the procedure and its exaggerated posterior vaginal deflection or to other inherent factors for anterior prolapse in those women who underwent the procedures. Other disadvantages of the procedure include (i) relative difficulty in adequately exposing the ligament, (ii) an unnatural lateral vaginal deflection toward the fixation site, (iii) an inability to perform without excessive tension when the vaginal length is compromised, as may be the case in repeat procedures, (iv) potential risk for sciatic nerve or pudendal nerve or vessel injury, and (v) occasional need to shorten or narrow the upper vagina when a fibromuscular defect involves much of the apical area. Some of these problems are not unique to this procedure.

Iliococcygeal Vaginal Suspension

Iliococcygeal vaginal suspension involves the attachment, usually bilaterally, of the vaginal apex to the iliococcygeus muscle and fascia (117,118,119). Extraperitoneal access is achieved via the posterior vagina. Compared with other vaginal suspension procedures, the iliococcygeal suspension has the fewest case series in the literature (118,119,120); however, cure rates appear comparable to the sacrospinous suspension technique (106). The dissection of the area to the ischial spine is approached from a midline posterior vaginal wall incision using the ischial spine as a landmark for identifying the sacrospinous ligament and the iliococcygeal fascia anteriorly and caudad to it. A no. 1 polydioxanone suture is placed through the fascia and attached to the vaginal apex as a pulley stitch. This procedure is more easily performed bilaterally than the sacrospinous suspension and should be considered particularly in the presence of a shortened vagina. Risk of major vessel, nerve, or ureteral injury should be relatively low compared with other transvaginal suspensions.

Uterosacral Ligament Suspension

Surgical variations of the uterosacral ligament suspension originally described in 1938 (121) have been used prophylactically during hysterectomy or therapeutically for vaginal apical suspension. **A therapeutic procedure in which the vaginal apex is suspended to the uterosacral ligaments above the level of the ischial spines had excellent success rates in an observational study of 302 subjects** (122). Once access to the posterior cul-de-sac has been attained, the uterosacral ligament remnant can usually be found adjacent to the pelvic sidewall peritoneum just cephalad to the palpable ischial spine. Up to three sutures were placed in each ligament and incorporated into the anterior and posterior fibromuscular layer of the vagina. Some surgeons approximate the ligaments in the midline to close the cul-de-sac with the intention to treat or prevent enterocele formation (123). Other surgeons suspend the right and left vaginal apex to the ipsilateral uterosacral ligament, leaving the cul-de-sac open to avoid impinging on the rectum and adversely affecting bowel function.

Outcome studies have shown that recurrent apical prolapse occurs in 2% to 5% of cases within the first few years following the procedure, which is a rate comparable or superior to other transvaginal apical repairs (122,124), and the incidence of recurrent anterior defects may be less than that reported with sacrospinous suspensions. The most common serious complication has been ureteral obstruction secondary to ureteral kinking or incorporation of an ureter in a suspension stitch. This has been shown to occur

P. 923

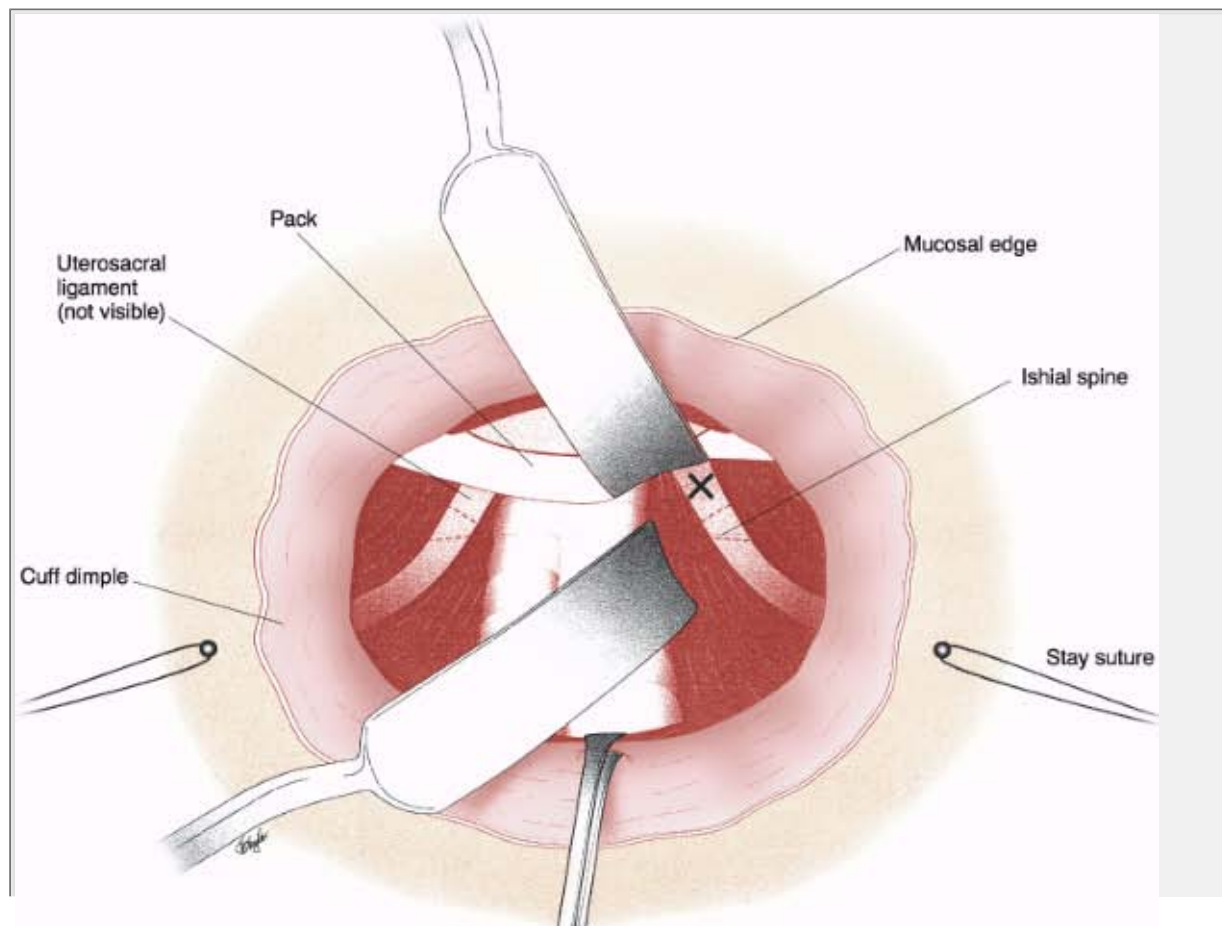

in as many as 11% of cases (124). Intraoperative cystoscopy—with documentation of ureteral patency after administration of indigo carmine dye, whereby such a problem can be corrected—is recommended.

Multiple sutures may increase the incidence of tissue devascularization and necrosis,

thus resulting in failure of the suspension. Exposure can be accomplished through the vaginal cuff after hysterectomy, a transverse incision at the vaginal cuff in cases of vaginal vault prolapse or descent, and, rarely, through a posterior colpotomy when uterine or cervical conservation is desired. When the apical vaginal wall is attenuated, it is excised. The pelvic side wall, lateral to the sigmoid colon, is exposed using Breisky–Navratil retractors and a pack to hold the small bowel cephalad and to place the sigmoid colon and side wall peritoneum on stretch (Fig. 24.13A). After palpation of the ischial spine, single permanent sutures of 0 or 1 polypropylene are placed through the peritoneum and adjacent ligament approximately 1 cm cephalad to and at the same posterior level as the ischial spines. Traction on the sutures and palpation of the site should reveal good purchase of the ligamentous structures. The sutures are tagged for use after repair of defects of the anterior compartment. The peritoneum is dissected off the vaginal fibromuscular wall posterior to the vaginal cuff. The suspension sutures are then secured with large bites into the posterior vaginal fibromuscular tissue and anterior fibromuscular tissue, then locked in place to

P.924

approximate anterior to posterior connective tissue and to fix the suture to the vaginal apex so that it may be moved up to the ligament (Fig. 24.13B). If a rectovaginal enterocele is present, it is dissected, reduced, and closed, approximating the prerectal fascia or anterior rectal wall to the posterior fibromuscular vaginal tissue just caudad to the suspension sutures. Absorbable cuff closure sutures are placed at each cuff angle and 1 to 2 bites are taken to approximate anterior to posterior vaginal cuff over the suspension suture sites. When indicated, plication of the central cuff anterior to the posterior fibromuscular tissue with a box stitch is also performed. These sutures are secured after the suspension (pulley) sutures are tied, then cuff closure is completed from each side with the absorbable sutures in a running fashion. Cystoscopy is performed to document ureteral patency. Ureteral compromise has been noted in only 2 of 150 cases performed. The procedure provides adequate support of POP–Q point C and D in all 58 subjects evaluated more than 1 year postoperatively.

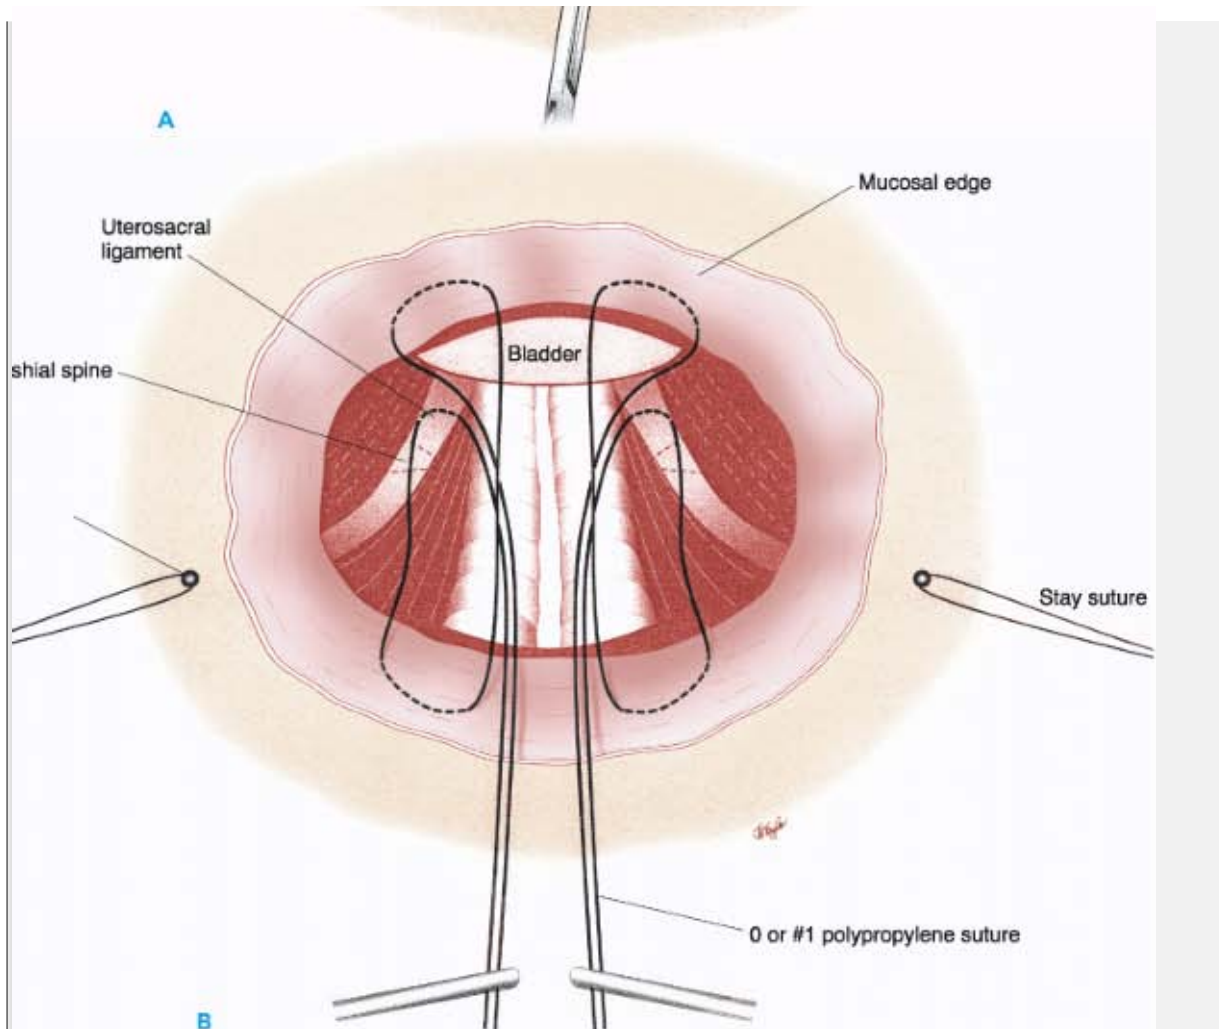

Figure 24.13 Diagrams illustrating open vaginal apical area with (A) exposure of site for suture placement or lateral pelvic side wall and (B) suture placement through ligament then through the posterior and anterior paravaginal tissue where they are locked to enable pulley action to the ligaments when tied. (Redrawn from an image by J. Taylor.)

Abdominal Procedures

Abdominal Uterosacral Suspension

Abdominal uterosacral colposuspension has been used prophylactically after hysterectomy and therapeutically for apical prolapse with cardinal/uterosacral defects. It can be performed through laparotomy incisions or by laparoscopic techniques. For the therapeutic procedure, a no. 1 polypropylene or delayed absorbable suture is placed cephalad and at the same level posterior as the ischial spines, which may be palpated transabdominally

P.925

or with a vaginal finger to push a vaginal fornix to the spine under observation with a laparoscope. One technique is to place one or two permanent sutures through one ligament, then, after reefing across the cul-de-sac peritoneum at the sigmoid border, through the contralateral ligament, then through the fibromuscular tissue just anterior to the vaginal cuff. Tying the suture suspends the vaginal cuff and obliterates any enterocele defect. Another technique employs separate sutures placed at the same level into each uterosacral ligament and anchored anteriorly and posteriorly to the ipsilateral side of the vaginal cuff, similar to procedures performed transvaginally. Cystoscopy is performed after the procedure to

document ureteral patency.

Abdominal Sacrocolpopexy

The standard approach to transabdominal apical vaginal suspension procedures is the abdominal sacrocolpopexy. A complete review of published data on these procedures developed by the Pelvic Floor Disorders Network, which is sponsored by the National Institute of Child Health and Human Development (NICHD), has been published (125). These procedures use graft material attached to the prolapsed region of the anterior and posterior vaginal walls at or encompassing the vaginal apex and suspended to the anterior longitudinal ligament of the sacrum. Cervical sacral suspensions may also be performed when uterine or cervical conservation is desired. Surgical variations abound and include configuration of the graft on the vagina, the extent to which the anterior and posterior vagina are attached to the graft, variable graft and suture materials, presence or absence of peritoneal closure over the graft, and obliteration of the cul-de-sac for treatment or prevention of the enterocele or sigmoidocele. **A thorough preoperative evaluation to exclude more distal defects or stress incontinence, which should be repaired concurrently, and other lower urinary tract or anorectal problems, is important.**

In published reports (126,127,128,129,130,131,132,133,134,135,136), cure rates for apical prolapse range from 78% to 100% (most greater than 90%); when cure is defined as no postoperative prolapse, the range widens from 56% to 100%, although subsequent anterior or posterior vaginal prolapse has not been as consistently reported as has apical prolapse. Potential advantages of this procedure over transvaginal procedures are less paravaginal scarring and denervation than may be present with transvaginal approaches, and fixation of the entire vaginal apical area by a permanent piece of material to a stable structure (the anterior sacral ligament), which may be more durable than the transvaginal techniques that use the subject's own connective tissue.

Complications of these procedures include (i) erosions of graft material or suture material, which may be caused by graft or suture infection usually secondary to vaginal wall penetration, or performing the procedure adjacent to a vaginal incision, or securing the graft to an attenuated avascular wall with inadequate fibromuscular tissue (3.4%); (ii) significant intraoperative hemorrhage (especially in the presacral space) (4.8%); (iii) postoperative ileus, which may be secondary to the need for excessive packing of bowel or to extensive Halban or Moschowitz culdoplasty procedures (3.6%); (iv) small bowel obstruction, requiring reoperation (1.1%); (v) development of intra-abdominal adhesions with resultant pain and bowel dysfunction (unknown incidence); and (vi) wound complications, such as seromas and infections (4.6%) (125).

Several management techniques have been advocated to minimize these problems. Empiric ways to prevent graft erosions include (i) preoperative tissue optimization with vaginal administration of estrogen and treatment of vaginitis and infection of eroded areas; (ii) the use of small-gauge monofilament sutures placed in the fibromuscular tissue, thus avoiding full thickness passage; and (iii) excision of a portion of the vaginal apex when the vaginal wall is thin and depleted of its fibromuscular layer and vascularity. Graft attachment to "healthy" fibromuscular tissue rather than to thin avascular tissue should help prevent erosion. **If such excision is necessary, or if the suspension is to be performed concurrently with a hysterectomy, good approximation of the fibromuscular layers above the mucosa, thorough irrigation, prophylactic use of antibiotics, and avoidance**

of graft placement across the suture line may decrease the likelihood of graft erosion. Choice of graft material may also be important. One would expect synthetic grafts to have greater durability than tissue grafts; however, erosion rates are more serious with

the synthetic grafts. Anecdotally, some surgeons are convinced that less porous graft material, such as GORE-TEX, has a greater likelihood of becoming infected and eroding than do porous, filamentous polypropylene meshes. Numerous case series report serious episodes of hemorrhage from the presacral venous plexus (mean incidence 4.8%; range 0.18%–16.9% of sacrocolpopexies requiring, at a minimum, transfusion) (125). This problem is less likely if dissection and graft fixation is limited to the level of S1 and S2 just caudad to the promontory and with the use of good light and meticulous dissection techniques to expose the anterior sacral ligament.

Careful tissue handling and packing technique may minimize postoperative ileus and adhesions. Incorporation of the sigmoid into a closure of the cul-de-sac posterior to the graft may also slow bowel function postoperatively. Small bowel obstruction has resulted from direct adhesive processes involving grafts to small bowel. Complete extra peritonealization of the graft using flaps of peritoneum dissected from the prolapsed area and the peritoneum anterior to the sacral promontory and lateral to the right side of the sigmoid colon should prevent this complication. However, loops of bowel have been seen to prolapse through small defects in peritoneal closure with the same effect. Careful technique with adherence to basic surgical principles may help prevent this and other complications related to laparotomy.

Laparoscopic Techniques

As with most pelvic operations, sacrocolpopexy has been successfully accomplished by the laparoscopic route and has the potential to offer patients the benefits of less postoperative discomfort and faster recovery as well as potential lower risks for adhesions and ileus. Outcomes depend on the expertise and experience of the surgeon; "cutting corners" to shorten the procedure could affect anatomical success. The applicability of the procedures is limited by the need for a relatively high level of technical skill.

For sacrocolpopexy, whether through laparotomy or laparoscopy, the pelvis should be completely exposed with the lower sigmoid colon stretched cephalad (Fig. 24.14).

- With a vaginal obturator (an EEA sizer) placed vaginally to visualize the area that is not covered by the bladder or rectum, the peritoneum is dissected from the underlying vaginal fibromuscular layer anteriorly to bladder reflection and posteriorly at least to the level of the sigmoid rectal junction, creating bilateral peritoneal flaps. Laterally, vascular bundles are visible.
- Two separate loosely woven polypropylene mesh grafts are shaped similar to boat paddles. The "paddle" portions are shaped to cover the areas anterior to the apex and posterior to the apex, respectively, and the "handles," which are approximately 8 to 10 cm in length and 1 cm wide, are anchored to the anterior sacral ligament. The paddle portions are secured circumferentially to the fibromuscular layers anteriorly and posteriorly with six to eight monofilament 3-0 nylon sutures and one or two sutures placed centrally (Fig. 24.14A).
- When the fibromuscular tissue in the area is attenuated, a portion of the vaginal wall is excised and closed as noted previously.
- The peritoneum overlying sacral vertebrae 1 and 2 is incised while retracting the sigmoid colon to the left, and careful dissection is employed down to the anterior ligament. Care is taken to stay well medial to the right ureter and hypogastric vessels.

- Hemoclips are placed caudad and cephalad on the middle sacral vessels if it is felt that this will allow more optimal suture placement. The peritoneal incision is extended into the right cul-de-sac area adjacent to the sigmoid.
- Closure of the cul-de-sac lateral to the sigmoid on the left and approximation of the distal presigmoid fat to the distal edge of the posterior graft is accomplished

with box stitches of 0-delayed absorbable sutures. It is thought that these procedures and the retroperitonealization of the graft through the right side of the cul-de-sac will prevent posterior enterocele and sigmoidocele as well as a Halban or Moschowitz procedure.

- The two "handle" ends of the graft are then brought to the point of sacral attachment, where their length is adjusted to remove any tension on the vaginal sutures and secured to the anterior sacral ligament with no. 1 permanent braided nylon sutures (Fig. 24.14B).
- Reperitonealization of the graft is then performed using the right cul-de-sac peritoneum and peritoneal flaps dissected from the vaginal apical area; occasionally presigmoid fat is used,

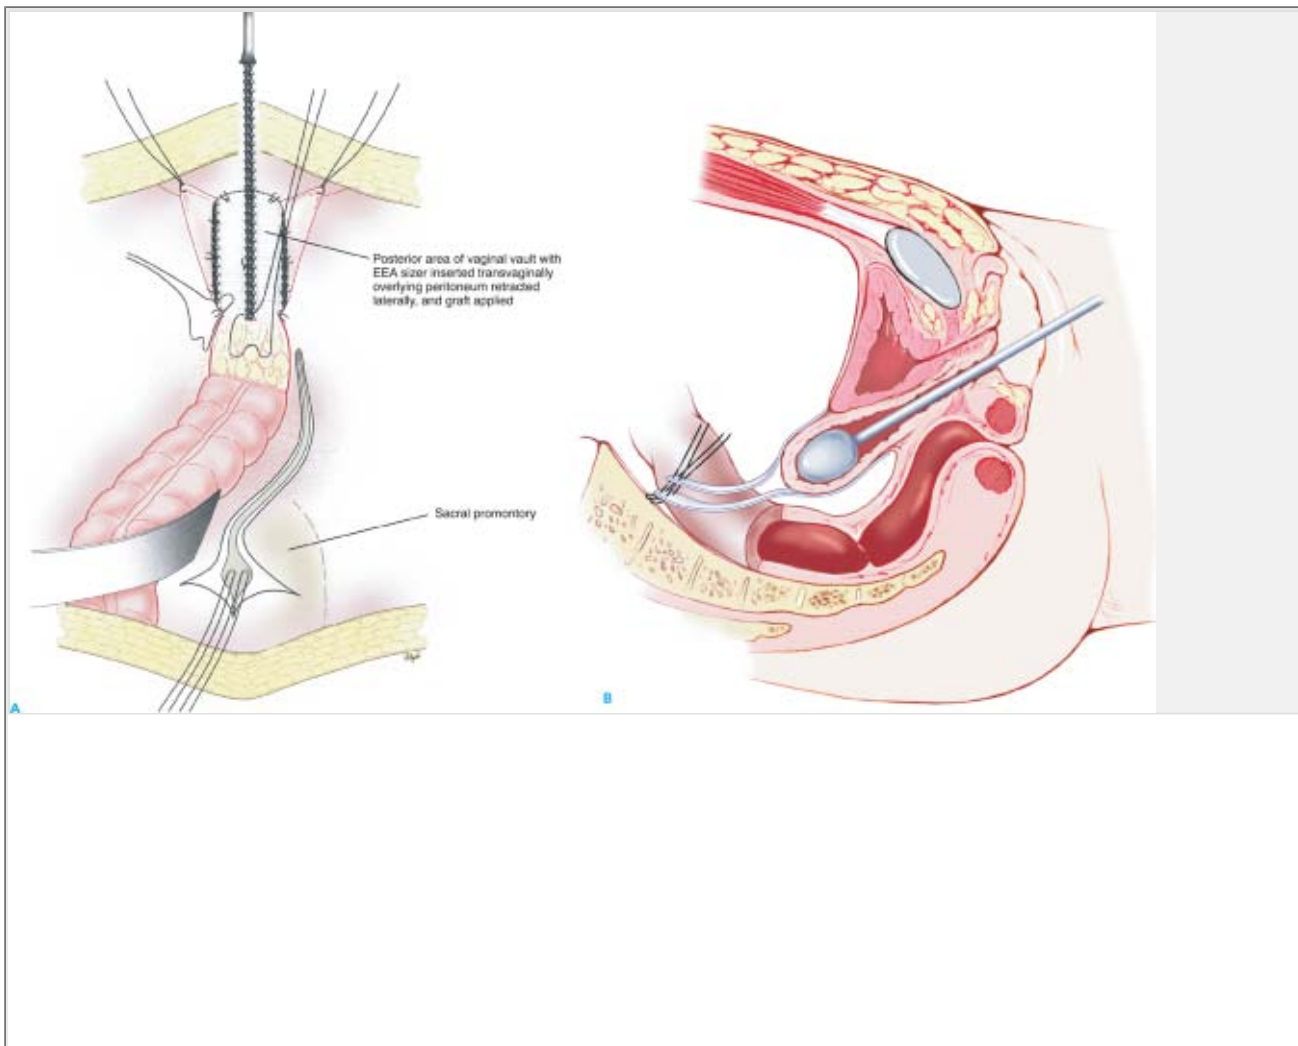

Figure 24.14 Sacrocolpopexy: (A) Illustrates (i) graft attachment to the posterior area of prolapsed vagina to or below the rectal-sigmoid junction after the overlying peritoneum has been dissected and flapped laterally and (ii) exposure of the presacral space with suture placement through the anterior sacral ligament. An appropriately shaped second graft is placed anteriorly. B: illustrates attachment of both grafts without tension to the sacrum. Prevention of subsequent enterocele and/or sigmoidocele is accomplished by box closure of the cul-de-sac peritoneum lateral to the left side of the sigmoid, attachment of the presigmoid fat to the graft centrally, and reperitonealization of the graft through the right side of the cul-de-sac. EEA, end-to-end anastomosis sizer. (Redrawn by J. Taylor.)

Following this procedure, adjunctive procedures such as paravaginal repair, Burch procedure, midurethral sling, and any transvaginal procedure that is indicated are performed. When rectocele and pelvic floor defects are present, one option is the sacral colpoperineopexy as discussed in the posterior compartment section (95). A vaginal pack is inserted for approximately 24 hours to ensure that the graft is well applied to the fibromuscular layer at points other than where sutures are placed.

P.929

Adjunctive or Graft Materials

Graft materials have been employed in repairing defects or hernias throughout the body. The purpose of grafts is to either completely replace "weak" tissue by spanning across that tissue or to provide a scaffold for fibroblast infiltration. The patient's own connective tissue may grow into the graft, and, if the graft is degradable, replace the graft as a supportive structure. An ideal graft material should (i) be nonantigenic, (ii) exhibit a low infection rate, (iii) decrease or negate recurrence of anatomic defects, (iv) cause no harm with respect to bowel or renal function, and (v) be relatively inexpensive. Graft materials include autologous tissues, cadaveric allografts and fascia, dermis and other connective tissues, xenografts from animal sources, and various synthetic materials. Allografts and xenografts are treated with processes to remove living cells, thus negating their antigenic potential and allowing them to serve as a temporary connective tissue scaffold. It is assumed that fresh, autologous grafts work similarly; however, there may be some fibroblast survival in fresh harvested tissue. Autologous grafts have limitations in size and shape compared with tissue taken from cadaveric or animal sources. Synthetic grafts are permanent and, as long as the tissues to which they are secured retain their position and strength, they should be durable. Autografts, allografts, and xenografts depend on adequate tissue growth from the subject and potentially may have higher failure rates than synthetic ones. Synthetic grafts are more subject to erosion. Graft erosion may produce bothersome discharge, pain, and sexual dysfunction with vaginal scarring. This may be more likely to occur in women with attenuated, scarred, or less vascular tissue at the time of the repair. More loosely woven polypropylene meshes appear to exhibit fewer problems with erosion and infection than previously used synthetic graft material.

The new midurethral sling procedures that use such mesh have reported erosion rates of 1% or less as compared with rates as high as 6% with more tightly woven polypropylene and polyethylene grafts. A greater incidence of graft infection has been reported when other synthetic grafts are used. One would expect higher rates of erosion and infection when large pieces of graft material are used adjunctively to the vaginal wall; however, there have been favorable reports in which loosely woven polypropylene mesh was used in this manner. Small areas of eroded polypropylene graft may be removed with the surrounding tissue to the point where there is good tissue growth into the graft, and the defect can then be closed. Graft erosion into the bladder, urethra, or rectum is less common than in

the vagina. When erosion occurs, however, management is more difficult and long-term adverse effects more common. Numerous surgeons have been reticent to use synthetic graft materials to augment paravaginal musculoconnective tissue support because of complications from erosion. There remains a need for long-term follow-up on subjects who have repairs with graft material, not only to assess anatomical results and complications, but also to assess subsequent sexual function, presence and absence of pain, and patient satisfaction.

Vaginal Obliterative Procedures

Colpocleisis or vaginal narrowing procedures may be appropriate choices for debilitated patients who do not desire vaginal function (137,138), because complete vaginal reconstructive procedures may last several hours and are associated with potentially higher blood loss and increased morbidity. Many variations exist, from partial colpocleisis (where some portion of the vaginal epithelium is left to provide drainage tracts for cervical or upper genital discharge) to total colpectomy (where all of the vaginal epithelium is removed from the hymen posteriorly to within 0.5–2 cm of the external urethral meatus anteriorly). If hysterectomy is performed, blood loss is greater and operative time is longer than procedures without hysterectomy (139). These techniques should include a high perineorrhaphy and often a plication of the puborectalis muscles to reinforce posterior support and to reduce the genital hiatus, with the goal of decreasing the chance of recurrent prolapse. Case series have reported success rates as high as 100%, although the population of patients, by nature of their relatively short life expectancy and limited activity, are probably at lower risk for recurrence. In some instances in which most of the defects are anterior and posterior, a modified anterior and posterior colporrhaphy

P.930

may be performed, whereby relatively large portions of the anterior and posterior vaginal wall are removed, and closed creating a narrow (1–2 cm diameter) cylindrical vagina. As with the colpocleisis, the success of the procedure is augmented by an extensive perineorrhaphy and puborectalis plication. Such a procedure may be performed quickly and with relatively low morbidity. The prevention or treatment of stress incontinence, voiding dysfunction, and colorectal dysfunction in the context of these procedures can be problematic. Careful preoperative history and evaluation, if indicated, is important so that additional conservative therapies or operative techniques such as pubourethral plications or less invasive tension-free slings may be employed.

Comparison of Abdominal versus Vaginal Approaches

In recent years there has been controversy as to whether transvaginal or transabdominal procedures for prolapse are best. One cannot discern which is optimal from reports of retrospective and prospective case series because of the considerable differences in numerous factors, including follow-up, characteristics of the subjects, definitions of success and failure, and the expertise or experience of the surgeons performing the procedures. Three prospective randomized trials have compared sacrocolpopexy and sacrospinous suspension procedures (140,141,142). All three trials showed some increased durability in the sacrocolpopexy group; however, in one of these studies the differences were not statistically significant (142). In the study in which sexual function was examined (141), there was a greater incidence of dyspareunia in the transvaginal group. Most case series reveal that the incidence of serious complications, such as small bowel obstructions, significant hemorrhage, presacral graft infections, pulmonary embolus, and short-term problems (i.e., ileus, hernias, wound seromas or infections, and longer hospitalizations), are more likely to occur in the group undergoing sacrocolpopexy. Vaginal scarring, strictures, and vaginal wall erosions or granulation tissue appear more likely in

the group undergoing transvaginal surgery. To date, there is no randomized comparison of vaginal procedures using high uterosacral suspensions and innovative repairs of the fibromuscular tissues, which are less likely to produce strictures than was the case 10 or more years ago.

Most pelvic surgeons would agree that (i) older, less healthy individuals who are more likely to have surgical and medical complications and cannot or will not tolerate a pessary would derive greater benefit from transvaginal approaches and occasionally obliterative approaches, and (ii) relatively healthy, sexually active women with relatively short vaginas and apical prolapse or with isolated apical defects would derive greater benefit from sacrocolpopexy. For the remainder of the patients with apical prolapse, with or without more distal defects, it would ideal if surgeons were equally skilled, knowledgeable, and experienced in both abdominal and vaginal approaches to provide care that is truly individualized, rather than emphasizing one approach to the exclusion of another.

Anorectal Dysfunction

Robert E. Gutman

Geoffrey W. Cundiff

- **Defecatory dysfunction and fecal incontinence are common conditions that have tremendous psychosocial and economic implications.**
- **The differential diagnosis for anorectal dysfunction is broad and can be classified into systemic factors, anatomic and structural abnormalities, and functional disorders.**
- **A thorough history and physical examination is critical for the evaluation of fecal incontinence and defecatory dysfunction, as well as appropriate ancillary testing.**

Treatment of anorectal dysfunction should focus on treatment of the underlying condition with nonsurgical management attempted before surgery.

- **Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter.**

Anorectal dysfunction encompasses a variety of conditions that disrupt normal anorectal function. Such conditions can be subdivided as those that cause defecatory dysfunction and fecal incontinence. Although anorectal dysfunction transcends any individual medical specialty, the pathophysiology, evaluation, and management of conditions relevant to obstetrician–gynecologists are presented in this chapter.

Normal Colorectal Function

Anal continence and defecation are complex physiologic processes that require intact and coordinated neurologic and anatomic function, including colonic absorption and motility, rectal compliance, anorectal sensation, and the multifaceted continence mechanism. An understanding of normal physiology and pathophysiology is essential to the treatment of women with anorectal dysfunction.

P.936

Stool Formation and Colonic Transit

The colon plays an important role in absorption and regulation of water and electrolytes. **As much as 5 liters of water and associated electrolytes can be absorbed in 1 day.** Parasympathetic–mediated peristaltic contraction of colonic smooth muscle transfers fecal material to the rectum. A delay in stool transit at the rectosigmoid region of the colon allows for maximal absorption of water and sodium.

Storage

As stool accumulates in the rectosigmoid, rectal distention triggers a transient decrease in the internal anal sphincter (IAS) tone and an increase in the external anal sphincter (EAS) tone known as the *rectoanal inhibitory reflex*. Exposure of the anal canal to fecal matter facilitates *sampling*, whereby the anal canal and its abundant sensory nerves determine stool consistency (i.e., solid, liquid, or gas). *Accommodation* occurs as the normally compliant rectal vault relaxes in response to increased volume. **This cycle, combined with increased rectal distention, stimulates an urge to defecate.** This urge can be voluntarily suppressed through cortical control, resulting in further accommodation and activation of the continence mechanism.

Continence Mechanism

Muscles

The key muscles of the continence mechanism are the puborectalis, IAS, and EAS.

The puborectalis muscle originates from the pubic rami at the level of the arcus tendineus levator ani and passes laterally to the vagina and rectum in a U-shaped configuration, creating a sling around the genital hiatus. Contraction of the puborectalis muscle narrows the genital hiatus, developing the near 90-degree anorectal angle. The resting tone of the puborectalis muscle serves as the primary continence mechanism for solid stool. The IAS and EAS are essential for continence of flatus and liquid stool. The internal sphincter maintains most of the resting tone for the sphincter complex through autonomic reflex arcs and is essential for passive continence. Although the external sphincter also maintains constant resting tone, it is ultimately responsible for preventing fecal urgency and stress incontinence associated with sudden increases in intra-abdominal pressure. This function is under both voluntary and involuntary control. The anal cushions act as the final anatomic barrier. They fill with blood, causing occlusion of the anal canal.

Nerves

Many pathologic states disrupt normal function through denervation. **The IAS receives its sympathetic supply from L5, which passes through the pelvic plexus via the hypogastric plexus.** The parasympathetic supply from S2–4 synapses at the pelvic plexus, where it joins the sympathetic nerves. The IAS acts through reflex arcs at the spinal cord without voluntary control. The puborectalis (levator ani) is innervated by branches of the S2–4 sacral roots and does not receive direct innervation from the pudendal nerve (1). The EAS is innervated bilaterally by the pudendal nerve (S2–4) via Alcock's canal. The pudendal nerve fibers cross over at the level of the spinal cord, allowing preservation of EAS function in the event of unilateral damage. The rich sensory supply from the anal canal travels along the inferior rectal branch of the pudendal nerve.

Evacuation

Initiation of defecation is normally under cortical control. As previously discussed, delivery of stool to the rectum stimulates the rectoanal inhibitory reflex, permitting sampling followed by accommodation. Further rectal distention results in an urge to defecate. Evacuation occurs with voluntary relaxation of the pelvic floor muscles (puborectalis muscle and EAS) in conjunction with increased intra-abdominal and intrarectal pressure

from Valsalva. This results in widening of the anorectal angle and shortening of the anal canal, which facilitates emptying. Coordinated peristaltic activity of the rectosigmoid assists evacuation. After this process is complete, the closing reflex is initiated, resulting in contraction of the pelvic floor muscles and activation of the continence mechanism.

Epidemiology

The epidemiology of anorectal dysfunction has been best defined in terms of the incidence and prevalence of fecal incontinence. Few studies have been done to assess the incidence and prevalence of defecatory dysfunction.

Defecatory Dysfunction

The term *defecatory dysfunction* often is used synonymously with the symptom of constipation. **Constipation is an imprecise term used by patients to report a variety of symptoms, including infrequent stools, dyschezia, straining, variation in stool consistency and caliber, incomplete emptying, bloating, and abdominal pain. The most common symptoms associated with constipation are straining and hard stools (2,3). Defecatory dysfunction is defined by many physicians as infrequent stools, typically fewer than three bowel movements per week.** This definition is based on stool frequency studies in which 95% of women have more than three bowel movements per week. Using this definition, the prevalence of constipation should be 5% (4). However, the prevalence of constipation has been estimated to range from 2% to 28%, depending on the definition applied (5,6,7).

There is an increased prevalence of constipation among women and elderly individuals, nonwhite individuals, and those with low income and low education levels (5,6,7). Based on an estimated 2.5 million visits to U.S. physicians per year for constipation (8), with an average cost of \$2,752 per patient (9), the annual cost for evaluation of constipation would be approximately \$6.9 billion. An estimated 85% of physician visits results in a prescription; thus, drug costs would increase this amount substantially (8). Constipation does have a detrimental effect on health-related quality of life (3,10). Constipation contributed to decreased mental and physical scores for quality of life on the SF-36 Health Survey in a Canadian-based population (10).

Fecal Incontinence

The reported prevalence of fecal incontinence varies between 2% and 3% for community-dwelling individuals, 3% to 17% for those of increased age, and 46% to 54% for nursing home residents (11). A prevalence of 28% has been reported among patients seeking benign gynecologic care (12). Epidemiological studies of fecal incontinence are compromised by social stigmata and the lack of a uniform definition. Definitions of fecal incontinence vary with respect to the type of material passed (solid, liquid, or gas), the frequency and duration of events (once in a lifetime to twice a week), and the impact on quality of life. Most authors agree that the true prevalence of this condition is underestimated in the current scientific literature. A large health survey in the United States found age, female sex, physical limitations, and poor general health to be independent risk factors associated with fecal incontinence (13).

Fecal incontinence has tremendous psychosocial and economic implications for individuals and society as a whole. The loss of such a basic function can be emotionally devastating, leading to poor self-esteem, depression, social isolation,

and decreased quality of life (12,14). Fecal incontinence is the second leading reason for nursing home placement in the United States, even though fewer than one third of individuals with this condition seek medical attention (12,14). The overall annual cost to treat

fecal incontinence is difficult to pinpoint, but accounts for more than \$400,000,000 per year in the cost of adult diapers alone (14).

Symptom-Based Approach to Colorectal Disorders

Several medical conditions cause defecatory dysfunction, fecal incontinence, or combined symptoms. Following is the differential diagnosis—a proposed classification system based on systemic factors, anatomic and structural abnormalities, and functional disorders.

Differential Diagnosis

Disordered Defecation

Causes of defecatory dysfunction have traditionally been divided into systemic disorders and idiopathic constipation (all nonsystemic causes). Idiopathic constipation can be subdivided into anatomic and structural abnormalities and functional disorders (Table 25.1).

Diabetes, hypothyroidism, and pregnancy are the most common endocrinologic systemic factors that cause constipation, and all have a component of decreased gastrointestinal motility and intestinal transit. In one study, gastrointestinal symptoms were present in 76% of patients with diabetes, including constipation, which occurred in 60% (15). In patients with diabetes, constipation is believed to be secondary to intestinal autonomic neuropathy, resulting in delayed or absent gastrocolic reflex and decreased bowel motility. This enteric neuropathy may also cause gastroparesis and diarrhea. Although diabetes has been classified with the endocrinologic causes, it should also be grouped with the enteric neuropathies. Pregnancy is not considered a disease state; however, there is an 11% to 38% prevalence of constipation that is believed to be due primarily to the effect of progesterone on smooth muscle (16). **The neurologic systemic factors can be divided into central and peripheral processes.** Spinal cord lesions, multiple sclerosis, and Parkinson disease affect the autonomic nervous system. Trauma to the sacral nerves often leads to severe constipation from decreased left-sided colonic motility, decreased rectal tone and sensation, and increased distention. These findings are also seen in patients with meningocele, damage to the lumbosacral spine, and pelvic floor trauma (17,18). Higher spinal cord lesions result in delayed sigmoid transit and decreased rectal compliance. In these upper motor neuron lesions, colonic reflexes are intact, and defecation can be initiated by digital stimulation of the anal canal (19,20). Individuals with multiple sclerosis can have no gastrocolic reflex, decreased colonic motility, decreased rectal compliance, and even rectosphincteric dyssynergia (21,22). Constipation worsens with the duration of illness and may be compounded by the side effects of medical therapy. Similar findings of

rectosphincteric dyssynergia and medication side effects are present with Parkinson disease.

Among the peripheral neurogenic disorders, dysfunction occurs at the level of the enteric nerves. The ultimate example of this finding is congenital aganglionosis (Hirschsprung disease). The absence of intramural ganglion cells in the submucosal and myenteric plexuses of the rectum causes loss of the rectosphincteric inhibitory reflex. Patients with this illness usually present with functional obstruction and proximal colonic dilation. In most patients, the condition is diagnosed within 6 months of age, although milder cases can be seen later in life.

Other systemic factors to consider are collagen vascular and muscle disorders. Importantly, some of the most commonly used prescription and over-the-counter medications, including aluminum antacids, beta-blockers, calcium channel blockers, anticholinergics, antidepressants, and opiates, cause defecatory dysfunction (Table 25.2). Lifestyle issues, such as

P.939

P.940

inadequate fiber intake and insufficient fluid intake, can exert similar effects independently or in conjunction with other disorders.

Diuretics

5-HT₃ antagonists (*ondansetron, granisetron*)

Ganglionic blockers

Structural abnormalities refer to the obstructive disorders, such as pelvic organ prolapse, perineal descent, intussusception, rectal prolapse, and tumors.

Functional disorders are those that do not have an identifiable anatomic or systemic etiology. Most functional disorders are motility disorders, such as slow-transit constipation/colonic inertia, irritable bowel syndrome (constipation predominant), and functional constipation. Patients also may have functional limitations, such as decreased mobility and cognition. It is important to understand that this classification system is somewhat arbitrary, and several of these conditions are interrelated.

Fecal Incontinence

Anal continence depends on a complex interaction of cognitive, anatomic, neurologic, and physiologic mechanisms. The continence mechanism can often compensate for a deficiency in one of these processes, but it can be overwhelmed with increased severity or decreased function over time. Systemic etiologies of fecal incontinence often are due to disease states that cause diarrhea. The rapid transport of large volumes of liquid stool to the rectum can produce urgency and incontinence even in healthy individuals (23). Fecal incontinence frequently results from infectious diarrhea caused by bacteria (e.g., *Clostridium*, *E. coli*, *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*), viruses (e.g., Rotavirus, Norwalk, human immunodeficiency virus [HIV]), and parasites (e.g., *Entamoeba*, *Giardia*, *Cryptosporidium*, *Ascaris*). Numerous medications and dietary items cause diarrhea and fecal incontinence (Table 25.3). Endocrine factors that can lead to fecal incontinence include diabetes mellitus and hyperthyroidism. With diabetes, diarrhea can develop from autonomic dysfunction, bacterial overgrowth, osmotic diarrhea with sugar substitutes, and pancreatic insufficiency. Inflammatory bowel disease is considered an idiopathic/autoimmune systemic factor. Ulcerative colitis and Crohn disease cause fecal incontinence during exacerbations with bouts of bloody diarrhea. Inflammatory bowel disease can also result in structural abnormalities, such as anal fissures, fistulas, abscesses, and operative complications that lead to fecal incontinence.

As with defecatory dysfunction, neurologic causes of fecal incontinence can be divided into central and peripheral disorders. Among the central nervous system disorders, upper motor neuron lesions above the level of the defecation center (located in the sacral cord) cause spastic bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The anal sphincter is under spastic contraction, but digital stimulation can be performed to initiate reflex evacuation. **Head trauma, neoplasms, and cerebral vascular accidents that damage portions of the frontal lobe result in loss of control of both micturition and defecation.** Greater loss of inhibition is present when the lesion is located more anteriorly in the frontal lobe. Spinal cord trauma and lower motor neuron lesions above the defecation center tend to cause permanent loss of cortical control. For 2 to 4 weeks following spinal cord injury, "spinal shock" occurs, resulting in a temporary loss of reflexes below the level of the lesion, flaccid bowel function, constipation, and fecal impaction. After the initial shock, spastic paralysis ensues with hyperactive bowel function. The gastrocolic reflex, along with digital stimulation, initiates reflex evacuation in the absence of cortical inhibition. Fortunately, IAS tone is maintained despite the loss of EAS control for stress and urge situations. Both constipation and fecal incontinence can occur in these patients.

The demyelination that is seen in multiple sclerosis is randomly distributed and can occur at any level in the central nervous system. In addition to the somatic disruption that is similar to spinal cord injury, autonomic dysfunction frequently is present. **People with dementia and other degenerative disorders that cause cognitive impairment frequently have fecal incontinence caused by overflow incontinence.** Although sensory nerves are functioning properly, these individuals lack the cognitive awareness necessary to inhibit defecation until a socially acceptable time, and they develop overflow incontinence.

Lower motor neuron lesions occurring at or below the level of the defecation center in the sacral cord cause flaccid bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The bowel reflexes, including the bulbocavernosus and anal reflexes, are interrupted. The anal sphincter is flaccid, and fecal retention with overflow incontinence usually occurs. Digital disimpaction and Valsalva often are required for evacuation. Digital stimulation has no effect, and medications tend to work

poorly. Examples of motor neuron lesions include tumor or trauma to the cauda equina, tabes dorsalis, spina bifida, and peripheral neuropathy.

The classic example of peripheral neuropathy is congenital aganglionosis (Hirschsprung disease), which was discussed earlier. The most common peripheral neuropathy occurs with diabetes. **Approximately 20% of individuals with diabetes have fecal incontinence**

(24). The cause tends to be multifactorial with the exact mechanism uncertain. Fecal incontinence can occur with diabetic diarrhea or years later from progressive disease. Individuals with diabetes frequently experience intestinal autonomic neuropathy, an abnormal gastrocolic reflex, and chronic constipation. The subsequent pelvic floor denervation causes fecal incontinence by sensory neuropathy, failure of the rectoanal inhibitory reflex, and sphincter dysfunction (25). Consequently, fecal incontinence from peripheral neuropathy can be the result of defective sampling, a disrupted rectoanal inhibitory reflex, or pudendal neuropathy with sphincter dysfunction. Patients may experience stress or urge incontinence as well as overflow incontinence.

Anatomic and structural causes of fecal incontinence are usually due to obstetric or surgical trauma. Damage or dysfunction of the IAS, EAS, and puborectalis can result in varying degrees of fecal incontinence. Those with impaired resting tone from a defective IAS will have passive incontinence (incontinence at rest), which is worse during sleep because of decreased EAS activity (26). An inability to respond to sudden distention and to suppress defecation is often seen with external sphincter dysfunction. External and internal sphincter dysfunction often result in incontinence of liquid stool. Incontinence of solid stool is usually seen with widening of the anorectal angle from damage to the puborectalis muscles. Damage to the anal cushions usually causes minor soiling. Other anatomic and structural abnormalities associated with fecal incontinence include obstructive disorders such as pelvic organ prolapse, descending perineum syndrome, anismus, and intussusception; fistulas from diverticulitis, inflammatory bowel disease, cancer, or surgical trauma; and decreased rectal compliance from inflammatory bowel disease, cancer, and radiation. Decreased compliance results in higher intraluminal pressures with smaller volumes of stool, poor storage capacity, urgency, and incontinence (27).

Functional disorders associated with fecal incontinence include irritable bowel syndrome (diarrhea variant), functional diarrhea, decreased mobility, and decreased cognition.

Combined Disorders of Defecation and Fecal Incontinence

Several conditions have the potential to cause both defecatory dysfunction and fecal incontinence (see Table 25.1). Most of these disorders cause combined symptoms through the development of fecal impaction followed by overflow incontinence. This situation can be seen with many of the neurological conditions, pelvic outlet obstructive disorders, functional disorders of irritable bowel syndrome, decreased mobility, and decreased cognition. The cause of these symptoms often is multifactorial.

Structural versus Functional Disorders

Disordered Defecation

Disordered defecation can result from outlet obstruction or functional motility disorders.

Outlet Obstruction

Anismus/Rectosphincteric Dyssynergia

Anismus is otherwise known as rectosphincteric dyssynergia, pelvic floor dyssynergia, spastic floor syndrome, and paradoxical puborectalis syndrome. The anorectal angle narrows as a result of paradoxical contraction of the puborectalis and external anal sphincter during defecation. Frequent symptoms

P.943

include dyschezia, straining, hard stools, incomplete emptying, and tenesmus. A recent prospective study of 120 consecutive patients with dyssynergic defecation found a higher prevalence in women (77%) (28,29). The need for digital assistance (digital disimpaction or splinting) to evacuate the rectum occurs in up to 58% of patients. **Psychosocial factors, such as a history of sexual abuse, depression, eating disorder, obsessive-compulsive disorder, and stress, may play an important role in this disease.** In this study, 22% reported a history of sexual abuse, and 31% reported a history of physical abuse. One third believed the problem began during childhood, and 24% reported a precipitating illness or surgery was related to a particular event. Five percent of women claimed that pregnancy or childbirth was a precipitating factor. This condition also is seen in young children with constipation and dyschezia. The response to biofeedback and pelvic floor physical therapy, as well as the aforementioned patient characteristics, indicate a learned response mechanism is involved (28,29).

Pelvic Organ Prolapse

Pelvic organ prolapse bears special mention because it is often seen by gynecologists but inconsistently associated with defecatory dysfunction. Prolapse is very common, although many women with this condition are asymptomatic. Those with symptoms may report incomplete evacuation and the need to apply digital pressure to the posterior vaginal wall or perineum to aid in evacuation of stool (digitation or splinting). It is important to rule out other causes of constipation, because these symptoms are nonspecific, and rectocele can result from chronic straining and increased intra-abdominal pressure. **Defecatory dysfunction related to pelvic organ prolapse can result from rectocele, enterocele, or perineal descent, either individually or in combination.**

Rectocele is a herniation of the rectal mucosa through a defect in the rectovaginal septum. These site-specific defects can be transverse or longitudinal through the inferior, middle, or superior regions of the rectovaginal septum (30). **Enterocele is a herniation of a peritoneal sac and bowel through the pelvic floor, typically between the uterus or vaginal cuff and rectum. It is more common following hysterectomy and retropubic urethropexy.** There are two theories surrounding the formation of an enterocele. The first theory implicates a defect in the fibromuscular endopelvic fascia of the vagina, allowing peritoneum and bowel to herniate. The second theory attributes its formation to a support defect with full thickness protrusion, including endopelvic fascia (31). Ultimately,

the mechanism might be attributed to a combination of the two theories because some support defects are secondary to superior breaks in the rectovaginal and pubocervical fascia. **Patients with rectocele and enterocele may have similar symptoms, including pelvic pain, pressure, vaginal protrusion, obstipation, fecal incontinence and sexual dysfunction.** Although associations have been made between defecatory dysfunction and advanced stages of pelvic organ prolapse, a causal relationship remains to be established. Controversy remains as to whether anatomic herniation is the cause of these symptoms or the effect of underlying colonic dysfunction, chronic constipation, and straining.

Descending perineum syndrome is defined as descent of the perineum (at the level of the anal verge) beyond the ischial tuberosities during Valsalva. Excessive perineal descent was first described in the colorectal literature by Parks et al. in 1966 (32,33). It occurs as a result of inferior detachment of the rectovaginal septum from the perineal body. As the condition progresses, the patient can develop pudendal neuropathy from stretch injury. Perineal descent has been associated with a variety of defecatory disorders, including constipation, fecal incontinence, rectal pain, solitary rectal ulcer syndrome, rectocele, and enterocele (34).

Rectal Intussusception

Rectal intussusception or intrarectal prolapse is the circumferential prolapse of the upper rectal wall into the rectal ampulla but not through the anal verge. It occurs most often in women in the fourth and fifth decade. The most common symptoms are obstructive, including incomplete emptying, manual disimpaction,

P.944

splinting, pain with defecation, and bleeding. Other symptoms include fecal incontinence, decreased urge to defecate, inability to distinguish between gas and feces, and mucus discharge with pruritus ani. Bleeding often originates from a solitary rectal ulcer or localized proctitis of the involved bowel segment (35). **Intussusception is frequently seen in as many as one third of women with defecatory dysfunction and other symptoms, such as constipation, rectal pain, and fecal incontinence** (36). It has also been seen in 29% of asymptomatic patients (37). The intussusception rarely develops into total rectal prolapse (38).

Functional Motility Disorders

Colonic Inertia/Slow-Transit Constipation

Severe constipation, defined as fewer than three stools per week and refractory to therapy, is relatively rare; however, these patients frequently suffer from motility disorders such as *global motility disorder* and *colonic inertia*. Women are more likely to be affected than men. Colonic inertia or slow-transit constipation is defined as the delayed passage of radiopaque markers through the proximal colon without retropulsion of markers from the left colon and in the absence of systemic or obstructive disorders. The cause remains unclear. Patients with this disorder have impaired phasic colonic motor activity

and diminished gastrocolic reflexes (39,40). Studies on the role of laxatives, absorption, hormones, psychological abnormalities, and endogenous opioids have been inconclusive. Current literature suggests a possible neurologic or smooth muscle disorder (40,41).

Functional Bowel Disorders

Functional bowel disorders, as defined by the Rome II Criteria (42), consist of irritable bowel syndrome, functional abdominal bloating, functional constipation, functional diarrhea, and unspecified functional bowel disorders. In this section we will focus primarily on IBS.

Irritable bowel syndrome (IBS) has been estimated to have a prevalence of 10% to 20% and is more common in women and younger individuals. It accounts for 25% to 50% of all referrals to gastrointestinal clinics. Irritable bowel syndrome has distinct diagnostic criteria, including the exclusion of structural or metabolic abnormalities. **These patients often have other gastrointestinal, genitourinary, and psychological illness, including gastroesophageal reflux disease, fibromyalgia, headache, backache, chronic pelvic pain, sexual dysfunction, lower urinary tract dysfunction, depression, and anxiety.** Stressful life events seem to correlate with the onset and exacerbation of symptoms. A detailed history frequently reveals past physical or sexual abuse (42). Currently, specific criteria allow for classification of IBS into diarrhea-, constipation-, and pain-predominant categories (Table 25.4). The constipation variant is most commonly associated with defecatory dysfunction, whereas the diarrhea variant causes fecal incontinence. The pain or spastic variant causes predominantly abdominal discomfort but can also be associated with both defecatory dysfunction and fecal incontinence. After excluding organic disease, the criteria listed in Table 25.4 have a sensitivity of 65%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 76% (43).

Functional constipation *is a term created by the Rome II criteria as a unifying definition of constipation* (Table 25.5). The rationale for the criteria listed in Table 25.5 stems from the variability in patient definitions of constipation (42).

Fecal Incontinence

Sphincter Disruption

In young women, obstetric injury is the most common cause of fecal incontinence.

The mechanism of injury can be from anatomic disruption of the anal sphincter complex, pelvic floor denervation, or a combination of the two conditions. The risk factors for anal

sphincter laceration are primiparity, high birth weight, forceps delivery, and episiotomy (44,45,46). Although there are limited long-term prospective studies demonstrating the natural history of anal sphincter injury, pelvic floor neuropathy, and the progression of these conditions to fecal incontinence, current literature supports the relationship of early-onset symptoms to sphincter damage and delayed-onset symptoms to neuropathy (47).

This relationship would account for the large discrepancy in the prevalence of fecal incontinence between younger men and women that decreases as the population ages (48).

Table 25.4 Diagnostic Criteria of Irritable Bowel Syndrome^a

At least 12 weeks, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that has two of three features:

1. Relieved with defecation and/or
2. Onset associated with a change in frequency of stool and/or
3. Onset associated with a change in form (appearance) of stool

Supporting symptoms of IBS

1. Fewer than three bowel movements a week
2. More than three bowel movements a day
3. Hard or lumpy stools
4. Loose (mushy) or watery stools
5. Straining during a bowel movement
6. Urgency (having to rush to have a bowel movement)
7. Feeling of incomplete bowel movement
8. Abdominal fullness, bloating, or swelling

Diarrhea-predominant 1 or more of 2, 4, or 6 and none of 1, 3, or 5; or 2 or more of 2, 4, or 6 and one of 1 or 5.

Constipation-predominant 1 or more of 1, 3, or 5 and none of 2, 4, or 6; or 2 or more of 1, 3, or 5 and one of 2, 4, or 6.

IBS, irritable bowel syndrome.

Table 25.5 Diagnostic Criteria of Functional Constipation^a

At least 12 weeks, which need not be consecutive, in the preceding 12 months of two or more of:

1. Straining >1/4 of defecations
2. Lumpy or hard stools >1/4 of defecations
3. Sensation of incomplete evacuation >1/4 of defecations
4. Sensation of anorectal obstruction/blockage >1/4 of defecations
5. Manual maneuvers to facilitate >1/4 of defecations (e.g., digital evacuation, support of the pelvic floor)
6. <3 defecations per week

If loose stools are not present, and there are insufficient criteria for IBS.

IBS, irritable bowel syndrome.

^a From **Thompson WG, Longstreth GF, Drossman DA, et al.** Functional bowel disorders and functional abdominal pain. In: **Drossman DA, Corazziari E, Talley NJ, et al. eds.** *Rome II: the functional gastrointestinal disorders*. 2nd ed. McLean, VA: Degnon Associates, 2000: 351–432.

Obstetric Trauma

Third- and fourth-degree lacerations at delivery are associated with an increased risk of fecal incontinence (odds ratio [OR] 3.09) (47). Whereas the incidence of clinically documented third- and fourth-degree anal sphincter tears is between 0.5% and 5.9% (44,46,49), occult third- and fourth-degree defects are present in 28% to 35% of primiparous women and 44% of multiparous women, and approximately one third of these patients have symptoms of anal incontinence. **Patients with occult anal sphincter tears are 8.8 times more likely to have fecal incontinence** (46,50). Forceps-assisted vaginal delivery significantly increases this risk, but the data on vacuum-assisted delivery are less conclusive (45,51,52). Elective cesarean delivery, in contrast with emergency cesarean delivery, was believed to prevent anal incontinence, but recent studies argue against any protective effect with cesarean delivery, irrespective of timing (46,51,53). **Midline episiotomy is strongly linked to sphincter damage and fecal incontinence** (45,54). One study of a large population found conflicting results, with an overall protective effect seen with episiotomy (OR 0.89). The likelihood of fourth-degree laceration was increased (OR 1.12) and of third-degree laceration was decreased (OR 0.81) (44). A Cochrane review supports the restrictive use of both midline and mediolateral episiotomy (55). In another study, an important finding was that one half of patients who underwent immediate repair of a third-degree laceration had symptoms of anal incontinence, and 85% had persistent sphincter defects on endoanal ultrasonography (56).

Surgical Trauma

Iatrogenic injury follows obstetric trauma as the second most common cause of direct sphincter damage. Surgical procedures that have been associated with fecal incontinence include anal fistula repair, anal sphincterotomy, hemorrhoidectomy, and anal dilation. Fistulotomy is the most common procedure that results in fecal incontinence. Rectovaginal or anovaginal fistulas can develop after obstetric injury, operative complications during pelvic surgery, and inflammatory bowel disease exacerbations. Fistulas cause fecal incontinence, and the degree of postoperative dysfunction depends on the location of the fistula and the amount of sphincter that is disrupted during the surgical repair. It also depends on the preoperative level of sphincter function and pudendal nerve function. Anal sphincterotomy to treat painful anal fissures can lead to incontinence by disruption of rectal sensory innervation and anal cushions and transection of the anal sphincter (57,58). Hemorrhoidectomy often results in minor soiling as a result of resection of the anal cushions, which act as the final mucosal barrier. Similar to sphincterotomy, rectal sensory innervation can be disrupted, and injury to

Sphincter Denervation

Idiopathic (primary neurogenic) fecal incontinence results from denervation of both the anal sphincter and pelvic floor muscles. Denervation injury related to obstetric trauma accounts for approximately three out of every four cases of idiopathic fecal incontinence and is the most common overall cause of fecal incontinence (60,61).

Obstetric Trauma

The two proposed mechanisms of pudendal neuropathy are stretch injury during the second stage of labor and compression of the nerve as it exits Alcock's canal (60). **Established risk factors for pelvic floor neuropathy include multiparity, high birth weight, forceps delivery, prolonged active second stage, and third-degree laceration** (62,63).

Several studies have shown increased pudendal nerve terminal motor latencies following vaginal delivery, especially after sphincter laceration (46,61,64). Most women will recover function within a few months postpartum. Others will have evidence of injury several years later, which may represent the cumulative effects of subsequent deliveries (61,65). However, fecal incontinence will develop in only a fraction of patients with neuropathy (63).

Descending Perineum Syndrome

As noted previously, prolonged straining for any reason can cause descending perineum syndrome. This syndrome is defined as descent of the perineum beyond the ischial tuberosities during Valsalva (32,33). Pudendal

P.947

neuropathy results from stretching and entrapment of the pudendal nerve. This diagnosis is supported by findings of elongation of the pudendal nerve, prolonged pudendal nerve motor terminal latency, and decreased anal sensation in women with perineal descent (66,67,68). As pudendal neuropathy progresses, it ultimately leads to fecal incontinence (34,69).

Table 25.6 Diagnostic Criteria of Functional Diarrhea^a

At least 12 weeks, which need not be consecutive, in the preceding 12 months of:

1. Loose (mushy) or watery stools
2. Present more than 3/4 of the time; and
3. No abdominal pain

From **Thompson WG, Longstreth GF, Drossman DA, et al.** Functional Bowel disorders and functional abdominal pain. In: **Drossman DA, Corazziari E, Talley NJ, et al. eds. Rome II: The Functional Gastrointestinal Disorders.** 2nd ed. McLean, VA: Degnon Associates, 2000: 351–432.

Functional Bowel Disorders

Irritable Bowel Syndrome

The diarrhea variant of irritable bowel syndrome is often associated with fecal incontinence as well as disordered defecation. The criteria for diagnosis are in Table 25.4.

Functional Diarrhea

The Rome II criteria create a unifying definition of diarrhea called functional diarrhea (Table 25.6). The rationale for the criteria listed in Table 25.6 stems from the variability in patients' descriptions of diarrhea (42).

Pitfalls for the Pelvic Floor Surgeon

It sometimes is easy to overlook or misinterpret signs and symptoms of constipation and defecatory dysfunction. Any acute change in bowel habits must be evaluated thoroughly, and malignancy must be considered in the differential diagnosis. Even in the presence of chronic disease, malignancy must still be excluded. Persistent symptoms after an empiric trial of medical therapy should prompt further evaluation, such as a colonoscopy or flexible sigmoidoscopy. It is also possible to mistakenly attribute symptoms of defecatory dysfunction and constipation to pelvic organ prolapse when prolapse is actually the result of an underlying bowel disorder. In this case, surgical treatment of prolapse will have little lasting benefit if the underlying bowel disorder remains untreated.

History and Physical Examination

History

A thorough history and physical examination are critical to the evaluation of fecal incontinence and defecatory dysfunction. The history of present illness should focus on the bowel habits, including frequency and consistency of bowel movements (hard versus soft, formed versus unformed, diarrhea versus constipation). The duration and severity of symptoms as well as exacerbating factors are important to understanding the impact on quality of life. Patients should be questioned about straining with bowel movements, symptoms of incomplete emptying, and splinting of the perianal region, perineal body, or posterior vaginal wall to assist with evacuation. They should also be asked about the need to perform digital disimpaction because they are unlikely to volunteer this information. With respect to fecal incontinence, information should be obtained about leakage with solids, liquid, and flatus and the ability to discriminate between these different types of stool (sampling). Similar to urinary incontinence, fecal incontinence can

be stress related, urge related, or unconscious. Questions about alternating diarrhea and constipation, mucus or blood in the stools, constitutional symptoms, and changes in stool caliber can help the investigator uncover systemic and functional etiologies. Finally, it is important to ask about adaptive behaviors, pad or diaper use, and past and present treatments including surgery, physical therapy, and medications.

A large amount of information can be obtained efficiently through questionnaires. Validated questionnaires quantify symptoms, which are subjective in nature, to objectively measure response to treatment. **A valuable survey to assess defecatory dysfunction is the Colorectal–Anal Distress Inventory (CRADI), which has been incorporated into the Pelvic Floor Distress Inventory (PFDI)** (70). The latter is a useful tool for evaluating symptoms of prolapse, urinary incontinence, fecal incontinence, voiding dysfunction, and defecatory dysfunction. Other useful symptom scales and bother scores for fecal incontinence include the Wexner Score (71), Fecal Incontinence Severity Index (72), and Fecal Incontinence Quality of Life Scale (73).

The medical history, surgical history, family history, and review of systems should focus on uncovering potential systemic and obstructive disorders shown in Table 25.1. **A complete obstetric history should include the number of vaginal deliveries, operative vaginal deliveries, or presence of a third- or fourth-degree laceration, which is critical for patients with fecal incontinence.** Length of the second stage of labor, birth weight, and the use of episiotomy should be ascertained because they may pose risk factors for sphincter damage and denervation. The sexual history should include questions about prior rape, anal intercourse, and dyspareunia. Use of over-the-counter, prescription, and illegal drugs should be recorded as well as food allergies.

Physical Examination

The evaluation of anorectal dysfunction requires a basic general examination as well as a focused abdominal and pelvic examination. The general physical survey should include a global assessment of mobility and cognitive function. Routine examination of the abdomen involves inspection, palpation, and auscultation to rule out the presence of masses, organomegaly, and areas of peritoneal irritation. This examination should be followed by a detailed evaluation of the vagina, perineum, and anorectum. The goals of the pelvic examination are to define objectively the degree of prolapse and determine the integrity of the connective tissue, neurologic function, and muscular support of the pelvic organs.

Neurologic Examination

Important elements of the neurologic examination are assessment of cranial nerve function, sensation and strength of the lower extremities, and reflexes for the lower extremities, bulbocavernosus, and anal wink. These examinations evaluate the function of the lower lumbar and sacral nerve roots, recognizing the importance of the second through fourth sacral nerve roots in pelvic floor dysfunction. The perineal reflexes can

be elicited by stroking the labia majora and perianal skin or tapping the clitoris with a cotton-tipped swab. The anal wink, bulbocavernosus, and cough reflexes all test the integrity of motor innervation to the external anal sphincter (S2–4). Sensation over the inner thigh, vulva, and perirectal areas should be tested for symmetry to light touch and pinprick.

Muscle Strength

The integrity of the pelvic floor muscles should be assessed at rest and with voluntary contraction to determine strength, duration, and anterior lift. The ability to relax these muscles and tenderness on palpation should also be evaluated.

Several standardized systems have been described to objectively measure muscle strength, but none has been accepted as a standard. The puborectalis muscle should be readily palpable posteriorly as it creates a 90-degree angle between the anal and rectal canals. Voluntary contraction of this muscle "lifts" the examining finger anteriorly toward the pubic rami. An intact

P.949

external anal sphincter muscle that has decreased tone and contractility often indicates pudendal neuropathy. Similarly, neuropathy affecting the puborectalis can be recognized by an obtuse anorectal angle and weak voluntary contraction. Similar to the urethral axis, the anorectal angle can also be tested using a cotton-tipped swab, although this test is rarely performed. Deflection is measured in the supine position at rest, with strain, and with squeeze.

Vaginal Support

The salient points of pelvic organ prolapse (see Chapter 24) for patients with defecatory dysfunction are the support of the vaginal apex, posterior wall, and perineal body, although some experts believe anterior wall defects can also affect defecatory dysfunction. The posterior wall is assessed while supporting the vaginal apex and anterior wall with a Sims' speculum. This permits the examiner to focus on identifying specific locations of rectovaginal fascial defects. A rectovaginal examination aids in identification of defects in the rectovaginal fascia or perineal body. Loss of vaginal rugation has also been reported overlying the site of a rectovaginal fascial tear (74). This technique is especially useful for enteroceles, which have a smooth, thin epithelium over the enterocele sac or peritoneum.

Normally, the perineum should be located at the level of the ischial tuberosities, or within 2 cm of this landmark. A perineum below this level, either at rest or with straining, represents perineal descent. Subjective findings of perineal descent include widening of the genital hiatus and perineal body, as well as flattening of the intergluteal sulcus. Women with perineal descent also tend to have less severe stages of pelvic organ prolapse based on the Pelvic **Organ Prolapse Quantification (POP-Q) staging system** (75) because it measures descent from the hymenal ring. Consequently, an increase in the length of the perineal body and genital hiatus with straining suggests perineal descent. The degree of perineal descent can also be measured objectively with a St. Mark's perineometer, although a thin ruler placed in the posterior introitus at the level of the ischial tuberosities also can be used. Descent is measured

as the distance the perineal body moves when the patient strains. Although pelvic floor fluoroscopy is the standard technique for measuring perineal descent, this technique is most useful in patients with symptoms of severe defecatory dysfunction and evidence of perineal descent on pelvic examination.

Anorectal Examination

Visual and digital inspection of the vagina and anus will help to identify structural abnormalities such as prolapse, fistulas, fissures, hemorrhoids, or prior trauma. As previously mentioned, a rectovaginal examination provides useful information regarding the integrity of the rectovaginal septum and can demonstrate laxity in the support of the perineal body. The rectovaginal examination also is helpful in the diagnosis of enteroceles, which can be felt as protrusion of bowel between the vaginal and rectal fingers with straining. Digital rectal examination should be performed at rest, with squeeze, and while straining. The presence of fecal material in the anal canal may suggest fecal impaction or neuromuscular weakness of the anal continence mechanism. Circumferential protrusion of the upper rectum around the examining finger during straining suggests intussusception, which often occurs in combination with laxity of the posterior rectal support along the sacrum.

The integrity of the external anal sphincter and puborectalis muscle can be evaluated by observation and palpation of these structures during voluntary contraction. Evidence of dovetailing of the perianal skin folds and the presence of a perineal scar with an asymmetric contraction often indicates a sphincter defect. When a patient is asked to contract her pelvic floor muscles, two motions should be present: The external anal sphincter should contract concentrically, and the anal verge should be pulled inward. These actions should also be apparent on digital rectal examination. As mentioned previously, the 90-degree angle created by the puborectalis should be readily palpable posteriorly and, with voluntary contraction, the examining finger should be lifted anteriorly toward the pubic rami.

P.950

Both the puborectalis and external anal sphincter should relax during Valsalva effort. Patients with anismus may experience a paradoxical contraction of these muscles during straining. Finally, defects in the anterior aspects of the external anal sphincter may be detected by digital examination.

Testing

Sophisticated diagnostic testing is currently being used in clinical research and in anorectal physiology laboratories to quantify the function of the colon and anorectum. Following is a description of these techniques as they relate to the management of fecal incontinence and disordered defecation.

Fecal Incontinence

Endoanal Ultrasonography

Endoanal ultrasonography permits accurate imaging of both the internal and external anal sphincters. It can assess the continuity and thickness of the muscle and currently is considered the single best method for detecting anal sphincter defects.

Endoanal ultrasonography is performed using a Bruel-Kjaer (Copenhagen, Denmark) ultrasound scanner with a 360-degree rectal endoprobe (type 1850) with a 7.0 MHz transducer (focal length, 2–5 cm) housed within a plastic cone (Fig. 25.1). The normal IAS is a continuous hypoechoic band of smooth muscle surrounded by the thick echogenic layer of the striated EAS. A sphincter defect occurs when there is disruption in these muscle bands. Location and severity of the defect can be described by circumferential distance in degrees, percent thickness, and distance from the anal verge (Fig. 25.2). Measurements are usually taken in the proximal, middle, and distal anal canal. It is important to recognize the physiologic split in the proximal EAS as it merges with the puborectalis muscle of the levator ani. Misinterpretation of this finding as a sphincter defect can result in an increased prevalence of reported defects. The puborectalis muscle appears as a U-shaped or V-shaped thick echogenic layer outside the IAS in the proximal anal canal. Magnetic resonance imaging (MRI) may be equally as effective or better at diagnosing sphincter defects, especially with the use of a vaginal or rectal coil. For this purpose, MRI is more expensive, and currently its use is largely investigational. It may be beneficial in cases in which endoanal ultrasonography results are inconclusive or the quality of the study is poor.

Electromyography

Electromyography (EMG) is used to evaluate neuromuscular integrity of the EAS following a traumatic injury such as childbirth, as well as to document the presence

P.951

P.952

of pelvic floor neuropathy (76). This technique measures the electrical activity arising in muscle fibers during contraction and at rest. Different types of electrodes may be employed, including surface electrodes, concentric needle electrodes, and single-fiber electrodes. Surface electrodes are less invasive because they are applied near or within the anal canal, but they are capable only of recording basic anal sphincter activity. This technique often is used in conjunction with biofeedback therapy. Concentric needle electrodes are most commonly used in anorectal physiology laboratories to selectively survey an individual muscle's activity. Insertion of the thin needlelike cannulas containing steel wire electrodes can be painful. Even smaller single-fiber EMG electrodes are used to record the activity of single muscle fibers, which can be quantified to calculate fiber density. Following denervation injury, increased muscle fiber density occurs during reinnervation. Thus, single-fiber EMG can provide indirect evidence of neurologic injury by mapping the EAS and identifying injured areas. This technique rarely is used in clinical practice. Endoanal ultrasonography offers increased patient comfort and more reliable results than EMG and has replaced this technique for the detection of EAS disruption because of increased patient comfort and more reliable results.

Figure 25.1 Bruel-Kjaer (Copenhagen, Denmark) ultrasound probe (type 1850) with a 7.0 MHz transducer (focal length, 2 to 5 cm) housed with a plastic cone.

Figure 25.2 A: Endoanal ultrasound image from the distal anal canal demonstrating defects in the internal sphincter from 10 to 3 o'clock and the external sphincter from 10 to 2 o'clock. **B: Endoanal ultrasound image from the middle anal canal** demonstrating defects in the internal sphincter from 12 to 2 o'clock and the external sphincter from 10 to 1 o'clock. **C: Endoanal ultrasound image from the proximal anal canal** demonstrating an intact IAS and a normal physiologic split in the external sphincter.

Motor nerve conduction studies provide another means of measuring pelvic

floor neuropathy. The axon of a nerve is stimulated, and the time it takes the action potential to reach the muscle supplied by the nerve is recorded. The delay between stimulation and the muscle response is called the nerve latency. Pudendal nerve terminal motor latency (PNTML) can be determined by transrectal stimulation of the pudendal nerve using a St. Mark's electrode (77). A nerve stimulator is mounted on an examination glove at the fingertip (Fig. 25.3) and positioned transrectally over each ischial spine. A stimulus of up to 50 mV over a duration of 0.1 milliseconds is applied, and the latency of the EAS muscle contraction is measured. A value of 2.2 milliseconds or less is considered normal. A recent study evaluating normative values for pudendal and perineal nerve latencies observed increased latencies with increased age (78). Prolongation of the PNTML is indicative of damage to that nerve or the presence of a demyelinating condition. Pudendal nerve function has prognostic value in the surgical repair of traumatic sphincter injuries (79) and is useful in preoperative counseling.

Figure 25.3 St. Mark's electrode used for measuring pudendal nerve motor terminal latency. The stimulating electrode is on the fingertip, and the receiving electrode is on the proximal finger near the knuckle.

Anal Manometry

Anal manometry is used to quantify function of the anal sphincter mechanism.

Water-perfused manometry catheters or water-filled balloons are most often used to measure anal canal pressures. Resting anal canal pressures reflect IAS function, and pressures in the lower anal canal during maximal voluntary contraction reflect EAS function. Vector analysis can be used to detect asymmetry within the anal sphincter. Anal manometry provides indirect evidence of sphincter injury; low resting tone indicates IAS injury, and decreased maximum squeeze pressures indicates EAS injury. Anal pressures are influenced by a variety of factors, including tissue compliance and muscular tone. Consequently, anal manometry results are difficult to interpret and correlate poorly with the specific anatomic defect. Interpretation is further complicated by the wide variation of normal pressure values that change with age and parity. Significant overlaps occur between manometric values for incontinent patients and those without incontinence. Thus, anal manometry may be of limited value in the evaluation and treatment of anal sphincter defects and fecal incontinence.

Proctoscopy and Flat Tire Test

Proctoscopy has an important role in the evaluation of fecal incontinence. It can be performed independently or during colonoscopy, flexible sigmoidoscopy, and flat tire test. **Proctoscopy can detect anorectal pathology, such as prolapsing hemorrhoids, intussusception, ulcerative or radiation proctitis, or a solitary rectal ulcer.** The flat tire test is added when a rectovaginal or colovaginal fistula is suspected but cannot be visualized on routine office evaluation. This test usually is performed under anesthesia but can also be done in the office setting. Saline or water is placed in the vagina with the patient Trendelenberg's position. Using a proctoscope or rigid sigmoidoscope, air is instilled into the rectum. Vaginal retractors provide visualization of the posterior vaginal epithelium and vaginal apex. Observation of bubbling into the vaginal fluid confirms the diagnosis of a rectovaginal or colovaginal fistula. The rectal site of the fistula usually is identifiable, depending on the size and location of the fistula as well as the quality of the bowel preparation.

Disordered Defecation

Sitzmark Study

Colonic transit studies are performed using ingested radiopaque markers followed by serial abdominal radiography. Patients are asked to follow a high-fiber diet over the test period and avoid the use of laxatives, suppositories, or enemas. A capsule containing 20 to 24 markers is ingested initially, and abdominal radiography is performed either daily or on the fourth day, the seventh day, and every 3 days thereafter until all the markers are gone. Segmental transit times are then calculated using a mathematical formula. Colonic transit study results are used to classify patients with constipation into delayed transit, normal transit, and outlet obstruction. After day 6, there should be fewer than five markers remaining in the colon. With slow transit, more than five markers are scattered throughout the colon. With outlet obstruction, more than five markers are in the rectosigmoid region, and transit is normal throughout the rest of the colon.

Pelvic Floor Fluoroscopy and Magnetic Resonance Imaging

Pelvic fluoroscopy permits radiological evaluation of pelvic floor and anorectal anatomy and physiology. It is particularly useful in obstructive defecation disorders, such as intussusception, rectocele, enterocele, anismus, and perineal descent. The patient is placed on a radiolucent commode, and contrast material is instilled into the rectum. The addition of vaginal, bladder, and oral contrast material is helpful diagnostically when multicompartamental prolapse is suspected. A series of lateral still images or continuous imaging using videography are made with fluoroscopy while the patient is at rest, during defecation, and with contraction of the anal sphincter. Similar films can be obtained for evacuation of the bladder. Pelvic fluoroscopy has many names, including defecography,

defecating proctography, defecating cystoproctography, and colpocystoproctography, depending on the technique used. The measurements obtained include size of the rectal ampulla, length of the anal canal, anorectal angle, puborectalis motion, and pelvic floor descent. Severity of

prolapse and pelvic floor descent is quantified in relation to the pubococcygeal line. Pelvic fluoroscopy is superior to physical examination for diagnosing enterocele (80), and this technique has the advantage of being able to distinguish enteroceles from sigmoidoceles. Rectosphincteric dyssynergia may be present when the patient experiences incomplete relaxation of the puborectalis muscle during rectal evacuation, the anorectal angle is preserved, and there is incomplete emptying. Pelvic fluoroscopy is considered the definitive test for diagnosing intussusception (81), and it is the preferred technique for quantifying perineal descent.

Dynamic MRI with luminal contrast is an imaging modality similar to pelvic fluoroscopy. Its ability to detect prolapse is similar to that of fluoroscopy, but MRI can visualize pelvic floor musculature and soft tissue, thus giving it the advantage of detecting ballooning of the levator muscles and levator ani hernias. The supine position of the testing is a drawback; however, there are isolated reports of upright dynamic MRI using open scanners that show results comparable to fluoroscopy for detection of anorectal pathology (82). Fluoroscopy and dynamic MRI can be used in situations involving severe multicompartmental prolapse or in which the severity of the symptoms is disproportionate to examination findings.

Anal Manometry

Anal manometry is used to determine maximum resting pressure, maximum squeeze pressure, rectal sensation and compliance, as well as the presence of an intact rectoanal inhibitory reflex. With disordered defecation, it can be used to diagnose Hirschprung disease and anismus. The addition of surface EMG to document relaxation helps exclude anismus as a cause of obstructed defecation. Failure of the anal sphincter to relax with defecation and increased electrical activity of the EAS and puborectalis are seen in patients with anismus. In contrast, there should be no increase in the electrical activity measured by surface electrodes for patients with Hirschprung disease.

Colonoscopy and Proctoscopy

Standard gastrointestinal evaluation for patients with symptoms of disordered defecation should include a barium enema or colonoscopy to eliminate the possibility of colorectal malignancy. Proctoscopy should be included as part of the routine examination because it may reveal anorectal pathology..

Therapeutic Approach to Fecal Incontinence

Treatment of fecal incontinence should first focus on nonsurgical options, including dietary modification, medical therapy, and biofeedback. Any underlying systemic conditions or gastrointestinal disorders should be treated before initiating an extensive evaluation for other causes of fecal incontinence. If symptoms persist, further investigation should be undertaken. If the evaluation discloses an underlying EAS defect and conservative therapy has been unsuccessful, it is reasonable to proceed with surgical treatment.

Following is an overview of treatment options and the efficacy of each approach. The lack of a consistent outcome measure makes it difficult to compare efficacy among treatments. Some studies base success on strict conformity with criteria for continence, but the results vary for continence of flatus, liquid, or solid stool. Other studies base success on more subjective criteria, such as improvement following treatment. Daily diaries can be maintained, but the results may be unreliable. Even if a validated symptom survey and quality-of-life scale are employed, few studies use the same outcome measure.

Nonsurgical Treatment

Nonsurgical management focuses on maximizing the continence mechanism through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one to two well-formed stools per day. The rationale for this approach is that formed stool is easier to control than liquid stool. Additionally, behavior modification can be employed using bowel regimens that focus on the predictable elimination of feces. Physical therapy and biofeedback can also be useful for strengthening the continence mechanism.

Pharmacologic Approaches

Dietary Modification and Fiber

Dietary modification for treatment of fecal incontinence frequently involves avoidance of foods that precipitate loose stools and diarrhea. Common dietary irritants include spicy foods, coffee and other caffeinated beverages, beer and alcohol, and citrus fruits. Avoidance of dairy products or the addition of lactase dietary supplements is essential for those with lactose intolerance. The addition of fiber may improve fecal incontinence by functioning as a stool bulking agent to increase volume and density. The average individual in the United States consumes less than one half of the recommended daily fiber intake (25–35 g). Various fiber sources are listed in Table 25.7, with the highest content found in fiber cereals. It is difficult to consume the recommended daily amount from diet alone, and fiber supplements often are required. Although the increased stool volume and density helps many individuals maintain continence, excessive fiber with inadequate fluid intake may predispose elderly patients to fecal impaction.

Constipating Agents

Constipating agents have the most value in patients with chronic loose stools or diarrhea. They can also help improve symptoms in patients with fecal frequency and urgency. *Loperamide (Imodium)* and *diphenoxylate hydrochloride with atropine (Lomotil)* are the most commonly used agents. *Loperamide* has been shown to prolong transit time and stimulate anal sphincter function. With either of these agents, careful titration is recommended

to prevent the primary side effect of constipation. It is generally preferable

to begin using 2 to 4 mg of *loperamide* daily and then titrate up to 4 mg three to four times per day. A 4-mg dose before meals has been shown to increase anal tone and improve continence (83). *Lomotil* is started at a dose of 1 to 2 tablets every day or every other day and titrated up to 1 to 2 tablets three to four times a day as needed. Caution should be exercised for patients taking other anticholinergic medications. Anticholinergic side effects include dry mouth, drowsiness, lightheadedness, and tachycardia. *Codeine* can also be used as a constipating agent. It should be used judiciously in those with chronic disorders and in elderly patients because of side effects common to narcotics, including addiction with prolonged usage and central nervous system and respiratory depression. A study of 82 geriatric patients documented the efficacy of pharmacologic treatment for fecal incontinence (84). Patients were treated based on the underlying cause. Those with fecal impaction received lactulose and enemas, whereas those with neurogenic fecal incontinence received codeine phosphate as a constipating agent and enemas. The rate of cure for fecal incontinence was 60% in the treatment group versus 32% for controls ($P < 0.001$).

Table 25.7 Fiber Sources

<i>Cereals</i>		<i>Fiber Supplements</i>	
All-Bran Extra Fiber (1/2 c)	15 g	Konsyl (1tsp)	6.0 g
Fiber One (1/2 c)	14 g	Perdiem (1tsp)	4.0 g
Raisin Bran (1/2 c)	7 g	Metamucil (1tsp)	3.4 g
All Bran (1/2 c)	6 g	Maalox w/fiber (1 tbs)	3.4 g
Fruit & Fiber (2/3 c)	5 g	Mylanta w/fiber (1tsp)	3.4 g
Frosted Mini Wheats (1/2 c)	3 g	Citrucel (1tbs)	2.0 g
<i>Breads</i>		<i>Vegetables</i>	
Whole wheat (1 slice)	2.0 g	Lettuce (1 c)	1.4 g
White (1 slice)	0.5 g	Celery (1)	0.5 g
Bagel (1)	1.0 g	Tomato, raw (1)	1.0 g

Modified from **Ellerkmann MR, Kaufman H.** Defecatory dysfunction. In: **Bent AE, Ostergard DR, Cundiff GW, et al, eds.** *Ostergard's urogynecology*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2002:362, with permission.

Medications for Irritable Bowel Syndrome

Dietary treatment of IBS consists of avoiding foods that are associated with symptoms, including alcohol, caffeine, sorbitol, and foods that increase gas production. Although increased dietary fiber or fiber supplementation has been shown to improve the constipation-predominant form of this illness, fiber supplementation has little effect on the diarrhea variant associated with fecal incontinence. Pharmacologic therapy is directed toward the predominant symptom. *Loperamide* and *Lomotil* tend to be useful first-line agents for treating diarrhea. Tricyclic antidepressants improve abdominal discomfort and are also

valuable in diarrhea–predominant patients because of their constipating effect. The serotonin type 3 (5HT3) antagonist *alosetron* (*Lotronex*) has been approved by the U.S. Food and Drug Administration for the treatment of severe diarrhea–predominant IBS refractory to treatment. It has shown improvement in global assessment measures, but its use is limited because of multiple isolated case reports of ischemic colitis. The recommended dose is 1 mg once or twice daily. It does not appear to be effective for the spastic–pain variant of IBS. Anticholinergics (*dicyclomine*, *hyoscyamine*) and antispasmodics (*mebeverine*, *pinaverine*) are targeted at the pain and bloating symptoms but may also be useful for the diarrhea variant because of their constipating side effects. Studies comparing anticholinergic medications to placebo show inconclusive results with only modest benefits. Antispasmodic agents may also be of value and are available in many countries but are not approved for use in the United States. Currently, additional 5HT3 antagonists and 5HT4 antagonists are under development. Most studies are poorly designed and difficult to interpret because of a high placebo response rate that often exceeds 30% (85,86).

Behavioral Approaches

Biofeedback

Biofeedback can be an effective therapeutic modality provided patients are motivated and comprehend instructions. The two proposed mechanisms through which biofeedback improves fecal continence are afferent and efferent training. Afferent training focuses on improving sensation in the anorectal canal through recruitment of adjacent neurons to decrease the sensory threshold of volume stimulation. The goal of this training is to enhance and restore anal sensation and the rectoanal inhibitory reflex. Efferent training enhances and restores voluntary contraction of the EAS, which permits additional recruitment of motor units and stimulates muscle hypertrophy. These two methods of training can be performed independently, but are often combined for additional therapeutic benefit. The most common training method uses an intrarectal balloon. The balloon acts to stimulate rectal distention and provide pressure feedback from coordinated or synchronized contraction of the

P.957

pelvic floor muscles. Other techniques focus on strength training of the EAS alone using anal pressure feedback or EMG or afferent training alone using an intrarectal balloon without pelvic floor muscle contraction in response to the stimulus.

More than 35 studies have been done to evaluate the efficacy of biofeedback for treatment of fecal incontinence, and several excellent review articles and meta–analyses have determined the effects of individual treatments and predictors of patient response to treatment (87,88,89). The results of all of these studies uniformly agree that biofeedback and pelvic floor exercises improve fecal incontinence and have a role in clinical practice. They also agree that the existing literature is fraught with methodologic problems and lacks validated outcomes and controls. Thus it is difficult to compare directly the study results.

Biofeedback is an ideal first–line therapy because it offers an effective, minimally invasive treatment without any reported adverse events. Biofeedback also appears

to provide a higher probability of successful outcome than standard medical care for treating functional fecal incontinence (67% versus 36%, respectively, $P < 0.001$) (87).

A **Cochrane review of biofeedback and exercises for treatment of fecal incontinence** found only five randomized or quasirandomized control trials that qualified for inclusion (90). The authors concluded that **there is insufficient evidence to evaluate the efficacy of exercises and biofeedback for treatment of fecal incontinence**. Specifically, they were not able to determine which patients are suitable for treatment, nor which method of treatment is optimal. A meta-analysis of biofeedback techniques included a review of 13 studies using strength training alone, 4 studies with sensory training alone, and 18 with coordinated sensory and strength training (89). The authors found no advantages between coordinated training (67% improved) and strength training (70% improved). However, strength training using EMG appeared to be better than strength training with anal canal pressure biofeedback (74% versus 64% improved, respectively, $P < 0.04$). The limitations of this study and the literature were acknowledged.

A large randomized control trial of biofeedback for fecal incontinence in 171 patients, divided into four treatment groups, showed no significant benefit when comparing standard care to similar care with the addition of biofeedback (54% versus 53% improvement, respectively) (91). In all groups, there was a high median rating of change of symptoms and median satisfaction with benefits relatively maintained at 1-year follow-up. All groups also displayed improvement in the validated symptom surveys and quality-of-life measures as well as in anal sphincter function. The authors concluded that interactions with the therapist, patient education, and development of better coping strategies seem to be the most important factors for improvement rather than pelvic muscle exercises or biofeedback. Additional benefit may be derived with augmented biofeedback using electrical stimulation (92).

There are no clear indicators to predict which patients will benefit from biofeedback. Potential factors include age, duration and severity of incontinence, prior treatments or surgery, and severity of neurologic or physical damage. Controversy exists as to whether response to biofeedback is dependent on the presence of a structurally intact anal sphincter or normal pudendal nerve function (93,94,95,96). There is an obvious need for well-designed control trials using validated symptom surveys and quality-of-life instruments. More objective measures are desirable, and studies should carefully document duration of treatment and length of follow-up.

Bowel Regimens

The goal of bowel regimens is to achieve predictable elimination of feces. This can be accomplished by using the gastrocolic reflex as well as by dietary and pharmacologic means. Defecation immediately following meals involves the physiologic response of the

gastrocolic reflex to facilitate predictable emptying. The strength of the gastrocolic reflex varies among individuals and may be hypoactive or hyperactive with certain systemic

disorders, such as diabetes and multiple sclerosis. This technique can be especially useful in the morning to give the individual freedom from fecal incontinence throughout the day. The use of suppositories or enemas in the morning or at night in conjunction with the gastrocolic reflex may provide further relief of daytime symptoms. The goal is to leave the rectum empty between evacuations. Enema use, typically once or twice daily, should be titrated to the patient's baseline colonic activity. **Regular toileting in elderly patients in nursing homes can improve fecal incontinence caused by overflow incontinence from fecal impaction.** The use of cone-tip colostomy-irrigation catheters is reserved for patients in whom other therapeutic modalities have failed. These catheters avoid the risk of rectal perforation and provide a dam to prevent efflux of the irrigating solutions (97).

Surgical Treatment

In general, surgical treatment should be employed after conservative measures have failed. Although there may be exceptions to this principle, most surgeons follow this recommendation because of the poor long-term outcomes and high complication rates with surgery for fecal incontinence.

Overlapping Sphincteroplasty

Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter. Most authorities believe that an overlapping technique is superior to an end-to-end repair, although there are few direct comparisons in the literature. The rationale for the overlapping technique is that a more secure repair can be accomplished by placing sutures through the scarred connective tissue rather than the sphincter muscle. Sutures should be less likely to tear through or pull out of connective tissue than muscle. Therefore, the key component of the overlapping technique is preservation of the scarred ends of the ruptured EAS for suture placement.

Technique

The initial step involves wide mobilization of the ruptured EAS without excision of the scarred ends of the sphincter. This is accomplished through an inverted semilunar perineal incision or a transverse incision near the posterior vaginal fourchette with inferiolateral extension. The latter incision facilitates repair in patients with damage to the rectovaginal septum attachment to the perineal body. Patients with EAS defects have either a band of intervening fibrous scar tissue between the viable muscular ends of sphincter or a complete separation with scar tissue present only on the ruptured ends of the sphincter. In the presence of complete separation of scar tissue, perineal body reconstruction usually is indicated at the time of repair to restore normal anatomy. A Peña muscle stimulator aids in identification of the distal ends of the EAS and differentiates viable muscle tissue from scar tissue. The stimulator can be used to outline the sphincter before incision as well as during the dissection. It is important to apprise the anesthesiologist of the stimulator usage so that paralytic agents are avoided.

Excessive lateral dissection of the EAS past the 3 and 9 o'clock positions should be avoided as this is where the inferior rectal branches of the pudendal nerve innervate the EAS. Moderate bleeding often is encountered during this dissection, and the use of needlepoint electrocautery can maximize hemostasis. Controversy exists regarding the need to separate the EAS and IAS before repair. Identification of the intersphincteric groove facilitates dissection of the EAS. Dissection in this plane is relatively simple and avoids damage to either sphincter. Defects in the IAS can be more difficult to visualize because this muscle is intimately associated with the rectal mucosa. Examination with a finger in the anal canal is often helpful.

P.959

The reconstruction begins with repair of an existing IAS defect using a 3–0 delayed absorbable monofilament suture. Next, the EAS defect is repaired with the primary goal of overlapping at least 2 to 3 cm to ensure adequate bulk of sphincter muscle encircling the anal canal. The EAS is overlapped using three to four mattress sutures of 2–0 delayed absorbable monofilament suture through the distal scar tissue. Once the sutures are tied, there should be resistance palpable with placement of a finger in the anal canal. Copious irrigation is performed throughout the procedure. Following sphincter repair, a perineal body reconstruction and rectocele repair should be undertaken, if indicated, to maximize the normal continence mechanism. Finally, the perineal skin is closed with interrupted absorbable monofilament sutures. Closure frequently requires modification of the initial incision because of changes in the perineal architecture that result from the repair. The most common approach is an inverted Y-shaped closure of the incision (Fig. 25.4).

Some surgeons recommend the overlapping repair regardless of whether it is performed immediately postpartum, delayed postpartum, or several years after obstetric injury. Performance of the overlapping technique is difficult immediately postpartum and requires

P.960

adequate anesthesia, exposure, and equipment. Many surgeons believe that this can only be accomplished in the operating room. This repair lacks the theoretical advantage of using scar tissue to improve suture holding; however, it maximizes surface area for scarification of the sphincter ends. For a delayed postpartum repair, it is recommended to wait 3 to 6 months to permit complete resolution of inflammation and reinnervation. Two randomized control trials compared end-to-end approximation to overlapping sphincteroplasty

P.961

P.962

(98,99). One study randomized 112 primiparous women undergoing immediate repair of a third- or fourth-degree sphincter tear (99). The authors did not detect any significant differences in objective or subjective outcomes between either of the two repairs at 3 months follow-up. Approximately one half of the women had minor alteration in fecal continence, whereas 7 (6%) had daily soiling. Despite good symptomatic results, 74 (66%) had full-thickness EAS defects on endoanal ultrasonography. The other randomized trial involved a delayed repair in

23 patients more than 1 year following delivery (99). The scar was preserved for each repair, and a puborectalis plication was performed. At a median follow-up of 18 months, there were no detectable differences in continence scores; however, the study was clearly underpowered.

Figure 25.4 Overlapping sphincteroplasty procedure. A: Inverted semilunar perineal incision with the distal ends of the external sphincter outlined using the Peña muscle stimulator. B: The external sphincter has been dissected, the scar divided in the midline, and the internal sphincter repaired. C: The external sphincter is overlapped using three mattress sutures of 2-0 delayed absorbable monofilament suture through the distal scar tissue. D: The sutures are tied. E: The skin is closed.

Efficacy

Despite the many large series reporting the outcomes of overlapping sphincteroplasty, almost all are retrospective in nature and lack validated measures of symptom severity and quality-of-life considerations. Several overlapping sphincteroplasty series with a total of 891 patients were evaluated from 1984 to 2001. Although the length of follow-up was variable, the results showed excellent and good outcomes in approximately two thirds of patients (median 67%, range 52%–83%) (100). None of these studies had long-term outcomes.

More recent studies suggest poor long-term outcomes for the overlapping sphincteroplasty. In a series of 55 women who underwent overlapping sphincteroplasty for fecal incontinence secondary to obstetric trauma (101), researchers contacted 47 (86%) patients by postal questionnaire and telephone interview with a median time since surgery of 77 months (range 60–96 months). The investigators observed less symptomatic improvement when compared with the results at 15 months postoperative evaluation. After excluding one patient because of Crohn disease, eight (17%) failed because they required additional surgery, such as colostomy, postanal repair, and artificial bowel sphincter. Among the remaining 38 patients, 27 (71%) reported improved bowel control, 5 (13%) were unimproved, and 6 (16%) were worse. No patient was fully continent to solid and liquid stool and flatus. Only 23 (50%) patients had “good” outcomes defined as not requiring further continence surgery and fecal incontinence less than once per month.

In another study, investigators contacted 49 (69%) of 71 patients by telephone interview (102). All underwent overlapping sphincteroplasty with a median follow-up of 62.5 months (range 47–141 months). Only 6 (12%) patients were totally continent, and another 18 (37%) were continent to liquid and solid stool. In other words, more than half of the patients had incontinence to liquid or solid stool. The largest series with long-term follow-up involved contact of 130 (71%) of

191 patients using a postal or telephone questionnaire (103). The median time from surgery for respondents was 10 years (range 7–16 years). Of those who responded, 6% had no incontinence, 16% were incontinent of flatus only, 19% had soiling only, and 57% were incontinent of solid stool. These outcomes were significantly worse than the previously reported 3-year assessment (104). Despite the fact that 61% had a poor outcome defined as having fecal incontinence or requiring additional surgery for incontinence, 62% still considered their bowel control to be better than before surgery, and 74% were satisfied with the results of their surgery. Thus, although control may be improved when compared with preoperative status, continence outcomes do not seem to be maintained at long-term follow-up.

The cause of this deterioration in long-term outcomes is unknown. Possible explanations include weakening of the muscles with normal aging, repair breakdown, and underlying nerve damage from either obstetric injury or the repair itself. A problem with most studies is the lack of a follow-up ultrasonography to determine if the repair is intact. The effect of

pubdental nerve function on overlapping sphincteroplasty is somewhat controversial. Significantly lower success rates have been shown in a comparison of those with normal pudendal nerve terminal motor latencies to those with abnormal latencies (63% versus 17%, $P < 0.01$) (105). Other studies have confirmed this finding (79,106,107), but the more recent studies fail to show a difference based on preoperative neurophysiologic testing (101,103). Other controversial factors that may affect outcome include age, duration of fecal incontinence, size of the defect, and anal manometry results.

Although there are many controversial aspects to overlapping sphincteroplasty, the literature is in agreement that **diverting colostomy is not necessary** (99,108,109); bowel confinement does not improve outcomes (99,108,110); clinical improvement correlates with postoperative endoanal ultrasonography results (101,111,112); and prior sphincteroplasty does not affect outcomes (105,111,113).

Subsequent Deliveries

Multiple studies confirm the impact of anal sphincter laceration during the first delivery on the risk of a sphincter laceration in a second delivery (114,115,116). These studies have calculated odds ratios ranging between 2.5 and 5.3 for a second sphincter disruption. Two recent population-based studies revealed adjusted odds ratios of 4.2 (95% CI, 3.9–4.6) and 4.3 (95% CI, 3.8–4.8) (115,116). These odds ratios probably represent underestimates because they do not take into account higher cesarean delivery rates in subsequent births for women with a history of sphincter laceration. Both of these studies observed significantly increased risk of recurrent sphincter laceration associated with increased birth weight. The studies estimated that approximately 25 cesarean deliveries have to be performed to prevent one recurrent sphincter laceration. In fact, only 10% of women with anal sphincter lacerations at second delivery had a history of prior sphincter laceration. Therefore, **although a history of prior sphincter laceration increases the risk of recurrent sphincter laceration, the risk remains relatively small**. Nevertheless, it is important to accurately counsel expectant mothers about their risk of sphincter laceration. Using

this information, they can decide whether the risk of recurrent laceration outweighs the risk of elective cesarean birth. The risk of subsequent vaginal delivery on symptoms of fecal incontinence is unknown for women with a repaired anal sphincter. The presence or absence of pre-existing fecal incontinence, as well as the estimated fetal weight, should be considered in counseling for a subsequent pregnancy.

Graciloplasty

Surgical reconstruction with a muscle flap should be considered in cases in which there is insufficient muscle to repair the EAS and all conservative measures have failed. Insufficient muscle can be caused by trauma or severe atrophy that results from denervation injury and congenital disease. Most patients considering this procedure have already undergone an overlapping sphincteroplasty that failed. Graciloplasty, first described by Pickrell et al. in 1952 (117), is a skeletal muscle transposition procedure that uses the gracilis to create a new anal sphincter. There are three suitable muscles for this type of procedure: the gracilis, sartorius, and gluteus maximus. Ideally, the muscle should be easily mobilized and transposed but not essential for locomotion or posture. The sartorius and gluteus maximus are suboptimal because the sartorius receives segmental vascularization, which restricts rotation, and the gluteus maximus is important in daily activities such as running, climbing stairs, and rising from a sitting position. **The gracilis is a better choice because it can easily be mobilized without damage.** As the most superficial adductor, it receives neurovascular supply proximally and has no important independent function.

Technique

Either one long incision or three small incisions are made in the medial thigh. The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. Anterior and posterior perianal incisions are made approximately 1.5 cm from the anal verge. Tunnels are developed in the extrasphincteric space and from the proximal thigh to the anterior perianal incision. The gracilis muscle is then gently delivered to the anterior perianal incision, guided around the anus to the posterior perianal incision, and returned to the anterior incision encircling the anal canal. The distal tendon of the gracilis is passed behind the muscle and anchored to the contralateral periosteum of the ischium. In cases when there is inadequate length, it can be sutured to the ipsilateral ischium. This procedure can also be performed bilaterally. In patients with a large rectovaginal fistula or cloaca, a myocutaneous flap can be mobilized and used to help close the defect. Improvement of fecal incontinence is caused by passive increase of the resistance of the anal canal by the bulk of the encircling muscle (Fig. 25.5).

Experimental efforts to improve the efficacy of this procedure have focused on developing resting tone in the transposed muscle through the use of an implanted neurostimulator. The intent of the stimulated graciloplasty is to convert the fast-twitch muscle fibers into slow-twitch muscle fibers, which are more fatigue resistant. Initially, implantation of the pacemaker was performed at 6 weeks after the graciloplasty, but now most are performed

concomitantly. Stimulation can be applied directly to the obturator nerve or intramuscularly to the nerve branches inside the muscle. The muscle is stimulated at a cyclic frequency, with gradual increases every 2 weeks. After 2 months, continuous stimulation is performed. Stimulation is adjusted to maintain tonic contraction around the anus, and it is interrupted or turned off to defecate.

Efficacy

An exhaustive review of the published literature identified 37 articles of patients undergoing dynamic graciloplasty (118). Most of these articles were case series, and there were no randomized trials or cohort studies evaluating safety and efficacy. Mortality rate was 1% (range 0%–13%, 95% CI, 1%–3%) after excluding cancer deaths. There was a high rate of morbidity (1.12 events per patient). Thus, most patients will have at least one adverse event, and several will have multiple complications. There is also a very high reoperation rate. The most common complications were infections (28%), stimulator and lead faults (15%), and leg pain (13%). Satisfactory continence was achieved 42% to 85% of the time, although satisfaction was not defined consistently across studies. The authors concluded that dynamic graciloplasty appeared to have equal or better efficacy than colostomy but carried a higher morbidity rate. Another review of the three largest case series (119,120,121) found success rates ranging from 55% to 78%. Major infections were found in 13% to 29%, pain in 27% to 28%, and device or lead problems in 12% to 18%. More recent series containing large numbers of patients found similar results for efficacy, morbidity, and reoperation rate (122,123). High rates of disturbed evacuation also were reported.

Artificial Sphincter

The artificial anal sphincter is an alternative to a graciloplasty. This is a modification of the device originally designed to treat urinary incontinence. The current device is the Acticon® Neosphincter (American Medical Systems, Minnetonka, Minnesota, USA) (Fig. 25.6). The indications for its use are similar to those for the graciloplasty.

Technique

Implantation of the artificial anal sphincter is performed, similar to the graciloplasty, through perianal tunnels. A Silastic inflatable cuff is placed around the native sphincter

to occlude the anal canal. A pressure-regulating balloon containing radio-opaque solution is situated in the retropubic space, and a control pump is positioned in the labia majora. Activation of the control pump deflates the cuff, permitting defecation (see Fig. 25.6).

Figure 25.5 Graciloplasty. A: The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. B: Anterior and posterior perianal incision are made approximately 1.5 cm from the anal verge. The muscle is then tunneled around the extrasphincteric space circumferentially. The distal tendon is passed behind the muscle and anchored to the contralateral periosteum of the ischium.

P.966

Efficacy

A recent extensive review of the literature summarized 13 case series and one case report from 1996 to 2003. There were no randomized trials or cohort studies (124). The largest series consisted of 112 patients (125). There was one series with 53 patients, and all others had fewer than 28 patients apiece (126). Explantation was required in 17% to 41% of patients. Reasons for explantation included infection, erosion, device malfunction, pain, incontinence, and dissatisfaction, with infection being the most common. Surgical revision was necessary in 13% to 50% of the reports. Almost everyone had at least one adverse event, and more than one third of these events required surgical intervention. Reasons for surgical revision were similar to those for explantation. Rates of fecal impaction ranged from 6% to 83%. All studies recorded statistically and clinically significant improvement in continence scores for patients with a functional artificial sphincter; however, most did not report the continence status for those in whom the device was explanted. The proportion of patients with a functional device ranged from 49% to 85%. The authors concluded that there is insufficient evidence on the safety and effectiveness of the artificial sphincter for fecal incontinence.

One randomized control trial of 14 patients compared artificial sphincter with a program of supportive care (127). Supportive care included all aspects of conservative management,

P.967

such as physiotherapy, dietary advice, pharmacotherapy, and advice regarding skin care, odor management, anxiety reduction, and use of incontinence aids or appliances. Significant improvements in continence scores and quality-of-life measures were seen in the artificial sphincter group but not in the control group at 6 months follow-up. Explantation rate was 14% (1 of 7 patients). Two other patients had complications, including severe fecal impaction and perineal wound erosion requiring reoperation. The authors conclude that **the artificial sphincter is safe and effective compared with supportive care alone.** They anticipate perioperative and late complications, which may require explantation in up to one third of patients. It is also remarkable that only one patient (14%) whose condition was managed conservatively had significant improvement based on continence scores, whereas the status of all others was relatively unchanged.

Another study compared the effectiveness of artificial sphincter with dynamic graciloplasty (128). Two surgeons each performed four consecutive operations with each technique to minimize the learning curve of a new operation. Each started with a different procedure to avoid discrepancies in the time of follow-up. This prospective cohort study involved eight patients in each group who had similar demographic variables. Length of follow-up was 44 months in the artificial sphincter group and 39 months in the dynamic graciloplasty group. Early postoperative complications were similar in each group at 50%, as were late complications, with both groups reporting a high reoperation rate of 63%. There were six (75%) late

complications in the artificial sphincter group, of which three (38%) were nonreversible and required explantation. Postoperative continence scores were significantly lower with the artificial sphincter than with graciloplasty. The authors conclude that **artificial sphincter has better efficacy and similar morbidity compared with dynamic graciloplasty**. The rate of late complications for the artificial sphincter exceeded that reported in the literature, which may indicate poor long-term durability. Postoperative continence scores reflect those reported for artificial sphincter but are far worse than those for dynamic graciloplasty. The authors feel that the learning curve with the artificial sphincter is less important than that with graciloplasty.

Sacral Nerve Root Stimulator

Sacral neuromodulation (InterStim®, Medtronic, Minneapolis, Minnesota, USA) **was approved by the U.S. Food and Drug Administration for treatment of urinary urge incontinence in 1997 and for nonobstructive urinary retention and urgency in 1999. It has been employed experimentally for the treatment of fecal incontinence.**

The exact mechanism of action has not been fully elucidated. The goal of sacral nerve stimulation is to recruit residual function of the continence mechanism through electrical stimulation of its peripheral nerve supply. Initially, indications were confined to patients with deficient EAS and levator ani function without gross morphologic defects and intact neuromuscular connections. More recently, the acceptable indications have expanded to include deficiency of the IAS, limited structural defects, and functional deficits of the internal and external anal sphincter.

Technique

The device is instilled exactly the same way as for treatment of urinary incontinence. Current application is performed as a two-stage outpatient surgical procedure. The first stage involves instillation of the electrodes. The electrode is placed through the S2–4 foramen using minimally invasive surgical technique. During the test phase, multiple electrodes can be employed either bilaterally or at different levels to determine the site with the best response. Proper location is confirmed intraoperatively using fluoroscopy as well as visualization of an appropriate pelvic floor muscle response (bellows) with minimal plantar flexion of the first and second toes, which usually corresponds to S3 stimulation. An interval testing phase utilizes an external pulse generator that typically lasts 1 to 2 weeks. Those with a good response (decrease in fecal incontinence episodes

of at least 50% documented by bowel-habit diary) will proceed to the second stage, implantation of the permanent pulse generator (IPG). Typically only one electrode is left in place at the end of the second stage. Once the permanent pulse generator is implanted, all adjustments are made using telemetry. The patient has a basic remote control that enables her to turn the device on or off and adjust the amplitude of the stimulation.

Efficacy

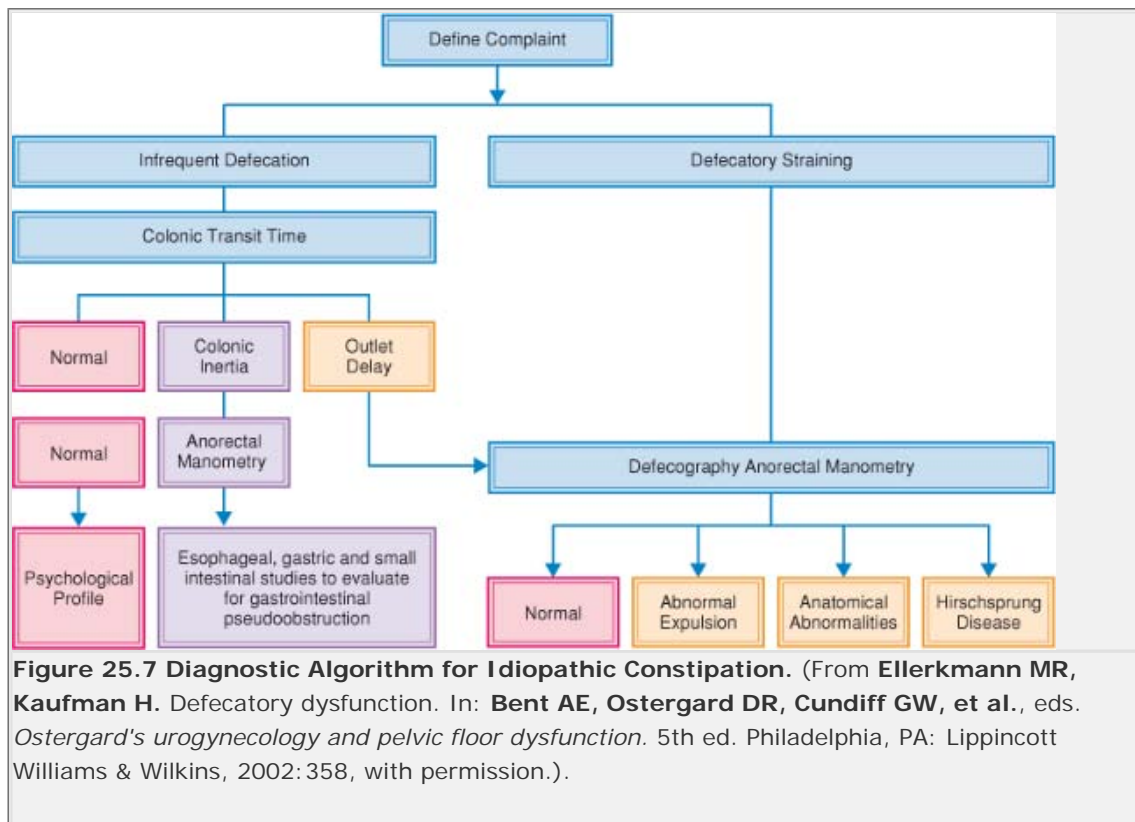

By the end of 2003, sacral nerve stimulation had been used to treat more than 1,300 patients

with fecal incontinence (129). Despite this large number, the analysis of the results is limited to several small case series. In all studies, significant improvements in continence scores lasting up to 99 months occurred. Most patients experienced at least a 75% improvement in continence scores, and improvement also occurred in the frequency of incontinence episodes, the ability to postpone defecation, and bowel emptying. Intent-to-treat analysis revealed 80% to 100% therapeutic success. There also were significant improvements in quality-of-life measures using validated measurement scales. Complications occurred in 0% to 50% of patients, with the most common complications consisting of pain at the electrode or IPG site, electrode migration, infection, or worsening of bowel symptoms. No permanent sequelae occurred, however. Effects of anorectal physiology varied among the published studies, highlighting the fact that the precise mechanism of action remains unclear.

A review of both fecal incontinence and constipation found that 149 (56%) of the 266 patients went on to permanent implantation (130). The rate of permanent implantation was higher for most studies, approximating 80%. Among implanted patients, 41% to 75% were completely continent to solid and liquid stool, and 75% to 100% had at least a 50% improvement in the number of incontinent episodes. One double-blind crossover trial with two patients had the stimulators set below the sensory threshold and turned on or off for 2-week intervals (131). The number of fecal incontinence episodes per week improved from two to zero for one patient and from ten to one for the other patient. In another review, 19 (13%) adverse events occurred in 149 patients, findings that were similar to those mentioned previously (130). **Thus, sacral nerve stimulation appears to be a promising new treatment for fecal incontinence with relatively limited complications.**

Therapeutic Approach to Constipation

As with fecal incontinence, it is imperative to attempt conservative management of constipation and defecatory dysfunction before performing surgery. Initial evaluation should focus on identifying any underlying systemic conditions (see Table 25.1) associated with disordered defecation and optimizing treatment for these conditions. In the absence of systemic etiologies, it is reasonable to proceed with empiric, nonsurgical management, such as diet, fiber supplementation, and toileting behavior. Biofeedback and laxatives can be used in more severe cases. Initially, disimpaction with regular enemas or laxatives is essential if the patient has fecal impaction. **Symptoms that persist despite a trial of conservative management indicate the need for further evaluation of colonic and anorectal function.** A diagnostic algorithm for idiopathic (nonsystemic) constipation is given in Figure 25.7. Treatment should then be tailored to the underlying cause. Some conditions associated with disordered defecation are best treated using nonsurgical techniques, whereas others may benefit from surgery once conservative management has failed. As with fecal incontinence, the lack of consistent outcome measures in the published literature makes it difficult to compare efficacy among treatments.

Nonsurgical Treatment

Nonsurgical management focuses on maximizing anorectal function through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one stool every day or every other day. Additionally, behavior modification can be employed using regular toileting to prevent fecal impaction. Physical therapy and biofeedback can also be useful for coordinating pelvic floor and anal sphincter relaxation with defecation.

Pharmacologic Approaches

Dietary Modification and Fiber

The role of increased fluid and fiber intake for the treatment of constipation is controversial. For years, it has been a commonly accepted belief that constipation is caused by low fluid intake and can be improved by increasing consumption. Several studies showed no association between fluid intake and constipation (132,133,134). However, one large study

of 21,012 nursing home residents found a weak association between decreased fluid intake and constipation with an odds ratio of 1.49 (135). In one interventional study, increased fluid intake failed to improve stool frequency, consistency, or defecatory dysfunction in children (136). Another interventional study using fiber and mineral water displayed an increase in stool frequency and a decrease in laxative use in adults with constipation (137). This study lacked baseline data collection resulting in recall bias, and the use of mineral water containing magnesium may confound the results because of its mild laxative effect. Overall, the existing data do not support increased fluid intake to treat constipation unless there is evidence of dehydration (132).

The addition of fiber may improve constipation through several mechanisms. Fiber acts as a stool bulking agent and improves stool consistency through water absorption. It can also act as a substrate for bacterial proliferation and gas production. These mechanisms of action are believed to result in increased colonic motility, decreased transit time, and increased stool frequency.

Fiber therapy appears to have a beneficial effect in the treatment of diverticular disease (138), constipation of pregnancy (139), and possibly IBS (140). Its efficacy for idiopathic (nonsystemic) constipation remains uncertain. Dietary fiber intake for patients with constipation was similar to that of controls in several studies (133,134). A meta-analysis of 36 randomized trials using laxatives or fiber therapy for the treatment of constipation showed that the use of fiber or laxatives resulted in increased stool frequency and improved symptoms without the presence of severe side effects (141). Conversely, another meta-analysis showed an inability to restore transit time and stool weight in constipated patients using dietary fiber (140). Approximately one half of the patients in another study responded to fiber treatment, but a much better response occurred in patients without an identifiable structural or motility disorder (142). Consequently, a low-fiber diet may be a contributing factor in chronic constipation, and an empiric trial of fiber therapy can be expected to help some patients. Side effects of increased gas production may limit compliance with treatment, so doses should be slowly titrated. Fiber therapy should be avoided in patients with impaction, megacolon or megarectum, or obstructive gastrointestinal lesions. Fiber therapy should also be used with caution in patients with cognitive dysfunction (dementia), difficulty with ambulation, and underlying neurogenic disease for fear of worsening the condition. There is no evidence to substantiate the recommendation for extra water intake with fiber supplements (143).

Laxatives

Laxatives are commonly used to treat constipation and disordered defecation. Many classes of laxatives are available over the counter.

Bulk-forming Laxatives

These come in natural forms (*psyllium*) as well as synthetic form, (*Metamucil, Konsyl, Citrucel*), and are felt to be the safest laxatives. They have mechanisms of action and side effects similar to that of fiber (144).

Hyperosmolar Laxatives

These consist of poorly absorbed substances that increase intraluminal osmolarity and water absorption. This action results in greater stool volume with decreased consistency. Examples include nonabsorbable sugars (*lactulose and sorbitol*), *glycerin*, and *polyethylene glycol (GoLytely)*. *Polyethylene glycol* is a common preoperative bowel preparation. Side effects are diarrhea, increased flatus, and abdominal cramping (144).

Emollient Laxatives

These agents are divided into two subsets: *docusate salts* and mineral oil. The *docusate salts* have hydrophilic and hydrophobic properties similar to detergents. They soften stool and decrease surface tension by increasing stool water and lipid content. Examples include *docusate calcium (Surfak)*, *docusate potassium (Dialose, Kasof)*, and *docusate sodium (Colace, Comfolax)*. They also improve the absorption of other laxatives and are combined in preparations with stimulant laxatives such as *Correctol*, *Peri-Colace*, and *Feen-a-Mint*. The limited absorption of mineral oil allows it to penetrate and soften the stool. It can be used orally or rectally. Prolonged daily use can lead to decreased absorption of the fat-soluble vitamins A, D, E, and K. Use of mineral oil should be avoided in elderly and debilitated patients, as well as in those with esophageal motility disorders because of the potential for aspiration pneumonia. Side effects include diarrhea, anal leakage, and pruritis ani (144,145,146).

P.971

Saline Laxatives

These usually contain magnesium cations and phosphate anions that are relatively nonabsorbable and produce an osmotic gradient with increased water absorption. They also stimulate intestinal motility by increasing cholecystokinin release. Fast-acting effects can be seen with both oral (2–6 hours) and rectal (15 minutes) preparations. Examples include *magnesium citrate*, *magnesium hydroxide (Milk of Magnesia)*, *magnesium sulfate*, *sodium phosphate*, and *biphosphate (Phospho-soda, Fleet enema)*. Although generally well tolerated, electrolyte abnormalities can occur. These side effects should be avoided in patients with renal insufficiency because of the potential for magnesium toxicity (144,145,146).

Stimulant Laxatives

These are found in three basic types: *castor oil*, anthraquinones, and *diphenylmethanes*. A metabolite of *castor oil*, *ricinoleic acid*, increases intestinal motility and secretion. Anthraquinones (*casacara sagrada*, *senna [Senekot]*, *casanthranol [aloe]*, and *danthron*) are absorbed by the small intestine and stimulate motility by increasing intraluminal fluid and electrolyte content. *Diphenylmethanes (phenolphthaleins [Feen-a-Mint, Correctol] and bisacodyl [Dulcolax])* have a mechanism of action similar to anthraquinones. These agents are potent and are intended for short-term use in cases refractory to bulk or osmotic laxatives.

It has been a long-standing belief that prolonged use can lead to a dilated atonic colon known as cathartic colon syndrome, melanosis coli, or neuronal degeneration. A recent article refutes the theory that stimulant laxatives damage the autonomic nervous system when used at recommended doses (132). Other side effects include cramping, nausea, and abdominal pain (144,145,146).

Prokinetic Agents

Medications that stimulate gastrointestinal motility primarily through neuromodulation of acetylcholine levels include *metoclopramide*, *cisapride*, cholinergic agonists (*bethanechol*), *cholinesterase inhibitors (neostigmine)*, and serotonin agonists. Their efficacy in the treatment of chronic idiopathic constipation is uncertain. *Metoclopramide* is better for upper gastrointestinal motility disorders, whereas *cisapride* appears to exert its effect at the level of the colon (144,145,146).

Behavioral Approaches

Behavioral techniques such as biofeedback and bowel regimens may have a role in certain conditions associated with constipation and defecatory dysfunction. Overall, these approaches have far less application to disordered defecation than to fecal incontinence. Biofeedback is important in the treatment of anismus. Relaxation techniques and behavioral modification may be helpful for IBS. Bowel regimens in conjunction with **laxatives, suppositories, and enemas can** facilitate emptying by optimizing the gastrocolic reflex and increased peristaltic activity.

Efficacy of Nonsurgical Treatment

Irritable Bowel Syndrome

The most commonly used first-line treatment for the constipation variant of IBS is fiber supplementation and osmotic laxatives. The efficacy of bulking agents for this condition is controversial, and many studies, including meta-analyses, exhibit an effect similar to placebo. There may be benefit to the use of fiber because of the high placebo effect with IBS treatment and lack of serious adverse events associated with its use. However, patients may experience exacerbation of bloating and abdominal discomfort with fiber therapy. There are limited data (no randomized control trials) to determine the efficacy of osmotic laxatives. They can be useful as adjunctive treatment options, but can also exacerbate abdominal pain and discomfort. A newer class of drugs, serotonin 5HT₄ agonist

tegaserod (Zelnorm), stimulates peristalsis, increases colonic motility, decreases intestinal transit times, and reduces visceral hypersensitivity. The recommended dose is 6 mg twice daily. Randomized trials have consistently shown an approximately 10% greater improvement in global IBS symptoms when compared with placebo. Improvement in the bloating and pain symptoms also occurred. No episodes of ischemic colitis or cardiac toxicity have been

reported with the use of this medication, and the most common side effects are diarrhea and headache. *Cisapride*, a 5HT₄ agonist with partial 5HT₃ antagonist actions, has been withdrawn from use secondary to rare cardiac toxicity. Additional 5HT₄ agonists, 5HT₃ agonists, and cholecystokinin antagonists are in development (85,86).

Colonic Inertia and Slow-Transit Constipation

Patients with slow-transit constipation tend to respond poorly to fiber supplementation, although most have already tried an empiric trial of fiber before testing to confirm the diagnosis (142). Some patients may benefit from regular toileting, either in the morning or after meals when there is increased colonic motor activity. Biofeedback may have modest short-term benefits, but the long-term effect is questionable (147). Enemas and suppositories can be used in conjunction with bowel regimens. It is also reasonable to attempt a trial of any of the laxatives listed in Table 25.8. Stimulant laxatives commonly are used, but questions remain about the development of neuronal degeneration with prolonged usage. It is imperative that patients adhere to and not exceed the recommended dosages. Data regarding laxative use for this condition have failed to show a significantly better response than placebo. Prokinetic agents are intuitively the ideal choice to stimulate colonic motility. Currently there is only one available prokinetic agent, *tegaserod*, approved for the treatment of constipation that improves colonic transit. Its data are almost entirely based on treatment of IBS, and there is a lack of information for its use in slow-transit constipation. Other prokinetic agents in various stages of testing include *bethanechol*, *neostigmine*, *cholecystokinin antagonists*, *misoprostol*, *colchicine*, *neurotrophin-3*, and other 5HT₄ agonists such as *prucalopride* and *mosapride* (40).

Anismus

As with slow-transit constipation, initial management using bowel regimens, laxatives, enemas, suppositories, and fiber supplementation is appropriate for patients with anismus, yet many will have already tried conservative management before undergoing testing to confirm the diagnosis. These treatments are relatively well tolerated with few serious side effects. They have not been shown to have greater efficacy when compared with placebo, and their role in the treatment of anismus remains uncertain.

Specific treatment for this condition tends to focus on biofeedback because of studies indicating that this is an acquired behavioral disorder of defecation. Modalities such as diaphragmatic muscle training, simulated defecation, and manometric or electromyography-guided anal sphincter and pelvic muscle relaxation have been employed independently or combined with other techniques. These techniques have yielded symptomatic improvement in approximately 60% to 80% of patients. Many patients with dyssynergic defecation also have abnormal rectal sensation, so rectal sensory conditioning may provide additional benefit (28,40,148,149). Others have tried *botulinum toxin* injections to paralyze the puborectalis and anal sphincter muscle. Small case series have shown modest early improvement but the results do not appear to be long lasting (150,151).

Pessary for Treatment of Pelvic Organ Prolapse

Pessaries of various shapes and sizes have been used for centuries to treat pelvic organ prolapse (152). They are a safe alternative to surgery, with the most common complications being increased vaginal discharge and erosion or ulceration of the vaginal wall. Although pessaries represent a common therapeutic modality, there are limited data regarding fitting and management (153). Even less is known about which type

P.973

of pessary is better for enteroceles and rectoceles, although the site of prolapse does not appear to affect the ability to retain a pessary (154). Pessaries can be divided into subtypes of supportive and space occupying (155). Some of the space-occupying pessaries, such as the Gellhorn and cube, use a suction mechanism to maintain vaginal retention, whereas others, like the donut, do not. In theory, space-occupying pessaries and those that exert forces against the posterior wall and vaginal apex (donut, inverted Gehrung) should aid in treatment of rectoceles and enteroceles. However, there is a lack of data regarding the efficacy of pessaries for relieving symptoms of disordered defecation. One prospective study

P.974

found that stage III–IV posterior vaginal wall prolapse was an independent predictor for discontinuation of pessary use in favor of surgical repair (156). More research is needed to determine the role of pessaries for treatment of rectoceles and enteroceles as well as symptoms that are likely to be improved using a pessary.

Table 25.8 Laxatives for the Treatment of Disordered Defecation

Type of Laxative	Adult Dose	Onset of Action	Side Effects
<i>Bulk-Forming Laxatives</i>			
Natural (<i>psyllium</i>)	7 g PO	12–72 h	Impaction above strictures
Synthetic (<i>methylcellulose</i>)	4–6 g PO	12–72 h	Fluid overload
<i>Emollient Laxatives</i>			
Docusate salts	50–500 mg PO	24–72 h	Skin rashes
Mineral oil	15–45 ml PO	6–8 h	Decreased vitamin absorption Lipid pneumonia
<i>Hyperosmolar Laxatives</i>			
<i>Polyethylene glycol</i>	3–22 L PO	1 h	Abdominal bloating
<i>Lactulose</i>	15–60 mL PO	24–48 h	Abdominal bloating
<i>Sorbitol</i>	120 mL 25% solution PO	24–48 h	Abdominal bloating
<i>Glycerine</i>	3 g suppository	15–60 min	Rectal irritation
	5–15 mL enema	15–30 min	Rectal irritation
<i>Saline Laxatives</i>			
<i>Magnesium sulfate</i>	15 g PO	0.5–3 h	Magnesium toxicity
<i>Magnesium phosphate</i>	10 g PO	0.5–3 h	
<i>Magnesium citrate</i>	200 mL PO	0.5–3 h	

<i>Stimulant Laxatives</i>			
Castor oil	15–60 mL PO	2–6 h	Nutrient malabsorption
<i>Diphenylmethanes</i>			
<i>Phenolphthalein</i>	60–100 mg PO	6–8 h	Skin rashes
Bisacodyl	30 mg PO	6–10 h	Gastric irritation
	10 mg PR	0.25–1 h	Rectal stimulation
<i>Anthraquinones</i>			
<i>Cascara sagrada</i>	1 mL PO	6–12 h	Melanosis coli
<i>Senna</i>	2 mL PO	6–12 h	Degeneration of Meissner and Auerbach plexuses
<i>Aloe (Casanthrol)</i>	250 mg PO	6–12 h	
<i>Danthron</i>	75–150 mg PO	6–12 h	Hepatotoxicity (w/docusate)

PO, by mouth; PR, per rectum.

Surgical Treatment

Following is a review of the efficacy of various surgical treatments for specific conditions associated with constipation and disordered defecation.

Slow Transit/Colonic Inertia

Subtotal colectomy with ileosigmoid or ileorectal anastomosis is considered by many to be the surgical treatment of choice for slow-transit constipation refractory to medical management.

Most surgeons restrict the use of this surgical procedure to the most extreme cases and typically operate on fewer than 10% of patients. Strict criteria for surgery include the following: chronic, severe, disabling symptoms unresponsive to medical therapy; slow transit in the proximal colon; no evidence of pseudo-obstruction; and normal anorectal function (144). Success rates are variable and depend on several factors. An extensive review of colectomy for slow-transit constipation analyzed 32 studies from 1981 to 1988 and found satisfaction rates ranged from 39% to 100% (157). Higher success rates occurred in studies in the United States (n = 11, median 94%, range 75%–100%) and prospective studies (n = 16, median 90%, range 50%–100%). Superior outcomes occurred in those who had a complete physiologic evaluation and proven slow-transit constipation. Patients with anismus had higher rates of recurrent symptoms and lower satisfaction levels (158). Poorer outcomes occurred with ileosigmoid and cecorectal anastomosis than with ileorectal anastomosis. Those with segmental resection (hemicolectomy) had the worst outcome. None of the studies had a comparison group, and outcomes were variable and lacking validated measures. Morbidity associated with the operation included small bowel obstruction (median 18%, range 2%–71%), need for reoperation (median 14%, range 0%–50%), diarrhea (median 14%, range 0%–46%), fecal incontinence (median 14%, range 0%–52%), recurrent constipation (median 9%, range 0%–33%), persistent abdominal pain

(median 41%, range 0%–90%), and permanent ileostomy (median 5%, range 0%–28%). Mortality ranged from 0%–6% (159). A quality-of-life study revealed that the score correlated poorly with frequency of bowel movements. However, a lower score was seen in those patients who had persistent abdominal pain, diarrhea, fecal incontinence, and permanent ileostomies. Overall satisfaction with the procedure was very high and correlated with the quality-of-life score (160).

Surgical alternatives to subtotal colectomy include ileostomy, cecostomy with antegrade continence enemas, and sacral nerve stimulation. Subtotal colectomy has never been directly compared with ileostomy, but those who had a permanent diversion after subtotal colectomy had lower quality-of-life scores. Patients undergoing cecostomy with antegrade continence enemas can expect to have satisfactory function approximately one half of the time, with most requiring additional revision procedures secondary to stomal complications (161). Although sacral nerve stimulation has primarily been used for fecal incontinence, the results of a few small studies evoke optimism for its use in chronic constipation and slow-transit constipation (130,162,163).

Pelvic Organ Prolapse

The variety of surgical treatment techniques for the repair of rectocele include posterior colporrhaphy, defect-directed repair, posterior fascial replacement, transanal repair, and abdominal repair with sacral colpopexy. When an enterocele is present, a culdoplasty usually is performed. In cases of perineal descent, abdominal sacral colpoperineopexy is the procedure of choice. Suture rectopexy can be performed in

P.975

conjunction with sacral colpoperineopexy if rectal prolapse is present. Despite the routine use of these procedures, data are limited regarding symptomatic improvement of disordered defecation. Greater detail regarding the specific techniques for many of these procedures will be provided in Chapter 24. This section will focus on surgical outcomes, including anatomic cure of prolapse, improvement of defecatory dysfunction symptoms, and morbidity associated with the procedure.

Posterior Colporrhaphy

Posterior colporrhaphy has been the surgical procedure for rectocele repair preferred by gynecologic surgeons for more than 100 years. Traditional posterior colporrhaphy narrows the vaginal caliber through plication of the rectovaginal septum and usually includes a perineorrhaphy, which narrows the introitus. Despite its broad use, there is a paucity of data regarding long-term anatomic success, symptomatic improvement, and sexual function following the procedure. The outcomes of several studies are summarized in Table

25.9

(164,165,166,167,168,169,170,171,172,173,174,175,176,177,178,179,180,181,182).

Anatomic cure and relief of vaginal bulge occurred in 76% to 96% of patients. In these studies,

the procedure was ineffective at treating constipation, vaginal digitations (splinting), and fecal incontinence. Dyspareunia developed in 8% to 26% of patients with and without levator plication (164,165,166,167,168,183). As early as 1961, high rates of dyspareunia have been reported with this procedure in as many as 50% of patients (184).

Many feel that the successful anatomic support obtained with this procedure is offset by the modest relief of functional symptoms and high rate of *de novo* dyspareunia. However, a recent prospective case series of 38 women undergoing posterior colporrhaphy along with concomitant procedures for rectocele and obstructed defecation revealed markedly different results (185). Fascial plication was performed without levator plication, and perineal body reconstruction rather than routine perineorrhaphy was employed when indicated. Anatomic cure rate was 87% at 12 months and 79% at 24 months. Subjective cure rate was 97% at 12 months and 89% at 24 months. There was significant improvement in preoperative and postoperative symptoms for constipation (76% versus 24%), digitations (100% versus 16%), awareness of prolapse (100% versus 5%), obstructed defecation (100% versus 13%), and dyspareunia (37% versus 5%). There was no difference in fecal incontinence and only 1 case of *de novo* dyspareunia. The authors attribute their improved anatomic and functional outcomes and combined improvement in dyspareunia to exclusion of levator plication, perineorrhaphy, and excision of vaginal epithelium. An additional benefit may be derived during mobilization of the vaginal epithelium, when scar tissue from prior episiotomy or surgery is divided. They also found that preoperative defecating proctography was of limited value and have stopped its routine use as part of the preoperative evaluation for women with symptomatic rectoceles and obstructive defecation.

Defect-Directed Repair

The goal of a defect-directed repair or site-specific repair is to restore normal anatomy (30). This procedure can be combined with a perineal body reconstruction, if necessary, but usually does not routinely involve perineorrhaphy. Table 25.9 lists the anatomic and functional outcomes for this type of repair. **Anatomic cure rates range from 82% to 100%, which are similar to those for posterior colporrhaphy. This procedure also resulted in modest improvement for symptoms of difficult evacuation, vaginal bulge, and vaginal digitations, which appear to be slightly better than for posterior colporrhaphy** (169,170,171,172,173,183). Constipation symptoms significantly decreased in only one study (169). All studies reported low rates of *de novo* dyspareunia with good functional and anatomic outcomes, but the long-term durability of the procedure is unknown. All but one of these studies included concomitant prolapse and urinary incontinence procedures.

There are no randomized trials comparing posterior colporrhaphy with defect-directed repair. A retrospective (historical) cohort study of 307 patients with at least 1 year

P.976

P.977

of post operative follow-up evaluated 124 women who underwent site-specific repair and 183 who underwent posterior colporrhaphy (186). The decision regarding the type of surgical repair

was made intraoperatively by the surgeon. If a discrete defect was identified, a site-specific repair was performed. Otherwise, posterior colporrhaphy was performed for cases with diffuse attenuation of the rectovaginal septum. Approximately 75% of patients in each group underwent perineorrhaphy for separation of the perineal muscles. **The recurrence rates for defect-directed repairs were more than double those for posterior colporrhaphy** (33% versus 14% for second degree, 11% versus 4% for third degree or greater respectively based on the Baden-Walker halfway system). Mean postoperative point Bp was -2.2 ± 0.3 vs. -2.7 ± 0.4 , respectively, based on the POP-Q system. There were no detectable differences in postoperative constipation and fecal incontinence between the two procedures. When comparing preoperative and postoperative outcomes, neither procedure improved symptoms of constipation (31% versus 35%), abdominal pain (11% versus 10%), or fecal incontinence (17% versus 19%). Dyspareunia was higher postoperatively (17% versus 8%, $p = 0.001$) with no difference between surgical techniques (16% versus 17%). The high rate of dyspareunia in the absence of levator plication is most likely attributed to the perineorrhaphy, which was commonly used in both groups. **Their outcomes must be interpreted with caution because of the large selection bias and lack of validated measures.** Differences in postoperative blood pressure measurements may be statistically significant but not necessarily clinically significant. The results are intriguing, but future randomized control trials are necessary to ultimately determine which procedure is optimal.

^a Prospective. ^b In sexually active patients. ^c Combined Transanal and Transvaginal Repair								

Transanal Repair

Transanal repair involves repair of the rectocele through a transanal incision with excision of redundant rectal mucosa and plication of the rectovaginal septum and rectal wall. The procedure was developed and is primarily used by colorectal surgeons to treat constipation or obstructed defecation associated with "low" or distal rectoceles. The advantages of this approach include excision of redundant rectal mucosa and the ability to treat other anorectal pathology, such as hemorrhoids or anterior rectal wall prolapse (187). Disadvantages include the inability to repair higher rectoceles, enteroceles, cystoceles, uterine prolapse, and defects in the perineal

P.978

body or anal sphincter (188). Major complications of infection (6%) and rectovaginal fistula (3%) are relatively rare (179). Most studies did not require vaginal bulging or protrusion symptoms as a prerequisite for surgery. The results of several studies are summarized in Table 25.8. The anatomic cure rate was 70% to 98%, and symptoms of constipation, difficult evacuation, and vaginal digitations appear to improve (178,179,180,181,182,183).

Recent reviews have compared transanal with transvaginal rectocele repair using the results of two small, randomized control trials (189,190,191,192). Women with compromised sphincter function and other symptomatic prolapse were excluded. **The results for transvaginal repair were superior to those for transanal repair with respect to subjective failure rate** (relative risk [RR] 0.36, 95% CI 0.13 -1) and objective failure rate (RR 0.24, 95% CI 0.09-0.64) (189). In one study, a significant decrease occurred in the depth of rectocele on postoperative defecography for the transvaginal group compared with the transanal group (2.73 cm versus 4.13 cm, respectively) (192). The transvaginal group had fewer problems with bowel evacuation, but this finding was not statistically significant. In one study, researchers discovered that 38% of patients developed fecal incontinence following transanal repair (164). In the two randomized trials, no significant differences were seen in the rate of fecal incontinence or dyspareunia, but the studies were underpowered to detect a difference (191,192). **Although a vaginal approach has been considered superior to a transanal approach for rectocele repair, studies are retrospective and impossible**

to compare because the indications for transanal repairs are generally different from those for transvaginal repairs. A prospective, randomized trial with adequate power to evaluate symptomatic outcomes of bowel and sexual function along with anatomic cure is warranted.

Posterior Fascial Replacement

Rectocele repair with graft augmentation is becoming more common despite a paucity of supporting evidence indicating its benefits over standard procedures. The reason for its emergence is the theory that vaginal hernia repairs behave similar to abdominal hernia repairs, which have a documented decrease in recurrence when augmented with grafts. A variety of graft materials have been employed with posterior colporrhaphy and defect-directed repairs including autograft, allograft, xenograft, and synthetic mesh. There are no comparison data to aid in selecting the optimal graft. The purpose of the graft is debatable. It can either be intended to replace existing fascia as a permanent barrier or to provide an absorbable scaffold for collagen deposition, scar formation, and remodeling. The ideal material should have a low erosion rate, be relatively inexpensive, and decrease recurrence rates without causing bowel or sexual dysfunction. The outcomes for rectocele repair using graft materials placed either vaginally or abdominally appear in Table 25.9 (34,168,174,175,176,177,183,193,194), High anatomic cure rates of 89% to 100% occurred, and symptoms of constipation, difficult evacuation, and vaginal bulge also appeared to improve.

The largest prospective study and only randomized trial used absorbable vaginal mesh for rectocele repair (168). Patients were randomly assigned to fascial replacement with polyglactin 910 mesh at the time of anterior and posterior colporrhaphy. There were no differences in recurrence rates when comparing 70 women with a traditional colpoperineorrhaphy with 73 women having a traditional repair plus mesh: 10% versus 8% respectively. This study did not describe changes in bowel or sexual function, and there were no mesh-related adverse events. The risks of vaginal mesh erosion and severe complications may be relatively low but carry significant morbidity, including rectovaginal fistula, persistent vaginal bleeding and discharge, dyspareunia, and the need for additional surgery (175,183). **Nonsynthetic grafts appear to be safer, with fewer erosions compared with synthetic grafts.** Future prospective, randomized trials are under way to assess the effect of fascial replacement on symptoms of bowel and sexual function as well as long-term anatomic cure.

Abdominal Rectocele Repair

The abdominal approach to rectocele repair may be of value when a superior defect in the rectovaginal fascia occurs in a patient with accompanying enterocele, uterine prolapse, or vault prolapse. If a patient is undergoing an abdominal or laparoscopic procedure such as a sacral colpopexy, the graft can be extended along the posterior vaginal wall to correct proximal defects in the rectovaginal septum (195). There are limited data regarding the efficacy of abdominal rectocele repair. The indication for this procedure, as well as the need for additional vaginal repair of distal defects, often is

determined intraoperatively.

Sacral Colpoperineopexy for Perineal Descent

Sacral colpoperineopexy is a modification of sacral colpoperineopexy aimed at correction of apical prolapse combined with rectocele and perineal descent (34). A continuous graft is placed from the anterior longitudinal ligament of the sacrum down to the perineal body.

This procedure can be accomplished either through a total abdominal approach or a combined abdominal and vaginal procedure. **If performing a total abdominal approach, the rectovaginal space is opened, and the rectum is dissected off the posterior vaginal wall and rectovaginal septum toward the perineal body. The graft is then sutured to the perineal body or as close to it as possible.** A rectovaginal examination with the surgeon's nondominant hand facilitates this attachment by supporting the perineal body. The graft is secured to additional points along the posterior vaginal wall and apex, and sacral colpoperineopexy is completed in the usual fashion.

If performing a combined abdominal and vaginal approach, the graft is secured to the perineal body vaginally. The posterior vaginal wall is opened, and a defect-directed rectocele repair is performed. Sacral colpoperineopexy is accomplished in the usual fashion except that the vaginal dissection is opened superiorly, creating a window to the abdominal dissection. The graft can then be passed down from the abdominal field to the vaginal field and anchored inferiorly to the perineal body and laterally to the arcus tendineus fascia rectovaginalis. Alternatively, perineal body stitches can be placed vaginally and then retrieved abdominally once the rectovaginal space is entered from above. The sutures are then incorporated into the caudal portion of the graft. The idea behind the latter technique is to minimize graft exposure to the vagina, which theoretically will decrease vaginal erosion rates (Fig 25.8).

Short-term outcomes for 19 patients who underwent sacral colpoperineopexy indicated good anatomic results for apical and posterior support as well as for perineal descent (34). Complete cessation of defecatory dysfunction symptoms was accomplished in 66% of patients. In a report of outcomes for a slightly different variation of the sacral colpoperineopexy, the authors' technique involved attachment of Marlex mesh to the perineal body using a needle carrier (194). The failure rate was 25% and mesh erosion rate was 5% for 205 patients with up to 10-year follow-up. A study of Mersilene mesh erosion rates related to sacral colpoperineopexy and sacral colpoperineopexy (196). They noted similar erosion rates between sacral colpoperineopexy and colpoperineopexy when the vagina was not opened, 3.2% versus 4.5%, respectively. However, the erosion rate was 16% with vaginal suture placement and 40% when the mesh was placed vaginally. The use of nonsynthetic grafts such as dermal allograft and xenograft may help prevent high erosion rates. In a case series of 11 patients, researchers performed sigmoid resection (if indicated) and suture rectopexy in conjunction with sacral colpoperineopexy using Alloderm for women with coexistent rectal prolapse, perineal descent, and defecatory dysfunction. Early follow-up (12.5 ± 7.7 months) revealed excellent improvement of defecatory dysfunction symptoms and quality-of-life considerations, with an 82% cure of perineal descent (197). **Sacral colpoperineopexy appears to have value for a select group of patients**, but larger prospective series with long-term anatomic and symptomatic outcomes are necessary to evaluate the durability of this procedure.

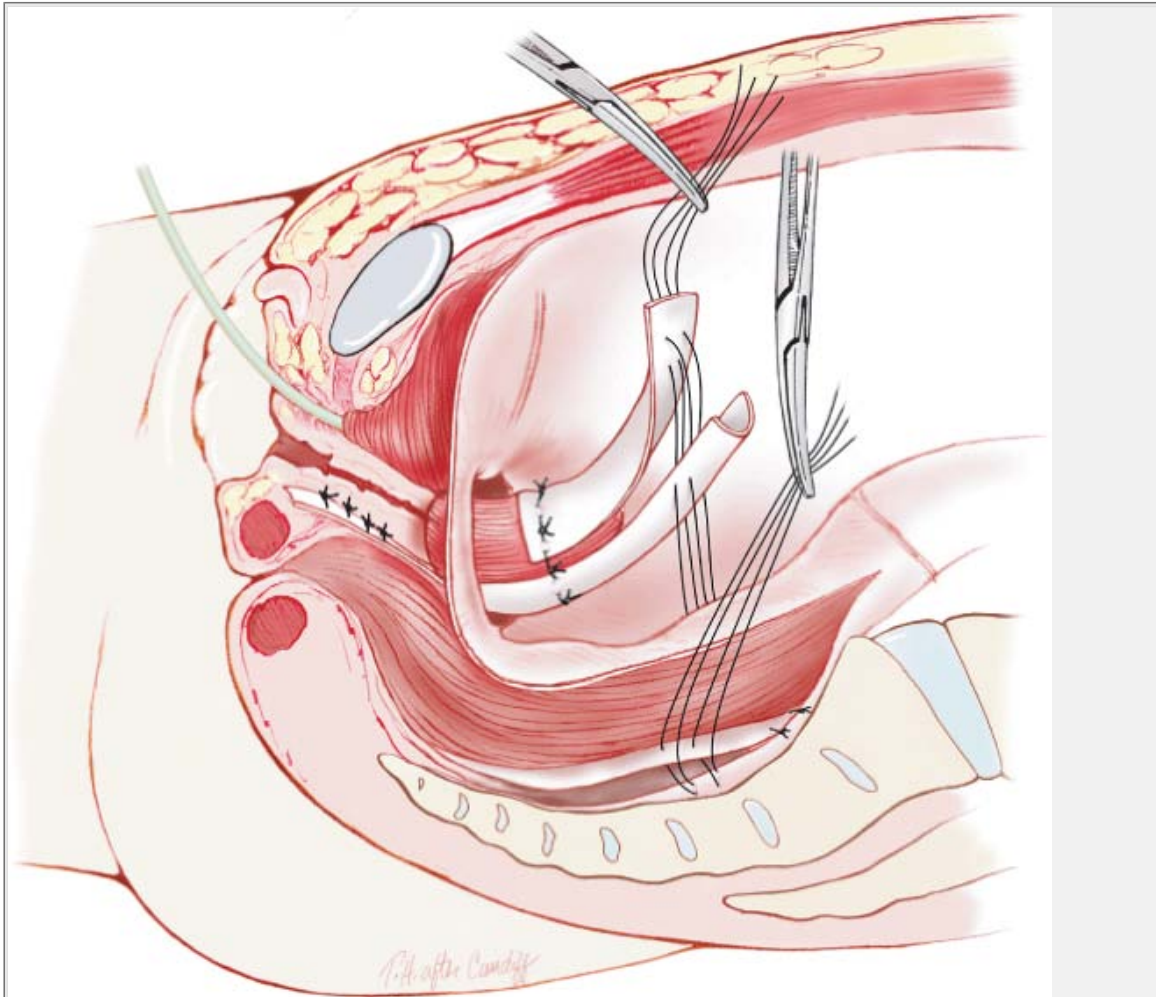

Figure 25.8 Abdominal sacral colpoperineopexy with sigmoid resection and suture rectopexy. This sagittal view shows the posterior graft sutured to the rectovaginal fascia and perineal body after defect-directed rectocele repair. The anterior graft is sutured to the pubocervical fascia. Both sheets will be secured to the sacral periosteum to the right of the rectum. Rectopexy sutures (*left*) have not yet been tied and secured. (Courtesy of Geoffrey W. Cundiff, M. D.).

Rectal Prolapse

Numerous surgical procedures have been described for the treatment of rectal prolapse and are broadly categorized into perineal or abdominal approaches. Most surgeons prefer an

abdominal procedure because of lower recurrence rates, reserving perineal procedures for more debilitated patients.

Abdominal Procedures

Abdominal procedures vary with respect to the extent of rectal mobilization, method of rectal fixation, and inclusion or exclusion of bowel resection. During abdominal rectopexy, the mesorectal plane is developed and the rectum mobilized down to the pelvic floor posteriorly, with care taken to identify and preserve the hypogastric nerves. Division of the lateral ligaments may or may not be performed. The concern is that division of the lateral ligaments will lead to rectal denervation and increased postoperative constipation. If performing a suture rectopexy, the fascia propria of the rectum is secured to the sacral periosteum from S-1 to S-3 (198). If performing a sigmoid resection with the rectopexy (Frykman-Goldberg resection rectopexy), the bowel resection is performed after mobilization and before suturing (199). The theoretical advantages of a rectosigmoid resection are creation of

P.981

a dense area of fibrosis between the anastomotic suture line and the sacrum; removal of abundant rectosigmoid, avoiding torsion or volvulus; additional fixation through straightening of the left colon and decreased mobility from the phrenocolic ligament; and relief of constipation in select patients. It is typically reserved for patients with a long redundant sigmoid colon, although specific criteria have not been proposed. Mesh rectopexies are usually avoided because of concern for increased complications and infections associated with placement of a foreign body at the time of bowel resection. There are two basic types of mesh rectopexy: **posterior mesh rectopexy** and **anterior sling rectopexy (Ripstein procedure)** (200,201). A variety of materials have been used for this procedure, including absorbable and permanent mesh. The assumption is that placement of this material will provide increased support through increased fibrous tissue formation. During the Ripstein procedure, an anterior sling of fascia lata or synthetic mesh is placed in front of the rectum and sutured to the sacrum. Most surgeons avoid this procedure because of fear of obstructed defecation. Modifications using a posterolateral wrap have been developed to resolve this problem.

In a series of greater than 10 patients, there were five open series and five laparoscopic reports for suture rectopexy (202). The recurrence rates ranged between 0% and 9%. Most reports showed an improvement in fecal incontinence symptoms, but the results for constipation were variable. There were no mortalities noted and no difference between laparoscopic and open results. For posterior mesh rectopexy, there were 14 open series and five laparoscopic reports. The recurrence rates ranged between 0% and 6%. As with suture rectopexy, there was general improvement in fecal incontinence, mixed results for constipation, and no differences between laparoscopic and open outcomes. The mortality rate was between 0% and 3%, with increased rates of infection if resection rectopexy was performed. For anterior sling rectopexy (Ripstein procedure), there were eight studies with a recurrence rate between 0% and 12%. Again, there was a trend toward improvement of fecal incontinence and mixed response for constipation. Mortality ranged from 0% to 3%. For resection rectopexy (Frykman-Goldberg procedure), there were nine open series and three

laparoscopic reports. Recurrence ranged between 0% and 5%. There was general improvement in continence as well as an overall reduction in constipation observed in most studies. Mortality rate was 0% for all studies but one, in which it was 6.7% (203). This study was a small, randomized trial comparing 15 patients undergoing resection rectopexy to 15 patients undergoing absorbable mesh rectopexy. The patient who died was in the resection group and had a myocardial infarction. The authors concluded that sigmoid resection did not seem to increase operative morbidity but tended to diminish postoperative constipation, possibly by causing less outlet obstruction. The study was underpowered to detect a difference in morbidity or mortality.

The laparoscopic series demonstrated similar safety and efficacy to the open techniques, and the effect on continence and constipation tended to mirror the type of rectopexy performed. **In a small, randomized trial, there were significant short-term benefits with laparoscopic rectopexy compared with open rectopexy, including earlier ambulation, more rapid return to normal diet, shorter hospital stay, and lower morbidity** (204). Most surgeons believe that there are no differences in recurrence rates between suture and mesh rectopexy. Consequently, the role of mesh in these procedures is suspect. The role of division of the lateral ligaments is somewhat controversial. A Cochrane Review performed in 2000 concluded that division of the lateral ligaments was associated with less recurrent prolapse but more postoperative constipation (205). The authors acknowledged the limitations of their review, which consisted of very few trials with small sample sizes and methodological weakness. A review of seven open and four laparoscopic series involving division of the lateral ligaments revealed a general improvement in fecal incontinence and either no change or worsening of constipation (202). Conversely, there were 15 open and four laparoscopic series with preservation of the ligaments that displayed improved continence and a trend toward reduced constipation. This study suggests that preservation of the lateral ligaments is associated with an improvement in fecal incontinence and constipation symptoms.

Perineal Procedures

Perineal procedures are more easily tolerated because they avoid laparotomy. Thus, they are ideal for patients at high-risk for perioperative and postoperative morbidity and mortality. There are basically two perineal procedures: the *Delorme procedure* and *perineal rectosigmoidectomy* (Altemeier operation). Perianal encirclement procedures such as the Thiersch procedure are not recommended because of poor success rates, high recurrence rates, and fecal impaction.

The **Delorme procedure** was first described in 1900 and involves separation of the rectal mucosa from the sphincter and muscularis propria, followed by resection of the rectal mucosa, and plication of the distal rectal wall (muscularis propria) (206) (Fig. 25.9). A review of 10 series found a recurrence rate ranging between 4% and 38% and mortality rates of 0% to 4% (202). The low mortality rates are impressive considering a higher-risk population; however, the recurrence rates make it a less desirable procedure among healthy patients. There was a general improvement in fecal incontinence and constipation. Fecal incontinence

(presumably indicating anal sphincter disruption or denervation), chronic diarrhea, and severe perineal descent are associated with failure of this procedure (207). The Delorme operation may be preferred in cases when the prolapsing segment is shorter than 3 to 4 cm or there is no circumferential full-thickness prolapse, making perineal rectosigmoidectomy difficult to perform (202,208).

Perineal rectosigmoidectomy (Altemeier operation) has become the perineal procedure of choice (209). Among 12 studies, performance of full thickness excision of the rectosigmoid was associated with recurrence rates from 0% to 16% and mortality rates of 0% to 5%. Patients generally have minimal pain and a relatively uneventful postoperative course. Recurrent prolapse probably reflects inadequate resection. Incontinence results are modest at best but seem to improve substantially with the addition of levatorplasty. The addition of levatorplasty also appears to decrease the short-term recurrence rate (210), but there is no significant change in constipation with this procedure. Most agree that perineal rectosigmoidectomy with levatorplasty is the best procedure for very elderly patients and those with profound comorbidity. This is the preferred approach for patients with incarcerated, strangulated, or even gangrenous prolapsed rectal segment who are not candidates for abdominal rectopexy. Although there is a general consensus that abdominal rectopexy is better than perineal rectosigmoidectomy, there is

P.983

only one small, prospective, randomized control trial comparing these procedures. This study did not have the power to detect a difference in recurrence rates but found that patients undergoing abdominal resection rectopexy had less fecal incontinence and better physiological results than patients who had perineal rectosigmoidectomy (205,211).

Figure 25.9 Delorme's procedure. After mucosal stripping to the full extent of the prolapse, the circular smooth muscle of the rectum is plicated. A mucosa-to-mucosa anastomosis is then performed.

Puberty

Robert W. Rebar

- **Normal pubertal development occurs in a predictable orderly sequence over a definite time frame..**
- **The major causes of delayed puberty include anatomic genital tract abnormalities and hypo- and hypergonadotropic amenorrhea..**
- **When pubertal development occurs asynchronously, with development of breasts in the absence of significant pubic and axillary hair, the diagnosis is usually androgen insensitivity..**
- **The most common cause of precocious puberty is constitutional (idiopathic), but more serious causes must be ruled out and therapy geared toward optimizing adult height..**
- **The most common cause of heterosexual development at the expected age of puberty is polycystic ovary syndrome (PCOS)..**

***Puberty* is the period during which secondary sexual characteristics develop**

and the capability of sexual reproduction is attained. The physical changes accompanying pubertal development result directly or indirectly from maturation of the hypothalamus, stimulation of the sex organs, and secretion of sex steroids. Hormonally, puberty in humans is characterized by the resetting of the classic negative gonadal steroid feedback loop, alterations in circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the woman of a positive estrogen feedback loop, which controls the monthly rhythm as an interdependent expression of gonadotropins and ovarian steroids.

The ability to evaluate and treat aberrations of pubertal development requires an understanding of the normal hormonal and physical changes that occur at puberty. An understanding of these changes is also important in evaluating young women with amenorrhea.

P.992

Normal Pubertal Development

Factors Affecting Time of Onset

The major determinant of the timing of the onset of puberty is no doubt genetic, but a number of other factors appear to influence both the age at onset and the progression of pubertal development. Among these influences are nutritional state, general health, geographic location, exposure to light, and psychological state **(1)**. The concordance of the age of menarche in mother–daughter pairs and between sisters and in ethnic populations illustrates the importance of genetic factors (1). Typically, the age of menarche is earlier than average in children with moderate obesity (up to 30% above normal weight for age), whereas delayed menarche is common in those with severe malnutrition. Children who live in urban settings, closer to the equator, and at lower altitudes typically begin puberty earlier than those who live in rural areas, farther from the equator, and at higher elevations. Blind girls apparently undergo menarche earlier than sighted girls, suggesting some influence of light (2).

In Western Europe, the age of menarche declined 4 months each decade between 1850 and 1960 (1). Recent data suggest that the trend toward earlier pubertal development may be continuing among girls (but not boys) who live in the United States (3). It has been presumed that these changes represent improved nutritional status and healthier living conditions.

One of the more controversial hypotheses has centered on the role of total body weight and body composition on the age of menarche. It has been argued that a girl must reach a critical body weight (47.8 kg) before menarche can occur (4). More importantly, body fat must increase to 23.5% from the typical 16% of the prepubertal state, which presumably is influenced by nutritional status (5). This hypothesis is supported by observations that menarche occurs earliest in obese girls, followed by normal–weight girls, then underweight girls, and lastly anorectic girls (Fig. 26.1). The importance of other factors is indicated by observations that menarche is often delayed in morbidly obese girls, those with diabetes, and those who exercise intensely but are of normal body weight and body fat percentage. Moreover, girls with precocious puberty may undergo menarche even if they have a low body fat percentage, and other girls show no pubertal development with a body fat percentage of 27% (6). The hypothesis linking menarche to body weight and composition does not always seem valid because menarche is a late event in pubertal development.

Physical Changes during Puberty

The changes associated with puberty occur in an orderly sequence over a definite time frame. Any deviation from this sequence or time frame should be regarded as abnormal. Moreover, the pubertal changes, their relationships to each other, and the ages at which they occur are distinctly different in girls and in boys. Although this chapter focuses on girls, changes in boys are considered briefly as well.

Tanner Stage

In girls, pubertal development typically takes place over 4.5 years (Fig. 26.2).

Although generally the first sign of puberty is accelerated growth, breast budding is usually the first recognized pubertal change, followed by the appearance of pubic hair, peak growth velocity, and menarche. The stages initially described by Marshall and Tanner are often used to describe breast and pubic hair development (7).

With regard to breast development (Fig. 26.3), *Tanner stage 1* refers to the prepubertal state and includes no palpable breast tissue, with the areolae generally less than 2 cm in diameter. The nipples may be inverted, flat, or raised. In ***Tanner stage 2***, breast budding occurs, with a visible and palpable mound of breast tissue. The areolae begin to enlarge,

P.993

the skin of the areolae thins, and the nipple develops to varying degrees. *Tanner stage 3* is reflected by further growth and elevation of the entire breast. When the individual is seated and viewed from the side, the nipple is generally at or above the midplane of breast tissue. In most girls, *Tanner stage 4* is defined by projection of the areola and papilla above the general breast contour in a secondary mound. Breast development is incomplete until *Tanner stage 5*, in which the breast is mature in contour and proportion. In most women, the nipple is more pigmented at this stage than earlier in development, and Montgomery's glands are visible around the circumference of the areola. The nipple is generally below the midplane of breast tissue when the woman is seated and viewed from the side. Full breast development usually occurs over 3 to 3.5 years, but it may occur in as little as 2

P.994

years or not progress beyond stage 4 until the first pregnancy. Breast size is no indication of breast maturity.

Figure 26.1 Normal twins at 12 years of age. The heavier twin (weighing 143 lb) is clearly more advanced in puberty than the lighter twin (weighing 87 lb). Anecdotal photographs and data such as these served to provide the basis for the theory that body fat, body mass, and menarche are linked. (From **Wilkins L.** *The diagnosis and treatment of endocrine disorders in childhood and adolescence.* 3rd ed. Springfield, IL: Charles C Thomas, 1965, with permission).

Figure 26.2 Schematic sequence of events at puberty. An idealized average girl and an idealized average boy are represented. (From **Rebar RW**. Practical evaluation of hormonal status. In: **Yen SSC, Jaffe RB**, eds. *Reproductive endocrinology: physiology, pathophysiology and clinical management*. 3rd ed. Philadelphia, PA: WB Saunders, 1991:830, with permission; based on data from **Marshall WA, Tanner JM**. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303, and **Marshall WA, Tanner JM**. Variation in the pattern of pubertal changes in boys. *Arch Dis Child* 1970;45:13–23, with permission.).

Pubic hair staging is related both to quantity and distribution (Fig. 26.4). In **Tanner stage 1**, there is no sexually stimulated pubic hair present, but some nonsexual hair may be present in the genital area. **Tanner stage 2** is characterized by the first appearance of coarse, long, crinkly pubic hair along the labia majora. In **Tanner stage 3**, coarse, curly hair extends onto the mons pubis. **Tanner stage 4** is characterized by adult hair in thickness and texture, but the hair is not distributed as widely as in adults and typically does not extend onto the inner aspects of the thighs. Except in certain ethnic groups, including Asians and American Indians, pubic hair extends onto the thighs in **Tanner stage 5**.

The staging of male pubertal sexual maturation is based on genital size and pubic hair development. **Tanner stage 1 is prepubertal**. **Tanner stage 2** of genital growth begins when testicular enlargement is first evident. Testis length along the longitudinal axis ranges from 2.5 to 3.2 cm. The size of the penis increases as well. Pigmented, curly pubic hair is first

visible around the base of the penis. In **Tanner stage 3**, there is further growth of the penis in both length and diameter, the scrotum develops further, and testis length increases to 3.3 to 4 cm. Thicker, curly hair extends above the penis. Tanner stage 4 involves further growth of the genitalia, with testis length ranging from 4 to 4.5 cm. Extension of pubic hair over the genital area continues, but the volume is less than in the adult. At this stage, the prostate gland is palpable by rectal examination. In **Tanner stage 5**, the genitalia are within the adult range in size. Stretched penile length measured along the dorsum averages 15.7 cm in adult men. Pubic hair spreads laterally onto the medial thighs. Hair may or may not extend from the pubic area toward the umbilicus and anus.

Figure 26.3 Diagrammatic depiction of Tanner breast stages in adolescent women. (From Ross GT, Van de Wiele RL, Frantz AG. *The ovaries and the breasts*. In: Williams RH, ed. *Textbook of endocrinology*. 6th edition. Philadelphia, PA: WB Saunders, 1981:355, with permission; adapted from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969; 44:291–303).

Pigmented pubic hair is often the first recognized sign of male puberty even though it typically occurs 6 months after genital growth begins. Tanner stage 3 puberty often is accompanied by symmetric or asymmetric gynecomastia, and mature sperm first can be identified with microscopic urinalysis.

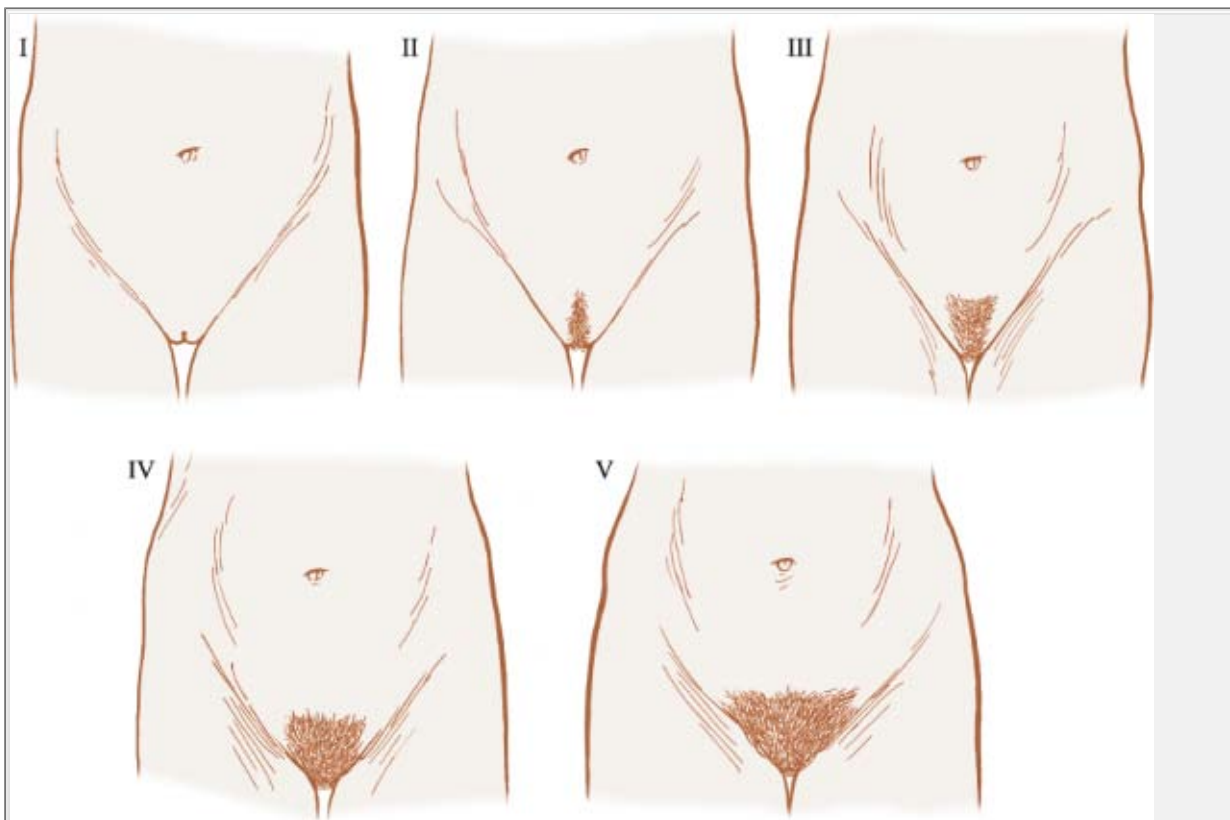

Figure 26.4 Diagrammatic depiction of Tanner pubic hair staging in adolescent women. (From Ross GT, VandeWiele RL, Frantz AG. The ovaries and the breasts. In: Williams RH, ed. *Textbook of endocrinology*. 6th ed. Philadelphia, PA: WB Saunders, 1981:355, with permission; adapted from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303.)

Height and Growth Rate

Plotting height increments (i.e., growth velocity) against the phases of puberty allows one to see relationships during puberty (see Fig. 26.2). Girls reach peak height velocity early in puberty before menarche. As a consequence, they have limited growth potential after menarche. In contrast, boys reach peak height velocity about 2 years later than girls. Boys grow an average of 28 cm during the growth spurt, in comparison to a mean of 25 cm for girls. Adult men eventually are an average of 13 cm taller than adult women largely because they are taller at the onset of the growth spurt. Hormonal control of the pubertal growth spurt is complex. Growth hormone (GH), insulinlike growth factor 1 (IGF-1), and gonadal steroids play major roles. Adrenal androgens appear to be less important. Mutations limiting conversion of androgens to estrogens in males have confirmed that estrogen is the major stimulus to the pubertal growth spurt in both boys and girls (8).

During the growth spurt associated with puberty, the long bones in the body lengthen, and the epiphyses ultimately close. The bone or skeletal age of any individual can be estimated closely by comparing x-rays documenting the development of bones in the nondominant hand (most commonly), knee, or elbow to standards of maturation for the normal population. The Greulich and Pyle atlas is used most often for this purpose (9). Skeletal age is more closely correlated with pubertal stage than with chronologic age during puberty. **With height and chronologic age, an individual's bone age can be used to predict final adult height using the Bayley–Pinneau tables** (10).

Another practical clinical approach to predicting adult height uses midparental height. **The adjusted midparental height is calculated by adding 13 cm to the mother's height (for boys) or subtracting 13 cm from the father's height (for girls) and then determining the mean of the heights of the parents, including the adjusted height of the opposite-sex parent. Adding and subtracting 8.5 cm to the calculated predicted height approximates the target range of the third to the ninety-seventh percentile for the anticipated adult height of the child.** This quick calculation can be of assistance in evaluating individuals with delayed or precocious pubertal development and those with short stature.

Several changes in body composition also occur during pubertal development. **Although lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men (1). The changes in body contour in girls, with accumulation of fat at the thighs, hips, and buttocks, occur during the pubertal growth spurt. In this regard, testosterone is a potent anabolic steroid and is responsible for the major changes in boys, whereas estrogen increases total body fat in a characteristic distribution at the thighs, buttocks, and abdomen in girls.**

Other physical changes show sexual dimorphism at puberty. In boys both the membranous and cartilaginous portions of the vocal cords lengthen much more than they do in girls, accounting for deepening of the voice. Comedones, acne, and seborrhea of the scalp begin because of increased secretion of adrenal and gonadal steroids at puberty. In general, early-onset acne correlates with the development of severe acne later in puberty. **The appearance of comedones in the nasal creases and behind the pinna may be the first indications of impending pubertal development.**

Hormonal Changes

By 10 weeks of gestation, gonadotropin-releasing hormone (GnRH) is present in the hypothalamus, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the pituitary gland (11). Gonadotropin levels are elevated in both female and male fetuses before birth; the levels of FSH are higher in females. At birth, gonadotropin and sex steroid concentrations are still high, but the levels decline during the first several weeks of life and remain low during the prepubertal years. The hypothalamic-pituitary unit appears to be suppressed by the extremely low levels of gonadal steroids present in childhood.

Gonadal suppression of gonadotropin secretion is demonstrated by higher gonadotropin levels in children with gonadal dysgenesis and those who undergo gonadectomy before puberty (12).

Several of the hormonal changes associated with pubertal development begin before any of the physical changes are obvious. Early in puberty, there is increased sensitivity of LH to GnRH. Sleep-entrained increases in both LH and FSH can be documented early in puberty (13). In boys, the nocturnal increases in gonadotropin levels are accompanied by simultaneous increases in circulating testosterone levels (14). In contrast, in girls, the nighttime increases in circulating gonadotropin levels are followed by increased secretion of estradiol the next day (15) (Fig. 26.5). This delay in estradiol secretion is believed to be due to the additional synthetic steps required in the aromatization of estrogens from androgens. Basal levels of both FSH and LH increase through puberty. The patterns differ in boys and girls, with LH levels (measured in mIU/mL) eventually becoming greater than FSH levels (16) (Fig. 26.6). Although it now appears that gonadotropins are always secreted in an episodic or pulsatile fashion, even before puberty, the pulsatile secretion of gonadotropins is more easily documented as puberty progresses and basal levels increase (17).

Figure 26.5 Patterns of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol in a stage 3 pubertal girl over a 24-hour period with the encephalographic stage of sleep indicated. (From Boyar RM, Wu RHK, Roffwarg H, et al. Human puberty: 24-hour estradiol patterns in pubertal girls. *J Clin Endocrinol Metab* 1976; 43: 1418–1421, with permission.)

P.998

Increased adrenal androgen secretion is important in stimulating adrenarche, the appearance of pubic and axillary hair, in both boys and girls. Pubarche specifically refers to the appearance of pubic hair. Progressive increases in circulating levels of the major adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), begin as early as 2 years of age, accelerate at 7 to 8 years of age, and continue until 13 to 15 years of age (18,19,20). The accelerated increases in adrenal androgens begin about 2 years before the increases in gonadotropin and gonadal sex steroid secretion when the hypothalamic-pituitary-gonadal unit is still functioning at a low prepubertal level.

In girls, estradiol, secreted predominantly by the ovaries, increases steadily during puberty (16). Although, as noted, increases in estradiol first appear during the daytime hours, basal levels eventually increase during both the day and night. Estrone, which is secreted in part by the ovaries and arises in part from extraglandular conversion of estradiol and androstenedione, also increases early in puberty but plateaus by midpuberty. Thus, **the ratio of estrone to estradiol decreases throughout puberty, indicating that ovarian production of estradiol becomes increasingly important and peripheral conversion**

of androgens to estrone becomes less important during maturation..

Figure 26.6 Increases (\pm standard error) in circulating levels of gonadotropins and adrenal and gonadal steroids through puberty in girls. DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate. (From **Emans SJH, Goldstein DP**. The physiology of puberty. P.999

P.1000

In boys, most of the testosterone in the circulation arises from direct secretion by the Leydig cells of the testis. Testosterone induces development of a male body habitus and voice change, whereas dihydrotestosterone (DHT), produced following 5 α reduction within target cells, induces enlargement of the penis and prostate gland, beard growth, and temporal hair recession during puberty. Mean plasma testosterone levels rise progressively during puberty, with the greatest increase occurring during Tanner stage 2 (21).

Growth hormone secretion increases along with increased gonadotropin secretion at the onset of puberty. It is believed that the increase in GH is mediated by estrogen, which in boys is dependent on aromatization of testosterone to estradiol and reflects increasing sex steroid production at puberty. Nonetheless, there are profound sex differences in GH secretion during puberty. Girls have higher basal levels of GH throughout puberty, reaching maximal levels around the time of menarche and decreasing thereafter. In contrast, basal concentrations of GH remain constant throughout puberty in boys. Growth hormone secretion is highly pulsatile, with most pulses occurring during sleep and with sex steroids increasing pulse amplitude rather than altering pulse frequency.

Growth hormone stimulates production of insulinlike growth factor 1 (IGF-1) in all tissues, with concentrations found in the circulation spilling over from the liver. During puberty the negative feedback effect of IGF-1 on GH secretion must be reduced because both IGF-1 and GH levels are high. Growth hormone and IGF-1 no doubt play significant roles in the changes in body composition that occur at puberty because both hormones are potent anabolic agents.

In the final stages of puberty in both boys and girls, GH secretion begins to diminish, returning to prepubertal levels in adult life, despite continued exposure to high levels of gonadal steroids.

Mechanisms Underlying Puberty

The mechanisms responsible for the numerous hormonal changes that occur during puberty are poorly understood, although it is recognized that a "central nervous system program" must be responsible for initiating puberty. It appears that the hypothalamic-pituitary-gonadal axis in girls develops in two distinct stages during puberty. First, sensitivity to the negative or inhibitory effects of the low levels of circulating sex steroids present in childhood decreases early in puberty. Second, late in puberty, there is maturation of the positive or stimulatory feedback response to estrogen, which is responsible for the ovulatory midcycle surge of LH.

Current evidence suggests that the central nervous system inhibits the onset of puberty until the appropriate time (22). Based on this theory, the neuroendocrine control of puberty is mediated by GnRH-secreting neurons in the medial basal hypothalamus, which together act as an endogenous pulse generator. At puberty, the GnRH pulse generator is reactivated (i.e., disinhibited), leading to increased amplitude and frequency of GnRH pulses. In turn, the increased GnRH secretion results in increased gonadotropin and then gonadal

steroid secretion. What causes this "disinhibition" of GnRH release is unknown.

The relationship between body mass and the onset of puberty has focused attention on leptin, produced by adipocytes, as a candidate for the factor initiating puberty. In the infertile leptin-deficient mouse, leptin therapy can induce sexual maturation and maintain fertility. Observations of two patients with leptin receptor mutations who failed to enter puberty suggest that leptin may have a similar role in humans.

Longitudinal studies of leptin secretion have noted that there is increased leptin secretion around the time of pubertal onset. Leptin levels are increased throughout puberty in girls but not in boys. Thus, it is not clear how important leptin is to pubertal development.

P.1001

Aberrations of Pubertal Development

Classification

Several aberrations of pubertal development, as detailed in Table 26.1, can occur in girls.

Pubertal aberrations can be classified in four broad categories:

- ***Delayed or interrupted puberty exists in girls who fail to develop any secondary sex characteristics by age 13, have not had menarche by age 16, or have not attained menarche 5 or more years since the onset of pubertal development..***

P.1002

P.1003

- ***Asynchronous pubertal development is characterized by pubertal development that deviates from the normal pattern of puberty..***

- ***Precocious puberty has been defined as pubertal development beginning before the age of 7 years in white girls and before the age of 6 years in African American girls (3).*** This new definition is controversial and has been challenged because some feel that evaluation for breast or pubic hair development before 9 or 8 years of age in white or African American girls, respectively, may be warranted (23). It is clear that, in most cases, development nearer to the mean age of puberty is less likely to have a pathologic basis. Precocious pubertal development is characterized in several ways. In *isosexual* precocious puberty, the early changes are common to the phenotypic sex of the individual. In *heterosexual* precocious puberty, the development is characteristic of the opposite sex. Precocious puberty is sometimes termed "true" when it is of central origin with activation of the hypothalamic-pituitary unit. In precocious pseudopuberty, also known as *precocious puberty of peripheral origin*, secretion of hormones in the periphery (commonly by neoplasms) stimulates pubertal development.

- ***Heterosexual puberty is characterized by a pattern of development that is typical of the opposite sex occurring at the expected age of normal puberty..***

Table 26.1 Aberrations of Pubertal Development

I. Delayed or interrupted puberty**A. Anatomic abnormalities of the genital outflow tract**

1. Müllerian dysgenesis (Rokitansky-Küster-Hauser syndrome)
2. Distal genital tract obstruction
 - a. Imperforate hymen
 - b. Transverse vaginal septum

B. Hypergonadotropic (follicle-stimulating hormone >30 mIU/mL) hypogonadism (gonadal "failure")

1. Gonadal dysgenesis with stigmata of Turner syndrome
2. Pure gonadal dysgenesis
 - a. 46,XX
 - b. 46,XY
3. Early gonadal "failure" with apparent normal ovarian development

C. Hypogonadotropic (luteinizing hormone and follicle-stimulating hormone <10 mIU/mL) hypogonadism

1. Constitutional delay
2. Isolated gonadotropin deficiency
 - a. Associated with midline defects (Kallmann syndrome)
 - b. Independent of associated disorders
 - c. Prader-Labhart-Willi syndrome
 - d. Laurence-Moon-Bardet-Biedl syndrome
 - e. Many other rare syndromes
3. Associated with multiple hormone deficiencies
4. Neoplasms of the hypothalamic-pituitary area
 - a. Craniopharyngiomas
 - b. Pituitary adenomas
 - c. Other
5. Infiltrative processes (Langerhans cell-type histiocytosis)
6. After irradiation of the central nervous system
7. Severe chronic illnesses with malnutrition
8. Anorexia nervosa and related disorders
9. Severe hypothalamic amenorrhea (rare)
10. Antidopaminergic and gonadotropin-releasing hormone-inhibiting drugs (especially psychotropic agents, opiates)
11. Primary hypothyroidism
12. Cushing syndrome
13. Use of chemotherapeutic (especially alkylating) agents

II. Asynchronous pubertal development**A. Complete androgen insensitivity syndrome (testicular feminization)****B. Incomplete androgen insensitivity syndrome****III. Precocious puberty****A. Central (true) precocious puberty**

1. Constitutional (idiopathic) precocious puberty
2. Hypothalamic neoplasms (most commonly hamartomas)
3. Congenital malformations
4. Infiltrative processes (Langerhans cell-type histiocytosis)

5. After irradiation
6. Trauma
7. Infection
B. Precocious puberty of peripheral origin (precocious pseudopuberty)
1. Gonadotropin-secreting neoplasms
a. Human chorionic gonadotropin secreting
i. Ectopic germinomas (pinealomas)
ii. Choriocarcinomas
iii. Teratomas
iv. Hepatoblastomas
b. Luteinizing hormone-secreting (pituitary adenomas)
2. Gonadal neoplasms
a. Estrogen-secreting
i. Granulosa-theca cell tumors
ii. Gonadal sex-cord tumors
b. Androgen-secreting
i. Arrhenoblastomas
ii. Teratomas
3. Congenital adrenal hyperplasia
a. 21-Hydroxylase (P450c21) deficiency
b. 11 β -Hydroxylase (P450c11) deficiency
c. 3 β -Hydroxysteroid dehydrogenase deficiency
4. Adrenal neoplasms
a. Adenomas
b. Carcinomas
5. Autonomous gonadal hypersecretion
a. Cysts
b. McCune-Albright syndrome
6. Iatrogenic ingestion/absorption of estrogens or androgens
IV. Heterosexual puberty
A. Polycystic ovarian syndrome
B. Nonclassic forms of congenital adrenal hyperplasia
C. Idiopathic hirsutism
D. Mixed gonadal dysgenesis
E. Rare forms of male pseudohermaphroditism (Reifenstein syndrome, 5α-reductase deficiency)
F. Cushing syndrome (rare)
G. Androgen-secreting neoplasms (rare)

Disorders of sexual development and amenorrhea may be considered in relation to this classification of the aberrations of puberty. It is very helpful to document the growth of the individual and to plot the individual's height and weight on one of several commonly available growth charts (Fig. 26.7).

Delayed or Interrupted Puberty

The history and physical examination, with particular attention to growth, are most important in the evaluation of individuals with delayed puberty. Pubertal delay is

much more common in boys than in girls. It is important to remember that puberty may be delayed in any child suffering from any severe chronic disease, including celiac disease, Crohn disease, sickle cell anemia, and cystic fibrosis. Thus, chronic illness should be excluded during the history and physical examination. One possible approach to evaluation is depicted in Figure 26.8.

Figure 26.7 Growth chart showing stature by age percentiles for girls aged 2 to 18 years.

Weight can be plotted in a similar fashion. Several excellent growth charts are available to clinicians, including those from Ross Laboratories (Columbus, OH), Serono Laboratories (Randolph, MA), and Genentech, Inc. (South San Francisco, CA). (From **Hamill PVV, Drizd TA, Johnson CL, et al.**

Physical growth: National Center for Health Statistics percentiles. *Am J Clin Nutr*

1979; 32: 607–629, with permission; based on data from the National Center for Health Statistics.)

Anatomic Abnormalities of the Genital Outflow Tract

Those girls who have mature secondary sex characteristics and any of a number of disorders of the outflow tract and uterus, often termed müllerian agenesis and dysgenesis, are most often identified on examination (Fig. 26.9). One of the most logical classification schemes that has been proposed is shown in Table 26.2 (24). The incidence of these anomalies was estimated to be 0.02% of the female population several years ago (25), but the incidence may have increased as a result of the maternal ingestion of diethylstilbestrol (DES) and the resultant increase in anomalies of the lumen of the uterus (class VI) (26). Of

the disorders unrelated to drug use, the septate uterus (class V) is most common.

Disorders of the outflow tract and uterus often occur as a part of a syndrome of malformations that include abnormalities of the skeletal and renal systems (*Rokitansky-Küster-Hauser syndrome*). Familial aggregates of the most common disorders of müllerian differentiation in girls—müllerian aplasia and incomplete müllerian fusion—are best explained on the basis of polygenic and multifactorial inheritance (27). It is clear that the *HOX* genes, a family of regulatory genes that encode for transcription factors, are essential for proper development of the müllerian tract in the embryonic period (28), and *HOXA 13* has been found to be altered in hand-foot-genital syndrome.

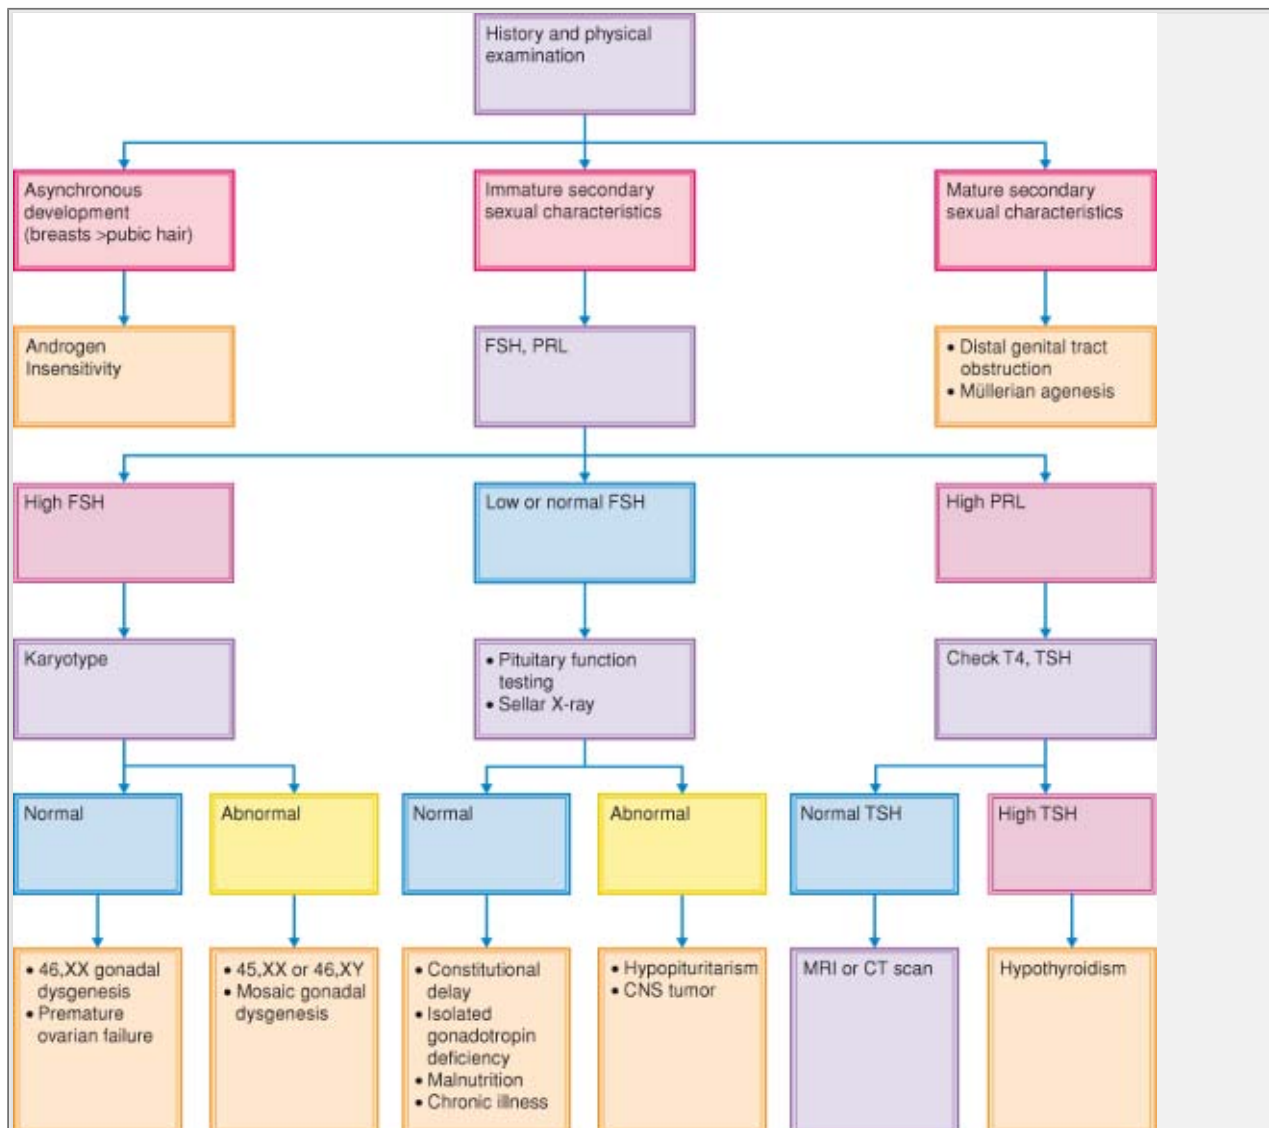

Figure 26.8 Flow diagram for the evaluation of delayed or interrupted pubertal development, including primary amenorrhea, in phenotypic girls. Girls with asynchronous development often present because of failure to menstruate. FSH, follicle-stimulating hormone; PRL, prolactin; T4, thyroxine; TSH, thyroid-stimulating hormone; CNS, central nervous system; MRI, magnetic resonance imaging; CT, computed tomography. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York, NY: Churchill Livingstone, 1993:97–133.).

The most common single anatomic disorder of puberty is the imperforate hymen, which prevents the passage of endometrial tissue and blood. These products can accumulate in the vagina (*hydrocolpos*) or uterus (*hydrometrocolpos*) and result in a bulging hymen that is often bluish in color. The affected individual often has a history of vague abdominal pain with approximately monthly exacerbations. It is sometimes difficult to distinguish an imperforate hymen from a transverse vaginal septum, and in most situations, examination under anesthesia is required.

Figure 26.9 Hysterosalpingograms of normal and abnormal female genital tracts.

The radiographic photographs have been reversed to accentuate the uterine cavities. **A:** Normal study with bilateral spill. **B:** Bicornuate uterus. **C:** Uterus didelphis. **D:** Uterus didelphis with double vagina. (Courtesy of **Dr. A. Gerbie**; from **Spitzer IB, Rebar RW**. *Counselling for women with medical problems: ovary and reproductive organs*. In: **Hollingsworth D, Resnik R**, eds. *Medical counselling before pregnancy*. New York, NY: Churchill Livingstone, 1988:213–248, with permission.).

Regardless of the cause, uterine anomalies not involving segmental müllerian agenesis or hypoplasia (class I) are compatible with normal pregnancy. However, increased fetal wastage has been reported in the presence of these anomalies (29). Uterine malformations have been associated with spontaneous abortion, preterm labor, abnormal presentations, and complications of labor (i.e., retained placenta). Many of these uterine anomalies can be identified with hysterosalpingography (see Fig. 26.9). Hysterosalpingography, laparoscopy, and hysteroscopy have been used to differentiate a septate uterus (class V) from a bicornuate uterus (class IV). It is now clear that magnetic resonance imaging (MRI) and endovaginal ultrasonography (sometimes with sonohysterography) are as accurate as these invasive techniques in identifying the

abnormality (30).

Obstruction or malformation of the distal genital tract must be distinguished from androgen insensitivity. Individuals with androgen insensitivity have breast development in the absence of significant pubic and axillary hair development; the vagina may be absent or foreshortened in these women.

Hypergonadotropic and Hypogonadotropic Hypogonadism

Basal levels of FSH and prolactin should be determined in individuals in whom secondary sex characteristics have not developed to maturity (see Fig. 26.8). Bone age should be estimated from x-rays of the nondominant hand. If prolactin levels are elevated, thyroid function should be assessed to determine whether the individual has primary hypothyroidism. Paradoxically, primary hypothyroidism can result in precocious puberty

P.1007

as well. If thyroid function is normal, a hypothalamic or pituitary neoplasm is possible, and careful evaluation of the hypothalamic and pituitary area by MRI or computed tomography (CT) is indicated.

Table 26.2 Classification of Müllerian Anomalies

<i>Class I. Segmented müllerian agenesis or hypoplasia</i>
A. Vaginal
B. Cervical
C. Fundal
D. Tubal
E. Combined
<i>Class II. Unicornuate uterus</i>
A. With a rudimentary horn
1. With a communicating endometrial cavity
2. With a noncommunicating cavity
3. With no cavity
B. Without any rudimentary horn
<i>Class III. Uterus didelphys</i>
<i>Class IV. Bicornuate uterus</i>
A. Complete to the internal os
B. Partial
C. Arcuate
<i>Class V. Septate uterus</i>
A. With a complete septum
B. With an incomplete septum
<i>Class VI. Uterus with internal luminal changes</i>
Adapted from Buttrarm VC Jr, Gibbons WE. Müllerian anomalies: a proposed classification (an analysis of 144 cases). <i>Fertil Steril</i> 1979;32:40, with permission.

The karyotype should be determined in any individual with delayed puberty and increased basal FSH concentrations. Regardless of the karyotype, the individual with hypergonadotropic hypogonadism has some form of ovarian "failure," (i.e., primary hypogonadism).

Forms of Gonadal Failure

Turner Syndrome

Most affected individuals have a 45,X karyotype and Turner syndrome; still others have mosaic karyotypes (i.e., 45,X/46,XX; 45,X/46,XY) and may present with the Turner phenotype as well. Intrauterine growth restriction is common in infants with a 45,X karyotype. After birth, these patients generally grow slowly, beginning in the second or third year of life. They typically have many of the associated stigmata, including lymphedema and sometimes large cystic hygromas of the neck at birth; a webbed neck; multiple pigmented nevi; disorders of the heart, kidneys (most commonly horseshoe), and great vessels (most commonly coarctation of the aorta); and small hyperconvex fingernails (31) (Fig. 26.10). Diabetes mellitus, thyroid disorders, essential hypertension, and other autoimmune disorders are often present in individuals

P.1008

with 45,X karyotypes. Most 45,X patients have normal intelligence, but many affected individuals have an unusual cognitive defect characterized by an inability to appreciate the shapes and relations of objects with respect to one another (i.e., space-form blindness). As they grow older, affected children typically are shorter than normal. Although they do not develop breasts at puberty, some pubic or axillary hair may develop because appropriate adrenarche can occur with failure of thelarche (i.e., breast development). **Although less severe short stature and some adolescent development may occur with chromosomal mosaicism, it is reasonable to assume that any short, slowly growing, sexually infantile girl has Turner syndrome until proved otherwise because this disorder is so prevalent (about 1 in 2,500 newborn phenotypic females).** In fact, the 45,X karyotype is the single most frequent chromosomal disorder in humans, but most affected fetuses are aborted spontaneously early in pregnancy. However, trisomy is the most common chromosomal type or category of abnormality in first-trimester losses.

Figure 26.10 Typical appearance of two individuals with 45,X gonadal dysgenesis. **A:** This 16-year-old individual has obvious short stature, a webbed neck, shortened fourth metatarsals, and a thoracotomy scar from the repair of the coarctation of the aorta that was performed at 13 years of age. **B:** This 11-year-old individual also has obvious short stature and stigmata of Turner syndrome. Note that these two individuals look more like each other than they might look like any genetic siblings.

The short stature commonly associated with the Turner phenotype appears largely to be due to the loss of a homeobox-containing gene (which encodes for an osteogenic gene)

P.1009

located on the pseudoautosomal region (PAR 1) of the short arms of the X (Xp22) and Y (Yp11.3) chromosomes (32). This gene, which is called either *SHOX* (short stature homeobox-containing gene) or *PHOG* (pseudoautosomal homeobox osteogenic gene), escapes X inactivation because of its pseudoautosomal location. The gene appears to account for about two thirds of the height deficit commonly associated with Turner syndrome.

Even in the presence of typical Turner stigmata, a karyotype is indicated to eliminate the possibility of the presence of any portion of a Y chromosome. If a Y chromosome is identified, surgical extirpation of the gonads is warranted to eliminate any possibility of a germ

cell neoplasm (estimated 20%–30% prevalence) (33,34). In individuals in whom there is no evidence of neoplastic dissemination, the uterus may be left *in situ* for donor *in vitro* fertilization and embryo transfer. **Individuals with Turner syndrome are at increased risk of sudden death from aortic rupture or dissection resulting from cystic medial necrosis during pregnancy, and the risk may be as great as 2% or more** (35). Echocardiography and counseling about this risk is warranted before pregnancy is contemplated. The evaluation of other commonly involved organ systems should include a careful physical examination, with special attention to the cardiovascular system, and thyroid function tests (including antibody assessment), fasting blood glucose, renal function tests, and intravenous pyelography or a renal ultrasonography.

Treatment of Turner Syndrome

To increase final adult height, commonly accepted treatment strategies include use of *exogenous GH* (36,37,38). With recombinant human GH use, the average height gain has varied from 4 to 16 cm. It appears that early initiation of therapy (between 2–8 years of age), gradually increasing the dose, and continuing treatment for a mean of 7 years can lead to achievement of a final height greater than 150 cm in most patients (37). Weekly doses of *GH* of 0.375 mg/kg divided into seven daily doses are typical. It is not clear if an anabolic steroid such as *oxandrolone* will provide additional growth.

The gonadal steroid treatment of patients with Turner syndrome is as follows:

- **To promote sexual maturation, therapy with *exogenous estrogen* should be initiated when the patient is psychologically ready, at about 12 to 13 years of age, and after *GH* therapy has been administered for several years. Low-dose *estrogen* can be introduced at this time without compromising final adult height (39).**
- **Because the intent is to mimic normal pubertal development, therapy with low-dose *estrogen* alone (such as 0.025 mg/day *transdermal estradiol* or 0.3–0.625 mg *conjugated estrogens* orally each day) should be initiated.**
- **Progestins (5–10 mg *medroxyprogesterone acetate* or 200 mg *micronized progesterone* orally for 12–14 days every 1–2 months) can be added to prevent endometrial hyperplasia after the patient first experiences vaginal bleeding or after 6 months of unopposed *estrogen* use if the patient has not yet had any bleeding.**
- **The dose of *estrogen* is increased slowly over 1 to 2 years until the patient is taking about twice as much *estrogen* as the amount administered to postmenopausal women.**
- **Girls with gonadal dysgenesis must be monitored carefully for the development of hypertension with *estrogen* therapy.**
- **The patients and their parents should be counseled regarding the emotional and physical changes that will occur with therapy.**

Mosaic Forms of Gonadal Dysgenesis

Individuals with rare mosaic forms of gonadal dysgenesis may develop normally at puberty. The decision to initiate therapy with exogenous estrogen should be based mainly on circulating FSH levels. Levels in the normal range for the patient's age imply the presence of functional gonads.

These individuals can become pregnant, with success rates of more than 50% using donor oocytes (40). The increased risk of sudden death during pregnancy resulting from aortic rupture should be assumed to be similar to that of other women with the Turner phenotype (35).

Pure Gonadal Dysgenesis

The term *pure gonadal dysgenesis* refers to **46,XX or 46,XY phenotypic females who have streak gonads. This condition may occur sporadically or may be inherited as an autosomal recessive trait or as an X-linked trait in XY gonadal dysgenesis** (Fig. 26.11). Affected girls typically are of average height and have none of the stigmata of Turner syndrome, but they have elevated levels of FSH because the streak gonads produce neither steroid hormones nor inhibin. When gonadal dysgenesis occurs in 46,XY individuals, it is sometimes termed *Swyer syndrome*. Surgical extirpation is warranted in individuals with a 46,XY karyotype to prevent development of germ cell neoplasms. Both 46,XX and 46,XY forms of gonadal dysgenesis benefit from exogenous estrogen and are potential candidates for donor oocytes.

In early gonadal failure, the ovaries apparently develop normally but contain no oocytes by the expected age of puberty. These disorders are considered further in the discussion delineating the evaluation of amenorrhea (see Chapter 27).

Hypogonadotropic Hypogonadism

Hypothalamic-pituitary disturbances are usually associated with low levels of circulating gonadotropins (with both LH and FSH levels less than or equal to 10 mIU/mL) (41). There are both sporadic and familial causes of hypogonadotropic hypogonadism, and the differential diagnosis is extensive. **Mutations in several genes have been shown to cause hypogonadotropic hypogonadism in humans** (42). This condition can arise from abnormalities in hypothalamic GnRH secretion, impaired release of gonadotropins from the pituitary gland, or both. At least six separate genes have been identified as causes of hypogonadotropic hypogonadism: (i) *KAL1*, (ii) *FGFR1/KAL2*, (iii) *DAX 1* (the gene for X-linked congenital adrenal hypoplasia), (iv) *GNRHR* (the gene for the GnRH receptor), (v) *PC1* (the gene for prohormone convertase 1), and (vi) *GPR54* (encoding a G-protein coupled receptor) (43,44,45). Because defects in these genes account for less than 20% of all cases of isolated hypogonadotropic hypogonadism, additional mutations probably exist but have yet to be identified. It is important to remember, however, that low levels of LH and FSH are normally present in the prepubertal years; thus, girls with constitutionally delayed puberty may mistakenly be presumed to have hypogonadotropic hypogonadism. In fact, **constitutional delay is the most common cause of delayed puberty.** In a normal population, 2% to 3% of normal children will be classified as having pubertal delay, and this finding may be considered a normal variant. **Constitutional delayed growth and adolescence can be diagnosed only after careful evaluation excludes other causes of delayed puberty and normal sexual development is documented by longitudinal follow-up.** The farther below the third percentile for height that the young girl is, the less likely it is that the cause is constitutional. Because some children are severely handicapped socially by constitutional pubertal delay, some physicians occasionally provide *exogenous estrogen* in

low doses for 3 to 4 months to stimulate some pubertal development. However, the benefits of treatment are not well documented, and there is little evidence to support the idea that treatment improves psychosocial function.

Kallmann Syndrome

As originally described in 1944 (46), *Kallmann syndrome* **consisted of the triad of anosmia, hypogonadism, and color blindness in men. Women may be affected as well, and other associated defects may include cleft lip and palate,**

P.1011

cerebellar ataxia, nerve deafness, and abnormalities of thirst and vasopressin release.

The frequency approximates 1 in 10,000 men and 1 in 50,000 women. Because autopsy studies have shown partial or complete agenesis of the olfactory bulb, the term *olfactogenital dysplasia* has also been used to describe the disorder. These anatomic findings coincide with embryologic studies documenting that GnRH neurons originally develop in the epithelium of the olfactory placode and normally migrate into the hypothalamus (47). In some affected individuals, gene defects have been found in one protein, anosmin, that facilitates this neuronal migration, thus leading to an absence of GnRH neurons in the hypothalamus and olfactory bulbs and consequent hypogonadotropic hypogonadism and anosmia (Kallmann syndrome) (48). The gene defect resulting in loss of this facilitory

P.1012

P.1013

adhesion protein has been localized to the Xp22.3 locus in an X-linked form of the syndrome, and this locus has been designated *KAL 1*. Because confirmed mutations in the coding sequence of the *KAL* gene occur only in a minority of individuals with Kallmann syndrome (49), other mutations no doubt will be identified in the future. Moreover, the disorder is so heterogeneous that it appears likely that it forms a structural continuum with other midline defects. Septo-optic dysplasia represents the most severe form of the disorder.

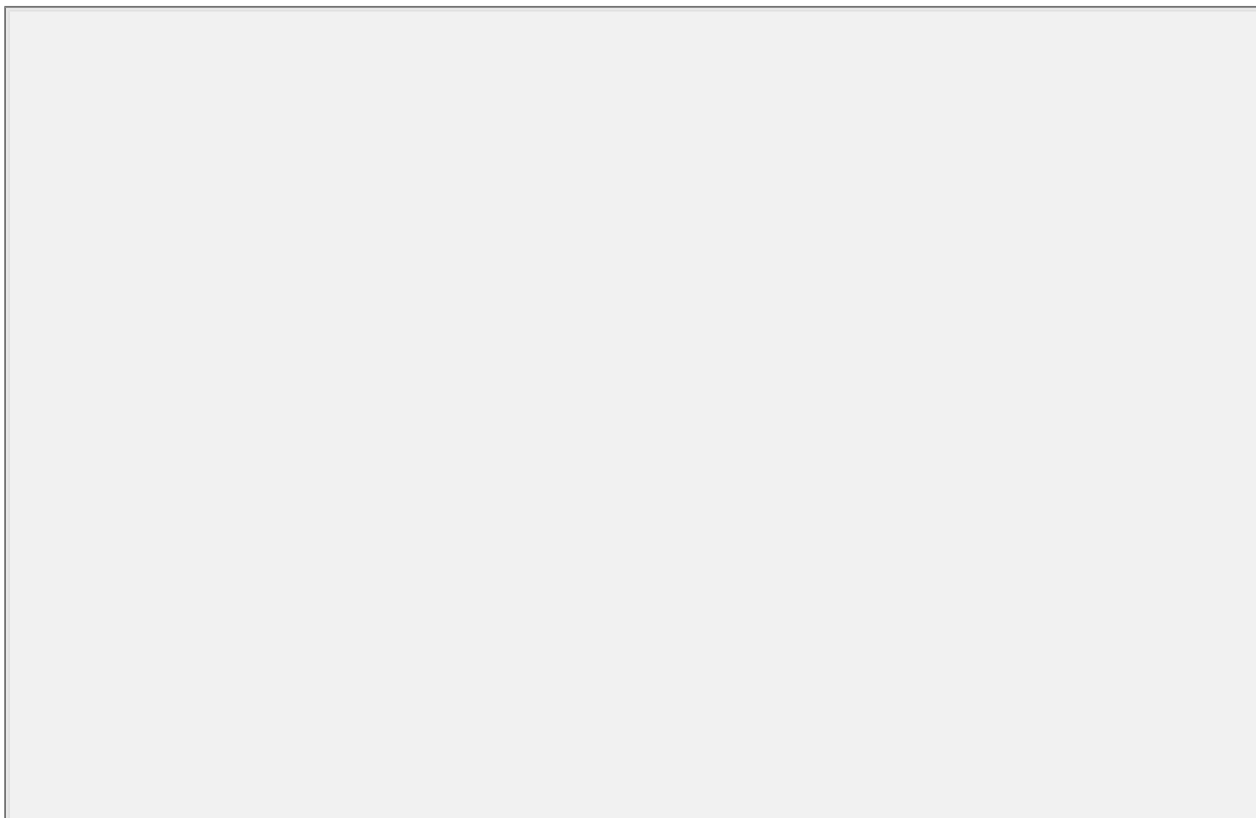

Figure 26.11 A: A 16-year-old individual with 46,XX gonadal dysgenesis and primary amenorrhea. Circulating follicle-stimulating hormone (FSH) levels were markedly elevated. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients. **B:** A 16-year-old individual with 46,XY gonadal dysgenesis who presented with primary amenorrhea and markedly elevated FSH levels. Most affected individuals do not present with as much pubic and axillary hair development. The right gonad contained a dysgerminoma, but there was no evidence of metastases. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York, NY: Churchill Livingstone, 1993:97-133, with permission.) **C:** Clitoromegaly noted in the girl with 46,XY gonadal dysgenesis depicted in Figure 26.11B. **D:** The same individual as depicted in Figure 26.11B and D with 46,XY gonadal dysgenesis 1 year after gonadectomy and replacement with exogenous estrogen.

Clinically, affected individuals typically present with sexual infantilism and an eunuchoid habitus, but some degree of breast development may occur (Fig. 26.12).

Primary amenorrhea is the rule. The ovaries are usually small, with follicles seldom developing beyond the primordial stage. Circulating gonadotropin levels are usually very low but almost invariably measurable. Affected individuals respond readily to pulsatile administration of exogenous GnRH, and clearly this is the most physiologic approach to ovulation induction (40). For women not seeking pregnancy, therapy with exogenous estrogen and progestin is indicated.

Isolated gonadotropin deficiency can also occur in association with the Prader-Labhart-Willi syndrome, which is characterized by obesity, short stature, hypogonadism, small hands and feet (acromicria), mental retardation, and infantile hypotonia. When the syndrome occurs in association with the Laurence-Moon-Bardet-Biedl syndrome, retinitis pigmentosa, postaxial polydactyly, obesity, and hypogonadism also may be present. Prader-Labhart-Willi syndrome apparently results from rearrangements of chromosome 15q11 to q13, an imprinted region of the human genome (50). Laurence-Moon-Bardet-Biedl syndrome, inherited in an autosomal recessive manner, is apparently heterogeneous, with at least four involved gene loci having been mapped to date (51).

Multiple pituitary hormone deficiencies, which are usually hypothalamic in origin, may be congenital and either part of an inherited constellation of findings or sporadic. If GH or thyroid-stimulating hormone (TSH) concentrations are subnormal, growth and pubertal development will be affected. Thus, the condition should be diagnosed before the age of puberty. Because individuals with hypopituitarism have a high mortality rate, predominantly caused by vascular and respiratory disease (52), it is important to identify affected individuals. Later age at diagnosis, female sex, and above all craniopharyngioma have been identified as significant independent risk factors. Untreated gonadotropin deficiency also is an important risk factor for early mortality.

Tumors of the Hypothalamus and Pituitary

Several different tumors of the hypothalamic and pituitary regions also may lead to hypogonadotropic hypogonadism (53) (Fig. 26.13A). Except for craniopharyngiomas, these tumors are relatively uncommon in children. Craniopharyngiomas are usually suprasellar in location and may be asymptomatic well into the second decade of life. Such tumors may present as headache, visual disturbances, short stature or growth failure, delayed puberty, or diabetes insipidus. Visual field defects (including bilateral temporal hemianopsia), optic atrophy, or papilledema may be seen on physical examination. Laboratory evaluation should

document hypogonadotropism and may also reveal hyperprolactinemia as a result of interruption of hypothalamic dopamine inhibition of prolactin release. Radiographically, the tumor may be either cystic or solid and may show areas of calcification. Appropriate therapy for hypothalamic–pituitary tumors may involve surgical excision or radiotherapy (with adequate pituitary hormone replacement therapy) and is best managed by a team of physicians that includes an endocrinologist, a neurosurgeon, and a radiotherapist.

Other Central Nervous System Disorders

Other central nervous system disorders that may lead to delayed puberty include infiltrative diseases, such as Langerhans cell–type

P.1014

histiocytosis, particularly the form known previously as *Hand–Schüller-Christian disease* (Figs. 26.13B and 26.13C). Diabetes insipidus is the most common endocrinopathy (because of infiltration of the supraoptic nucleus in the hypothalamus), but short stature resulting from GH deficiency and delayed puberty caused by gonadotropin deficiency are not uncommon in this disorder (54).

Figure 26.12 Left A 21½-year-old woman with Kallmann syndrome. Note that the patient has some pubic and axillary hair. Bone age was 16 years. It is rare to see affected individuals today who were not given oral contraceptive agents to induce menses (with some consequent breast development). (From **Wilkins L.** *The diagnosis and treatment of endocrine disorders in childhood and adolescence.* 3rd ed. Springfield, IL: Charles C Thomas, 1965, with permission.).

Figure 26.13 Right A: A 16-year-old girl with delayed puberty. Breast budding began at 11 years of age, but there was no further development. During the year before presentation, her scholastic performance in school deteriorated, she gained 25 lb, she became increasingly lethargic, and nocturia and polydipsia were noted. Initial evaluation documented low follicle-stimulating hormone, elevated prolactin, and a bone age of 10.5 years. Computed tomography scanning documented a large hypothalamic neoplasm that proved to be an ectopic germinoma. The patient was also documented to be hypothyroid and hypoadrenal and to have diabetes insipidus. Despite the elevated prolactin, she had no galactorrhea because of the minimal breast development. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York, NY: Churchill Livingstone, 1993:97-133, with permission.). B: A 16-year-old girl (frontal view) with primary amenorrhea who progressed in puberty until about 12 years of age. Breast budding occurred at about 10 years of age. The patient's short stature is obvious. She proved to have hypopituitarism. Classic radiographic findings established the diagnosis of Langerhans cell-type histiocytosis (Hand-Schüller-Christian disease). C: Side view of girl shown in Figure 26.13B.

P.1015

Irradiation of the central nervous system for treatment of any neoplasm or leukemia may result in hypothalamic dysfunction. Although GH deficiency is the most frequent finding, partial or complete gonadotropin deficiency may develop in some patients.

Severe chronic illnesses, often accompanied by malnutrition, also may lead to slowed growth in childhood and delayed adolescence. Regardless of the cause, weight loss to less than 80% to 85% of ideal body weight often results in hypothalamic GnRH deficiency. If adequate body weight and nutrition are maintained in chronic illnesses such as Crohn disease or chronic pulmonary or renal disease, sufficient gonadotropin secretion usually is present to initiate and maintain pubertal development.

Anorexia Nervosa and Bulimia

Significant weight loss and psychological dysfunction occur simultaneously with anorexia nervosa (55,56). Although many anorectic girls experience amenorrhea after pubertal development has begun, if the disorder begins sufficiently early, pubertal development may be delayed or interrupted (Fig. 26.14). **The following constellation of associated findings confirms anorexia nervosa in most individuals:**

- **Relentless pursuit of thinness.**
 - **Amenorrhea, sometimes preceding the weight loss.**
 - **Extreme inanition.**
 - **Obsessive–compulsive personality often characterized by overachievement.**
-
- **Distorted and bizarre attitude toward eating, food, or weight.**
 - **Distorted body image.**

P.1016

Figure 26.14 A: A 20-year-old college woman with anorexia nervosa. B: A 16-year-old student with anorexia nervosa. In both cases, as is true of most such patients, pubertal development had been completed and menses initiated before anorexia led to marked weight loss.

Because normal body weight is commonly maintained in bulimia, it is unusual for bulimic patients to experience either delayed development or amenorrhea. Girls with anorexia nervosa may have, in addition to hypogonadotropic hypogonadism, partial diabetes insipidus, abnormal temperature regulation, chemical hypothyroidism with low serum triiodothyronine (T_3) and high reverse T_3 levels, and elevated circulating cortisol levels in the absence of evidence of hypercortisolism (57).

Fear of obesity, a syndrome of self-induced malnutrition common among teenage gymnasts and ballet dancers, also may slow growth and delay pubertal development (58). These children voluntarily reduce their caloric intake as much as 40%, leading to nutritional growth retardation. An additive role for endurance training in the delayed development is possible, but the mechanisms are unclear at this point. These conditions are essentially severe forms of hypothalamic amenorrhea. It is clear, however, that delayed puberty will occur inevitably unless adequate caloric intake is provided.

P.1017

Hyperprolactinemia

Low levels of LH and FSH may be associated with hyperprolactinemia. As noted, galactorrhea cannot occur in the absence of complete breast development. Pituitary prolactinomas are rare during adolescence but must be considered when certain signs and symptoms are present. **Many individuals with prolactinomas have a history of delayed menarche.** The association between the ingestion of certain drugs (most often psychotropic agents and opiates in this age group) is well established. Primary hypothyroidism also is associated with hyperprolactinemia because increased levels of thyrotropin-releasing hormone (TRH) stimulate secretion of prolactin. The *empty sella syndrome*, in which the sella turcica is enlarged but has been replaced by cerebrospinal fluid, may also be associated with hyperprolactinemia.

Use of Chemotherapeutic Agents

As survival rates following treatment for childhood malignancy improve, the effects of cancer therapy become ever more important. **Both radiation therapy to the abdomen and systemic chemotherapeutic agents, particularly alkylating agents, have toxic effects on germ cells. Although prepubertal gonads appear less vulnerable than those of adults, ovarian failure is common.** An argument can be made for endocrine assessment as early as 1 year following completion of therapy to identify children who will suffer from hypogonadism. Spontaneous ovarian activity can resume even years after therapy.

Asynchronous Puberty

Asynchronous pubertal development is characteristic of androgen insensitivity (i.e., testicular feminization). **Affected individuals typically present with breast development (usually only to Tanner stage 3) out of proportion with the amount of pubic and axillary hair present (Fig. 26.15).** In this disorder, 46,XY individuals have bilateral testes, female external genitalia, a blindly ending vagina (often foreshortened and sometimes absent), and no müllerian derivatives (i.e., uterus and fallopian tubes) (59). Infrequently, patients may have clitoral enlargement and labioscrotal fusion at puberty, which is referred to as *incomplete androgen insensitivity*.

Asynchronous puberty is heterogeneous but is always related to some abnormality of the androgen receptor or of androgen action (60). In perhaps 60% to 70% of cases, androgen receptors cannot be detected (i.e., the patient is receptor negative). In the remaining cases, androgen receptors are present (i.e., receptor positive), but mutations in the androgen receptor have been detected or there is a defect at a more distal step in androgen action (i.e., a postreceptor defect). Receptor-positive individuals are indistinguishable clinically from receptor-negative individuals. Several different mutations in the androgen receptor gene, most of which occur within the androgen-binding domain of the receptor, have been identified in affected individuals who are receptor positive. Severe X-linked androgen receptor gene mutations cause complete androgen insensitivity, whereas mild mutations impair virilization with or without infertility, and moderate mutations result in a wide phenotypic spectrum of expression among siblings (61).

Because the Sertoli cells of the testes make antimüllerian hormone (AMH), müllerian derivatives are absent in this disorder; thus, müllerian regression occurs normally. The testes are often normal in size and may be located anywhere along the path of embryonic testicular descent—in the abdomen, inguinal canal, or labia. Half of all individuals with androgen insensitivity develop inguinal hernias. Recognizing that most such girls will be 46,XX, it is important to determine the karyotype in prepubertal girls with inguinal hernias, especially if a uterus cannot be detected with certainty by ultrasound.

The frequency of gonadal neoplasia is increased with this condition, but the extent is uncertain (33). Most clinicians believe the risk for neoplasia is low before 25 years of age;

P.1018

P.1019

thus, **the testes should be left in place until after pubertal feminization, especially because the risk of neoplasia appears to increase with age.** Exogenous estrogen should be provided after gonadectomy.

Figure 26.15 A: This 17-year-old individual presented with primary amenorrhea and was found to have a blind-ending vagina and bilateral inguinal masses. Circulating levels of testosterone were at the upper limits of the normal range for men, and the karyotype was 46,XY, confirming androgen insensitivity. **B:** Two inguinal testes were found at surgery. (From **Simpson JL, Rebar RW.** Normal and abnormal sexual differentiation and development. In: **Becker KL,** ed. *Principles and practice of endocrinology and metabolism*. 2nd ed. Philadelphia, PA: JB Lippincott, 1995: 788–822, with permission.)

The diagnosis is often suspected by the typical physical findings and strongly suggested by normal (or even somewhat elevated) male levels of testosterone, normal or somewhat elevated levels of LH, and normal levels of FSH. The diagnosis is confirmed by a 46,XY karyotype.

Interacting with the patient and family requires sensitivity and care. It may be inadvisable to begin by informing the patient of the karyotype; the psychological implications may be devastating because the patient has been reared as a girl. Family members should be informed initially that müllerian aplasia occurred and that the risk for neoplasia mandates gonadectomy after puberty. Because the disorder can be inherited in an X-linked recessive fashion, families should undergo appropriate genetic counseling and screening to identify the possible existence of other affected family members.

Precocious Puberty

Although precocious pubertal development may be classified in several ways, it is perhaps simplest to think of the development as gonadotropin dependent (in which case it is almost invariably of central origin) or gonadotropin independent (of peripheral origin). Precocious puberty is 20 times more common in girls than in boys. In fully 90% of girls, the precocious development is idiopathic, whereas this appears to be true for only 10% of boys. Family history, the rapidity with which secondary sexual characteristics are developing, the rate of growth, and the presence or absence of central nervous system disease should all be considered in deciding whether to pursue evaluation of a girl for precocious puberty. The evaluation of precocious puberty is as follows: .

- **Measurement of basal gonadotropin levels is the first step in the evaluation of a child with sexual precocity** (Fig. 26.16).
- **Thyroid function should also be evaluated** to rule out primary hypothyroidism as the cause of precocious development.
- **High levels of LH (which really may be human chorionic gonadotropin detected because of cross-reactivity with LH in immunoassays) suggest a gonadotropin-producing neoplasm**, most often a pinealoma (ectopic germinoma) or choriocarcinoma or, less often, a hepatoblastoma. (Gonadotropin-producing neoplasms are the only causes of precocious puberty in which the gonadotropin dependence does not equate with central precocious puberty.)
- **Low or pubertal levels of gonadotropins indicate the need to determine circulating estradiol concentrations in girls with isosexual development** and to assess androgen levels, specifically testosterone, DHEAS, and 17 α -hydroxyprogesterone in girls

with heterosexual development.

- **Increased estradiol levels suggest an estrogen-secreting neoplasm, probably of ovarian origin.**

- **Increased testosterone levels suggest an androgen-producing neoplasm of the ovary or the adrenal gland.** Such neoplasms may be palpable on abdominal or rectal examination. Increased 17 α -hydroxyprogesterone levels are diagnostic

P.1020

of 21-hydroxylase deficiency (ie, congenital adrenal hyperplasia [CAH]). Levels of DHEAS are elevated in various forms of CAH as well.

- **If the estradiol levels are compatible with the degree of pubertal development observed, evaluation of the central nervous system by MRI or CT scanning is warranted.**

- **Bone age should always be assessed in evaluating an individual with sexual precocity.**

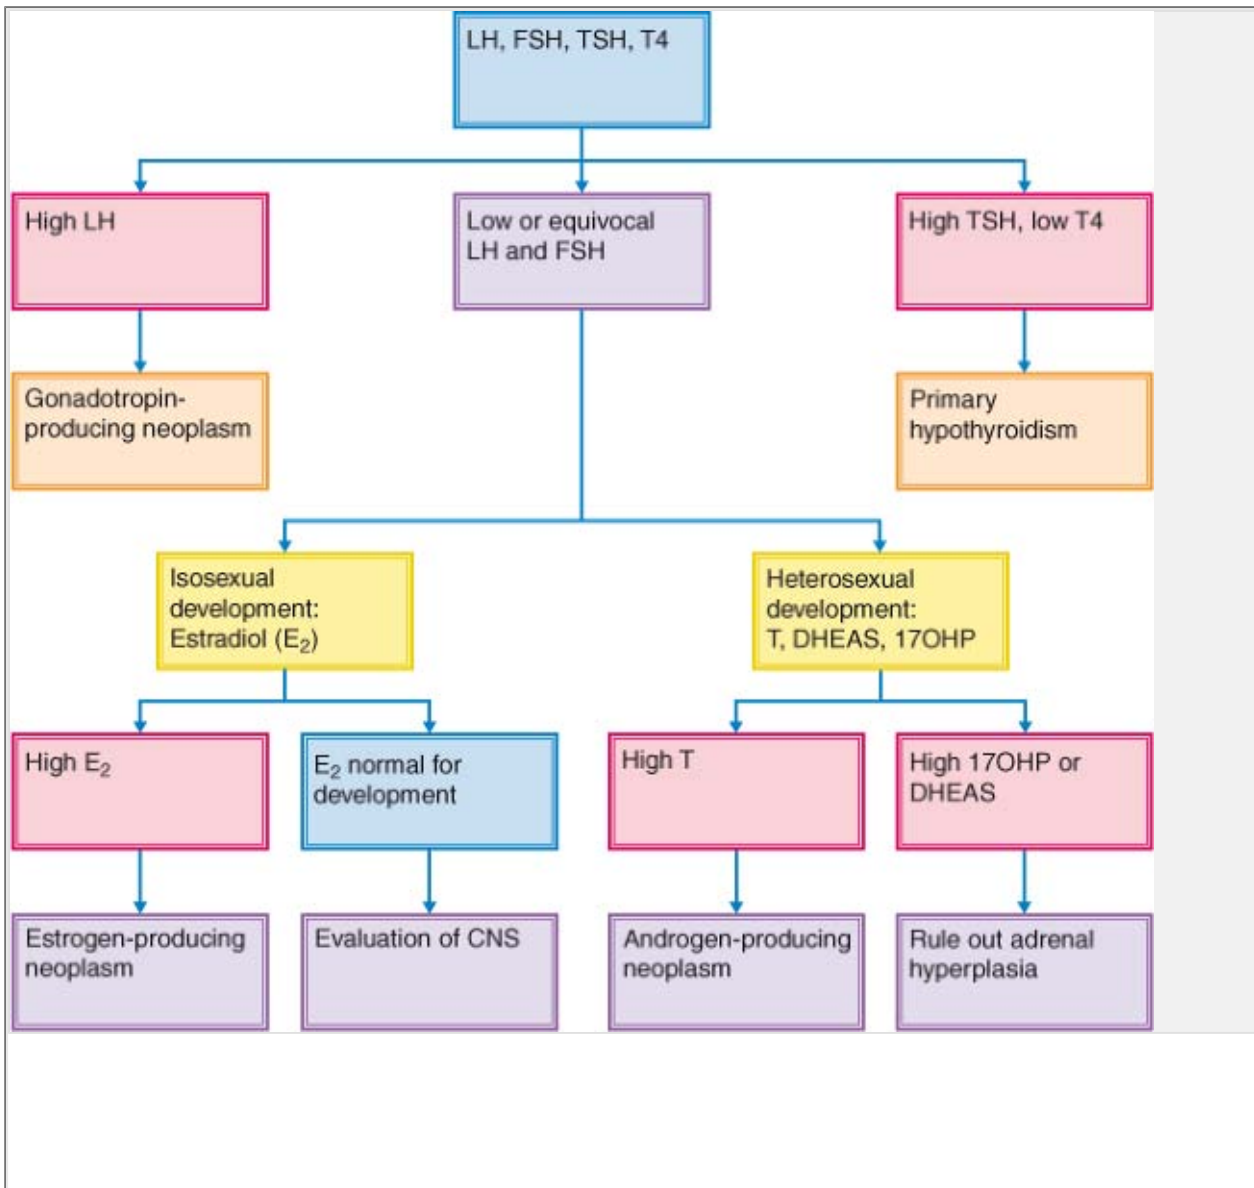

Figure 26.16 Flow diagram for the evaluation of precocious puberty in phenotypic

females. LH, luteinizing hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; T4, thyroxine; T, testosterone; DHEAS, dehydroepiandrosterone sulfate; 17OHP, 17-hydroxyprogesterone; CNS, central nervous system. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al.**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York, NY: Churchill Livingstone, 1993:97–133, with permission.)

Perhaps the most difficult decision for the gynecologist is determining how much evaluation is warranted for the young girl brought in by her mother for precocious breast budding only (*precocious thelarche*) or the appearance of pubic or axillary hair alone (*precocious pubarche* or *adrenarche*) (Fig. 26.17). In such cases, it is acceptable to many clinicians to follow the patient at frequent intervals and to proceed with evaluation if there is evidence of pubertal progression. The feasibility of this approach may depend on the concerns of the parents. Premature thelarche may be caused by

P.1021

increased sensitivity of the breasts to low levels of estrogen or to increased estradiol secretion by follicular cysts. Premature adrenarche or pubarche may be due to increased sensitivity to low levels of androgens and must be distinguished from late-onset (nonclassic) CAH. If there is no evidence of breast development and the appearance of sexually stimulated hair (i.e., precocious puberty) or of progression, these conditions are virtually always benign.

Some girls with premature adrenarche are at risk of developing polycystic ovarian syndrome (PCOS) (62). Although mean androgen levels are within the normal range, a significant minority have an exaggerated response to corticotropin stimulation. Moreover, the magnitude of this response is inversely related to insulin sensitivity. Thus, premature adrenarche may be the first sign of insulin resistance or PCOS in some individuals. Treatment of coexisting obesity and long-term follow-up are indicated to address potential complications of PCOS and insulin resistance.

Constitutional (idiopathic) sexual precocity is the most common cause of precocious puberty. It is often familial and represents the so-called "tail" of the gaussian curve (i.e., the early 2.5% for the age distribution for the onset of puberty). In many of these girls, puberty is slowly progressive, but in a few, development progresses rapidly. The major complication of sexual precocity is limitation of height. Thus, therapy, may be warranted to prevent this consequence.

Central (True) Precocious Puberty

In central precocious puberty, GnRH prematurely stimulates increased gonadotropin secretion. Central precocious puberty may occur in children in whom there is no structural abnormality, in which case it is termed *constitutional* or *idiopathic*.

Alternatively, central precocious puberty may result from a tumor, infection, congenital abnormality, or traumatic injury affecting the hypothalamus. Tumors of the hypothalamus include hamartomas and, less frequently, neurogliomas and pinealomas. It appears that hamartomas produce GnRH in a pulsatile manner and thus stimulate gonadotropin secretion (63) (Fig. 26.18). A number of congenital malformations, including hydrocephalus, craniostenosis, arachnoid cysts, and septo-optic dysplasia, also can be associated with precocious puberty (as well as with sexual infantilism).

Precocious Puberty of Peripheral Origin

In gonadotropin-independent precocious puberty, production of estrogens or androgens from the ovaries, adrenals, or rare steroid-secreting neoplasms leads to early pubertal development. Small functional ovarian cysts, typically asymptomatic, are common in children and may cause transient sexual precocity (64). Simple cysts (with a benign ultrasonographic appearance) can be observed and usually resolve over time. Of the various ovarian neoplasms that can secrete estrogens, granulosa-theca cell tumors occur most frequently but are still rare (65). Although such tumors may grow rapidly, more than two thirds are benign.

The *McCune-Albright syndrome* is characterized by **polyostotic fibrous dysplasia of bone, irregular café-au-lait spots on the skin**, and hyperfunctioning endocrinopathies. Girls develop sexual precocity as a result of functioning ovarian cysts. Other endocrinopathies may include hyperthyroidism, hypercortisolism, hyperprolactinemia, and acromegaly. It is now known that mutations of the G α subunit of the G protein, which couples extracellular hormonal signals to the activation of adenylate cyclase, are responsible for the autonomous hyperfunction of the endocrine glands and, presumably, for the other defects present in this disorder (66). Exposure to exogenous estrogens can mimic gonadotropin-independent precocious puberty. Ingestion of oral contraceptives, other estrogen-containing pharmaceutical agents, and estrogen-contaminated foods, as well as the topical use of estrogens, have been implicated in cases of precocious development in infants and children. Severe primary

P.1022

P.1023

hypothyroidism has also been associated with sexual precocity; associated hyperprolactinemia may result in galactorrhea in affected individuals.

Figure 26.17 Five-year-old girl with development of pubic hair (A) as shown more closely in (B) (precocious adrenarche). Gonadotropin levels were prepubertal, and bone age was appropriate for age. No further development occurred until breast budding at approximately age 9.

Congenital Adrenal Hyperplasia

Heterosexual precocious puberty is always of peripheral origin and is most often caused by CAH. Three adrenal enzyme defects—21-hydroxylase deficiency, 11 β -hydroxylase deficiency, and 3 β -hydroxysteroid dehydrogenase deficiency—can lead not only to heterosexual precocity but also to virilization of the external genitalia because of increased androgen production beginning *in utero* (67). The clinical presentation of the various forms of CAH depends on the following factors: (i) the affected enzyme, (ii) the extent of residual enzymatic activity, and (iii) the physiologic consequences of deficiencies in the end products and excesses of precursor steroids.

21-Hydroxylase Deficiency

Most patients with classic CAH have 21-hydroxylase deficiency (Fig. 26.19). All forms of 21-hydroxylase deficiency are caused by homozygous or compound heterozygous mutations in the human *CYP21A2* gene, which encodes the 21-hydroxylase enzyme; in the carrier, heterozygote state, only one allele is mutated (68). Two *CYP21A2* genes, a 3' *CYP21A2B* gene encoding the functional enzyme and a pseudogene termed *CYP21A2A*, are situated very close to each other within the major histocompatibility locus on the short arm of chromosome 6. At least one fourth of cases of 21-hydroxylase deficiency are due to unequal crossover and

genetic recombination between the two genes during meiosis. However, severe mutations do not correlate with severe phenotype, and phenotypic variability likely depends on the activity of other interacting genes.

Neonatal screening suggests an incidence of about 1 in 15,000 births. Because of the location of the gene within the major histocompatibility locus, siblings with 21-hydroxylase deficiency usually have identical human leukocyte antigen (HLA) types. There are various forms of 21-hydroxylase deficiency, including simple virilizing or classic (typically identified at birth because of genital ambiguity), salt-wasting (in which there is impairment of mineralocorticoid as well as glucocorticoid secretion), and late-onset or nonclassic (in which heterosexual development occurs at the expected age of puberty). The nonclassic form is discussed in the following section on heterosexual pubertal development.

Deficiency of 21-hydroxylase results in the impairment of the conversion of 17 α -hydroxyprogesterone to 11-deoxycortisol and of progesterone to deoxycorticosterone (Fig. 26.20). As a consequence, precursors accumulate, and there is increased conversion to adrenal androgens. Because the development of the external genitalia is controlled by androgens, in the classic form of this disorder, girls are born with ambiguous genitalia, including an enlarged clitoris and fusion of the labioscrotal folds and the urogenital sinus. The internal female organs (including the uterus, fallopian tubes, and ovaries) develop normally because they are not affected by the increased androgen levels. Almost two thirds of affected newborns rapidly develop salt-wasting 21-hydroxylase deficiency, hyponatremia, hyperkalemia, and hypotension. During childhood, untreated girls with either the classic or salt-wasting form grow rapidly but have advanced bone ages, enter puberty early, experience early closure of their epiphyses, and ultimately are short in stature as adults. CAH, with appropriate therapy, is the only inherited disorder of sexual differentiation in which normal pregnancy and childbearing are possible. The classic and salt-wasting forms of 21-hydroxylase deficiency are easily diagnosed based on the presence of genital ambiguity and markedly elevated levels of 17 α -hydroxyprogesterone. Some states have initiated neonatal screening programs to detect 21-hydroxylase deficiency at birth.

3 β -Hydroxysteroid Dehydrogenase

Deficiency of 3 β -hydroxysteroid dehydrogenase (3 β -HSD), caused by mutations in the *HSD3B2* gene encoding the 3 β -HSDII enzyme,

P.1024

affects the synthesis of glucocorticoids, mineralocorticoids, and sex steroids. Typically, levels of 17-hydroxypregnenolone and DHEA are elevated (see Fig. 26.20). The classic form of the disorder, detectable at birth, is quite rare, and affected girls may be masculinized only slightly. In severe cases, salt wasting may also be present.

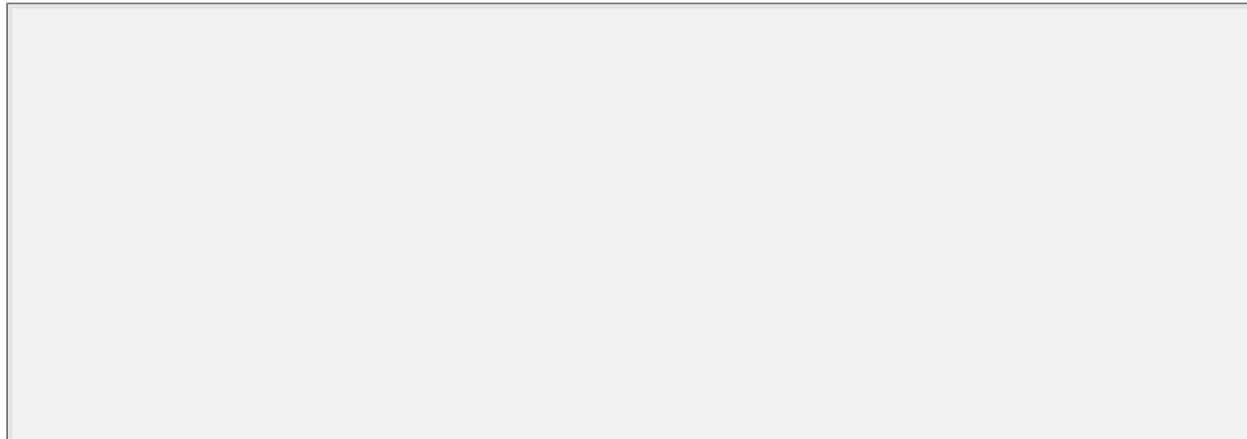

Figure 26.18 Left: A 7½-year-old girl with Tanner stage 4 pubertal development who began menstruating 1 month earlier. She was 57 inches tall (above the ninety-fifth percentile). Luteinizing hormone and follicle-stimulating hormone levels were consistent with her development. A large neoplasm that proved to be a hypothalamic hamartoma was present on computed tomography scan. Pubertal development began at about 5 years of age.

Figure 26.19 Right: A: A 10½-year-old girl with 21-hydroxylase deficiency before treatment. 17-Ketosteroid (KS) excretion was 34 mg/day. **B:** The same patient after 9 months of therapy with cortisone (17-KS excretion: 4.6 mg/day). (From **Wilkins L.** *The diagnosis and treatment of endocrine disorders in childhood and adolescence*. 3rd ed. Springfield, IL: Charles C Thomas, 1965: 439, with permission.).

A nonclassic form of this disorder may be associated with heterosexual precocious pubertal development (as is the classic form if untreated), but postpubertal hyperandrogenism occurs more often. The androgen excess in individuals with nonclassic 3β -HSD deficiency appears to result from androgens derived from the peripheral conversion of increased serum concentrations of DHEA. This disorder is inherited in autosomal recessive fashion, with allelism at the 3β -HSD gene on chromosome 1 believed to be responsible for the varying degrees of enzyme deficiency.

Figure 26.20 Gonadal and adrenal steroid pathways and the enzymes required for steroid conversion. DOC = deoxycorticosterone; 17 α -OH Preg = 17 α -hydroxypregnenolone; 17 α -OH Prog = 17 α -hydroxyprogesterone; DHEA = dehydroepiandrosterone sulfate. (From **Rebar RW, Kenigsberg D, Hodgen GD.** The normal menstrual cycle and the control of ovulation. In: **Becker KL,** ed. *Principles and practice of endocrinology and metabolism.* 2nd ed. Philadelphia, A: JB Lippincott, 1995:868–880, with permission.).

P.1025

P.1026

11-Hydroxylase Deficiency

The classic form of 11-hydroxylase deficiency is believed to constitute 5% to 8% of all cases of CAH. Deficiency in 11-hydroxylase, caused by mutations in the *CYP11B1* gene, results in the inability to convert 11-deoxycortisol to cortisol and the consequent accumulation of androgen precursors (see Fig. 26.20). Markedly elevated levels of 11-deoxycortisol and deoxycorticosterone are present in the disorder. Because deoxycorticosterone acts as a mineralocorticoid, many individuals with this disorder become hypertensive. A mild nonclassic form of 11-hydroxylase deficiency has been reported but apparently is very uncommon.

Treatment of Congenital Adrenal Hyperplasia

The treatment of CAH involves providing replacement doses of the deficient steroid hormones. *Hydrocortisone* (10–20 mg/m² body surface area) or its equivalent is given daily in divided doses to suppress the elevated levels of pituitary corticotropin present and thus suppress the elevated androgen levels. With such treatment, signs of androgen excess should regress. In children, growth velocity and bone age should be monitored carefully because both overreplacement and underreplacement can result in premature closure of the epiphyses and short stature. Data now indicate that early diagnosis and compliance with therapy lead to adult height within 1 standard deviation of the anticipated target height in girls with 21-hydroxylase deficiency (69).

Mineralocorticoid replacement is generally required in individuals with 21-hydroxylase deficiency whether or not they are salt losing. The intent of glucocorticoid therapy should be to suppress morning 17 α -hydroxyprogesterone levels to between 300 and 900 ng/dL. Sufficient *fluorocortisone* should be given daily to suppress plasma renin activity to less than 5 mg/mL per hour.

Girls with ambiguous genitalia may require reconstructive surgery, including clitoral recession and vaginoplasty. Timing of such surgery is debated, but the girl must be of appropriate size to permit the surgery to be as simple as possible.

Heterosexual Pubertal Development

The most common cause of heterosexual development at the expected age of puberty is **PCOS (Fig. 26.21)**. **Because the syndrome is heterogeneous and poorly defined, clinical difficulties result in diagnosis and management (70).** **For the sake of simplicity,** PCOS may be defined as LH-dependent hyperandrogenism **(71)**. **Most clinical manifestations arise as a consequence of the hyperandrogenism and often include hirsutism beginning at or near puberty and irregular menses from the age of menarche because of oligo-ovulation or anovulation.** Clinical manifestations are as follows: .

- **Affected girls may be but are not necessarily somewhat overweight.**
- **In rare instances, menarche may be delayed, and primary amenorrhea also may occur.**
- **Basal levels of LH tend to be elevated in most affected individuals, and androgen production is invariably increased, even though circulating levels of androgens may be near the upper limits of the normal range in many affected women.**
- **In anovulatory women, estrone levels are typically greater than estradiol levels.**
-

Because circulating levels of estrogens are not diminished in PCOS and androgen levels are only mildly elevated, affected girls become both feminized and masculinized at puberty. This is an important feature because girls with classic forms of CAH who do not experience precocious puberty (and even those who do) only become masculinized at puberty (i.e., they do not develop breasts).

P.1027

- Some degree of insulin resistance may be present, even in the absence of overt glucose intolerance (72).
- Polycystic ovaries are frequently, but not always present in ultrasound examination.

Figure 26.21 Typical facial hirsutism in 3 women with polycystic ovarian syndrome. A: 25 year-old. B: 21 year-old C: 17 year-old.

Differential Diagnosis and Evaluation

Distinguishing PCOS from the nonclassic forms of CAH is problematic and controversial (73,74). The evaluation is as follows:.

- **Some clinicians advocate measurement of 17 α -hydroxyprogesterone in all women who develop hirsutism.** Although values of 17 α -hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxylase deficiency, they may or may not be elevated in nonclassic late-onset forms of the disorder.
 - **Measurement of 17 α -hydroxyprogesterone also can identify women with various forms of 11-hydroxylase deficiency..**
 - **Basal levels of DHEAS as well as 17 α -hydroxyprogesterone may be moderately elevated in patients with PCOS, making the diagnosis even more difficult.**
-
- **To screen for CAH, 17 α -hydroxyprogesterone should be measured in early morning..**
 - **In women with regular cyclic menses, it is important to measure 17 α -hydroxyprogesterone only in the follicular phase because basal levels increase at midcycle and in the luteal phase..**

P.1028

Measurements of 17 α -hydroxyprogesterone appear to be of value in populations at high risk for nonclassic late-onset 21-hydroxylase deficiency. In the white population, the gene occurs in only about 1 in 1,000 individuals, but it occurs in 1 in 27 Ashkenazi Jews, 1 in 40 Hispanics, 1 in 50 Yugoslavs, and 1 in 300 Italians (67). The incidence is also increased among Eskimos and French Canadians. Alternatively, screening might be restricted to hirsute teenagers presenting with the more "typical" features of nonclassic 21-

the breasts (i.e., defeminization), shorter stature than other family members, and increased DHEAS levels (between 5,000 and 7,000 ng/mL). Women with a strong family history of hirsutism or hypertension might be screened as well (41) (Fig. 26.22).

Basal Levels of 17 α -Hydroxyprogesterone

Basal levels of 17 α -hydroxyprogesterone higher than 800 ng/dL are virtually diagnostic of CAH. Levels between 300 and 800 ng/dL require stimulatory testing with corticotropin to distinguish between PCOS and CAH. To complicate the situation even further, nonclassic 21-hydroxylase deficiency may occur even when basal levels of 17 α -hydroxyprogesterone are below 300 ng/dL, thus requiring stimulatory testing in those cases as well..

Cosyntropin Stimulation Test

The most commonly used stimulatory test involves measurement of 17 α -hydroxyprogesterone 30 minutes after administration of a bolus of 250 mg of synthetic cosyntropin (*Cortrosyn*) (75). In normal women, this value seldom exceeds 400 ng/dL. Patients with classic 21-hydroxylase deficiency achieve peak levels of 3,000 ng/dL or higher. Patients with nonclassic 21-hydroxylase deficiency commonly achieve levels of 1,500 ng/dL or more. Heterozygous carriers achieve peak levels up to about 1,000 ng/dL. In hirsute women with hypertension, 11-deoxycortisol levels can be determined during the test. If both 11-deoxycortisol and 17 α -hydroxyprogesterone levels are increased, the rare 11-hydroxylase deficiency is present. Only measurements of several steroid precursors after corticotropin stimulation can identify individuals with nonclassic forms of 3 β -HSD deficiency.

The elevated levels of 17 α -hydroxyprogesterone present in all forms of 21-hydroxylase deficiency are rapidly suppressed by administration of exogenous corticoids. Even a single dose of a glucocorticoid such as *dexamethasone* will suppress 17 α -hydroxyprogesterone in CAH but not in virilizing ovarian and adrenal neoplasms.

Hirsutism

It has been suggested that androgen-receptor blockade may be preferable to glucocorticoids as primary treatment of nonclassic 21-hydroxylase deficiency (76). Although menses usually (but not always) become regular shortly after beginning therapy with glucocorticoids, the hirsutism in this disorder has proved to be remarkably refractory to glucocorticoids.

Distinguishing nonclassic forms of CAH from idiopathic hirsutism also may be problematic. Individuals with idiopathic hirsutism have regular ovulatory menses, thus effectively eliminating PCOS from consideration. Confusion can be created by the fact that some women with nonclassic CAH may continue to ovulate. Basal levels of 17 α -hydroxyprogesterone are normal in idiopathic hirsutism, as is the response to adrenocorticotrophic hormone stimulation. Idiopathic hirsutism represents enhanced androgen action at the hair follicle (77).

Mixed Gonadal Dysgenesis

The term *mixed gonadal dysgenesis* is used to designate those individuals with asymmetric gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other side.

Most individuals with this rare disorder have a mosaic karyotype of 45,X/46,XY and are raised as girls who then experience virilization at puberty. Gonadectomy is indicated to remove the source of androgens and eliminate any risk for neoplasia.

Rare Forms of Male Pseudohermaphroditism

Individuals who have rare forms of male pseudohermaphroditism, especially 5 α -reductase deficiency (the so-called *penis at 12 syndrome*) and the *Reifenstein syndrome*, generally have ambiguous female genitalia with variable virilization at puberty. *Cushing syndrome*, too, may occur rarely during the pubertal years, as may adrenal or ovarian androgen-secreting neoplasms.

Figure 26.22 A 19-year-old girl with secondary amenorrhea and severe acne and hirsutism beginning at the normal age of puberty. Stimulatory testing with corticotropin documented nonclassic 21-hydroxylase deficiency. Flattening of the breasts is apparent. She was shorter than her one sister and her mother.

Figure 26.23 Newborn girl with 46,XX karyotype and genital ambiguity. There is obvious clitoral hypertrophy, paired frenula, so-called scrotalization of the labia, and a common urogenital sinus (shown by the probe). She had 21-hydroxylase deficiency. (From **Rebar RW**. Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al**, eds. *Gynecology and obstetrics: a longitudinal approach*. New York, NY: Churchill Livingstone, 1993:97–133, with permission.)

Genital Ambiguity at Birth

Because of the concerns of the parents and the need to prevent life-threatening complications, the infant with genital ambiguity should be evaluated promptly. Evaluation and treatment is best conducted by a team of physicians.

The initial evaluation is as follows:.

- **Cytogenetic and endocrine studies should be initiated promptly.** Use of specific probes for the Y chromosome and fluorescent *in situ* hybridization can assist in obtaining a karyotype within 48 hours. Probes for many specific inherited disorders are now available.
- **To exclude CAH, the most common cause of genital ambiguity, serum levels of sodium, potassium, and 17 α -hydroxyprogesterone and urinary excretion of 17-ketosteroids, pregnanetriol, and tetrahydrodeoxycortisol should be measured.** Infants should be monitored closely to prevent development of dehydration, hyponatremia, and hyperkalemia.
- **It has been suggested that antimüllerian hormone be measured in infants with**

genital ambiguity because it is elevated in boys and undetectable in girls in the first several years of life (78).

Table 26.3 Androgens and Progestogens Potentially Capable of Producing Genital Ambiguity^a

Proved	No Effect	Insufficient Data
<i>Testosterone enanthate</i>	<i>Progesterone</i>	<i>Ethinodiol diacetate</i>
<i>Testosterone propionate</i>	<i>17α-Hydroxyprogesterone</i>	<i>Dimethisterone</i>
<i>Methylandrostenediol</i>	<i>Medroxyprogesterone</i>	<i>Norgestrel</i>
<i>6α-Methyltestosterone</i>	<i>Norethynodrel</i>	<i>Desogestrel</i>
<i>Ethisterone</i>		<i>Gestodene</i>
<i>Norethindrone</i>		<i>Norgestimate</i>
<i>Danazol</i>		

^a Those agents proved to cause genital ambiguity do so only when administered in relatively high doses. Insufficient data exist regarding effects of *dimethisterone* and *norgestrel*. In low doses (e.g., as in oral contraceptives), progestins, even including *norethindrone*, seem unlikely to virilize a female fetus.

P.1031

Physical Signs

During the 3 to 4 days required for evaluation, it is important to be supportive of the parents. Many clinicians believe that it is important not to attach any unusual significance to the genital ambiguity and to treat the abnormality as just another "birth defect." Physicians should emphasize that the child should undergo normal psychosexual development regardless of the sex-of-rearing selected. Either a name compatible with either sex should be chosen, or the naming of the infant should be delayed until the studies have been completed.

Although the diagnosis is not usually obvious on examination, there are some helpful distinguishing features (Fig. 26.23). **In normal boys, there is only a single midline frenulum on the ventral side of the phallus; in normal girls, there are two frenula lateral to the midline. A girl with clitoral enlargement still has two frenula, and a boy with hypospadias has a single midline frenulum or several irregular fibrous bands (chordee).** It is important to determine whether any müllerian derivatives are present. Recent studies suggest that MRI may be the most effective way of evaluating the infant for the presence of müllerian tissue (79).

The location or consistency of the gonad may be helpful in deducing its composition. A gonad located in the labial or inguinal regions almost always contains testicular tissue. A testis is generally softer than an ovary or a streak gonad and is more apt to be surrounded by blood vessels imparting a reddish cast. An ovary is more often white, fibrous, and convoluted. A gonad that varies in consistency may be an ovotestis or a testis or a streak gonad that has undergone neoplastic transformation. If a well-differentiated fallopian tube is absent on only one side, the side without the tube probably contains a testis or ovotestis.

Diagnosis and Management

Although genital ambiguity is usually identified at birth, it may not be recognized for several years. Questions about changing the sex-of-rearing may arise. It has been believed that sex-of-rearing may be changed before 2 years of age without

psychologically damaging the child, but experience with individuals with 5 α -reductase deficiency suggests that gender changes may be made after 2 years of age in certain instances (80). In any case, **surgery for genital ambiguity to make the external genitalia (and development) as compatible with the sex-of-rearing of the child is warranted but has not always been successful.** Clitoral recession and clitorrectomy are the most frequently performed surgical procedures.

P.1032

It is possible to diagnose 21-hydroxylase deficiency prenatally in patients known to be at risk (67). The diagnosis is established by documenting elevated levels of 17 α -hydroxyprogesterone or 21-deoxycortisol in amniotic fluid. Genetic diagnosis using specific probes and cells obtained by chorionic villus sampling or amniocentesis also is possible. Prenatal treatment of the fetus by administering *dexamethasone* to the mother is usually but not always successful in preventing genital ambiguity (81). Moreover, maternal complications, including hypertension, massive weight gain, and overt Cushing syndrome, have been noted in about 1% of pregnancies in which the mothers are given low doses of *dexamethasone*. Despite the risks and the nonuniformity of beneficial outcome to affected female fetuses, many parents may choose prenatal medical treatment because of the psychological impact of ambiguous genitalia.

Teratogens

It is important to recognize that ambiguous genitalia can result from the maternal ingestion of various teratogens, most of which are synthetic steroids (Table 26.3). Exposure to the teratogen must occur early in pregnancy, during genital organogenesis. Moreover, not all exposed fetuses manifest the same anomalies or even the presence of any anomalies. In principle, most synthetic steroids with androgenic properties, including weakly androgenic progestins, can affect female genital differentiation. However, the doses required to produce genital ambiguity are generally so great that the concern is only theoretical. The one agent that clearly can lead to genital ambiguity when ingested in clinically used quantities is *danazol*. There is no evidence that inadvertent ingestion of oral contraceptives, which contain relatively low doses of either *mestranol* or *ethinyl estradiol* and a 19-nor-steroid, results in virilization **(82,83)**..

Amenorrhea

Wendy J. Schillings

Howard D. McClamrock

- **Girls have experienced menarche at increasingly younger ages during the past century. To continue to represent two standard deviations above the mean age for development of secondary sexual characteristics and menses, respectively, the age limitations defining primary amenorrhea have been lowered. Primary amenorrhea is now defined as absence of menses at age 13 years when there is no visible secondary sexual characteristic development or age 15 years in the presence of normal secondary sexual characteristics.**
- **When premature gonadal failure occurs in conjunction with primary amenorrhea, it is associated with a relatively high incidence of genetic abnormalities (30%).**
- **The anatomic causes of amenorrhea are relatively few, and the majority may be diagnosed by history and physical examination.**
- **The most important elements in the diagnosis of amenorrhea include physical examination for secondary sexual characteristics and anatomic abnormalities measurement of human chorionic gonadotropin (hCG)**

to rule out pregnancy, and assessment of follicle-stimulating hormone (FSH) levels to differentiate between hypergonadotropic and hypogonadotropic forms of hypogonadism.

- **Therapeutic measures may include specific therapies (medical or surgical) aimed at correcting the primary cause of amenorrhea, hormone replacement to initiate and maintain secondary sexual characteristics and provide symptomatic relief, treatments aimed at maintenance of bone mass (bisphosphonates), and ovulation induction for patients desiring pregnancy.**

A complex hormonal interaction must take place in order for normal menstruation to occur. The hypothalamus must secrete gonadotropin-releasing hormone (GnRH) in a pulsatile fashion, which is modulated by neurotransmitters and hormones. The GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary, which promotes ovarian follicular development and ovulation. A normally functioning ovarian follicle secretes estrogen; after ovulation, the follicle is

P.1036

converted to a corpus luteum, and progesterone is secreted in addition to estrogen. These hormones stimulate endometrial development. If pregnancy does not occur, estrogen and progesterone secretion decrease, and withdrawal bleeding begins. If any of the components (hypothalamus, pituitary, ovary, outflow tract, and feedback mechanism) are nonfunctional, bleeding cannot occur. Amenorrhea occurs in 3% to 4% of reproductive age women who are not pregnant.

The mean age of menarche has become younger during this century. Therefore, the definition has changed: Primary amenorrhea is defined as the absence of menses by 13 years of age when there is no visible secondary sexual characteristic development or by 15 years of age in the presence of normal secondary sexual characteristics. It has been adjusted by 1 year to continue to represent two standard deviations above the mean age of developing secondary sexual characteristics and menses, respectively (1). A woman who has previously menstruated can develop secondary amenorrhea, which is defined as absence of menstruation for three normal menstrual cycles or 6 months (2).

Patients may develop slight alterations in the hypothalamic-pituitary-ovarian axis that are not severe enough to cause amenorrhea but instead cause anovulation. Anovulatory patients usually have irregular menses and may bleed excessively during menstruation because estrogen is unopposed. This often occurs at the beginning and end of the reproductive years. Luteal phase defect is caused by minimal alterations in the hypothalamic-pituitary-ovarian axis, and patients have regular menses along with infertility or recurrent pregnancy loss. Except for anatomic and chromosomal etiologies, luteal phase defects and anovulation have causes similar to those of amenorrhea, but the hypothalamic, pituitary, or ovarian hormonal dysfunction is less severe or of shorter duration than with amenorrhea.

To detect the cause of amenorrhea, it is useful to determine whether secondary sexual characteristics are present (Fig. 27.1). The absence of secondary sexual characteristics indicates that a woman has never been exposed to estrogen stimulation..

Amenorrhea without Secondary Sexual Characteristics

Although the diagnosis and treatment of disorders associated with hypogonadism

have been discussed in another chapter, they also will be mentioned here because these conditions may present as primary amenorrhea. Because breast development is the first sign of estrogen exposure in puberty, patients without secondary sexual characteristics have primary not secondary amenorrhea. The absence of a uterus suggests certain enzyme deficiencies (see Fig 27.1) and indicates the presence of antimüllerian hormone (AMH) in an XY individual. Because these conditions are very rare, it is easier to categorize the causes of amenorrhea in the absence breast development on the basis of gonadotropin status.

Causes of Primary Amenorrhea

Hypergonadotropic Hypogonadism

Primary gonadal failure and the resulting impaired secretion of gonadal steroids are manifested by elevated levels of LH and FSH that arise from decreased negative feedback. Gonadal failure as well as primary amenorrhea are most often associated with genetic abnormalities (Table 27.1). Approximately 30% of patients with primary amenorrhea

P.1037

P.1038

have an associated genetic abnormality (3). The syndrome of gonadal dysgenesis, or Turner syndrome, and its variants represent the most common form of hypogonadism in women (see Chapter 26). **Other disorders associated with primary amenorrhea include structurally abnormal X chromosomes, mosaicism, pure gonadal dysgenesis (46,XX and 46,XY with gonadal streaks), enzyme deficiencies that prevent normal estrogen production, and gonadotropin–receptor inactivating mutations. Individuals with these conditions have gonadal failure and cannot synthesize ovarian steroids. Therefore, gonadotropin levels are elevated because of the lack of negative estrogen feedback on the hypothalamic–pituitary axis.** Most patients with these conditions have primary amenorrhea and lack secondary sexual characteristics. **However, occasionally patients with a partial deletion of the X chromosome, mosaicism, or pure gonadal dysgenesis (46,XX) may synthesize enough estrogen in early puberty to induce breast development and a few episodes of uterine bleeding. Ovulation and, occasionally, pregnancy are possible..**

Genetic Disorders

Gonadal Dysgenesis

It appears that patients with Turner syndrome initially have normal ovarian development. Amenorrhea is the result of accelerated atresia of the follicles. The fibrotic ovaries are called streak ovaries.

Abnormal X Chromosome

46,XX individuals with partial deletions of the X chromosome have variable phenotypes depending on the amount and location of the missing genetic material.

Patients with a deletion of the long arm of the X chromosome (Xq-) from Xq13 to Xq26 have sexual infantilism, normal stature, no somatic abnormalities, and streak gonads (6,7).

Some patients may be eunuchoid in appearance and have delayed epiphyseal closure. Patients with a deletion of the short arm of the X chromosome (Xp) usually are phenotypically similar to individuals with Turner syndrome (8). Many genes on the Xp chromosome escape X inactivation and act similarly to genes on autosomes. The effective monosomy created by the deletion results in the phenotypic

P.1040

features of Turner syndrome (5). Most patients with a ring X have ovarian failure and phenotypes similar to Turner syndrome, although some have been able to reproduce successfully. These patients differ from those with Turner syndrome in that they are more likely to be mentally retarded and have syndactyly. Patients with isochromosome of the long arm of the X chromosome ($i[Xq]$) are also similar to XO patients, with the exception that autoimmune disorders are more common. Half of the women with balanced translocations of the X chromosome to an autosome have gonadal failure. Typically, the normal X is inactivated to preserve the balance of autosomal genes. The gonadal failure can be caused by the chromosomal break occurring in a gene that is required for ovarian function, abnormal meiosis, or X inactivation of the translocated X and adjacent autosomal genes (5,9).

Mosaicism

Primary amenorrhea is associated with various mosaic states, the most common of which is 45,X/46,XX (10). As discussed in Chapter 26, the clinical findings in 45,X/47,XXX and 45,X/46,XX/47,XXX are similar to those in 45,X/46,XX and vary in estrogen and gonadotropin production, depending on the number of follicles in the gonads. When compared with the pure 45,X cell line, individuals with 45,X/46,XX are taller and have fewer abnormalities, although 80% of those with 45,X/46,XX mosaics are shorter than their peers, and 66% have some somatic abnormalities. Spontaneous menstruation occurs in approximately 20% of these patients (10).

Pure Gonadal Dysgenesis

Individuals who are phenotypically female with sexual infantilism, primary amenorrhea, normal stature, and no chromosomal abnormalities (46,XX or 46,XY) have pure gonadal dysgenesis The gonads are usually streaks, but there may be some development of secondary sexual characteristics, as well as a few episodes of uterine bleeding.

Swyer syndrome occurs when mutations in the SRY (sex-determining region gene on the Y chromosome) located at Yp11 result in XY females with gonadal dysgenesis (11,12). This explains 15% to 20% of women who are 46,XY. Most of the mutations in SRY cause abnormalities in the DNA-binding domain (the human menopausal gonadotropin box) of the protein (13).

Mutations in other genes such as SOX9, DAX1, WT-1, and SF 1, which affect testicular differentiation and inhibit antimüllerian hormone production, also result in XY pure gonadal dysgenesis. The SOX9 gene located at 17q24 has a role in testis differentiation and promotes antimüllerian hormone secretion. Some but not all mutations in the SOX9 gene are known to cause XY sex reversal, along with campomelic dysplasia (severe skeletal abnormalities) (14,15). Duplications of the DAX 1 gene at Xp21 cause dose-sensitive XY sex reversal (16). DAX 1 is hypothesized to antagonize the SRY gene, preventing testis development. Transgenic XY mice with overexpression of the DAX 1 gene develop as phenotypic females, supporting this hypothesis (13). Mutation in the WT 1 gene (Wilms' tumor suppressor gene 1) located at 11p13 causes several different syndromes, depending on where the mutation in the gene occurs. In Frasier syndrome, there is alternative splicing, which causes the protein product to lack a highly conserved KTS triplet repeat. The normal +KTS isoform of the protein is believed to synergize with SF 1 (steroidogenic factor 1) to promote the expression of antimüllerian hormone. Lack of the +KTS isoform in an XY patient results in normal female internal and external genitalia, streak gonads, and progressive glomerulopathy. **These women frequently develop gonadoblastomas but rarely develop Wilms' tumor, which is associated with mutations in other locations in the WT 1 gene.** XX patients with the mutation that prevents the +KTS isoform have similar

kidney abnormalities but develop normal ovaries and genitalia (13,17,18). One XY patient with a heterozygous mutation of the *SF 1* gene had adrenal failure and sex reversal (19). *SF 1* is an orphan nuclear receptor that not only regulates AMH expression but also regulates all the cytochrome P450 steroid hydroxylase enzymes (18).

Duplication of 1p, which encodes the *WNT 4* gene, has caused XY sex reversal. *WNT 4* may upregulate DAX 1 transcripts. A TRX mutation has also caused XY sex reversal. Other genes that cause XY gonadal dysgenesis are likely to be identified in the future. Mutations at 9p24 and 10q cause XY sex reversal, but the exact genes causing the defects have not yet been elucidated (13,18,20).

XX pure gonadal dysgenesis can be caused by the presence of small Y chromosome fragments in their genome. It is estimated that 5% to 40% of patients with Ullrich–Turner syndrome were found to have Y sequences by polymerase chain reaction (PCR), depending on the DNA sequences targeted for testing (21,22). If Y sequences are present, gonadectomy is advised because of the risk of gonadoblastoma (21). In other patients with XX gonadal dysgenesis, the condition is likely to be caused by genes that lead to ovarian failure before pubertal development, resulting in streak gonads. Genes that cause ovarian failure are discussed later in this chapter.

Mixed Gonadal Dysgenesis

Most patients are XY and have ambiguous genitalia with a streak gonad on one side and a malformed testis on the opposite. A small proportion of these patients have mutations in the *SRY* gene (13).

Enzyme Deficiencies

Congenital Lipoid Adrenal Hyperplasia

Patients with this autosomal recessive disorder are unable to convert cholesterol to pregnenolone, which is the first step in steroid hormone biosynthesis. A defect has not been found in the *P450scc* gene, which is the conversion enzyme responsible for this step in the pathway. Instead, 15 different mutations have been identified in the steroidogenic acute regulatory protein (StAR), which facilitates the transport of cholesterol from the outer to the inner mitochondrial membrane. This protein appears to be the rate-limiting step for steroid hormone biosynthesis stimulated by tropic hormones. These patients present in infancy with hyponatremia, hyperkalemia, and acidosis. Both XX and XY individuals are phenotypically female. Genetic clusters of the disorder are found in the Japanese/Korean and Palestinian Arab populations. With appropriate mineralocorticoid and glucocorticoid replacement, these patients can survive into adulthood. Most patients are XY and do not have a uterus. Without hormone replacement, they remain sexually infantile. XX patients may acquire secondary sexual characteristics at puberty but develop large ovarian cysts and early ovarian failure as a result of accumulation of cholesterol in the ovaries (23,24).

17 α -Hydroxylase and 17,20-Desmolase Deficiency

Mutations in the *CYP17* gene cause abnormalities in both the **17 α -hydroxylase and 17,20-desmolase functions of the protein that is active in the adrenal and gonadal steroidogenic pathways.** More than 20 mutations that alter the reading frame of the gene have been identified, even though fewer than 200 people have the disorder (25).

Patients have either 46,XX or 46,XY karyotypes. The uterus is absent in individuals with 46,XY karyotype, a feature distinguishing them from individuals with 46,XX karyotype. Individuals with CYP17 mutations have primary amenorrhea, no secondary sexual characteristics, female phenotype, hypertension, and hypokalemia (26). The diminished levels of 17 α -hydroxylase that characterize this disorder lead to a reduction in cortisol production, which in turn causes an increase in adrenocorticotrophic hormone (ACTH). 17 α -hydroxylase is not required for production of mineralocorticoids; thus, excessive amounts of mineralocorticoid are produced, resulting in sodium retention, loss of potassium, and hypertension. Patients with **17 α -hydroxylase deficiency have primordial follicles, but gonadotropin levels are elevated because the enzyme deficiency prevents synthesis of sex steroids.**

Aromatase Deficiency

This rare autosomal recessive abnormality, which has only been reported in six cases, prevents the affected individual from aromatizing androgens to estrogen. **This syndrome may be suspected even before birth because most mothers of**

P.1042

affected children also become virilized during pregnancy. This occurs because the placenta cannot convert the fetal androgens to estrogen, and they are diffused into the maternal circulation. At birth, a female child has clitoromegaly and posterior labioscrotal fusion. At puberty, there is no breast development, primary amenorrhea, worsening virilization, absent growth spurt, delayed bone age, and multicystic ovaries. The diagnostic hormonal pattern consists of an elevation of FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) levels, and undetectable levels of estradiol. Estrogen therapy has been shown to improve the ovarian and skeletal abnormalities but must be titrated to mimic normal estrogen levels. Therefore, amounts given should be minimal during childhood and then increased at puberty (27,28).

Gonadotropin Receptor Mutations

Luteinizing Hormone Receptor Mutation

Inactivation of LH receptors has been identified in XY pseudohermaphrodites with primary amenorrhea in the absence of secondary sexual characteristics caused by homozygous premature stop codon, deletions, and missense mutations in the LHR gene located on chromosome 2. The Leydig cells in these individuals are unable to respond to LH, causing Leydig cell hypoplasia. This leads to early testicular failure and prevents masculinization. XX siblings with the same mutations develop normal secondary sexual characteristics but are amenorrheic with elevated LH levels, normal FSH levels, and cystic ovaries (29,30).

Follicle-Stimulating Hormone Receptor Mutation

An autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor, which prevents FSH binding, has been identified in six families in Finland. This condition leads to primary or early secondary amenorrhea, variable development of secondary sexual characteristics, and high levels of FSH and LH (31).

Other Causes of Primary Ovarian Failure

Amenorrhea and premature ovarian failure can occur in association with irradiation of the ovaries (32), chemotherapy with alkylating agents (e.g., cyclophosphamide) (33), or combinations of radiation and other chemotherapeutic agents. In girls, galactosemia often

is associated with premature ovarian failure, but it usually is detected by newborn screening programs. **Gonadotropin resistance, autoimmune ovarian failure, and ovarian failure resulting from infectious and infiltrative processes have also been described.**

Hypogonadotropic Hypogonadism

Primary amenorrhea resulting from hypogonadotropic hypogonadism occurs when the hypothalamus fails to secrete adequate amounts of GnRH or when a pituitary disorder associated with inadequate production or release of pituitary gonadotropins is present.

Physiologic Delay

Physiologic or constitutional delay of puberty is the most common manifestation of hypogonadotropic hypogonadism. Amenorrhea may result from the lack of physical development caused by delayed reactivation of the GnRH pulse generator.

Levels of GnRH are functionally deficient in relation to chronologic age but normal in terms of physiologic development.

Kallmann Syndrome

The second most common hypothalamic cause of primary amenorrhea associated with hypogonadotropic hypogonadism is insufficient pulsatile secretion of GnRH (Kallmann syndrome), which has varied modes of genetic transmission, as discussed in Chapter 26. Insufficient pulsatile secretion of GnRH leads to deficiencies in FSH and LH. Deficiencies in GnRH may also be caused by developmental or genetic defects, inflammatory processes, tumors, vascular lesions, or trauma. Patients with isolated deficiencies of LH and FSH usually are a normal height for their age, whereas

P.1043

patients with physiologic delay of puberty are usually short for their chronologic age but normal for their bone age (34).

Central Nervous System Tumors

Central nervous system tumors that lead to primary amenorrhea, the most common of which is craniopharyngioma, are usually extracellular masses that interfere with the synthesis and secretion of GnRH or stimulation of pituitary gonadotropins. Virtually all of these patients have disorders in the production of other pituitary hormones as well as LH and FSH (35,36). Prolactin-secreting pituitary adenomas are rare in childhood and more commonly occur after development of secondary sexual characteristics.

Genetic Disorders

5 α -Reductase Deficiency

5 α -Reductase deficiency should also be considered as a cause of amenorrhea (37). Patients with this disorder are genotypically XY, frequently experience virilization at puberty, have testes (because of functioning Y chromosomes), and have no müllerian structures as a result of functioning AMH. 5 α -Reductase converts testosterone to its more potent form, dihydrotestosterone. **Patients with 5 α -reductase deficiency differ from patients with androgen insensitivity because they do not develop breasts at puberty. These patients have**

low gonadotropin levels as a result of testosterone levels that are sufficient to suppress breast development and allow normal feedback mechanisms to remain intact. Normal male differentiation of the urogenital sinus and external genitalia do not occur because dihydrotestosterone is required for this development. However, normal internal male genitalia derived from the wolffian ducts are present because this development requires only testosterone. Male pattern hair growth, muscle mass, and voice deepening are also testosterone dependent.

Gonadotropin-releasing Hormone Receptor Mutations

Several mutations have been identified in the GnRH receptor gene that cause abnormal GnRH function. Most affected patients are compound heterozygotes, but homozygous autosomal recessive mutations have also been identified. The GnRH receptor is a G-protein-coupled receptor. Functional studies show that the mutations either cause marked decrease in binding of GnRH to its receptor or prevent second-messenger signal transduction. Without a functional signal transduction, FSH and LH are not stimulated and are unable to promote follicular growth (38). All patients are normosomic. **Receptor mutations in GnRH cause 17% of sporadic cases of idiopathic hypogonadotropic hypogonadism with normal olfaction** (39).

Follicle-stimulating Hormone Deficiency

Patients with FSH deficiency usually seek treatment for delayed puberty and primary amenorrhea caused by hypoenestrogenism. They are distinguished from other hypoenestrogenic patients by having decreased FSH levels and increased LH levels. These patients have low serum androgen levels despite the abnormal LH-to-FSH ratio, indicating that FSH-stimulated follicular development is a prerequisite for thecal cell androgen production. In some of these patients, autosomal recessive mutations in the FSH β subunit, which impair dimerization of α and β subunits and prevent binding to the FSH receptor, have been identified (40). Pregnancy was achieved in one patient after induction of ovulation with injectable gonadotropins (41).

Other Hypothalamic/Pituitary Dysfunctions

Functional gonadotropin deficiency results from malnutrition, malabsorption, weight loss or anorexia nervosa, excessive exercise, chronic disease, neoplasias, and marijuana use (42,43,44,45,46). Hypothyroidism, polycystic ovarian syndrome (PCOS), Cushing syndrome, hyperprolactinemia, and infiltrative disorders of the central nervous system are rare causes of primary amenorrhea (47,48). Constitutional delay without

P.1044

underlying causes is less common in girls than in boys, and the reason for lack of development should be vigorously pursued (49).

Diagnosis

A careful history and physical examination are necessary to appropriately diagnose and treat primary amenorrhea associated with hypogonadism. The physical examination may be particularly helpful in patients with Turner syndrome. A history of short stature but consistent growth rate, a family history of delayed puberty, and normal physical findings (including assessment of smell, optic disks, and visual fields) may suggest physiologic delay. Headaches, visual disturbances, short stature, symptoms of diabetes insipidus, and weakness of one or more limbs suggest central nervous system lesions (36). Galactorrhea may be seen with prolactinomas. The history of galactorrhea may provide helpful information in

the diagnosis of postinfectious, inflammatory, or vascular lesions of the central nervous system; trauma; anorexia nervosa; stress-related amenorrhea; or other systemic disease process.

The diagnostic workup is summarized as follows: .

- **The initial laboratory test should be assessment of serum FSH levels unless the history and physical examination suggest otherwise.** The FSH level differentiates hypergonadotropic and hypogonadotropic forms of hypogonadism. If the FSH level is elevated, a karyotype should be obtained. An elevated FSH level in combination with a 45, X karyotype confirms the diagnosis of Turner syndrome. Partial deletion of the X chromosome, mosaicism, pure gonadal dysgenesis, and mixed gonadal dysgenesis are diagnosed by obtaining a karyotype.
- **Because of the association with coarctation of the aorta (up to 30%) and thyroid dysfunction, patients with Turner syndrome should undergo echocardiography every 3 to 5 years and thyroid function studies yearly.** They should also be evaluated for hearing loss and hypertension.
- **If the karyotype is abnormal and contains the Y chromosome, as in gonadal dysgenesis, the gonads should be removed to prevent tumors.** Patients should also be screened for nephrotic syndrome, which can occur in Frasier syndrome.
- **If the karyotype is normal and the FSH level is elevated, it is important to consider the diagnosis of 17 α -hydroxylase deficiency because it may be a life-threatening disease if untreated.** This diagnosis should be considered when testing indicates elevated serum progesterone (>3.0 ng/mL) levels, a low 17 α -hydroxyprogesterone (0.2 ng/mL) level, and an elevated serum deoxycorticosterone level (DOS) (50). The diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of serum progesterone compared with baseline levels and no change in serum 17 α -hydroxyprogesterone levels.
- **If the screening FSH level is low, the diagnosis of hypogonadotropic hypogonadism is established..**
- **Central nervous system lesions should be ruled out by imaging using computed tomography (CT) or magnetic resonance imaging (MRI), especially if galactorrhea, headaches, or visual field defects are identified.** Suprasellar or intrasellar calcification in an abnormal sella is found in approximately 70% of patients with craniopharyngioma (36).

- **Physiologic delay is a diagnosis of exclusion that is difficult to distinguish from insufficient GnRH secretion.** The diagnosis can be supported by a history suggesting physiologic delay, an x-ray showing delayed bone age, and the absence of a central nervous system lesion on computed tomography (CT) or MRI scanning.
- **Gonadotropin-deficient patients can usually be distinguished from patients**

with physiologic delay by their response to GnRH stimulation. Patients with physiologic delay have a normal LH response to GnRH stimulation for their bone age, in contrast with gonadotropin-deficient patients, in whom the LH and FSH responses are low (51).

Treatment of Amenorrhea

Individuals with primary amenorrhea associated with all forms of gonadal failure and hypergonadotropic hypogonadism need cyclic estrogen and progestin therapy to initiate, mature, and maintain secondary sexual characteristics. Prevention of osteoporosis is an additional benefit of estrogen therapy:

- **Therapy is usually initiated with 0.625 mg/day of conjugated estrogens or 1 mg/day of estradiol.**
- **If the patient is short in stature, higher doses should not be used in an attempt to prevent premature closure of the epiphyses.** Most of these patients are of normal height, however, and higher estrogen doses may be used initially and then reduced to the maintenance doses after several months.
- **Estrogen can be given daily in combination with progestin (*medroxyprogesterone acetate*) or progesterone to prevent unopposed estrogen stimulation of the endometrium in patients with a uterus.** *Medroxyprogesterone acetate* may be administered at a dose of 2.5 mg daily or 5 to 10 mg for 12 to 14 days every 1 to 2 months. Oral micronized progesterone may be administered at a dose of 100 mg daily or 200 mg for 12 to 14 days every 1 to 2 months. Likewise, progesterone suppositories may be administered at a dose of 50 mg daily or 100 mg for 12 to 14 days every 1 to 2 months.
- **Occasionally, individuals with mosaicism and gonadal streaks may ovulate and be able to conceive either spontaneously or after the institution of estrogen replacement therapy (52).**
- **If 17 α -hydroxylase deficiency is confirmed, treatment is instituted with corticosteroid replacement as well as estrogen.** Progestin is added if the patient has a uterus.

If possible, therapeutic measures are aimed at correcting the primary cause of amenorrhea:

- **Craniopharyngiomas may be resected with a transsphenoidal approach or during craniotomy,** depending on the size of the tumor. Some studies have shown improved prognosis with radiation therapy used in combination with limited tumor removal (36,53).
- **Germinomas are highly radiosensitive, and surgery is rarely indicated (54).**
- **Prolactinomas and hyperprolactinemia often may respond to dopamine agonists (*bromocriptine or cabergoline*) (55).**

- **Specific therapies are directed toward malnutrition, malabsorption, weight loss, anorexia nervosa, exercise amenorrhea, neoplasia, and chronic diseases..**
- **Logically, it would appear that patients with hypogonadotropic hypogonadism of hypothalamic origin should be treated with long-term administration of pulsatile GnRH. This form of therapy is often impractical,** however, because of the necessity to use an indwelling catheter and a portable pump for prolonged periods. Therefore, these patients should be treated with cyclic estrogen and progestin therapy at least until sexual maturity is achieved. Once sexual maturation is achieved, hormone replacement therapy can be continued to treat hypoestrogenic symptoms. Alternatively, consideration may be given to nonestrogenic regimens, such as bisphosphonates for maintenance of bone mass and prevention of osteoporosis.
- **Patients with Kallmann syndrome, as well as patients with exercise or stress amenorrhea and anorexia and weight loss, are treated with hormone replacement in a similar fashion as described for hypogonadotropic hypogonadism.**
- **If the patient has physiologic delay of puberty, the only management required is reassurance** that the anticipated development will occur eventually (56).

Individuals whose karyotypes contain a Y cell line (45,X/46,XY mosaicism, or pure gonadal dysgenesis 46,XY) are predisposed to gonadal ridge tumors, such as gonadoblastomas, dysgerminomas, and yolk sac tumors. The gonads of these individuals should be removed when the condition is diagnosed to prevent malignant transformation (34,50). There is some evidence that hirsute individuals without Y chromosomes should also undergo gonad removal. One patient with hirsutism and the karyotype 45,X was noted to have a streak gonad; the contralateral gonad was dysgenic and contained developing follicles, well-differentiated seminiferous tubules, and Leydig cells. This patient was found to be HY antigen-positive (57). Clomiphene citrate is ineffective in inducing ovulation in patients with hypogonadism who desire pregnancy because such patients are hypoestrogenic. In patients with hypogonadism, ovulation induction with injectable gonadotropins is generally successful, and pulsatile treatment with GnRH may be used in patients who have normal pituitary function. In patients without ovarian function, oocyte donation may be appropriate. **There have been recent reports of deaths in pregnant patients with Turner syndrome resulting from aortic dissection and rupture** (58). Careful counseling and investigation should be undertaken in patients with Turner syndrome before treating them with donated oocytes. Because most patients with hypogonadism and lack of sexual development are young, pregnancy is not desired.

Amenorrhea with Secondary Sexual Characteristics and Anatomic Abnormalities

Causes

Anatomic Abnormalities

Amenorrhea occurs if there is blockage of the outflow tract or if the outflow tract is missing (Table 27.2). An intact outflow tract includes a patent vagina as well as a functioning cervix and uterus. Any transverse blockage of the müllerian system (Buttram and Gibbons classification I) will cause amenorrhea (59). Such outflow obstructions include imperforate hymen, transverse vaginal septum, and hypoplasia or absence of

P.1047

the uterus, cervix, and vagina (Mayer–Rokitansky–Küster–Hauser syndrome).

Mayer–Rokitansky–Küster–Hauser syndrome has been associated with abnormal galactose metabolism (60). Of the patients with this syndrome, 15% have an absent, pelvic, or horseshoe kidney; 40% have a double urinary collecting system (61,62); and 5% to 12% have skeletal abnormalities (63). Transverse blockage of the outflow tract with an intact endometrium frequently causes cyclic pain without menstrual bleeding in adolescents. The blockage of blood flow can cause hematocolpos, hematometra, or hemoperitoneum. Endometriosis may develop.

Table 27.2 Anatomic Causes of Amenorrhea
<i>Secondary sexual characteristics present</i>
Müllerian anomalies
Imperforate hymen
Transverse vaginal septum
Mayer–Rokitansky–Küster–Hauser syndrome
Androgen insensitivity
True hermaphrodites
Absent endometrium
Asherman's syndrome
Secondary to prior uterine or cervical surgery
Curettage, especially postpartum
Cone biopsy
Loop electroexcision procedure
Secondary to infections
Pelvic inflammatory disease
IUD-related
Tuberculosis
Schistosomiasis
IUD, intrauterine device.

When the findings of the physical examination are normal, anatomic abnormalities may still be considered. A congenitally absent endometrium is a rare finding in patients with primary amenorrhea. Asherman syndrome, which is more common with secondary amenorrhea or hypomenorrhea, may occur in patients with risk factors for endometrial or cervical scarring. Such risk factors include a history of uterine or cervical surgery, infections related to use of an intrauterine device, and severe pelvic inflammatory disease. Asherman syndrome is found in 39% of patients undergoing hysterosalpingography who have previously undergone postpartum curettage (64). Infections such as tuberculosis and schistosomiasis may cause Asherman syndrome but are rare in the United States. Cervical stenosis resulting from surgical removal of dysplasia (cone biopsy, loop electroexcision procedure) may also lead to amenorrhea.

Androgen Insensitivity

Phenotypic females with complete congenital androgen insensitivity (previously called testicular feminization) develop secondary sexual characteristics but do not have menses. These patients are male pseudohermaphrodites. Genotypically, they are male (XY) but have a defect that prevents normal androgen receptor function, leading to the development of the female phenotype. Defects in the androgen receptor

P.1048

gene located on the X chromosome include absence of the gene that encodes for the androgen receptor and abnormalities in the binding domains of the receptor.

Androgen receptor deficits are diverse and may result from diminished receptor function or concentration. The diversity of androgen receptor mutations may be related to diversity in phenotype. More than 250 extremely diverse mutations have been described, with amino acid substitution being the far most common (65,66). Postreceptor defects also exist (67).

Total serum testosterone concentration is in the range of normal males. Because antimüllerian hormone is present and functions normally in these patients, internal female (müllerian) structures such as a uterus, vagina, and fallopian tubes are absent.

Testes rather than ovaries are present in the abdomen or in inguinal hernias because of the presence of normally functioning genes on the Y chromosome. Patients have a blind vaginal pouch and scant or absent axillary and pubic hair. These patients experience abundant breast development at puberty; however, the nipples are immature and the areolae are pale. Testosterone is not present during development to suppress the formation of breast tissues; at puberty, the conversion of testosterone to estrogen stimulates breast growth.

P.1049

Patients are unusually tall with eunuchoidal tendency (long arms with big hands and feet) (Fig. 27.2).

Figure 27.2 A: A well-developed patient with complete androgen insensitivity. Note the characteristic paucity of pubic hair and well-developed breasts. (From **Yen SSC, Jaffe RB.** *Reproductive endocrinology*. 3rd ed. Philadelphia, PA: WB Saunders, 1991:497, with permission.)
B: Another patient with androgen insensitivity syndrome with a contrasting thin body habitus. This is a 17-year-old twin 46,XY. (From **Jones HW Jr, Scott WW.** *Hermaphroditism, genital anomalies, and related endocrine disorders*. 2nd ed. Baltimore, MD: Williams & Wilkins, 1971, with permission.).

True Hermaphroditism

True hermaphroditism is a rare condition that should be considered as a possible cause of amenorrhea. Both male and female gonadal tissue are present in these patients, in whom XX, XY, and mosaic genotypes have been found. Two thirds of the patients menstruate, but menstruation has never been reported in XY genotypes. The external genitalia usually is ambiguous, and breast development frequently occurs in these individuals. **Fifteen percent of XX true hermaphrodites have SRY translocations, and another 10% have Y chromosomal mosaicism within the gonad (13).**

Diagnosis

Most congenital abnormalities can be diagnosed by physical examination:

- **An imperforate hymen is diagnosed by the presence of a bulging membrane that distends during Valsalva maneuver.** Ultrasonography or MRI is useful to identify the müllerian anomaly when the abnormality cannot be found by physical examination. The patient should also be examined for skeletal malformations and assessed with intravenous pyelography to detect concomitant renal abnormalities. These abnormalities occur less frequently than in müllerian agenesis (62).
- **It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a male pseudohermaphrodite. Androgen insensitivity is diagnosed when pubic and axillary hair is absent.** To confirm the diagnosis, a karyotype determination should be performed to see whether a Y chromosome is present. In some patients, the defect in the androgen receptor is not complete, and virilization occurs.
- **An absent endometrium is an outflow tract abnormality that cannot be diagnosed by physical examination in a patient with primary amenorrhea.** This abnormality is so rare that in a patient with normal physical findings, it may be advisable to proceed with evaluation of endocrine abnormalities. Absence of the endometrium should be suspected in patients with primary amenorrhea and normal secondary sexual characteristics when the results of

hormonal studies are normal and the patients do not bleed after withdrawal of combined estrogen and progesterone replacement.

Asherman syndrome also cannot be diagnosed by physical examination. It is diagnosed by performing hysterosalpingography, saline infusion, ultrasonography, or hysteroscopy. These tests will show either complete obliteration or multiple filling defects caused by synechiae (Fig. 27.3). If tuberculosis or schistosomiasis is suspected, endometrial cultures should be performed.

Figure 27.3 A: Intrauterine adhesion seen on hysterosalpingogram in a patient with Asherman syndrome. B: Hysteroscopic view of intrauterine adhesion in a patient with Asherman syndrome (From **Donnez J, Nisolle M.** *The encyclopedia of visual medicine series—an atlas of laser operative laparoscopy and hysteroscopy.* New York, NY: Parthenon Publishing Group, 1994: 306, with permission.).

Treatment

The treatment of congenital anomalies can be summarized as follows:.

- **Treatment of an imperforate hymen involves making a cruciate incision to open the vaginal orifice.** Most imperforate hymens are not diagnosed until a hematocolpos forms. It is unwise to place a needle into a hematocolpos without completely removing the obstruction because a pyocolpos may occur.
- **If a transverse septum is present, surgical removal is required.** Forty-six percent of transverse septa occur in the upper third of the vagina, and 40% occur

P.1050

in the middle third of the vagina (68). Frank dilators should be used to distend the vagina until it is healed to prevent vaginal adhesions (69). Patients have a fully functional reproductive system after surgery; however, patients with repaired high transverse septa have lower pregnancy rates (70).

- **Hypoplasia or absence of the cervix in the presence of a functioning uterus is more difficult to treat than other outflow obstructions.** Surgery to repair the cervix has not been successful, and hysterectomy is required (71). Endometriosis is a common finding, and it is questionable whether this condition should be treated initially with surgery or if it will resolve spontaneously after surgical repair of the obstruction. The ovaries should be retained to provide the benefits of estrogen and to allow for the possibility of future childbearing by removing mature oocytes for *in vitro* fertilization using a gestational carrier mother.
- **If the vagina is absent or short, progressive dilation is usually successful in making it functional** (69,72). If dilation fails or the patient is unable to perform dilation, the McIndoe split thickness graft technique may be performed (62,73,74). The initial use of vaginal dilators is required to maintain a functional vagina.

P.1051

In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration (75). In patients with testes, 52% develop a neoplasia, most often a gonadoblastoma. Almost one half of the testicular neoplasms are malignant (dysgerminomas), but transformation usually does not occur until after puberty (76). In patients who develop virilization and have an XY karyotype, the testes should be removed immediately to preserve the female phenotype and to promote female gender identity. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intra-abdominal testes.

Adhesions in the cervix and uterus (Asherman syndrome) can be removed using hysteroscopic resection with scissors or electrocautery. A pediatric Foley catheter should be placed in the uterine cavity for 7 to 10 days postoperatively (along with systemic administration of broad-spectrum antibiotic therapy), and a 2-month course of high-dose estrogen therapy with monthly progesterone withdrawal is used to prevent reformation of adhesions. Eighty percent of patients thus treated achieve pregnancy, but complications including miscarriage, preterm labor, placenta previa, and placenta accreta are common (77). Cervical stenosis can be treated by cervical dilation.

P.1052

Amenorrhea with Secondary Sexual Characteristics and Nonanatomic Causes

Pregnancy must be considered in all women of reproductive age with amenorrhea.

Thyroid dysfunction and hyperprolactinemia also are frequent causes of amenorrhea and are discussed further in Chapter 28. Amenorrhea with secondary sexual characteristics and normal anatomy can be caused by ovarian failure, pituitary/hypothalamic lesions, and abnormal hypothalamic GnRH secretion.

Causes

Ovarian Failure

Ovarian failure is a normal occurrence during menopause. The age of menopause is determined by genetic inheritance. Once a patient is exposed to estrogen, estrogen withdrawal causes hot flashes and vaginal dryness. This occurs in approximately 50% of patients, whether ovarian failure is premature or occurs at the normal age (78). Physical examination reveals vaginal mucosal atrophy and no cervical mucus. **Ovarian failure occurs before 40 years of age in 1% to 5% of women and is considered pathologic (premature ovarian failure).** Early failure may be caused by decreased follicular endowment or accelerated follicular atresia. **If ovarian failure occurs before puberty, the patient's breasts will not develop (i.e., Turner syndrome), and gonadal agenesis results** (Tables 27.1 and 27.3).

Table 27.3 Causes of Ovarian Failure after Development of Secondary Sexual Characteristics

Chromosomal etiology.
Iatrogenic causes.
Radiation.
Chemotherapy.
Surgical alteration of ovarian blood supply.
Infections
Autoimmune disorders
Galactosemia (mild form or heterozygote)
Savage syndrome
Cigarette smoking
Idiopathic

Despite the array of causes of ovarian failure, in most cases the etiology cannot be determined. In some patients, ovarian failure resolves spontaneously. Pregnancies have been reported to occur after the diagnosis of ovarian failure in less than 0.09% to 8.2% of patients (78,79).

Cigarette smoking has been shown to have a clear inverse dose–response relationship with age of menopause (80). Other studies have confirmed this association, some eliminating potential confounding factors such as body weight, which could affect the age of menopause (81). Cigarette smoking alters both gametogenesis and hormonogenesis, suggesting an effect on the follicle. Smoking has also been shown to increase the risk of diminished ovarian reserve (82).

P.1053

Sex Chromosome Disorders

Deletion of the X chromosome (Turner syndrome) is associated with premature ovarian failure despite normal development of the ovaries because of accelerated atresia of the follicles (83). Mosaicism of an XO or XY cell line may cause ovarian failure in patients younger than 30 years of age. A deletion of a portion of the X chromosome may be present in patients with premature ovarian failure. The Xq21–28 region is critical (7,84). Several genes in this region have been identified as the cause of ovarian failure in humans. Examples include the *POF1B* gene located at Xq21 (85), the *DIAPH2* gene located at distal Xq21 (85), and the *XPNPEP2* gene located at Xq25 (86). The specific functions of these genes require further investigation. Undoubtedly, more genes that cause ovarian failure will be identified (87). In addition, a mutation of the *BMP15* gene located at Xp11.2 has been identified in two patients with premature ovarian failure (88). Mutations in the autosomal genes *FOXL2* and *ATM* have been shown to cause premature ovarian failure (13,89).

Individuals with a 47,XXX karyotype also may develop ovarian failure. Familial ovarian failure is inherited by dominant Mendelian inheritance in some cases (90).

Fragile X Carriers

Fragile X syndrome is the most common cause of inherited (X–linked) mental retardation. It is caused by inactivation of the *FMR1* gene located on Xq27.3 as a result of expansion of a CGG triplet repeat of more than 200 copies. The normal population has an average size repeat of 30. Female carriers of the disorder have between 60 to 200 repeats (premutations) and are not mentally retarded. These premutations are unstable and can expand in the next generation to transmit fragile X syndrome to male offspring, especially with individuals who have more than 100 repeats. Women who have premutations have a 15%

to 25% chance of premature ovarian failure (91,92). Interestingly, women with full mutations are not at higher risk for premature ovarian failure. It is hypothesized that expression of abnormal FMR1 mRNA produced by patients with the premutation causes dysfunction in the ovary, which does not occur when the *FMR1* gene is inactivated and not transcribed (91,92). **Patients with premature ovarian failure have a 4% to 5% chance of having the premutation for fragile X . If premature ovarian failure is present in another family member, the chance of finding a premutation increases to 15% (91,93).**

Iatrogenic Causes

Radiation, chemotherapy (especially alkylating agents such as cyclophosphamide) (94), surgical interference with ovarian blood supply, and infections can cause ovarian failure from early loss of follicles. A radiation dose of 800 cGy causes sterility in most individuals. Ovarian failure can be caused by as little as 150 cGy in some patients, especially if they are older than 40 years of age with limited follicle reserves.

In an evaluation of ovarian function in 100 childhood cancer survivors, 17 had premature ovarian failure. Those with spontaneous menses had smaller ovarian volume, fewer antral follicles, and lower inhibin B levels when compared with controls (95). Ovarian suppression with GnRH agonists and oral contraceptives to reduce the risk of ovarian failure have not been promising (96,97). Improvements in techniques of oocyte and ovarian tissue cryopreservation may allow future pregnancies in patients requiring treatments that cause follicular destruction (98,99).

Infections

In rare cases, mumps has been associated with premature ovarian failure (100). Tubo-ovarian abscess, even in the absence of surgical treatment, has also been associated with follicular destruction and premature ovarian failure (49). Cytomegalovirus has been shown postmortem to cause oophoritis, but premature ovarian failure had not developed yet clinically in the patient, so the relationship of cytomegalovirus to ovarian failure is unclear (101).

Autoimmune Disorders

Premature ovarian failure may be part of a polyglandular autoimmune syndrome. Antibodies are present in a variable number of patients with premature ovarian failure, depending on the autoimmune studies performed. One study showed that 92% of patients with premature ovarian failure had autoantibodies (102).

P.1054

However, only 20% of these patients exhibited signs of immunologic dysfunction, most frequently in the form of a thyroid disorder (79). Before treatment for thyroid deficiency, adrenal insufficiency characterized by hyperpigmentation, weakness, nausea, vomiting, diarrhea, and weight loss should be ruled out; otherwise, adrenal crisis may occur (12). Rarely, premature ovarian failure is associated with myasthenia gravis, idiopathic thrombocytopenia purpura, rheumatoid arthritis, vitiligo, autoimmune hemolytic anemia, diabetes mellitus, and other autoimmune disorders (103,104,105).

Galactosemia

Galactosemia is caused by a lack of functional galactose-1-phosphate uridylyl transferase. Galactose metabolites appear to have toxic effects on ovarian follicles, causing their premature destruction (106). Cataracts and mental retardation are also associated with galactosemia. There is also evidence that heterozygote carriers of this disorder may

Pituitary and hypothalamic

Craniopharyngioma

Germinoma

Cushing's disease

Acromegaly

Primary hyperthyroidism

Infarction

Lymphocytic hypophysitis

Surgical or radiologic ablations

Sheehan's syndrome

Diabetic vasculitis

Pituitary Lesions

Hypopituitarism is rare because a large portion of the gland must be destroyed before decreased hormonal secretion affects the patient clinically. The pituitary gland may be destroyed by tumors (nonfunctioning or hormone secreting), infarction, infiltrating lesions such as lymphocytic hypophysitis, granulomatous lesions, and surgical or radiologic ablations.

P.1055

Sheehan syndrome is associated with postpartum necrosis of the pituitary resulting from a hypotensive episode that, in its severe form (pituitary apoplexy), presents with the patient in shock. The patient may develop a localized, severe, retro-orbital headache or abnormalities in visual fields and visual acuity. Patients with a mild form of postpartum pituitary necrosis cannot lactate, lose pubic and axillary hair, and do not menstruate after delivery.

Diabetic vasculitis and sickle cell anemia rarely manifest as pituitary failure. Hypopituitarism is associated with hyposecretion of ACTH and thyroid-stimulating hormone (TSH) as well as gonadotropins; therefore, thyroid and adrenal function also must be evaluated.

If hypopituitarism occurs before puberty, menses and secondary sexual characteristics will not develop..

Growth hormone (GH), TSH, ACTH, and prolactin also are secreted by the pituitary, and the excess production of each by pituitary tumors causes menstrual abnormalities. **Excess prolactin secretion is one of the more common causes of amenorrhea (2).** The menstrual abnormalities are caused by adverse effects of these hormones on the GnRH pulse generator and not by direct effects on the ovary. Prolactinomas are the most common hormone-secreting tumors in the pituitary (see Chapter 28).

Altered Hypothalamic Gonadotropin-releasing Hormone Secretion

Abnormal secretion of GnRH accounts for one third of patients with amenorrhea

(110). Chronic disease, malnutrition, stress, psychiatric disorders, and exercise inhibit GnRH pulses, thus altering the menstrual cycle (Table 27.5). Other hormonal systems that produce excess or insufficient hormones can cause abnormal feedback and adversely affect GnRH secretion. In hyperprolactinemia, Cushing disease (excess ACTH), and acromegaly (excess GH), excess pituitary hormones are secreted that inhibit GnRH secretion. It is uncommon

to have functional hypothalamic amenorrhea without a secondary cause. Prognosis for recovery is better if the precipitating cause of the amenorrhea can be reversed (111).

Idiopathic

^aSeverity of the condition determines estrogen status—the more severe, the more likely to manifest as hypoestrogenism.

When the decrease in GnRH pulsatility is severe, amenorrhea results. With less severe alterations in GnRH pulsatility, anovulation can occur. Even slight defects in the pulsatility may result in luteal phase defect.

The pulsatile secretion of GnRH is modulated by interactions with neurotransmitters and peripheral gonadal steroids. Endogenous opioids, corticotropin–releasing hormones (CRH), melatonin, and α -aminobutyric acid (GABA) inhibit the release of GnRH, whereas catecholamines, acetylcholine, and vasoactive intestinal peptide stimulate GnRH pulses. Dopamine and serotonin have variable effects (112).

Decreased leptin levels have been associated with hypothalamic amenorrhea

(113,114) regardless of whether it is caused by exercise, eating disorders, or idiopathic

factors. Leptin is a hormone secreted by adipocytes that is involved in energy hemostasis. Receptors are found in the hypothalamus and bone, making it an excellent candidate for a modulator of menstrual function and bone mass. Levels correlate with nutritional changes and body mass index. Administration of leptin to women with hypothalamic amenorrhea increases levels of LH, estradiol, insulinlike growth factor-1 (IGF-1), and thyroid hormone. Ovulation and increased bone mass also occurred in these patients (114).

Weight Loss and Dieting

Weight loss can cause amenorrhea even if weight doesn't decrease below normal. Loss of 10% body mass in 1 year is associated with amenorrhea. Some but not all of these women have an underlying eating disorder. Prognosis is good for the return of menses if the patients recover from the weight loss. Dieting without weight loss and changes in diet can also lead to amenorrhea (111).

Anorexia Nervosa

Anorexia nervosa is an eating disorder that affects 5% to 10% of adolescent women in the United States. The criteria for diagnosis of anorexia nervosa as stated in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) are refusal to maintain body weight above 15% below normal, an intense fear of becoming fat, altered perception of one's body image (ie, patients see themselves as fat despite being underweight), and amenorrhea. Patients attempt to maintain their low body weight by food restriction, induced vomiting, laxative abuse, and intense exercise. **This is a life-threatening disorder with a mortality rate as high as 9%.** Amenorrhea may precede, coincide, or follow the weight loss. Multiple hormonal patterns are altered. The 24-hour patterns of FSH and LH may show constantly low levels as seen in childhood or increased LH pulsatility during sleep consistent with the pattern seen in early puberty. Hypercortisolism is present despite normal ACTH levels, and the ACTH response to CRH administration is blunted. Circulating triiodothyronine (T₃) is low, yet circulating inactive reverse T₃ concentrations are high (115).

Patients may develop cold and heat intolerance, lanugo hair, hypotension, bradycardia, and diabetes insipidus. They may have yellowish discoloration of the skin resulting from elevated levels of serum carotene caused by altered vitamin A metabolism.

Patients with anorexia nervosa have combinations of restrictive and binge eating. Binge eating is associated with bulimia consisting of vomiting, laxative abuse, and diuretics to control weight. Signs of bulimia include tooth decay, parotid gland hypertrophy (chipmunk jowls), hypokalemia, and metabolic alkalosis (116).

Exercise

In patients with exercise-induced amenorrhea, there is a decrease in the frequency of GnRH pulses, which is assessed by measuring a decreased frequency of LH pulses. These patients are usually hypoestrogenic, but less severe alterations may cause minimal menstrual dysfunction (anovulation or luteal phase defect). The decrease in LH pulsatility can be caused by hormonal alterations, such as elevations in endogenous opioids, ACTH, prolactin, adrenal androgens, cortisol, and melatonin (117). Differences in body-fat content have been used to explain the different rates of amenorrhea by sport. Runners and

ballet dancers are at higher risk for amenorrhea than swimmers (118). It has been suggested that a minimum of 17% body fat is required for the initiation of menses and 22% body fat for the maintenance of menses (119). However, newer studies suggest that inappropriately low caloric intake during strenuous exercise is more important than body fat (120). **Higher-intensity training, poor nutrition, stress of competition, and associated eating disorders increase an athlete's risk for menstrual dysfunction (121). The "female athlete triad" consists of amenorrhea, osteoporosis, and eating disorders.**

P.1058

Osteoporosis may result in stress fractures during training and lifelong increased fracture risk. Stress fractures most commonly occur in the weight-bearing cortical bone such as the tibia, metatarsal, fibula, and femur. These athletes fail to reach peak bone mass and have abnormal bone mineralization. Scoliosis is also common (117).

Stress-induced Disorders

Stress-related amenorrhea can be caused by abnormalities in neuromodulation in hypothalamic GnRH secretion, similar to those that occur with exercise and anorexia nervosa. Excess endogenous opioids and elevations in CRH secretion inhibit the secretion of GnRH (112). These mechanisms are not fully understood but appear to be the common link between amenorrhea and chronic diseases, pseudocyesis, and malnutrition.

Obesity

Most obese patients have normal menstrual cycles, but the percentage of women with menstrual disorders increases from 2.6% in normal-weight patients to more than 8.4% in women above 75% ideal body weight. The menstrual disorder is more often irregular uterine bleeding with anovulation rather than amenorrhea. **Obese women have an excess number of fat cells in which extraglandular aromatization of androgen to estrogen occurs. They also have lower circulating levels of sex hormone-binding globulin, which allows a larger proportion of free androgens to be converted to estrone. Excess estrogen creates a higher risk for endometrial cancer for these women.** The decrease in sex hormone-binding globulin also allows an increase in free androgen levels, which initially are eliminated by an increased rate of metabolic clearance. This compensatory mechanism diminishes over time, and hirsutism can develop. Frequently, these patients are classified as having PCOS. Alterations in the secretion of endorphins, cortisol, insulin, growth hormone, and IGF-1 may interact with the abnormal estrogen and androgen feedback to the GnRH pulse generator to cause menstrual abnormalities.

Other Hormonal Factors

The secretion of hypothalamic neuromodulators can be altered by feedback from abnormal levels of peripheral hormones. Excesses or deficiencies of thyroid hormone, glucocorticoids, androgens, and estrogens can cause menstrual dysfunction. Even though **PCOS usually causes irregular bleeding rather than amenorrhea, it remains one of the most common causes of amenorrhea (2). It is likely that PCOS is the result of peripheral alteration in IGF-1, androgen, and estrogen levels, which leads to hypothalamic dysfunction** (see Chapter 28). Elevations in androgens (e.g., Sertoli-Leydig, hilus, and lipoid cell tumors) and estrogens (e.g., granulosa cell tumors) by ovarian tumors may lead to abnormal menstrual patterns, including amenorrhea. In patients who are hirsute and amenorrheic, androgen-secreting adrenal tumors and congenital adrenal hyperplasia should be considered.

Excess secretion of GH, TSH, ACTH, and prolactin from the pituitary gland can cause abnormal feedback inhibition of GnRH secretion, leading to amenorrhea.

Growth hormone excess causes acromegaly, which may be associated with anovulation, hirsutism, and polycystic ovaries as a result of stimulation of the ovary by IGF-1. More commonly, GH excess is accompanied by amenorrhea, low gonadotropin levels, and elevated prolactin levels. Acromegaly is recognized by enlargement of facial features, hands, and feet; hyperhidrosis; visceral organ enlargement; and multiple skin tags. Cushing disease is caused by an ACTH-secreting pituitary tumor, which is manifested by truncal obesity, moon facies, hirsutism, proximal weakness, depression, and menstrual dysfunction.

Diagnosis

A pregnancy test (urine or serum hCG) should be performed in a reproductive-age woman who has amenorrhea with normal secondary sexual characteristics and a normal pelvic examination. If the results of the pregnancy test are negative, the evaluation of amenorrhea is as follows:

P.1059

- **Serum TSH.**
- **Serum prolactin.**
- **FSH levels.**
- **Estrogen status.**
- **Imaging of the pituitary and hypothalamic assessment as necessary.**

Thyroid-stimulating Hormone and Prolactin Levels

Consideration should be given to thyroid disorders and hyperprolactinemia in women with amenorrhea due to the relatively common incidence of these conditions..

- **Sensitive TSH assays can be used to evaluate hypothyroidism and hyperthyroidism.** Further evaluation of a thyroid disorder is required if abnormalities in TSH levels are found.
- **Hyperprolactinemia is a common cause of anovulation in women. If elevated TSH and prolactin levels are found, the hypothyroidism should be treated before hyperprolactinemia is treated.** Often, the prolactin level will normalize with treatment of hypothyroidism because thyroid-releasing hormone, which is elevated in hypothyroidism, stimulates prolactin secretion.
- **Magnetic resonance imaging should be performed for persistently elevated prolactin levels..**

Follicle-stimulating Hormone Levels

Assessment of serum FSH levels is required to determine whether the patient has hypergonadotropic, hypogonadotropic, or eugonadotropic amenorrhea. **A circulating FSH level of greater than 25 to 40 mIU/mL indicated on at least two blood samples is indicative of hypergonadotropic amenorrhea.** Hypergonadotropism signifies that the cause of amenorrhea is at the level of the ovary. The history should establish whether the cause of ovarian failure is chemotherapy or radiation therapy. A galactose-1 phosphate uridyl transferase level should be measured to assess the patient for galactosemia or carrier status. Fragile X carrier status should be evaluated in patients with first-degree relatives with premature ovarian failure.

In patients younger than 30 years of age with hypergonadotropic amenorrhea, a karyotype is required to rule out the presence of a Y cell line. *In situ* hybridization studies may prove the existence of Y chromosomal material with a Y-specific probe when the karyotype is normal (122). It is important to identify Y chromosomal material so it may be removed to prevent malignant degeneration.

There is much debate regarding the extent of an autoimmune workup required for a patient with ovarian failure: .

- It is reasonable to screen patients with nonspecific tests such as those to detect antinuclear antibodies, rheumatoid factor, and erythrocytic sedimentation rate.
 - A normal partial thromboplastin time is sufficient to exclude lupus anticoagulant.
 - Assessments of serum electrolytes, calcium, and phosphorus concentrations can be used to evaluate the possibility that parathyroid autoantibodies are active.
-
- Other assessments that should be performed include TSH, antithyroglobulin antibodies, antimicrosomal antibodies to evaluate thyroid status, and 24-hour urinary free cortisol to detect the presence of antiadrenal antibodies.
 - A more extensive workup may include parietal cell antibodies, islets of Langerhans antibodies, and antiadrenal antibodies; it is unclear, however, if the results of these tests will alter clinical management.

P.1060

Tests should be repeated yearly because of the transient nature of autoimmune disorders.

In a patient with hypergonadotropic amenorrhea, ovarian biopsy to determine whether follicles are present is not advised. Even if oocytes are found, there is no good method of stimulating those oocytes to ovulate. Some patients with negative biopsy results later ovulate spontaneously. This can be explained by considering that the biopsies sample only a small portion of the ovary (79).

Assessment of Estrogen Status

Traditionally, estrogen status has been determined by giving medroxyprogesterone acetate, either 5 mg or 10 mg, for 10 days. Withdrawal bleeding usually occurs within 2 to 10 days after the last dose. There is a debate as to how much bleeding constitutes withdrawal bleeding. There is a 20% false-positive rate in women who do not bleed despite having estrogen, and a 40% false-negative rate in women who bleed despite low estrogen states caused by hypothalamic dysfunction. A 50% false-negative rate occurs with ovarian failure (2). If vaginal bleeding does not occur after oral administration of progesterone, frequently 100 to 200 mg progesterone in oil is given intramuscularly. Other ways of testing for estrogen status may be quicker and easier. The development of vaginal dryness and hot flashes increase the likelihood of a diagnosis of hypoestrogenism. A sample of vaginal secretions can be obtained during the physical examination, and mucosal estrogen response can be demonstrated by the presence of superficial cells. A serum estradiol level higher than 40 pg/mL is considered adequate, but interassay discrepancies often exist. A DEXA (dual-energy x-ray absorptiometry) scan to determine bone mineral density should be performed in any patient in whom hypoestrogenism is suspected.

The finding of vaginal bleeding after progesterone challenge is important when Asherman syndrome is suspected. In a patient with primary amenorrhea and an apparently normal estrogen status, a progesterone challenge will diagnose the rare finding of congenitally absent endometrium. If estrogen status is questioned, 2.5 mg *conjugated estrogen* or 2 mg *micronized estradiol* can be given for 25 days with 5 to 10 mg of *medroxyprogesterone acetate* added for the last 10 days. Congenital absence of the endometrium is confirmed if no bleeding occurs with this regimen in a patient with primary amenorrhea and no physical abnormalities. Transvaginal ultrasound to assess endometrial thickness may also be helpful. If similar findings occur in patients with secondary amenorrhea, Asherman syndrome is diagnosed. **Asherman syndrome must be confirmed by showing filling defects on hysterosalpingography or by visualizing adhesions with hysteroscopy.**

Assessment of the Pituitary and Hypothalamus

If the patient is hypoestrogenic and the FSH level is not high, pituitary and hypothalamic lesions should be excluded.

- **A complete neurologic examination**, including electroencephalography, may help localize a lesion.
 - **Either CT or MRI scanning should be performed** to confirm the presence of a tumor. MRI will identify smaller lesions than CT; if a lesion is too small for identification by CT, it may be clinically insignificant.
-
- **After anatomic lesions have been excluded, the patient's history** of weight changes, exercise, eating habits, body image, and career or school achievements are important factors in differentiating anorexia nervosa, malnutrition, obesity, or exercise-induced or stress-induced menstrual disorders.

Amenorrheic patients who have hypothalamic dysfunction and are hypoestrogenic may have disorders similar to those who have normal estrogen levels. **The hypothalamic**

dysfunction caused by chronic disease, anorexia nervosa, stress, and malnutrition may be more severe or may exist for a more prolonged time in hypoestrogenic patients than in euestrogenic patients..

Patients with appropriate clinical findings should undergo screening for other hormonal alterations: .

- **Androgen levels should be assessed** in any hirsute patient to ensure that adrenal and ovarian tumors are not present as well as to diagnose PCOS (see Chapter 28).
- **Acromegaly** is suggested by coarse facial features, large doughy hands, and hyperhidrosis and **may be confirmed by measuring IGF-1 levels..**
- In patients with truncal obesity, hirsutism, hypertension, and erythematous striae, **Cushing syndrome should be ruled out** by assessing 24-hour urinary cortisol levels or performing a 1-mg overnight dexamethasone suppression test.

Treatment

The treatment of nonanatomic causes of amenorrhea associated with secondary sexual characteristics varies widely according to the cause. The underlying disorder should be treated whenever possible. Patients who are pregnant may be counseled regarding the options for continued care. When thyroid abnormalities are detected, thyroid hormone, radioactive iodine, or antithyroid drugs may be administered as appropriate. When hyperprolactinemia is present, treatment may include discontinuation of contributing medications, treatment with dopamine agonists such as *bromocriptine* or *cabergoline*, and, rarely, surgery for particularly large pituitary tumors. When ovarian failure causes amenorrhea, hormone replacement may be considered to diminish menopausal symptoms as well as to prevent osteoporosis. Counseling regarding the risks and benefits of hormone replacement therapy is indicated (123). Gonadectomy is required when a Y cell line is present.

Surgical removal, radiation therapy, or a combination of both is generally advocated for treatment of central nervous system tumors other than prolactinomas. It may be necessary to treat individuals who have panhypopituitarism with various replacement regimens once all the deficits have been elucidated. These regimens include estrogen replacement for lack of gonadotropins, corticosteroid replacement for lack of ACTH, thyroid hormone for lack of TSH, and *desmopressin acetate (1-deamino-8-D-AVP [DDAVP])* to replace vasopressin.

The treatment of amenorrhea associated with hypothalamic dysfunction also depends on the underlying cause: .

- **Hormonally active ovarian tumors are surgically removed..**
- **Obesity, malnutrition or chronic disease, Cushing syndrome, and acromegaly should be specifically treated.**

Pseudocyesis and stress-induced amenorrhea may respond to psychotherapy..

Exercise-induced amenorrhea may improve with moderation of activity and weight gain, when appropriate. If hypoestrogenism persists, higher doses of estrogen may be needed in these women than in older menopausal women to maintain bone density. In addition, 1,200 to 1,500 mg of calcium and 400 IU of vitamin D daily is advised. Bisphosphonates do not improve bone density in amenorrheic athletes because it is lack of bone formation rather than increased resorption that causes the osteopenia. In addition, the use of bisphosphonates is not advised because they can be deposited into the bone, and long-term effects, especially during pregnancy, are unknown (117).

Treatment of anorexia nervosa generally demands a multidisciplinary approach, with severe cases requiring hospitalization..

Chronic anovulation or PCOS may be treated after identifying the desires of the patient. Patients often are concerned about their lack of menstruation but not about hirsutism or infertility. **The endometrium of these individuals should be protected from the environment of unopposed estrogen** that accompanies the anovulatory state. Oral contraceptives are a good alternative for those patients who also require contraception. For those patients who are not candidates for oral contraceptive use, cyclic administration of progestin is advised. This treatment option presumes an adequate estrogenic environment to induce proliferation of the endometrium and is not sufficient to cause withdrawal bleeding in patients who are hypoestrogenic (i.e., those who have anorexia nervosa). **In these individuals, estrogen replacement must be added to the progestin regimen for successful menstrual regulation and prevention of osteoporosis. The most common progestin used to induce withdrawal bleeding and thus protect the endometrium from hyperplastic transformation is medroxyprogesterone acetate** (10 mg for 10 days per month). Occasionally, ovulation may occur; therefore, patients should be made aware that pregnancy is possible and appropriate contraceptive measures should be used. There is concern that *medroxyprogesterone acetate* used in early pregnancy may increase the incidence of pseudohermaphroditism (124). Alternatively, *progesterone* suppositories (50–100 mg) or *micronized progesterone* (200 mg) could be given for 10 days to induce withdrawal bleeding. No increased incidence of birth defects has been associated with the use of these natural progesterones (125).

When chronic anovulation is caused by attenuated congenital adrenal hyperplasia, glucocorticoid administration (i.e., dexamethasone 0.5 mg at bedtime) is sometimes successful in restoring the normal feedback mechanisms, thereby permitting regular menstruation and ovulation.

Hirsutism

Patients who have oligomenorrhea or amenorrhea resulting from chronic anovulation may have hirsutism (Chapter 28). **After ruling out androgen-secreting tumors and congenital adrenal hyperplasia, treatment may be aimed at decreasing coarse hair growth.**

Oral Contraceptives

Oral contraceptives may be effective by decreasing ovarian androgen production as well as increasing circulating levels of sex hormone-binding globulin, leading to decreased free androgen circulation.

Antiandrogens

Spirolactone decreases androgen production and competes with androgens at the androgen receptor level. Side effects include limited diuresis and dysfunctional uterine bleeding.

P.1063

Flutamide is approved by the U.S. Food and Drug Administration (FDA) for adjuvant therapy in prostatic cancer and for treatment of hirsutism. Its effects are similar to those of *spironolactone* with fewer side effects (126). Liver function should be monitored because of the rare complication of hepatotoxicity.

Cyproterone acetate, a strong progestin and antiandrogen, is used widely abroad but is not currently available in the United States. It is usually administered in combination with *ethinyl estradiol* in an oral contraceptive. By decreasing circulating androgen and LH levels, and by inducing antagonism of androgen effects at the peripheral level, *cyproterone acetate* is effective in treating hirsutism (127).

GnRH Agonist

GnRH agonist administration with add-back therapy is increasingly being used in the United States. Administration of GnRH agonist agents virtually eliminates ovarian steroid production, and estrogen-progestin add-back therapy allows long-term administration and protection against osteoporosis.

5 α -Reductase Inhibitors

Finasteride, a 5 α -reductase inhibitor, is approved by the FDA for the treatment of benign prostatic hypertrophy (*Proscar*) and male pattern baldness (*Propecia*). It is effective in treating hirsutism, although perhaps no more effective than other available agents (128,129). *Finasteride* has significant teratogenic potential, which precludes its use in any woman who may become pregnant. Its major advantage is that it is exceptionally well tolerated and may be used when side effects preclude the use of other therapeutic options for hirsutism.

Eflornithine hydrochloride, a topical cream, has been approved by the FDA for use on the face and chin. Improvements in facial hirsutism may be seen in 4 to 8 weeks of twice-daily applications.

Ovulation Induction

A large subset of patients with amenorrhea or oligomenorrhea and chronic anovulation seek care because they are unable to conceive (Chapter 30). Ovulation induction therapy is generally the treatment of choice for such patients, but pretreatment counseling should be provided in sufficient detail to ensure realistic expectations. The patient should be provided with information regarding the chances of a successful pregnancy (considering age of the patient and treatment modality), potential complications (hyperstimulation and multiple gestation), expense, time, and psychological impact involved in completing the course of therapy (130). **Patients may be advised that there is no increase in congenital anomalies in children born following ovulation induction** (131).

Earlier studies have raised the possibility of a relationship between ovulation induction and the risk of ovarian cancer (132,133). Ongoing studies are attempting to address this issue

conclusively, but **data support an increase of approximately 2.5-fold in ovarian cancer in patients with infertility, which appears unrelated to the use of ovulation-inducing drugs** (134,135). **There is no conclusive evidence to date to link fertility drug use and ovarian cancer** (136); thus, no change in current ovulation induction practices seems warranted at present. **Pregnancy and treatment with oral contraceptives before or after childbearing may protect against ovarian cancer.**

Clomiphene citrate is the usual first choice for ovulation induction in most patients because of its relative safety, efficacy, route of administration (oral), and relatively low cost (137). *Clomiphene citrate* is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is generally ineffective in hypogonadotropic patients who already have a poor estrogen supply (138). Patients with inappropriate gonadotropin release (an increased LH-to-FSH ratio), such as that which occurs in PCOS, are also candidates for therapy with *clomiphene citrate*. **As many as 80% of**

P.1064

certain patients can be expected to ovulate after clomiphene citrate therapy, and pregnancy rates approach 40% (130). Contraindications to the use of *clomiphene citrate* include pregnancy, liver disease, and pre-existing ovarian cysts. Side effects include hot flashes (>11% of patients) and poorly understood visual symptoms, which generally have been viewed as an indication to discontinue subsequent *clomiphene citrate* use. The incidence of multiple gestation ranges from 6.25% to 12.3% (130). The most commonly recommended treatment regimen is 50 mg daily for 5 days, beginning on the third to fifth day of menstrual or withdrawal bleeding. Cycles are easily monitored by measuring midluteal progesterone levels to assess ovulation. Measurement of midcycle estradiol levels and ultrasonographic monitoring to assess folliculogenesis may also be helpful, especially when hCG is used to induce ovulation. Endometrial thinning caused by the antiestrogenic effects of *clomiphene citrate* may also be detected with midcycle ultrasound. With these data, it is possible to immediately adjust the dose in the subsequent cycle if a given regimen is ineffective. Dosage increases of 50 mg/day are usually used, and more than 70% of conceptions occur at doses no higher than 100 mg/day for 5 days (139). Dosages higher than 150 mg/day for 5 days are usually ineffective, and patients who remain anovulatory with this dosage should undergo further evaluation accompanied by changes in the therapeutic plan. Longer courses of *clomiphene citrate* therapy, as well as adjunctive therapy with glucocorticoids and hCG, have been recommended (138). **Patients with PCOS, especially those with insulin resistance, may benefit from the use of insulin-sensitizing agents**, used either as primary or adjunctive therapy (140). These agents include the biguanide *metformin* and thiazolidinediones (*rosiglitazone* and *pioglitazone*). Thinning of the endometrium at midcycle in the face of adequate midcycle estradiol and midluteal progesterone levels is generally an indication to change therapy to injectable gonadotropins.

Women who do not ovulate or become pregnant with *clomiphene citrate*, as well as women with hypogonadotropic hypoestrogenic anovulation, may be candidates for therapy with injectable gonadotropins. Much higher pregnancy rates (up to 90%) occur in the latter category. Available preparations include recombinant FSH or products purified from the urine of menopausal women (FSH or FSH-LH combinations). Oral gonadotropin therapy is undergoing research and development. Administration protocols and dosages vary widely and should be adjusted to individual needs. Safe administration requires careful monitoring of ovarian response with ultrasonography and serial estradiol measurements. In general, gonadotropins are administered at a dose of 50 to 150 IU/day by subcutaneous or intramuscular injection for 3 to 5 days, after which time estradiol and follicular monitoring commence. In most cycles, gonadotropin is administered 7 to 12 days. Ovulation is triggered by subcutaneous or intramuscular injection of 5,000 to 10,000 IU hCG or

subcutaneous injection of 250 µg of recombinant hCG once the lead follicle reaches 16 to 20 mm in diameter based on ultrasonographic assessments. Ovulation generally occurs approximately 36 hours after hCG administration. Luteal phase support is sometimes provided with the administration of progesterone supplementation or with additional injections of hCG.

The two major complications associated with induction of ovulation with gonadotropins are multiple pregnancy (10%–30%) and ovarian hyperstimulation syndrome.

The incidence of both of these complications can be lowered by careful monitoring. Cycles complicated by the recruitment of numerous follicles or by estradiol levels approaching or exceeding 2,000 pg/mL may be canceled by withholding the ovulatory dose of hCG. Selected patients may be converted safely to *in vitro* fertilization. Because severe ovarian hyperstimulation syndrome is life-threatening and may lead to prolonged hospitalization, ovulation induction with gonadotropins generally is performed by experienced practitioners who devote a significant portion of their practice to the treatment of infertility.

Ovulation induction with GnRH may be effective in patients who have chronic anovulation associated with low levels of estrogen and gonadotropins. For therapy to

P.1065

be successful, a functional ovary and pituitary gland must be present. Therefore, patients with ovarian or pituitary failure do not respond to GnRH therapy. To be effective, GnRH must be administered in a pulsatile fashion, either intravenously or subcutaneously by a programmable pump. Ovulation induction with GnRH, as compared with gonadotropins, is associated with a relatively low incidence of ovarian hyperstimulation and multiple births. In addition, the need for appropriate timing of the ovulatory dose of hCG is avoided because patients treated with pulsatile GnRH have an appropriately timed endogenous LH surge. Disadvantages are mainly related to maintaining the programmable pump and injection site. After ovulation, luteal phase support is necessary and may be provided with hCG, progesterone, or continuation of the GnRH therapy.

Patients who lack oocytes (ovarian failure) and desire pregnancy may be candidates for oocyte donation.

Oocytes may be harvested after ovulation induction from appropriate donors, fertilized with sperm from the recipient's husband, and transferred into the recipient's uterus after the endometrium has been appropriately prepared with hormonal regimens. Estrogen and progesterone are used to prepare the endometrium for implantation of the transferred embryo(s).

C. Matthew Peterson

- **Hyperandrogenism most often presents as hirsutism, which usually arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands. By contrast, virilization is rare and indicates marked elevations in androgen levels..**
- **The most common cause of hyperandrogenism and hirsutism is polycystic ovarian syndrome (PCOS). There are only two major criteria for the diagnosis of PCOS: anovulation and the presence of hyperandrogenism as established by clinical or laboratory means. Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia..**
- **Combination oral contraceptives (OCs) decrease adrenal and ovarian androgen production and reduce hair growth in nearly two thirds of hirsute patients..**
- **Because hyperinsulinemia appears to play a role in PCOS-associated**

anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities..

- Excluding cases that are of iatrogenic or factitious etiology, adrenocorticotrophic hormone (ACTH)–independent forms of *Cushing syndrome* are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest..

- *Congenital adrenal hyperplasia* is transmitted as an autosomal recessive disorder. Deficiency of 21–hydroxylase is responsible for more than 90% of cases of adrenal hyperplasia resulting from adrenal synthetic enzyme deficiency..

- Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen–secreting neoplasm. Ovarian neoplasms are the most frequent androgen–producing tumors..

P.1070

- Elevations in prolactin may cause amenorrhea or galactorrhea. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women. In patients with both galactorrhea and amenorrhea, approximately two thirds will have hyperprolactinemia; of those, approximately one third will have a pituitary adenoma. In more than one third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (> 1 cm) is found..

- Because levels of thyroid–stimulating hormone (TSH) are sensitive to excessive or deficient levels of circulating thyroid hormone, and because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland, TSH levels are used to screen for these disorders. The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced. Severe primary hypothyroidism is associated with amenorrhea or anovulation. The classic triad of exophthalmos, goiter, and hyperthyroidism in *Graves disease* is associated with symptoms of hyperthyroidism..

The endocrine disorders encountered most frequently in gynecologic patients are those related to disturbances in the regular occurrence of ovulation and accompanying menstruation. **The most prevalent problems are those characterized by androgen excess, often with insulin resistance, including what is arguably the most common endocrinopathy in women—polycystic ovary syndrome (PCOS).** Other conditions leading to ovulatory dysfunction, hirsutism, or virilization, as well as common disorders of the pituitary and thyroid glands associated with reproductive abnormalities, are reviewed in this chapter.

Hyperandrogenism

Hyperandrogenism most often presents as hirsutism, which usually arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands, constitutive increase in expression of androgen effects at the level of the pilosebaceous unit, or a combination of the two. **By contrast, virilization is rare and indicates marked elevations in androgen levels.** Virilization usually is caused by an ovarian or adrenal neoplasm, which may be benign or malignant.

Hirsutism

The most frequent manifestation of androgen excess in women, hirsutism is defined as excessive growth of terminal hair in a male distribution. This condition refers particularly to midline hair, sideburns, moustache, beard, chest or intermammary hair, and inner thigh and midline lower back hair entering the intergluteal area. The response of the pilosebaceous unit to androgens in these androgen-responsive areas transforms vellus hair (fine, nonpigmented, short) that is normally present into terminal hair (coarse, stiff, pigmented, and long).

Androgen effects on hair vary in relation to specific regions of the body surface. Hair that shows no androgen dependence includes lanugo, eyebrows, and eyelashes. The hair of the limbs and portions of the trunk exhibits minimal sensitivity to androgens. Pilosebaceous units of the axilla and pubic region are sensitive to low levels of androgens. Even the modest androgenic effects of adult levels of androgens of adrenal origin are sufficient for substantial expression of terminal hair in these areas. Follicles in the distribution associated with male patterns of facial and body hair (midline, facial, inframammary) require higher levels of androgens, such as those seen with normal testicular function or abnormal

P.1071

ovarian or adrenal androgen production. Scalp hair is inhibited by gonadal androgens in varying degrees, as determined by age and genetic determination of follicular responsiveness, resulting in the common frontal–parietal balding seen in some men and in virilized women. **Hirsutism results from both increased androgen production and skin sensitivity to androgens. Skin sensitivity depends on the genetically determined local activity of 5 α -reductase, the enzyme that converts testosterone to dihydrotestosterone (DHT), the bioactive androgen in hair follicles.**

Hair demonstrates cyclic activity between growth (*anagen*), involution (*catagen*), and resting (*telogen*) phases. The durations of both the growth and resting phases vary according to region of the body, genetic factors, age, and hormonal effects. The cycles of growth, rest, and shedding are normally dyssynchronous, but when synchronous entry into telogen phase is triggered by major metabolic or endocrine events such as pregnancy and delivery or severe illness, dramatic (although transient) hair loss may occur in the following months (*telogen effluvium*).

Hirsutism is a relative, rather than absolute, designation. What is normal in one setting may be considered abnormal in others; social and clinical reactions to hirsutism may vary significantly, reflecting ethnic variation in skin sensitivity to androgens and cultural ideals. Androgen-dependent hair (excluding pubic and axillary hair) occurs in only 5% of premenopausal Caucasian women and is considered abnormal by white women of North America, whereas considerable facial and male pattern hair in other parts of the body may be more common and acceptable among groups such as Inuit women and women of Mediterranean background.

Hypertrichosis and Virilization

Two conditions should be distinguished from hirsutism. **Hypertrichosis is the term reserved for the presence of androgen-independent terminal hair in nonsexual areas, such as the trunk and extremities.** This condition may result from an autosomal-dominant congenital disorder, a metabolic disorder (such as anorexia nervosa, hyperthyroidism, porphyria cutanea tarda), or medication use (e.g., acetazolamide, corticosteroids, cyclosporine, diazoxide, interferon, minoxidil, phenytoin, streptomycin). **Virilization is a marked and global masculine transformation that includes coarsening of the voice, increase in muscle mass, clitoromegaly (normal clitoral dimensions plus or minus standard deviation are 3.4 + 1 mm width by 5.1 + 1.4 mm length), and features of defeminization (loss of breast volume and body fat contributing to feminine body contour)** (1). Although hirsutism accompanies virilization, the presence of virilization indicates a high likelihood of a more serious condition than those that occur with hirsutism alone. The history should focus on the age at onset and rate of progression of hirsutism or virilization. **A rapid rate of progression of androgen effects or the presence of virilization, regardless whether it occurs before, during, or after puberty, is associated with a more severe degree of hyperandrogenism and should raise suspicion of ovarian and adrenal neoplasms or Cushing syndrome.** Anovulation, manifesting as amenorrhea or oligomenorrhea, increases the probability of underlying hyperandrogenism. Hirsutism occurring with regular cycles is more often associated with normal androgen levels; it is attributed to increased genetic sensitivity of the pilosebaceous unit and is termed *idiopathic hirsutism*. Anovulation virtually always occurs in the presence of virilization.

Determining the extent of hirsutism requires a sensitive and tactful approach by the physician and should include questions about shaving and the use of chemical or mechanical depilatories. Typically, clinical evaluation of the degree of hirsutism is subjectively classified as mild, moderate, or severe. Objective assessment is helpful, however, especially in establishing a baseline from which therapy can be evaluated. A hirsutism scoring scale of androgen-sensitive hair in nine body areas rated on a scale of 0 to 4 has been used (2). Hirsutism is defined as a score higher than 8.

P.1072

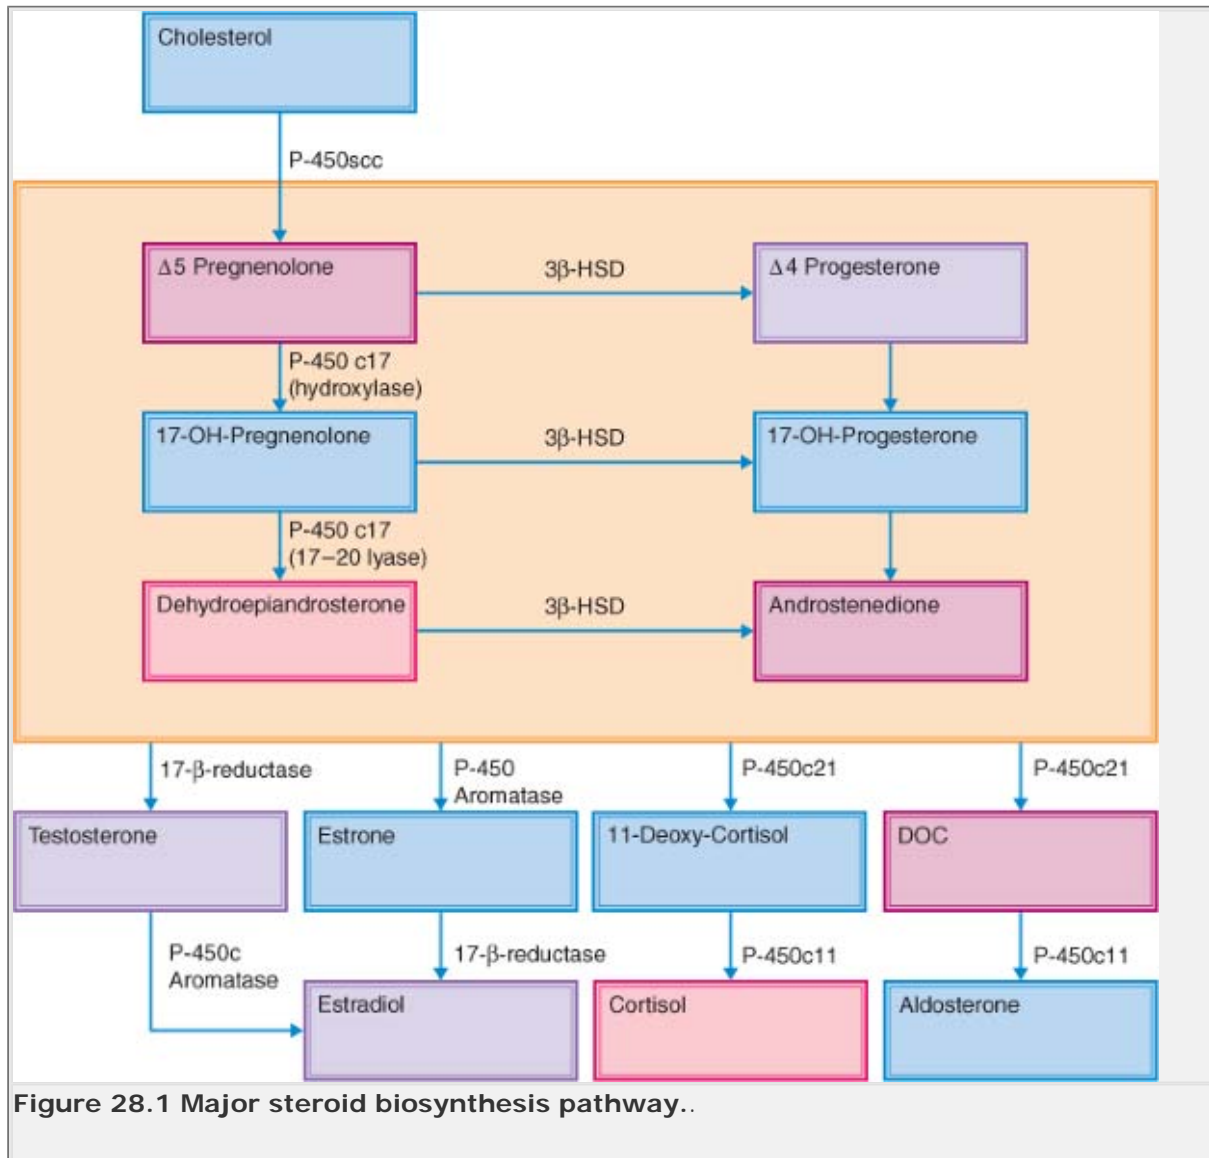

A family history should be obtained to disclose evidence of idiopathic hirsutism, PCOS, congenital or adult onset adrenal hyperplasia (CAH or AOA), diabetes mellitus, and cardiovascular disease. A history of drug use should also be obtained. In addition to drugs that commonly cause hypertrichosis, anabolic steroids and testosterone derivatives may cause hirsutism and even virilization. During the physical examination, attention should be directed to obesity, hypertension, galactorrhea, male-pattern baldness, acne (face and back), and hyperpigmentation. Hirsutism often is the presenting symptom of Cushing syndrome, which may mimic AOA and PCOS. Physical signs of the syndrome include "moon face," plethora, purple striae, dorsocervical and supraclavicular fat pads, and proximal muscle weakness. The preservation or enhancement of the radial musculature, which is present in other hyperandrogenic disorders, may be a useful finding in determining the differential diagnosis.

Role of Androgens

Androgens and their precursors are produced by both the adrenal glands and the ovaries in response to adrenocorticotrophic hormone (ACTH) and luteinizing hormone (LH), respectively (Fig. 28.1). Biosynthesis begins with the rate-limiting conversion of cholesterol to pregnenolone by side-chain cleavage enzyme. Thereafter, pregnenolone undergoes a two-step conversion to the 17-ketosteroid dehydroepiandrosterone (DHEA) along the δ -5 steroid pathway. This conversion is accomplished by

P.1073

CYP17, an enzyme with both 17 α -hydroxylase and 17,20-lyase activities. In a parallel fashion, progesterone undergoes transformation to androstenedione in the δ -4 steroid pathway. The metabolism of δ -5 to δ -4 intermediates is accomplished via a δ -5-isomerase, 3 β -hydroxysteroid dehydrogenase (3 β -HSD).

Adrenal 17-Ketosteroids

Secretion of adrenal 17-ketosteroids increases prepubertally, independent of pubertal maturation of the hypothalamic-pituitary-ovarian axis. This alteration in adrenal steroid secretion is termed *adrenarche* and is characterized by a dramatic change in the response of the adrenal cortex to ACTH and preferential secretion of δ -5 steroids, including 17-hydroxyprogesterone, DHEA, and 17-hydroxy progesterone sulfate (DHEAS). The basis for this action is related to the increase in the zona reticularis and in the increased activity of the 17-hydroxylase and the 17,20-lyase enzymes. The increase in adrenal androgens that occurs with adrenarche causes significant increases in the growth of pubic and axillary hair and production of sweat by the axillary pilosebaceous units.

Testosterone

Approximately one half of a woman's serum testosterone is derived from peripheral conversion of secreted androstenedione, and the other half is derived from direct glandular (ovarian and adrenal) secretion. The ovaries and adrenal glands contribute about equally to testosterone production in women. The contribution of the adrenal glands is achieved primarily through secretion of androstenedione.

Approximately 66% to 78% of circulatory testosterone is bound to sex hormone-binding globulin (SHBG) and is considered biologically inactive. Most of the proportion of serum testosterone that is not bound to SHBG is weakly associated with albumin (20%–32%). A small percentage (1%–2%) of testosterone is entirely unbound or free.

The fraction of circulating testosterone that is unbound by SHBG has an inverse relationship with the SHBG concentration. Increased SHBG levels occur in situations associated with high estrogen levels such as pregnancy, the luteal phase, and use of estrogen (including oral contraceptives). Conditions causing elevated thyroid hormone levels and cirrhosis of the liver are associated with reduced fractions of free testosterone, which result from elevated SHBG levels. Conversely, as levels of SHBG decrease, free testosterone fractions increase in response to androgens, which can derive from androgenic disorders (i.e., PCOS, adrenal hyperplasia, Cushing syndrome), medications (i.e., progestational agents with androgenic biologic activities, danazol, glucocorticoids), growth hormone, hyperinsulinemia, obesity, and prolactin.

Assessment of Hyperandrogenemia

In hyperandrogenic states, increases in testosterone production are not proportionately reflected in increased total testosterone levels because of the depression of SHBG levels that occurs concomitant with increasing androgen effects on the liver. Therefore, when moderate hyperandrogenism occurs, which is characteristic of many functional hyperandrogenic states, elevations in total testosterone levels may remain within the normal range, and only free testosterone levels will reveal the hyperandrogenism.

Severe hyperandrogenism, as occurs with virilization and neoplastic production of testosterone, can be detected by measures of total testosterone, however.

Therefore, determination of the total testosterone level in concert with clinical assessment of a patient with hyperandrogenism is frequently sufficient for diagnosis and management. When more precise delineation of the degree of hyperandrogenism is desired, free testosterone levels can be measured to assess increases in testosterone production. Although such measurements are not necessary in evaluating most patients, they are often performed in research and may be useful in some clinical settings.

P.1074

Because many practitioners measure some form of testosterone level, they should understand the methods used and their accuracy. Although equilibrium dialysis is the standard technique used for measuring free testosterone, it is expensive, complex, and usually limited to research settings. In a clinical setting, free testosterone levels can be estimated by assessment of testosterone binding to albumin and SHBG.

Testosterone that is nonspecifically bound to albumin (AT) is linearly related to free testosterone (FT) by the following equation:

$$AT = K_a [A] \times FT$$

In this equation, AT is the albumin-bound testosterone, K_a is the association constant of albumin for testosterone, and [A] is the albumin concentration.

In many cases of hirsutism, albumin levels are within a narrow physiologic range and thus do

not significantly affect the concentration of free testosterone. When physiologic albumin levels are present, the free testosterone level can be estimated by measuring total testosterone as well as SHBG. In individuals with normal albumin levels, this method has reliable results compared with those of equilibrium dialysis. It provides a rapid, simple, and accurate determination of the total and calculated free testosterone level as well as the concentration of SHBG.

The level of bioavailable testosterone is based on the relationship of albumin and free testosterone in addition to the levels of actual albumin, total testosterone, and SHBG. This combination of total testosterone, SHBG, and albumin measurements can be used to obtain a more accurate estimate of available bioactive testosterone and thus the androgen effect derived from testosterone (3).

Pregnancy can alter the accuracy of measurements of bioavailable testosterone.

During pregnancy, estradiol, which shares with testosterone a high affinity for SHBG, occupies a large proportion of SHBG binding sites. Thus, measurement of SHBG levels can result in overestimating the binding capacity of SHBG for testosterone. Derived estimates of free testosterone, as opposed to direct measure by equilibrium dialysis, are therefore inaccurate during pregnancy. Testosterone measurements in pregnancy are useful when autonomous secretion of testosterone by tumor or luteoma is suspected. In these instances, total testosterone determinations provide sufficient information for diagnosis.

For testosterone to exert its biologic effects on target tissues, it must be converted into its active metabolite, DHT, by 5 α -reductase (a cytosolic enzyme that reduces testosterone and androstenedione). Two isozymes of 5 α -reductase exist: type 1, which predominates in the skin, and type 2, or acidic 5 α -reductase, which is found in the liver, prostate, seminal vesicles, and genital skin. The type 2 isozyme has a 20-fold higher affinity for testosterone than type 1. Both type 1 and 2 deficiencies in men result in ambiguous genitalia, and both isozymes may play a role in androgen effects on hair growth. Dihydrotestosterone is more potent than testosterone, primarily because of its higher affinity and slower dissociation from the androgen receptor. Although DHT is the key intracellular mediator of most androgen effects, measurements of circulating levels are not clinically useful. **The relative androgenicity of androgens is as follows:.**

- **DHT = 300.**
- **Testosterone = 100.**
- **Androstenedione = 10.**
- **DHEAS = 5.**

Until adrenarche, androgen levels remain low. Around 8 years of age, adrenarche is heralded by a marked increase in DHEA and DHEAS. The half-life of free DHEA is

P.1075

extremely short (about 30 minutes) but extends to several hours if DHEA is sulfated. Although no clear role is identified for DHEAS, it is associated with stress, and levels decline steadily throughout adult life. **After menopause, ovarian estrogen secretion ceases, and DHEAS levels continue to decline, whereas testosterone levels are maintained or may even increase.** Although postmenopausal ovarian steroidogenesis contributes to testosterone production, testosterone levels retain diurnal variation, reflecting an ongoing

and important adrenal contribution. Peripheral aromatization of androgens to estrogens increases with age, but because small fractions (2%–10%) of androgens are metabolized in this fashion, such conversion is rarely of clinical significance.

Laboratory Evaluation

When laboratory testing for the assessment of hirsutism is indicated, a bioavailable testosterone level (total testosterone, SHBG, and albumin level) or a calculated free testosterone level (if albumin levels are assumed to be normal) provides the most accurate assessment of the androgen effect derived from testosterone. In most clinical situations, however, total testosterone (less than or equal to 200 ng/mL), DHEAS, and 17-hydroxyprogesterone (17-OHP) measurements can be used to help detect conditions requiring further workup (Table 28.1). When hirsutism is accompanied by absent or abnormal menstrual periods, assessment of LH, follicle-stimulating hormone (FSH), prolactin, and thyroid-stimulating hormone (TSH) values are required to diagnose an ovulatory disorder. Hypothyroidism and hyperprolactinemia may be associated with reduced levels of SHBG and may increase the fraction of unbound testosterone levels, occasionally resulting in hirsutism. Elevated LH:FSH ratios are noted in some women with PCOS, but cannot be used to confirm the diagnosis. In cases of suspected Cushing syndrome, patients should undergo screening with a 24-hour urinary cortisol (most sensitive and specific) assessment or an overnight dexamethasone suppression test. For this test, the patient takes 1 mg of dexamethasone at 11:00 PM, and a blood cortisol assessment is performed at 8:00 AM the next day. Cortisol levels of 2 µg/dL or higher after overnight dexamethasone suppression require a further workup for evaluation of Cushing syndrome. Elevated 17-OHP levels identify patients with AOA and are found in 1% to 5% of hirsute women. Levels of 17-OHP vary significantly within the menstrual cycle, increasing in the periovulatory and luteal phases, and may be modestly elevated in PCOS. Standardized testing requires evaluation in the morning during the follicular phase.

Table 28.1 Normal Values for Serum Androgens^a

Testosterone (total)	20–80 ng/dL
Free testosterone (calculated)	0.6–6.8 pg/mL
Percent free testosterone	0.4–2.4%
Bioavailable testosterone	1.6–19.1 ng/dL
SHBG	18–114 nmol/L
Albumin	3,300–4,800 mg/dL
Androstenedione	20–250 ng/dL
Dehydroepiandrosterone sulfate	100–350 µg/dL
17-hydroxyprogesterone (follicular phase)	30–200 ng/dL

SHBG, sex hormone-binding globulin.

^aNormal values may vary among different laboratories. Free testosterone is calculated using measurements for total testosterone and sex hormone-binding globulin, whereas bioavailable testosterone is calculated using measured total testosterone, sex hormone-binding globulin, and albumin. Calculated values for free and bioavailable testosterone compare well with equilibrium dialysis methods of measuring unbound testosterone when albumin levels are normal. Bioavailable testosterone includes free plus very weakly bound (non-SHBG, nonalbumin) testosterone. Bioavailable testosterone is the most accurate assessment of bioactive testosterone in the serum without performing equilibrium dialysis.

Normal morning baseline follicular phase 17-OHP levels are less than 200 ng/dL (6 nmol/L). When levels are greater than 200 ng/dL but less than 800 ng/dL (24 nmol/L), ACTH testing should be performed to distinguish PCOS from AOA. Levels greater than 800 ng/dL (24 nmol/L) also warrant ACTH testing but are virtually diagnostic of AOA because of 21-hydroxylase deficiency.

Some hirsute women manifest total testosterone levels above normal (20–80 ng/dL [0.723 nmol/L]). Because increased testosterone production is not reliably reflected by total testosterone levels, the diagnosis can be based on the presence of typical male pattern hirsutism or measurement of free or unbound testosterone (bioavailable or calculated free testosterone levels). Total testosterone does, however, serve reliably as a marker for testosterone-producing neoplasms. **Total testosterone levels greater than 200 ng/dL should prompt a workup for ovarian or adrenal tumors, and DHEAS levels greater than twice the upper limit of normal should prompt evaluation for adrenal neoplasm. Both total testosterone and DHEAS should be measured in the presence of virilization.**

In the past, testing for androgen conjugates (e.g., 3 α -androstenediol G [3 α -diol G] and androsterone G [AOG]) as markers for 5 α -reductase activity in the skin) has been advocated. However, routine determination of androgen conjugates to assess hirsute patients is not recommended. Hirsutism itself is an excellent bioassay of free testosterone action on the hair follicle, and androgen conjugates arise from adrenal precursors and are likely markers of adrenal and not ovarian steroid production (4).

In most laboratories, the upper limit of a DHEAS level is 350 μ g/dL (9.5 nmol/L). A random sample is sufficient because the level of variation is minimized as a result of the long half-life characteristic of sulfated steroids. **A normal level essentially rules out adrenal disease, and moderate elevations are a common finding in the presence of PCOS.** A DHEAS level of more than twice the upper limit of normal, 700 μ g/dL (20nmol/L), usually indicates the need to rule out an adrenal tumor or Cushing syndrome. Absolute ceilings for this threshold vary significantly with age, with levels declining steadily after a peak at around age 20 years; laboratories commonly provide reference levels for age. Rarely, ovarian tumors are associated with high DHEAS levels.

Polycystic Ovary Syndrome

The most common cause of hyperandrogenism and hirsutism is PCOS. The association of amenorrhea with bilateral polycystic ovaries and obesity was first described in 1935 by Stein and Leventhal (5) and was known for decades as the Stein-Leventhal syndrome. Subsequently, it is now recognized that **PCOS is a disorder that is characterized principally by oligomenorrhea or amenorrhea with clinical or laboratory evidence of hyperandrogenemia. Furthermore, it is now recognized that a significant proportion of overweight women with PCOS have hyperinsulinemia.** Its origins are likely polygenic or multifactorial or both (6). Following are diagnostic criteria based on the modified consensus of the National Institutes of Health and Child Health and Human Development.

Major

- Chronic anovulation

-

Hyperandrogenemia

-
- **Clinical signs of hyperandrogenism**
-
- **Other etiologies excluded**

Minor

- - **Insulin resistance**
 -
 - **Perimenarchal onset of hirsutism and obesity**
 -
 - **Elevated LH-to-FSH ratio**
-
- - **Intermittent anovulation associated with hyperandrogenemia (free testosterone, DHEAS).**

P.1077

In this schema, there are only two major criteria for the diagnosis of PCOS: anovulation and the presence of hyperandrogenism as established by clinical or laboratory means. These features alone are sufficient for the diagnosis in the absence of other pathologies accounting for hyperandrogenism (i.e., AOA, adrenal or ovarian neoplasm, Cushing syndrome) or anovulation (i.e., hypogonadotropic or hypergonadotropic disorders, hyperprolactinemia, thyroid disease).

Other frequently encountered manifestations are less consistent findings and, therefore, qualify only as minor criteria. They include elevated LH:FSH ratio, insulin resistance, oligo-ovulation, perimenarchal onset of hirsutism and obesity, and ultrasonographic evidence of PCOS.

Hirsutism occurs in approximately 70% of patients with PCOS in the United States (7) and in only 10% to 20% of patients with PCOS in Japan (8). A likely explanation for this discrepancy is the genetically determined differences in skin 5 α -reductase activity (9,10).

The menstrual dysfunction that occurs with PCOS arises from anovulation or oligo-ovulation and ranges from amenorrhea to oligomenorrhea. When anovulation is present, it is uncommon for women with PCOS to have regular menses, although one report found that among hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (11). **Classically, the disorder may be lifelong, characterized by abnormal menses from puberty with acne and hirsutism arising in the teens. It may arise in adulthood, concomitant with the emergence of obesity, presumably because obesity is accompanied by increasing hyperinsulinemia** (12).

Obesity occurs in more than 50% of patients with PCOS. The body fat is usually deposited centrally (android obesity). A higher waist-to-hip ratio is associated with insulin resistance, which indicates an increased risk of diabetes mellitus and cardiovascular disease (13).

Insulin resistance, resulting in hyperinsulinemia, is commonly exhibited in PCOS. Insulin resistance may eventually lead to the development of hyperglycemia and type 2 diabetes mellitus (14). About one third of obese PCOS patients have impaired glucose tolerance (IGT), and 7.5% to 10% have type 2 diabetes mellitus (15). These rates are

mildly increased even in nonobese women who have PCOS (10% IGT; 1.5% diabetes) (16), compared with the general population of the United States (7.8% IGT; 1% diabetes) (17).

Abnormal lipoproteins are a common finding in PCOS and include elevated total cholesterol, triglycerides, and low-density lipoproteins (LDL); and low levels of high-density lipoproteins (HDL) and apoprotein A-I (13,18). According to one report, the most characteristic lipid alteration is decreased levels of HDL (19).

Other findings that occur in women with PCOS include impaired fibrinolysis as shown by elevated circulating levels of plasminogen activator inhibitor (20), an increased incidence of hypertension over time that approaches 40% by perimenopause (18), a greater prevalence of atherosclerosis and cardiovascular disease (21,22), and an estimated sevenfold increased risk for myocardial infarction (23).

Pathology

Macroscopically, ovaries in women with PCOS are 2 to 5 times the normal size. A cross-section of the surface of the ovary discloses a white, thickened cortex with multiple cysts that are typically less than a centimeter in diameter. Microscopically, the superficial

P.1078

cortex is fibrotic and hypocellular and may contain prominent blood vessels. In addition to smaller atretic follicles, there is an increase in the number of follicles with luteinized theca interna. The stroma may contain luteinized stromal cells (24).

Pathophysiology and Laboratory Findings

The hyperandrogenism and anovulation that accompany PCOS may be caused by abnormalities in four endocrinologically active compartments: (i) the ovaries, (ii) the adrenal glands, (iii) the periphery (fat), and (iv) the hypothalamus-pituitary compartment.

In patients with PCOS, the ovarian compartment is the most consistent contributor of androgens. Dysregulation of CYP17, the androgen-forming enzyme in both the adrenals and the ovaries, may be one of the central pathogenetic mechanisms underlying hyperandrogenism in PCOS (25). The ovarian stroma, theca, and granulosa contribute to ovarian hyperandrogenism and are stimulated by LH (26). This hormone relates to ovarian androgenic activity in PCOS in a number of ways: .

- Total and free testosterone levels correlate directly with LH levels (27).
- The ovaries are more sensitive to gonadotropic stimulation, possibly as a result of CYP17 dysregulation (25).
- Treatment with a gonadotropin-releasing hormone (GnRH) agonist effectively suppresses serum testosterone and androstenedione levels (28).
- Larger doses of a GnRH agonist are required for androgen suppression than for endogenous gonadotropin-induced estrogen suppression (29).

The increased testosterone levels that occur in patients with PCOS are considered ovarian in origin. The serum total testosterone levels are usually no more than twice

the upper normal range (20–80 ng/dL). However, in *ovarian hyperthecosis*, values may reach 200 ng/dL or more (30). The adrenal compartment also plays a role in the development of PCOS. Although the hyperfunctioning CYP17 androgen-forming enzyme coexists in both the ovaries and the adrenal glands, DHEAS is increased in only about 50% of patients with PCOS (31,32). The hyperresponsiveness of DHEAS to stimulation with ACTH (30), the onset of symptoms around puberty, and the observation that 17,20-lyase activation (one of the two CYP17 enzymes) is a key event in adrenarche have led to the hypothesis that PCOS arises as an exaggeration of adrenarche.

The **peripheral compartment**, defined as the skin and the adipose tissue, manifests its contribution to the development of PCOS in several ways: .

- The presence and **activity of 5 α -reductase** in the skin largely **determines the presence or absence of hirsutism** (9,10).
- Aromatase and 17 β -HSD activities are increased in fat cells (33), and **peripheral aromatization is increased** with body weight (34).
- With obesity, the **metabolism of estrogens**, by way of reduced 2-hydroxylation and 17 α -oxidation, **is decreased** (35), and metabolism via estrogen active 16-hydroxyestrogens (estriol) is increased.
- Whereas E₂ is at a follicular phase level in patients with PCOS, **E₁ levels are increased** as a result of peripheral aromatization of androstenedione (36).
- A **chronic hyperestrogenic state**, with reversal of the E₁:E₂ ratio, results and is unopposed by progesterone.

P.1079

The **hypothalamic–pituitary compartment** also participates in aspects critical to the development of PCOS: .

- An **increase in LH pulse frequency** relative to those in the normal follicular phase is the result of increased GnRH pulse frequency (37).
- This increase in LH pulse frequency explains the frequent observation of **elevated LH and LH:FSH ratios**.
- **FSH is not increased** with LH, which may result from the combination of increased gonadotropin pulse frequency and the synergistic negative feedback of chronically elevated estrogen levels and normal follicular inhibin.
- About 25% of patients with PCOS exhibit **mildly elevated prolactin levels**, which may result from abnormal estrogen feedback to the pituitary gland. In some patients with PCOS,

administration of *bromocriptine* has reduced LH levels and restored ovulatory function (38).

At present, **genetic studies of PCOS have reported allele sharing in large PCOS patient populations, and linkage studies have focused on candidate genes most likely to be involved in the pathogenesis of PCOS.** Recent linkage reports have identified the *follistatin* (39), *CYP11A* (40), *Calpain 10* (41), *IRS-1* and *IRS-2* regions and loci near the insulin receptor (*19p13.3*) (39,42), *SHBG* (43), and the insulin gene (44) as candidate genes associated with PCOS. Using theca cells derived from women with PCOS, elevated mRNA levels were noted for *CYP11A*, *3BHSD2*, and *CYP 17* genes with corresponding overproduction of testosterone, 17 alpha-hydroxyprogesterone, and progesterone. Despite the characteristically heightened steroidogenesis in PCOS, the *STARB* gene was not found to be overexpressed (39). Recent data derived from theca cells from PCOS women did not identify any genes near the *19p13.3* locus that were differentially expressed; however, the mRNAs of several genes that map to *19p13.3*, including the insulin receptor, *p114-Rho-GEF*, and several expressed sequence tags, were detected in both PCOS and normal theca cells. Those studies further identified new factors that might affect theca cell steroidogenesis and function, including *cAMP-GEFII*, genes involved in all-transretinoic acid (*atRA*) synthesis signaling, genes that participate in the signal transduction pathway, and transcription factor *GATA6*. These findings suggest that a *19p13.3* locus or some other candidate gene may be a signal transduction gene that results in overexpression of a suite of genes downstream that may affect steroidogenic activity (45).

Insulin Resistance

Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia.

Insulin resistance and hyperinsulinemia participate in the ovarian

steroidogenic dysfunction of PCOS. Insulin alters ovarian steroidogenesis independent of gonadotropin secretion in PCOS. Insulin and insulinlike growth factor I (IGF-I) receptors are present in the ovarian stromal cells. A specific defect in the early steps of insulin receptor-mediated signaling (diminished autophosphorylation) has been identified in 50% of women with PCOS (46).

The most common cause of insulin resistance and compensatory hyperinsulinemia is obesity, but despite its frequent occurrence in PCOS, obesity alone does not alone explain this important association (38). The following observations provide evidence that the insulin resistance associated with PCOS is not the result of hyperandrogenism: .

- Hyperinsulinemia is not a characteristic of hyperandrogenism in general but is uniquely associated with PCOS (47).

- In obese women with PCOS, 30% to 45% have glucose intolerance or frank diabetes mellitus, whereas ovulatory hyperandrogenic women have normal insulin levels and glucose tolerance (47). The associations between PCOS and obesity on the action of insulin appear to be synergistic.
- Suppression of ovarian steroidogenesis with long-acting GnRH analogs in women with PCOS does not change insulin levels or insulin resistance (48).
-

Oophorectomy in patients with hyperthecosis accompanied by hyperinsulinemia and hyperandrogenemia does not change insulin resistance, despite a decrease in androgen levels (49).

***Acanthosis nigricans* is a reliable marker of insulin resistance in hirsute women. This thickened, pigmented, velvety skin lesion is most often found in the vulva and may be present on the axilla, over the nape of the neck, below the breast, and on the inner thigh (50). The HAIR-AN syndrome (46,51) consists of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN).** These patients often have high testosterone levels (>150 ng/dL), fasting insulin levels of greater than 25 μ IU/mL (normal <20 to 24 μ IU/mL), and maximal serum insulin responses to glucose load (75 g) exceeding 300 μ IU/mL (normal <160 μ IU/mL at 2 hours postglucose load).

Screening Strategies for Diabetes and Insulin Resistance

Multiple testing and screening approaches have been proposed to assess the presence of hyperinsulinemia and insulin resistance. In one approach, the fasting glucose:insulin ratio is determined, and values less than 4.5 indicate insulin resistance. Using the 2-hour glucose tolerance test (GTT) with insulin levels, 10% of nonobese and 40% to 50% of obese women with PCOS have impaired glucose tolerance (IGT = 2 hr glucose level \geq 140 or \leq 199 mg/dL) or overt type II diabetes mellitus (any glucose level >200 mg/dL). Some research studies have utilized a peak insulin level of more than 150 μ IU/mL or a mean level of more than 84 μ IU/mL over the three blood draws of a 2-hour GTT as criteria for the diagnosis of hyperinsulinemia (Table 28.2).

The documentation of hyperinsulinemia using either the glucose:insulin ratio or the 2-hour GTT with insulin is problematic. When compared with the standard measure for insulin resistance, the hyperinsulinemic-euglycemic clamp, the glucose:insulin ratio does not always accurately portray insulin resistance. Furthermore, a relative insulin secretion deficit exists in the presence of hyperglycemia. This deficit in appropriate insulin secretion exacerbates the effects of insulin resistance and renders inaccurate the use of hyperinsulinemia as an index of insulin resistance. Thus, routine measurements of insulin levels may not be particularly useful.

Table 28.2 2-Hour Glucose Tolerance Test Results^a

<i>Glucose Levels</i>
Fasting 64–128 mg/dL
1 hour 120–170 mg/dL
2 hour 70–140 mg/dL
<i>2-Hour Glucose Values for Impaired Glucose Tolerance and Type II Diabetes</i>
Normal <140 mg/dL
Impaired = 140–199 mg/dL
Type II Diabetes mellitus \geq 200 mg/dL
^a WHO Criteria, after 75-g glucose load.

Although detection of insulin resistance per se is not of practical importance to the diagnosis or management of PCOS, **testing women with PCOS for glucose intolerance is of value because their risk of cardiovascular disease correlates with this finding.**

An appropriate frequency for such screening depends on age, body mass index, and waist circumference, all of which increase risk.

Interventions

Abnormal glucose metabolism may be significantly improved with weight reduction, which also may reduce hyperandrogenism and restore ovulatory function (52). In obese, insulin-resistant women, caloric restriction that results in weight reduction will reduce the severity of insulin resistance (a 40% decrease in insulin level with a 10-kg weight loss) (53). This decrease in insulin levels should result in a marked decrease in androgen production (a 35% decrease in testosterone levels with a 10-kg weight loss) (54). Exercise also reduces insulin resistance, independent from any associated weight loss, but data on the impact of exercise on the principal manifestations of PCOS are lacking.

Insulin resistance/hyperinsulinemia has been recognized as a cluster syndrome now called the *metabolic syndrome* or *dysmetabolic syndrome X*. Its importance as a risk factor for cardiovascular disease has led to the establishment of diagnostic criteria. Three criteria confirm the diagnosis, and the greater the number of dysmetabolic syndrome X diagnostic criteria present, the higher the level of insulin resistance and its consequences. Patients who may be candidates for treatment with an insulin-lowering agent may be identified by the following diagnostic criteria:

- **Female waist >35 inches.**
- **Triglycerides >150 mg/dL.**
- **HDL cholesterol <50 mg/dL.**
- **Blood pressure >130/85 mm Hg.**
- **Fasting glucose: 110–125 mg/dL.**
- **2-hour GTT (75 g): 140–199 mg/dL.**

Risk factors include non-Caucasian race, sedentary lifestyle, body mass index (BMI) >25, age older than 40 years, cardiovascular disease, hypertension, PCOS, hyperandrogenemia, insulin resistance, HAIR-AN syndrome, nonalcoholic steatohepatosis, and a family history of type II diabetes mellitus or gestational diabetes or impaired glucose tolerance.

Ultrasonographic Studies

Ultrasonographic examination often shows characteristic abnormalities in women with PCOS (55,56). Ovarian size often is increased. **The most important ultrasonographic finding is a bilateral increase in the number of microcysts measuring 0.5 to 0.8 cm, with generally more than five microcysts in any given imaging plane in each ovary.** These findings are neither sufficiently sensitive nor specific to be considered an important part of

the evaluation of women in whom PCOS is suspected.

Long-term Risks

In patients with PCOS who have chronic anovulation, persistently elevated estrogen levels, unopposed by progesterone, increase the risk of endometrial carcinoma (57). These endometrial cancers are usually well-differentiated, stage I lesions with cure rates approaching 100% (see Chapter 33). Endometrial biopsy should be considered in PCOS patients, as they may occasionally have these cancers as early as the third decade of life. Abnormal bleeding, increasing weight, and age are factors that should influence the

P.1082

decision to perform endometrial sampling. **Prevention of endometrial cancer is a goal of management in patients with PCOS.** If other dimensions of management do not induce regular ovulation (e.g., clomiphene) or impose continuous progestational influence (e.g., oral contraceptives), regular secretory transformation and menstruation should be induced with periodic administration of a progestational agent. Likewise, the hyperestrogenic state is associated with an increased risk of breast cancer (58) and ovarian cancer (two- to threefold increase) (59). **The risk is greater in nonobese women and those who have not been taking oral contraceptives (OCs).**

Treatment of Hyperandrogenism and PCOS.

Treatment depends on a patient's goals. **Some patients require hormonal contraception, whereas others desire ovulation induction. In all cases in which there is significant ovulatory dysfunction, progestational interruption of unopposed estrogen effects on the endometrium is required.** This may be accomplished by periodic luteal function resulting from ovulation induction, progestational control via contraceptive formulations, or intermittent administration of progestational agents for endometrial or menstrual regulation. **Interruption of the steady state of hyperandrogenism and control of hirsutism usually can be accomplished simultaneously. An exception is those patients desiring pregnancy, in whom effective control of hirsutism may not be possible.** Treatment regimens for hirsutism are listed in Table 28.3. The induction of ovulation and treatment of infertility are discussed in Chapter 30.

Weight Reduction

Weight reduction is the initial recommendation for patients with accompanying obesity because it promotes health; reduces insulin, SHBG, and androgen levels; and may restore ovulation either used alone or in combination with ovulation-induction agents (53). Weight loss of as little as 5% to 7% over a 6-month period can reduce the bioavailable or calculated free testosterone level significantly and restore ovulation and fertility in more than 75% of women (60). Exercise involving large muscle groups

P.1083

reduces insulin resistance and can be an important component of nonpharmacologic, lifestyle-modifying management.

Table 28.3 Medical Treatment of Hirsutism

Treatment Category	Specific Regimens
Weight loss	
Hormonal suppression	Oral contraceptives
	Medroxyprogesterone
	Gonadotropin-releasing hormone analogs
	Glucocorticoids
Steroidogenic enzyme inhibitors	Ketoconazole
	5 α -reductase inhibitors
Antiandrogens	Finasteride
	Spiroglactone
	Cyproterone acetate
	Flutamide
Insulin Sensitizer	Metformin
Mechanical	Temporary
	Permanent
	Electrolysis
	Laser hair removal

Oral Contraceptives

Combination OCs decrease adrenal and ovarian androgen production (61,62,63,64) and reduce hair growth in nearly two thirds of hirsute patients. **Treatment with OCs offers the following benefits:**

- The **progestin component suppresses LH**, resulting in diminished ovarian androgen production.
- The **estrogen increases hepatic production of SHBG**, resulting in decreased free testosterone concentration (65,66).
- **Circulating androgen levels are reduced**, including those of DHEAS, which to some extent is independent of the effects of both LH and SHBG (13,67).
- **Estrogens decrease conversion of testosterone to DHT** in the skin by inhibition of 5 α -reductase.

When an OC is used to treat hirsutism, a balance must be maintained between the decrease in free testosterone levels and the intrinsic androgenicity of the progestin. Three progestin compounds that are present in OCs (*norgestrel*, *norethindrone*, and *norethindrone acetate*) are believed to be androgen dominant. The androgenic bioactivity of these steroids may be a factor of their shared structural similarity with 19-nortestosterone steroids (68). Oral contraceptives containing the so-called *new progestins* (*desogestrel*, *gestodene*, *norgestimate*, and *drospirenone*) have minimized androgenic activity. There is limited evidence that there is a difference in clinical outcome determined by these differences in *in vitro* estimates of androgenic potency, however.

The use of OCs alone may be relatively ineffective (less than 10% success rate) in the treatment of hirsutism in women with PCOS (69). Insulin resistance may also be exacerbated by OCs in these patients (70). Therefore, effective protocols for

pharmacologic management of hirsutism with OCs usually include coadministration of agents that impede androgen action.

Medroxyprogesterone Acetate

Oral or intramuscular administration of *medroxyprogesterone acetate* has been used successfully for treatment of hirsutism (71). It directly affects the hypothalamic–pituitary axis by decreasing GnRH production and the release of gonadotropins, thereby reducing testosterone and estrogen production by the ovary. Despite a decrease in SHBG, total and free androgen levels are decreased significantly (72). The recommended oral dosage is 20 to 40 mg daily in divided doses or 150 mg given intramuscularly every 6 weeks to 3 months in the depot form. **Hair growth is reduced in as many as 95% of patients (73).** Side effects of the treatment include amenorrhea, bone mineral density loss, depression, fluid retention, headaches, hepatic dysfunction, and weight gain.

Gonadotropin–releasing Hormone Agonists

Administration of GnRH agonists may allow the differentiation of androgen produced by adrenal sources from that of ovarian sources (29). It has been shown to suppress ovarian steroids to castrate levels in patients with PCOS (74). Treatment with *leuprolide acetate* given intramuscularly every 28 days decreases hirsutism and hair diameter in both idiopathic hirsutism and hirsutism secondary to PCOS (75). Ovarian androgen levels are significantly and selectively suppressed. The addition of OC or estrogen replacement therapy to GnRH agonist treatment (add–back therapy) prevents bone loss and other side effects of menopause, such as hot flushes and genital atrophy. The hirsutism–reducing

P.1084

effect is retained (72,76). Suppression of hirsutism is not potentiated by the addition of estrogen therapy to GnRH agonist treatment (77).

Glucocorticoids

Dexamethasone may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian hyperandrogenism. Doses of *dexamethasone* as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to less than 400 µg/dL. **Because *dexamethasone* has 40 times the glucocorticoid effect of cortisol, daily doses greater than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing syndrome.** To avoid oversuppression of the pituitary–adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 µg/dL). Reduction in hair growth rate has been reported (78), as well as significant improvement in acne associated with adrenal hyperandrogenism.

Ketoconazole

Ketoconazole, an antifungal agent approved by the U.S. Food and Drug Administration, inhibits the key steroidogenic cytochromes. Administered at a low dose (200 mg/day), it can significantly reduce the levels of androstenedione, testosterone, and calculated free testosterone (79).

Spirolactone

Spirolactone is a specific antagonist of aldosterone, which competitively binds to the aldosterone receptors in the distal tubular region of the kidney. It is an effective potassium–

sparing diuretic that was originally used for treatment of hypertension. The effectiveness of *spironolactone* in the treatment of hirsutism is based on the following mechanisms: .

- Competitive inhibition of DHT at the intracellular receptor level (9).
- Suppression of testosterone biosynthesis by a decrease in the *CYP* enzymes (80).
- Increase in androgen catabolism (with increased peripheral conversion of testosterone to estrone).
- Inhibition of skin 5 α -reductase activity (9).

Although total and free testosterone levels are significantly reduced in patients with both PCOS and idiopathic hirsutism (hyperandrogenism with regular menses) after treatment with *spironolactone*, total and free testosterone levels in patients with PCOS remain higher than those with idiopathic hirsutism (hyperandrogenism with regular menses) (81). In both groups, SHBG levels are unaltered. The reduction in circulating androgen levels observed within a few days of *spironolactone* treatment partially accounts for the progressive regression of hirsutism.

At least a modest improvement in hirsutism can be anticipated in 70% to 80% of women using at least 100 mg of *spironolactone* daily for 6 months (82). Spironolactone reduces the daily linear growth rate of sexual hair, hair-shaft diameters, and daily hair volume production (83). **The most common dosage is 50 to 100 mg twice daily. Women treated with 200 mg/day show a greater reduction in hair-shaft diameter than women receiving 100 mg/day** (84). Maximal effect on hair growth is noted between 3 and 6 months but continues for 12 months. Electrolysis can be recommended 9 to 12 months after the initiation of *spironolactone* for permanent hair removal.

The most common side effect of *spironolactone* is menstrual irregularity (usually metrorrhagia), which may occur in more than 50% of patients with a dosage of

P.1085

200 mg/day (84). Normal menses may resume with reduction of the dosage. Infrequently, other side effects—such as mastodynia, urticaria, or scalp hair loss—occur. Nausea and fatigue can occur with high doses (82). Because *spironolactone* can increase serum potassium levels, its use is not recommended in patients with renal insufficiency or hyperkalemia. Periodic monitoring of potassium and creatinine levels is suggested.

Return of normal menses in amenorrheic patients is reported in as many as 60% of cases (81). Patients must be counseled to use contraception while taking *spironolactone* because it theoretically can feminize a male fetus.

Cyproterone Acetate

Cyproterone acetate is a synthetic progestin derived from 17-OHP that has potent antiandrogenic properties. The primary mechanism of *cyproterone acetate* is competitive inhibition of testosterone and DHT at the level of androgen receptors (80). This agent also induces hepatic enzymes and may increase the metabolic clearance rate of plasma androgens (85). A European formulation of *ethinyl estradiol* with *cyproterone acetate* significantly reduces plasma testosterone and androstenedione levels, suppresses gonadotropins, and increases SHBG levels (86). *Cyproterone acetate* also shows mild glucocorticoid activity (87) and may reduce DHEAS levels (88). Administered in a

reverse sequential regimen (*cyproterone acetate* 100 mg/day on days 5 to 15, and *ethinyl estradiol* 30–50 mg/day on cycle days 5 to 26), this cyclic schedule allows regular menstrual bleeding, provides excellent contraception, and is effective in the treatment of even severe hirsutism and acne (89).

Side effects of *cyproterone acetate* include fatigue, weight gain, decreased libido, irregular bleeding, nausea, and headaches. These symptoms occur less often when *ethinyl estradiol* is added. *Cyproterone acetate* administration has been associated with liver tumors in beagles and is not approved by the U.S. Food and Drug Administration for use in the United States.

Flutamide

Flutamide, a pure nonsteroidal antiandrogen, is approved for treatment of advanced prostate cancer. Its mechanism of action is inhibition of nuclear binding of androgens in target tissues. Although it has a weaker affinity to the androgen receptor than spironolactone or *cyproterone acetate*, larger doses (250 mg given two or three times daily) may compensate for the reduced potency. **Flutamide** is also a weak inhibitor of testosterone biosynthesis.

In a single, 3-month study of *flutamide* alone, most patients demonstrated significant improvement in hirsutism with no change in androgen levels (90). Significant improvement in hirsutism with a significant drop in androstenedione, DHT, LH, and FSH levels was observed in an 8-month follow-up of *flutamide* and low-dose OCs in women who did not respond to OCs alone (91). The side effects of *flutamide* treatment combined with a low-dose OC use included dry skin, hot flashes, increased appetite, headaches, fatigue, nausea, dizziness, decreased libido, liver toxicity, and breast tenderness (92).

In hyperinsulinemic, hyperandrogenemic nonobese adolescents with PCOS taking a combination of *metformin* (850 mg/day) and *flutamide* (62.5 mg/day), a low-dose OC containing *drospirenone* was more effective than an OC with *gestodene* in reducing total and abdominal fat excess (93). The combination of *ethinyl-drospirenone*, *metformin*, and *flutamide* is effective in reducing excess total and abdominal fat as well as attenuating dysadipocytokemia in young women with the hyperinsulinemic PCOS. The antiandrogen *flutamide* appeared to exert critical effects (94).

Many patients taking *flutamide* (50%–75%) report dry skin and a blue-green discoloration of urine. The risk of liver enzyme elevation may preclude *flutamide* as a routine

P.1086

option for the treatment of hirsutism. *Flutamide* should not be used in women desiring pregnancy.

Cimetidine

Cimetidine is a histamine H₂ receptor antagonist that has demonstrated a weak antiandrogenic effect as a result of its ability to occupy androgen receptors and inhibit DHT binding at the level of the hair follicles. Although *cimetidine* has been reported to reduce hair growth in women with hirsutism (95), two later studies show no beneficial effect (96,97).

Finasteride

Finasteride is a specific inhibitor of type 2 5 α -reductase enzyme activity that has been approved in the United States at a 5-mg dose for the treatment of benign prostatic hyperplasia and at a 1-mg dose to treat male pattern baldness. In a study in which *finasteride* (5 mg daily) was compared with *spironolactone* (100 mg daily) (98), both drugs resulted in similar significant improvement in hirsutism despite differing effects on androgen levels. Most of

the improvement in hirsutism occurred after 6 months of therapy with 7.5 mg of finasteride daily (99). The improvement in hirsutism in the presence of rising testosterone levels serves as convincing evidence that it is the binding of DHT and not testosterone to the androgen receptor that is responsible for hair growth. *Finasteride* does not prevent ovulation or cause menstrual irregularity. The increase in SHBG caused by OCs further decreases free testosterone levels; OCs used in combination with *finasteride* are more effective in reducing hirsutism than *finasteride* alone. As with *spironolactone* and flutamide, finasteride could theoretically feminize a male fetus; therefore, both of these agents should be used only with additional contraception.

Ovarian Wedge Resection

Bilateral ovarian wedge resection is associated with only a transient reduction in androstenedione levels and a prolonged minimal decrease in plasma testosterone (100,101). In patients with hirsutism and PCOS who have had wedge resection, hair growth was reduced by approximately 16% (5,102). Although Stein's original report cited a pregnancy rate of 85% following wedge resection and maintenance of ovulatory cycles, subsequent reports show lower pregnancy rates and an increased incidence of periovarian adhesions (103).

Laparoscopic Electrocautery

Laparoscopic ovarian electrocautery is used as an alternative to wedge resection in patients with severe PCOS whose condition is resistant to *clomiphene citrate*. In a recent series (104), ovarian drilling was achieved laparoscopically with an insulated electrocautery needle, using 100-W cutting current to aid in entry and 40-W coagulating current to treat each microcyst over 2 seconds (8-mm needle in ovary). In each ovary, 10 to 15 punctures were created. This led to spontaneous ovulation in 73% of patients, with 72% conceiving within 2 years. Of those who had undergone a follow-up laparoscopy, 11 of 15 were adhesion free. To reduce adhesion formation, a technique that cauterized the ovary only in four points led to a similar pregnancy rate (105), with a miscarriage rate of 14%. Most series report a decrease in both androgen and LH concentrations and an increase in FSH concentrations (106,107). Unilateral diathermy has been shown to result in bilateral ovarian activity (108). **The risk of adhesion formation should be discussed with the patient.**

Physical Methods of Hair Removal

Depilatory creams remove hair only temporarily. They break down and dissolve hair by hydrolyzing disulfide bonds. Although depilatories can have a dramatic effect, many women cannot tolerate these irritative chemicals. The topical use of corticosteroid cream may prevent contact dermatitis. *Eflornithine hydrochloride* cream, also known as *difluoromethylornithine (DMFO)*, irreversibly blocks ornithine decarboxylase (ODC), the

P.1087

enzyme in hair follicles that is important in regulating hair growth. It also has proved effective in the treatment of unwanted facial hair (109).

Shaving is effective and, contrary to common belief, it does not change the quality, quantity, or texture of hair (110). However, plucking, if done unevenly and repeatedly, may cause inflammation and damage to hair follicles and render them less amenable to electrolysis. Waxing is a grouped method of plucking in which hairs are plucked out from under the skin surface. The results of waxing last longer (up to 6 weeks) than shaving or depilatory creams (110).

Bleaching removes the hair pigment through the use of hydrogen peroxide (usually 6% strength), which is sometimes combined with ammonia. Although hair lightens and softens during oxidation, this method is frequently associated with hair discoloration or skin irritation and is not always effective (109).

Electrolysis and laser hair removal are the only permanent means recommended for hair removal. Under magnification, a trained technician destroys each hair follicle individually. When a needle is inserted into a hair follicle, galvanic current, electrocautery, or both used in combination (blend) destroy the hair follicle. After the needle is removed, a forceps is used to remove the hair. Hair regrowth ranges from 15% to 50%. Problems with electrolysis include pain, scarring, and pigmentation. Cost can also be an obstacle (111). Laser hair removal destroys the hair follicle through photoablation. These methods are most effective after medical therapy has arrested further growth.

Insulin Sensitizers

Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities..

Metformin (Glucophage) is an oral biguanide antihyperglycemic drug used extensively for non-insulin-dependent diabetes. Preliminary studies evaluating *metformin* use in pregnancy (category B status) suggest no teratogenicity and a reduced miscarriage rate but a potential increased risk of preeclampsia and perinatal mortality (112,113). *Metformin* lowers blood glucose mainly by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake. *Metformin* enhances insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal (114). The hyperandrogenism of PCOS is substantially relieved with *metformin* therapy, which leads to a drop in insulin levels and improved reproductive function (115,116,117). *Metformin* (500 mg three times daily) increases ovulation rates both spontaneously and when used in combination with *clomiphene citrate* in obese patients with PCOS. In this group, a 90% ovulation rate has been achieved (118).

In a Cochrane meta-analysis, *metformin* monotherapy improved the ovulation rate 3.9-fold over placebo, and the combination of *metformin* and *clomiphene citrate* improved both the ovulation and pregnancy rates 4.4-fold compared with *clomiphene citrate* use alone (119)..

The most common side effects are gastrointestinal, including nausea, vomiting, diarrhea, bloating, and flatulence. Because the drug has caused fatal lactic acidosis in men with diabetes who have renal insufficiency, baseline renal function testing is suggested (120). The drug should not be given to women with elevated serum creatinine levels (114).

In light of the association between the dysmetabolic syndrome and PCOS, it has been suggested that *metformin* may be an appropriate first-line agent for ovulation induction. Regardless of whether *metformin* is used as a primary ovulation induction agent or in combination with *clomiphene citrate*, **weight loss should be encouraged..**

Current concepts regarding the role of obesity and insulin resistance/hyperinsulinemia in PCOS suggest that the primary intervention should be weight loss (5%–10% of body

weight). In those with an elevated BMI, *orlistat* has proven to be helpful in initiating and maintaining weight loss. **A percentage of PCOS patients will respond to weight loss alone with spontaneous ovulation.** In those who do not respond to weight loss alone or who are unable to lose weight, the sequential addition of *clomiphene citrate* followed by an

insulin sensitizer alone, followed by a combination of these agents, may promote ovulation without the need to proceed to injectable gonadotropin therapy.

The increased incidence of spontaneous abortions in women with PCOS is a prevailing concern. Because of the potential reduction afforded by insulin sensitizers, these agents may be beneficial in combination with gonadotropin therapy for ovulation induction or *in vitro* fertilization (121).

Women with early pregnancy loss have a low level of circulating glycodelin, which has immunomodulatory effects protecting the developing fetus, and of IGF-binding protein (IGFBP)-1. Use of metformin increases levels of both factors, which might explain early findings suggesting it may reduce the high spontaneous abortion rates seen among women with PCOS (122). In an assessment of 68 women treated with *metformin* during pregnancy versus 31 not treated, early pregnancy loss rates were 6/68 versus 13/31, respectively (123). Information regarding an optimal timing for such treatment is unknown.

Cushing Syndrome

The adrenal cortex produces three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex steroids (androgen and estrogen precursors). Hyperfunction of the adrenal gland can produce clinical signs of increased activity of any or all of these hormones. Increased glucocorticoid action results in nitrogen wasting and a catabolic state. This state causes muscle weakness; osteoporosis; atrophy of the skin with striae, nonhealing ulcerations, and ecchymoses; reduced immune resistance that increases the risk of bacterial and fungal infections; and glucose intolerance resulting from enhanced gluconeogenesis and antagonism to insulin action.

Although most patients with Cushing syndrome gain weight, some lose it. **Obesity is typically central, with characteristic redistribution of fat over the clavicles around the neck and on the trunk, abdomen, and cheeks.** Cortisol excess may lead to insomnia, mood disturbances, depression, and even overt psychosis. With overproduction of sex steroid precursors, women may exhibit hyperandrogenism (hirsutism, acne, oligomenorrhea or amenorrhea, thinning of scalp hair). Masculinization is rare, and its presence suggests an autonomous adrenal origin, most often an adrenal malignancy. With overproduction of mineralocorticoids, patients may manifest arterial hypertension and hypokalemic alkalosis. The associated fluid retention may cause pedal edema.

Characteristic clinical laboratory findings associated with hypercortisolism are confined mainly to a complete blood count showing evidence of granulocytosis and reduced levels of lymphocytes and eosinophils. Increased urinary calcium secretion may be present.

Causes

The six recognized noniatrogenic causes of Cushing syndrome can be divided between those that are ACTH dependent and those that are ACTH independent (**Table 28.4**). The ACTH-dependent causes can result from ACTH secreted by pituitary adenomas or from an ectopic source. The hallmark of ACTH-dependent forms of Cushing syndrome is the presence of normal or high plasma ACTH concentrations with increased cortisol levels. The adrenal glands are hyperplastic bilaterally. Pituitary ACTH-secreting adenoma, or Cushing disease, is the most common cause of Cushing syndrome. **These pituitary adenomas are usually microadenomas (<10 mm in diameter) that may be as small as 1 mm. They behave as if they are resistant, to a variable degree, to the feedback effect of cortisol. As with the normal gland, these tumors secrete**

ACTH in a pulsatile fashion; unlike the normal gland, the diurnal pattern of cortisol secretion is lost. Ectopic ACTH syndrome most often is caused by malignant tumors. About one half of these tumors are small-cell carcinomas of the lung (124). Other tumors include bronchial and thymic carcinomas, carcinoid tumors of the pancreas, and medullary carcinoma of the thyroid.

Table 28.4 Causes of Cushing Syndrome

Category	Cause	Relative Incidence
ACTH-dependent	Cushing syndrome	60% ^a
	Ectopic ACTH-secreting tumors	15%
	Ectopic CRH-secreting tumors	Rare
ACTH-independent	Adrenal cancer	15%
	Adrenal adenoma	10%
	Micronodular adrenal hyperplasia	Rare
	Iatrogenic/factitious	Common

ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone.
^aACTH-dependent Cushing syndrome may be caused by pituitary adenoma, basophil hyperplasia, nodular adrenal hyperplasia, or cyclic Cushing syndrome.

Ectopic corticotropin-releasing hormone (CRH) tumors are rare and include such tumors as bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma (124). The presence of an ectopic CRH-secreting tumor should be suspected in patients whose dynamic testing suggests pituitary ACTH-dependent disease but who have rapid disease progression and very high plasma ACTH levels.

The most common cause of ACTH-independent Cushing syndrome is exogenous or iatrogenic (i.e., superphysiologic therapy with corticosteroids) or factitious (self-induced). Corticosteroids are used in pharmacologic quantities to treat a variety of diseases with an inflammatory component. Over time, such therapy will result in Cushing syndrome. When corticosteroids are taken by the patient but not prescribed by a physician, the diagnosis may be especially challenging. The diagnostic workup for Cushing syndrome focuses on the ability to suppress autonomous cortisol secretion and determine whether ACTH is elevated or suppressed; it is summarized in Figure 28.2, Tables 28.5, and 28.6 (125,126,127,128,129,130,131).

Treatment of ACTH-independent Forms of Cushing Syndrome

Excluding cases that are of iatrogenic or factitious etiology, ACTH-independent forms of Cushing syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest. This is because the tumors are relatively inefficient in the synthesis of steroid hormones. In general, tumors are larger than 6 cm in diameter and are easily detectable by computed tomography (CT) scanning or magnetic resonance imaging (MRI). Adrenal cancers often produce steroids other than cortisol. Thus, when Cushing syndrome is accompanied by hirsutism or virilization in women, or by feminization in men, adrenal cancer should be suspected.

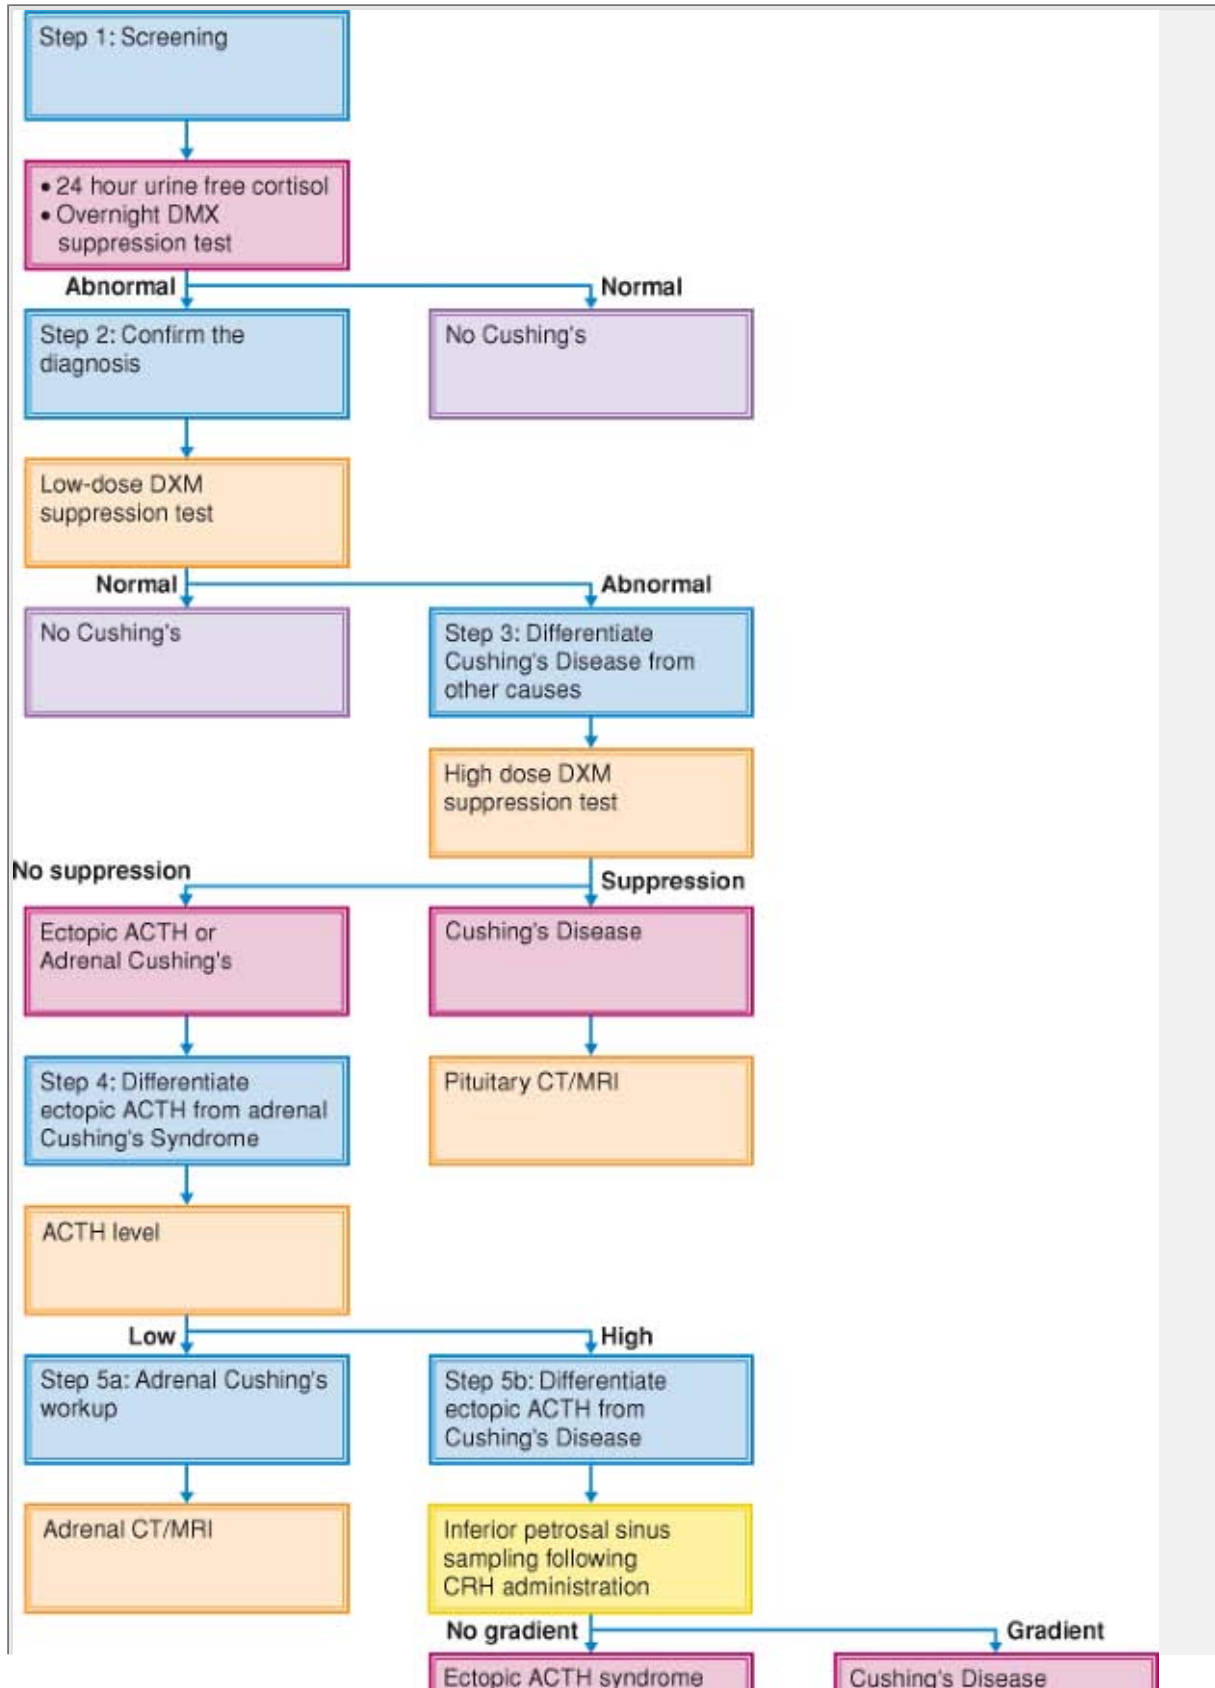

An adrenal tumor that appears large and irregular on radiologic imaging is suggestive of carcinoma. In these cases, a unilateral adrenalectomy through an abdominal exploratory approach is preferable. In most malignant tumors, complete resection is virtually impossible. However, a partial response to postoperative chemotherapy or radiation may

be achieved. Most patients with malignancy die within 1 year. When administered

P.1090

P.1091

immediately after surgery, *mitotane* (*O,P*-DDD, *adrenocorticolytic drug*) may be of benefit in preventing or delaying recurrent disease (132). Manifestations of Cushing syndrome in these patients are controlled by administration of adrenal enzyme inhibitors.

Table 28.5 Diagnostic Workup for Cushing Syndrome

Screening	<p>Women with hirsutism who are suspected of having Cushing syndrome should be tested for urinary free cortisol in a 24-hour collection and should undergo an overnight <i>dexamethasone</i> suppression test. Two consecutive collections are recommended with creatinine determination. Normal urinary free cortisol should range from 30 to 80 $\mu\text{g}/\text{day}$. The overnight <i>dexamethasone</i> suppression test is an 8:00 am cortisol determination after the patient is given 1 mg of <i>dexamethasone</i> at 11:00 PM the previous night.</p>
Confirmation of diagnosis	<p>Confirmation of diagnosis at this stage can be performed by the 2-day, low-dose <i>dexamethasone</i> suppression test of Liddle (117). The patient is given 0.5 mg of <i>dexamethasone</i> every 6 hours for 2 days. A 24-hour urine specimen is collected during the second day. Cushing syndrome is ruled out if there is suppression of urinary 17-hydroxycorticosteroids to $<3 \text{ mg}/24 \text{ hr}$ (or to 0% of baseline), suppression of plasma cortisol to $<4 \mu\text{g}/\text{day}$, or suppression of urinary free cortisol to $<25 \mu\text{g}/24 \text{ hr}$.</p>
Differentiation of Cushing syndrome	<p>The high-dose <i>dexamethasone</i> suppression test is used to differentiate Cushing syndrome from other causes (2 mg every 6 hours). Normally, urinary 17-hydroxycorticoids should be 40% of baseline after 2 days. This test partially suppresses ACTH secretion with a resulting decrease in cortisol production in most patients with Cushing syndrome; however, it has no effect on the majority of patients with ectopic or adrenal Cushing syndrome.</p>
Differentiation of ectopic ACTH syndrome	<p>High plasma ACTH ($>4.5 \text{ pmol}/\text{L}$ or $>20 \text{ pg}/\text{mL}$) is consistent with ectopic ACTH production from adrenal glands. A low ACTH level ($<1.1 \text{ pmol}/\text{L}$ or $<5 \text{ pg}/\text{mL}$) identifies a patient who most likely has adrenal Cushing syndrome.</p>

ACTH-independent and -dependent.

A patient with ACTH-independent Cushing syndrome should undergo an adrenal scan by MRI and should be prepared for adrenal surgery. A patient with ACTH-dependent Cushing syndrome should initially receive an administration of cortisol-releasing hormone (1 µg/kg IV over 1 minute), which is followed 3–5 minutes later by simultaneous sampling of both the inferior petrosal sinuses and of the peripheral vein. The ratio of ACTH levels from the inferior petrosal sinuses to peripheral plasma is then calculated. An inferior petrosal sinus is virtually diagnostic of a pituitary tumor. Moreover, 95% of patients with Cushing syndrome are found to have ratios higher than 2. If the test indicates a patient has Cushing syndrome, a pituitary MRI with gadolinium enhancement should be obtained in preparation for transsphenoidal surgery. If the results indicate ectopic ACTH secretion, a CT scan of the chest and possibly the abdomen should be performed.

ACTH, adrenocorticotrophic hormone; IV, intravenous; MRI, magnetic resonance imaging; CT, computed tomography.

Adrenal adenomas are smaller than carcinomas and average 3 cm in diameter.

These tumors are usually unilateral and infrequently are associated with other steroid-mediated syndromes. Micronodular adrenal disease is a disorder of children, adolescents, and young adults. The adrenal glands contain numerous small (>3 mm) nodules, which often are pigmented and secrete sufficient cortisol to suppress pituitary ACTH. This condition can be sporadic or familial.

Surgical removal of a neoplasm is the treatment of choice (133,134). If a unilateral, well-circumscribed adenoma is identified by MRI or CT scanning, the flank approach may be the most convenient. The cure rate following surgical removal of adrenal adenomas approaches 100%. Because normal function of the hypothalamic-pituitary-adrenal axis is suppressed by autonomous cortisol production, cortisol replacement should follow

P.1092

surgery. The dosage is titrated downward over several months, during which recovery of normal adrenal function is monitored.

Table 28.6 Laboratory Diagnosis of Cushing Syndrome

Diagnosis	24-Hour Urinary Cortisol	DEX Low-Dose	DEX High-Dose	ACTH
ACTH-dependent				
Cushing syndrome (60%)	Increased	Increased	Decreased	Normal
Pituitary adenoma				
Basophil hyperplasia				
Nodular adrenal hyperplasia				
Cyclic Cushing syndrome				
Ectopic ACTH (15%)	Increased	Increased	Increased	Increased
Ectopic CRH (rare)	Increased	Increased	Increased or decreased	Increased
ACTH-independent				

Adrenal neoplasia	Increased	Increased	Increased	Decreased
Adenoma (10%)				
Carcinoma (15%)				
Primary adrenocorticoid nodular dysplasia (<1%)>				
Pseudo-Cushing syndrome (alcohol-related, <1%)	Increased	Increased	Decreased	Normal
Exogenous glucocorticoids/factitious (not cortisol)	Increased or Decreased	Decreased	Decreased	Decreased
DEX, dexamethasone; ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone.				

Treatment of Cushing Disease

The treatment of choice for Cushing disease is transsphenoidal resection. The cure rate is approximately 80% in patients with microadenomas who undergo surgery (128) and is less than 50% in patients with macroadenomas (129). Following surgery, transient diabetes insipidus and enduring compromise of anterior pituitary secretion of growth hormone, gonadotropins, and TSH are common (130).

Radiation Therapy

High-voltage external pituitary radiation (4,200–4,500 cGy) is given at a rate not exceeding 200 cGy/day. Although only 15% to 25% of adults show total improvement (130), approximately 80% of children respond (131).

Medical Therapy

Mitotane can be used to induce medical adrenalectomy during or after pituitary radiation (132). The role of medical therapy is to prepare the severely ill patient for surgery and to maintain normal cortisol levels while a patient awaits the full effect of radiation. Occasionally, medical therapy is used for patients who respond to therapy with only partial remission. Adrenal enzyme inhibitors include *aminoglutethimide*, *metyrapone*, *trilostane*, and *etomidate*.

P.1093

A combination of *aminoglutethimide* and *metyrapone* may cause a total adrenal enzyme block requiring corticosteroid-replacement therapy. *Ketoconazole* also inhibits adrenal steroid biosynthesis at the side arm cleavage and 11 β -hydroxylation steps. The dose of *ketoconazole* for adrenal suppression is 600 to 800 mg/day for 3 months to 1 year (135). *Ketoconazole* is effective for long-term control of hypercortisolism of either pituitary or adrenal origin.

Nelson syndrome results from adenomatous progression of ACTH-secreting cells in patients with Cushing syndrome treated by bilateral adrenalectomy. The macroadenoma that causes this syndrome produces sellar pressure symptoms of headaches, visual field disturbances, and ophthalmoplegia. Extremely high ACTH levels in Nelson syndrome are associated with severe hyperpigmentation (melanocyte-stimulating hormone activity). The treatment is surgical removal or radiation. The offending adenomatous tissue is often resistant to complete surgical removal (136). This syndrome reportedly complicates 10% to 50% of bilateral adrenalectomy cases. Nelson syndrome is less common today because bilateral adrenalectomy is less frequently used as initial treatment.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is transmitted as an autosomal recessive disorder. Several adrenocortical enzymes necessary for cortisol biosynthesis may be affected. Failure to synthesize the fully functional enzyme has the following effects: .

- A relative decrease in cortisol production.
- A compensatory increase in ACTH levels.
- Hyperplasia of the zona reticularis of the adrenal cortex.
- An accumulation of the precursors of the affected enzyme in the bloodstream.

21-Hydroxylase Deficiency

Deficiency of 21-hydroxylase is responsible for more than 90% of cases of adrenal hyperplasia resulting from adrenal synthetic enzyme deficiency. The disorder produces a spectrum of conditions of CAH, with or without salt wasting, and milder forms that are expressed as hyperandrogenism of pubertal onset (AOAH). Salt-wasting CAH, the most severe form, affects 75% of patients with congenital manifestations during the first 2 weeks of life, and results in a life-threatening hypovolemic salt-wasting crisis, accompanied by hyponatremia, hyperkalemia, and acidosis. The salt-wasting form arises from a severity of enzyme deficiency sufficient to result in ineffective aldosterone synthesis. With or without salt-wasting and newborn adrenal crisis, the condition is usually diagnosed earlier in affected female newborns than in male newborns because genital virilization (e.g., clitoromegaly, labioscrotal fusion, and abnormal urethral course) is apparent at birth.

In simple virilizing CAH, affected patients are diagnosed as virilized newborn girls or as rapidly growing masculinized boys at 3 to 7 years of age. The diagnosis is based on basal levels of the substrate for 21-hydroxylase, 17-hydroxyprogesterone (17-OHP) in cases of congenital adrenal hyperplasia caused by 21 hydroxylase deficiency. In milder forms of the disorder with manifestations later in life (acquired, late-onset, or adult-onset adrenal hyperplasia), the diagnosis depends on basal and ACTH-stimulated levels of 17-OHP.

- Basal follicular phase 17-OHP less than 200 ng/dL virtually excludes the disorder; no further testing is required.
- Basal 17-OHP greater than 500 ng/dL establishes the diagnosis; there is no need for further testing (137).
- Basal 17-OHP greater than 200 ng/dL and less than 500 ng/dL requires ACTH stimulation testing.
- In the ACTH stimulation test, plasma levels of 17-OHP are checked 1 hour following

intravenous administration of a bolus of 0.25 mg ACTH 1–24 (*cosyntropin* [*Cortrosyn*]) (Fig. 28.3). 17–OHP levels after ACTH stimulation in adult–onset adrenal hyperplasia are generally greater than 1,000 ng/dL (137) (see Fig. 28.3).

Individuals who are heterozygous (carriers) for both adult–onset adrenal hyperplasia and CAH reveal stimulated 17–OHP values less than 1,000 ng/dL. In many cases, an overlap with the values seen in the normal population is observed (138) (see Fig. 28.3).

Nonclassic Adult–onset Congenital Adrenal Hyperplasia

The nonclassic type of 21–hydroxylase deficiency represents partial deficiency in 21–hydroxylation, which produces a late–onset, milder hyperandrogenemia. Its occurrence depends on some degree of functional deficit resulting from mutations affecting both alleles for the 21–hydroxylase enzyme. Heterozygote carriers for mutations in the 21–hydroxylase enzyme will demonstrate normal basal and modestly elevated stimulated levels of 17–OHP but no abnormalities in circulating androgens. Some women with a mild gene defects in both alleles demonstrate modest elevations in circulating 17–OHP concentrations but no clinical symptoms or signs.

The hyperandrogenic symptoms of AOAHA are mild and typically present during or after puberty. Following are the three phenotypic varieties (137):.

- Those with ovulatory abnormalities and features consistent with PCOS (39%).
- Those with hirsutism alone without oligomenorrhea (39%).
- Those with elevated circulating androgens but without symptoms (cryptic) (22%).

The need for screening patients with hirsutism for adult-onset adrenal hyperplasia depends on the patient population. The frequency of some form of the disorder varies by ethnicity and is estimated at 0.1% of the general population, 1% to 2% of Hispanics and Yugoslavs, and 3% to 4% of Ashkenazi Jews (139).

Genetics of 21-Hydroxylase Deficiency

- The 21-hydroxylase gene is located on the short arm of chromosome 6, in the midst of the HLA region.
- The 21-hydroxylase gene is now termed *CYP21*. Its homologue is the pseudogene *CYP21P* (140).
- Because *CYP21P* is a pseudogene, the lack of transcription renders it nonfunctional. The *CYP21* is the active gene.
- The *CYP21* gene and the *CYP21P* pseudogene alternate with two genes called *C4B* and *C4A*, both of which encode for the fourth component (*C4*) of serum complement (140).
- The close linkage between the 21-hydroxylase genes and *HLA* alleles has allowed the study of 21-hydroxylase inheritance patterns in families through blood *HLA* typing (e.g., linkage of *HLA-B14* was found in Ashkenazi Jews, Hispanics, and Italians) (141).

Prenatal Diagnosis and Treatment

Women with congenital and adult-onset forms of the disorder are at a significant risk for having affected infants because of the high frequency of mutations in 21-hydroxylase mutations in the general population. This fact represents an important rationale for screening hyperandrogenic women for this disorder if they anticipate childbearing. **In families at risk for CAH, and in instances in which one partner expresses the congenital or adult-onset form of the disease, first-trimester prenatal screening using chorionic villus sampling is advocated** (140). Currently, the fetal DNA is used for specific amplification of the *CYP21* gene using polymerase chain reaction (PCR) (142). When there is evidence of fetal involvement, an aggressive and controversial approach involves the use of **dexamethasone treatment for all pregnant women at risk of having a child with CAH.** The dosage is 20 mg/kg in three divided doses administered as soon as pregnancy is recognized and no later than 9 weeks of gestation. This is done before performing chorionic villus sampling or amniocentesis in the second trimester. *Dexamethasone* crosses the placenta and

suppresses ACTH in the fetus. If the fetus is found to be an unaffected female or a male, treatment is discontinued. If the fetus is an affected female, *dexamethasone* therapy is continued. When *dexamethasone* is administered before 9 weeks of gestation and is continued to term, it effectively reduces genital ambiguity in genetic females (140). However, **at least two thirds of treated females may still require surgical repair of the genitalia.** Although prenatal treatment reduces

virilization in females, the efficacy and safety to both mother and baby have not been verified, and the unnecessary treatment of seven of every eight pregnancies poses a ethical dilemma (143).

11 β -Hydroxylase Deficiency

In a small percentage of patients with CAH, hypertension rather than mineralocorticoid deficiency develops. The hypertension responds to corticosteroid replacement (144). Most of these patients have a deficiency in 11 β -hydroxylase. In most populations, 11 β -hydroxylase deficiency accounts for 5% to 8% of the cases of CAH, or 1 in 100,000 births (145). A much higher incidence, 1 in 5,000 to 7,000, has been described in Moroccan Jewish immigrants (146).

Two 11 β -hydroxylase isoenzymes, *CYP11-B1* and *CYP11-B2*, are responsible for synthesis of cortisol and aldosterone, respectively,. They are encoded by two genes on the middle of the long arm of chromosome 8 (147,148).

Inability to synthesize a fully functional 11 β -hydroxylase enzyme causes a decrease in cortisol production, a compensatory increase in ACTH secretion, and increased production of androstenedione, 11-deoxycortisol, 11-deoxycorticosterone, and DHEA. The diagnosis of 11 β -hydroxylase-deficient late-onset adrenal hyperplasia is determined when 11-deoxycortisol levels are higher than 25 ng/mL 60 minutes after ACTH 1-24 stimulation (149).

Patients with 11 β -hydroxylase deficiency may present with either a classic pattern of the disorder or symptoms of a mild deficiency. The severe, classic form is found in about two thirds of the patients with mild-to-moderate hypertension during the first years of life. In about one third of the patients, it is associated with left ventricular hypertrophy, with or without retinopathy, and death is occasionally reported from cerebrovascular accident (144). Signs of androgen excess are common in the severe form and are similar to those seen in the 21-hydroxylase deficiency.

In the mild, nonclassic form, children are found to have virilization or precocious puberty but not hypertension. Adult women seek treatment for postpubertal onset of hirsutism, acne, and amenorrhea.

3 β -Hydroxysteroid Dehydrogenase Deficiency

Deficiency of 3 β -hydroxysteroid dehydrogenase occurs with varying frequency in hirsute patients (150,151). The enzyme is found in both the adrenal glands and ovaries (unlike 21- and 11-hydroxylase) and is responsible for transforming δ -5 steroids into the corresponding δ -4 compounds, a step integral to the synthesis of glucocorticoids, mineralocorticoids, as well as testosterone and estradiol. In severe forms, cortisol and mineralocorticoids are deficient. In mild forms, elevated ACTH levels overcome these critical deficiencies, and the diagnosis of this disorder relies on the relationship of δ -5 and δ -4 steroids. A marked elevation of DHEA and DHEAS in the presence of normal or mildly elevated testosterone or androstenedione may be a signal to initiate a screening protocol for 3 β -hydroxysteroid dehydrogenase deficiency using exogenous ACTH stimulation (150). Following intravenous administration of a 0.25-mg ACTH 1-24 bolus, 17-hydroxypregnenolone levels rise significantly within 60 minutes in women

with 3 β -hydroxysteroid dehydrogenase deficiency compared with normal women (2,276 ng/dL compared with normal of 1,050 ng/dL). The mean poststimulation ratio between 17-hydroxypregnenolone and 17-OHP is markedly elevated (mean ratio of 11 compared with 3.4 in normal controls and 0.4 in 21-hydroxylase deficiency). Because of the rarity of this disorder, routine screening of hyperandrogenic patients is not justified (150,151).

Treatment of Adult-onset Congenital Adrenal Hyperplasia

In adults with CAH, dexamethasone has been shown to suppress the hypothalamic-pituitary axis better than cortisone acetate or hydrocortisone administered in equivalent doses. It also may induce less fluid retention than other corticosteroids. Evening administration with a dosage of 0.25 to 0.5 mg is most effective (152). In some patients, alternate-day therapy using the same dosage is sufficient. Periodic evaluation of serum cortisol is recommended. If morning serum cortisol concentrations are maintained at greater than 2 μ g/dL, oversuppression, with consequent impaired hypothalamic-pituitary-adrenal responsiveness to acute stress, is unlikely (153). Many patients with AOA undoubtedly are treated, undiagnosed, with therapies for ovarian hyperandrogenism or PCOS, with progestins for endometrial regulation, *clomiphene citrate* or gonadotropins for ovulation induction, or progestins and antiandrogens for control of hirsutism. These therapies may be appropriate as an alternative to glucocorticoid therapy, even when AOA is recognized as the cause for the patient's symptoms.

Androgen-secreting Ovarian and Adrenal Tumors

Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. In prepubertal girls, virilizing tumors may cause signs of heterosexual precocious puberty in addition to hirsutism, acne, and virilization. All patients with rapidly progressing or severe hyperandrogenism should undergo determination of levels of testosterone and DHEAS. A markedly elevated total testosterone level (2.5 times the upper normal range or >200 ng/dL) is typical of an ovarian androgen-secreting tumor, and a DHEAS level greater than 800 μ g/dL is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in the normal basal range and the serum cortisol concentration is less than 3.3 μ g/dL after *dexamethasone* administration (154). The results of other dynamic tests, especially testosterone suppression and stimulation, are unreliable (155).

A vaginal and abdominal ultrasonographic examination is the first step in the evaluation of findings suggesting ovarian neoplasm. Duplex Doppler scanning may increase the accuracy of tumor diagnosis and localization (156).

Computed tomography scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors or benign incidental nodules (157). In the ovaries, CT scanning cannot help differentiate hormonally active from functional tumors (156,157).

Magnetic resonance imaging is comparable, if not superior, to CT scanning in detecting ovarian neoplasms, but it is neither more sensitive than high-quality ultrasonography nor more useful in clinical decision making when a likely neoplasm is identified by ultrasonography. Nuclear medicine imaging of the abdomen and pelvis after injection with NP-59 ([¹³¹-iodine] 6- β -iodomethyl-19-norcholesterol), preceded by adrenal and thyroid suppression, may facilitate tumor localization (150). In the rare circumstances when

imaging fails to provide clear evidence of a neoplastic source of excess androgens, selective venous catheterization with measurement of site-specific androgen levels to identify an occult source of androgen excess may be utilized (158). If all four vessels are catheterized transfemorally, selective venous catheterization allows direct localization of the tumor. Samples are obtained for hormonal analysis, with positive localization defined as a 5:1 testosterone gradient compared with lower vena cava values (159). Under such circumstances, specificity approaches 80%, but this rate should be weighed against the 5% rate of significant complications, such as adrenal hemorrhage and infarction, venous thrombosis, hematoma, and radiation exposure (160).

Androgen-producing Ovarian Neoplasms

Ovarian neoplasms are the most frequent androgen-producing tumors. *Granulosa cell tumors* constitute 1% to 2% of all ovarian tumors and occur mostly in adult women (in postmenopausal more frequently than in premenopausal women) (see Chapter 35). Usually associated with estrogen production, they are the most common functioning tumors in children and lead to isosexual precocious puberty (161). Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the treatments of choice. If fertility is desired, in the absence of contralateral ovarian or pelvic node involvement, unilateral salpingo-oophorectomy is justifiable. The malignant potential of these lesions is variable. The 10-year survival rates vary from 60% to 90%, depending on the stage, tumor size, and histologic atypia (161).

Thecomas are rare and occur in older patients. In one study, only 11% were found to be androgenic, even in the presence of steroid-type cells (luteinized thecomas) (161). The tumor is rarely malignant and rarely bilateral, and a simple oophorectomy is sufficient treatment.

Sclerosing stromal tumors are benign neoplasms that usually occur in patients younger than 30 years (161). A few cases with estrogenic or androgenic manifestations have been reported.

Sertoli-Leydig cell tumors, previously classified as androblastoma or arrhenoblastoma, account for 11% of solid ovarian tumors. They contain various proportions of Sertoli cells, Leydig cells, and fibroblasts (161). Sertoli-Leydig cell tumors are the most common virilizing tumors in women of reproductive age; however, masculinization occurs in only one third of patients. The tumor is bilateral in 1.5%. In 80% of cases, it is diagnosed at stage IA (161). Treatment with unilateral salpingo-oophorectomy is justified in patients with stage IA disease who desire fertility. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and adjuvant therapy are recommended for postmenopausal women who have advanced-stage disease.

Pure Sertoli cell tumors are usually unilateral. For a premenopausal woman with stage I disease, a unilateral salpingo-oophorectomy is the treatment of choice. Malignant tumors are rapidly fatal (162).

Gynandroblastomas are benign tumors with well-differentiated ovarian and testicular elements. A unilateral oophorectomy or salpingo-oophorectomy is sufficient treatment.

Sex cord tumors with annular tubules (SCTATs) are frequently associated with Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous melanin pigmentation) (163). Their morphologic features range between those of the granulosa cell and Sertoli cell tumors. Whereas SCTATs with Peutz-Jeghers syndrome tend to be bilateral and benign, SCTATs without Peutz-Jeghers syndrome are almost always unilateral and are malignant in one fifth of cases (161).

Steroid Cell Tumors

Steroid cell tumors are composed entirely of steroid-secreting cells subclassified into stromal luteoma, Leydig cell tumors (hilar and nonhilar), and steroid cell tumors that are not otherwise specific (161). Virilization or hirsutism is encountered with three fourths of Leydig cell tumors, with one half of steroid cell tumors that are not otherwise specific, and with 12% of stromal luteomas.

Nonfunctioning Ovarian Tumors

Ovarian neoplasms that do not directly secrete androgens are occasionally associated with androgen excess resulting from secretion by adjacent ovarian stroma. Such tumors include serous and mucinous cystadenomas, Brenner tumors, Krukenberg tumors, benign cystic teratomas, and dysgerminomas (164). Gonadoblastomas arising

P.1099

in the dysgenetic gonads of patients with a Y chromosome may be associated with androgen and estrogen secretion (165,166).

Stromal Hyperplasia and Stromal Hyperthecosis

Stromal hyperplasia is a nonneoplastic proliferation of ovarian stromal cells. *Stromal hyperthecosis* is defined as the presence of luteinized stromal cells at a distance from the follicles (167).

Stromal hyperplasia, which is typically seen in patients between 60 and 80 years of age, may be associated with hyperandrogenism, endometrial carcinoma, obesity, hypertension, and glucose intolerance (167). *Hyperthecosis* also is seen in a mild form in older patients. In patients of reproductive age, hyperthecosis may demonstrate severe clinical manifestations of virilization, obesity, and hypertension. Hyperinsulinemia and glucose intolerance may occur in as many as 90% of patients with hyperthecosis and may play a role in the etiology of stromal luteinization and hyperandrogenism (50). Hyperthecosis is found in many patients with hyperandrogenemia, insulin resistance, and acanthosis nigricans (HAIR-AN syndrome).

In patients with hyperthecosis, levels of ovarian androgens, including testosterone, DHT, and androstenedione are increased, usually in the male range. The predominant estrogen, as in PCOS, is estrone, which is derived from peripheral aromatization. The $E_1:E_2$ ratio is increased. Unlike in PCOS, gonadotropin levels are normal (168).

Wedge resection for the treatment of mild hyperthecosis has been successful and has resulted in resumption of ovulation and even in a pregnancy (169). However, in cases of more severe hyperthecosis and high total testosterone levels, the ovulatory response to wedge resection is only transient (168). In a study in which bilateral oophorectomy was used to control severe virilization, hypertension and glucose intolerance sometimes disappeared (170). Moreover, when a GnRH agonist was used to treat patients with severe hyperthecosis, ovarian androgen production was dramatically suppressed (171).

Virilization during Pregnancy

Luteomas of pregnancy are frequently associated with maternal and fetal masculinization. This is not a true neoplasm but rather a reversible hyperplasia, which usually regresses postpartum. A review of the literature reveals a 30% incidence of maternal virilization and a 65% incidence of virilized female newborns in the presence of a pregnancy luteoma and maternal masculinization (172).

Other tumors causing virilization in pregnancy include (in descending order of frequency) Krukenberg tumors, mucinous cystic tumors, Brenner tumors,

serous cystadenomas, endodermal sinus tumors, and dermoid cysts (161).

Virilizing Adrenal Neoplasms

The most common virilizing adrenal neoplasms are adrenal carcinomas. When these malignancies virilize, they are invariably associated with elevations in DHEAS, which are usually accompanied by hypercortisolism. These tumors often are large and detectable on abdominal examination. Less commonly, the adrenals are the site for testosterone-secreting adenomas. Therefore, high testosterone levels (in the tumor range), accompanied by normal or only moderately elevated DHEAS levels, should not divert attention from the adrenal gland to the ovary. In fact, patients with these adenomas manifest increased testosterone production following stimulation with human chorionic gonadotropin (hCG) or LH and decreased testosterone secretion following LH suppression.

Of the fewer than 100 reported cases of pure virilizing adrenal neoplasms, 90% were benign. Although the peak age for the diagnosis of adenomas was 20 to 40 years, most of

P.1100

the pure testosterone-producing tumors occurred in menopausal women. With one exception, all cases of adenomas were unilateral. Fifty percent were palpable abdominally in children; in adults, none was detected solely by physical examination (173).

Prolactin Disorders

Prolactin was first identified as a product of the anterior pituitary in 1933 (174). Since that time, it has been found in nearly every vertebrate species. Its presence in humans was long inferred by the association of the syndrome of amenorrhea and galactorrhea in the presence of pituitary macroadenomas, although it was not definitively identified as a human hormone until 1971. The specific activities of human prolactin (hPRL) were defined initially by the separation of its activity from growth hormone (175) and subsequently by radioimmunoassay (176,177). **Although the initiation and maintenance of lactation is the primary function of prolactin, many studies have documented roles for prolactin activity both within and beyond the reproductive system.**

Prolactin Secretion

There are 199 amino acids within human prolactin, with a molecular weight (MW) of 23,000 daltons (Fig. 28.4). Although human growth hormone and placental lactogen have significant lactogenic activity, they have only a 16% and 13% amino acid sequence homology with prolactin, respectively. In the human genome, a single gene on chromosome 6 encodes prolactin. The prolactin gene (*10 kb*) has five exons and four introns. Its transcription is regulated in the pituitary by a proximal promoter region and in extrapituitary locations by a more upstream promoter (178).

Figure 28.4 Amino acid sequence of prolactin. Three cysteine disulfide bands are located within the molecule. (From **Bondy PK.** *Rosenberg leukocyte esterase: metabolic control and disease.* 8th ed. Philadelphia, PA: WB Saunders, 1980, with permission.).

P.1101

In the basal state, three forms are released, a monomer, a dimer, and a multimeric species, called *little*, *big*, and *big-big* prolactin, respectively (179,180,181). The two larger species can be degraded to the monomeric form by reducing disulfide bonds (182). The proportions of each of these prolactin species vary with physiologic, pathologic, and hormonal stimulation (182,183,184,185). The heterogeneity of secreted forms remains an active area of research. Overall, studies thus far indicate that little prolactin (MW 23,000 daltons) constitutes more than 50% of all combined prolactin production and is most responsive to extrapituitary stimulation or suppression (182,184,185). **Clinical assays for prolactin measure little prolactin, and in all but extremely rare circumstances, these measures are sufficient for assessment of diseases of abnormal pituitary production of the hormone.** Prolactin and its relatives, growth hormone and placental lactogen, do not require glycosylation for most of their primary activities, as is the case with the gonadotropins and TSH. Glycosylated forms are secreted, however, and glycosylation does affect the bioactivity and immunoreactivity of little prolactin (186,187,188,189). It appears that the glycosylated form is the predominant species secreted, but the most potent biologic form appears to be the 23,000-dalton nonglycosylated form of prolactin (188). Prolactin has more than 300 known biological activities, the most recognized of which include those associated with reproduction (lactation, luteal function, and reproductive behavior) and homeostasis (immune responsivity, osmoregulation, and angiogenesis) (190). Despite these many activities, **the only known disorder associated with deficiency of prolactin secretion is inability to lactate.**

To some degree, the physical heterogeneity of prolactin may explain the biologic heterogeneity of this hormone. Although this heterogeneity complicates the physiologic evaluation of prolactin's myriad effects, it is of little importance to the diagnosis and management of hyperprolactinemic states.

In contrast to other anterior pituitary hormones, which are controlled by hypothalamic-releasing factors, prolactin secretion is primarily under inhibitory control mediated by dopamine. **Multiple lines of evidence suggest that dopamine, which is secreted by the tuberoinfundibular dopaminergic neurons into the portal hypophyseal vessels, is the primary prolactin-inhibiting factor.** Dopamine receptors have been found on pituitary lactotrophs (191), and treatment with dopamine or dopamine agonists suppresses prolactin secretion (192,193,194,195,196,197). The dopamine antagonist metoclopramide abolishes the pulsatility of prolactin release and increases serum prolactin levels (193,194,198). **Interference with dopamine transit from the hypothalamus to the pituitary by mass lesions or blockade of the dopamine receptor, which occurs with antipsychotic agents and other medications, increases serum prolactin levels.** Thyrotropin-releasing hormone (TRH), when present at supraphysiologic levels (as in primary hypothyroidism), causes prolactin release, but does not appear to play an important modulatory role in the normal physiologic regulation of prolactin secretion. γ -Aminobutyric acid (GABA) and other neurohormones and neurotransmitters also may function as prolactin-inhibiting factors (see Table 28.7) (199,200,201,202). Several hypothalamic polypeptides that modulate prolactin-releasing activity are listed in Table 28.7. It appears that dopamine and TRH act as primary neurohormones, whereas others (e.g., neuropeptide Y, galanin, and enkephalin) act as modulators. It is likely that under differing physiologic conditions (e.g., pregnancy, lactation, stress, aging), a modulator may become a principal regulator of hormone secretion.

The prolactin receptor is a member of the class 1 cytokine receptor superfamily and is encoded by a gene on chromosome 5 (203). Transcriptional regulation of the prolactin receptor is accomplished through three tissue-specific promoter regions: promoter I for the gonads, promoter II for the liver, and promoter III, a generic promoter that includes the mammary gland (204).

Hyperprolactinemia

Physiologic disturbances, pharmacologic agents, or markedly compromised renal function may cause elevations in prolactin levels, and transient elevations occur with

P.1102

P.1103

P.1104

acute stress or painful stimuli. The most common cause of elevated prolactin levels is likely pharmacologic; most patients using antipsychotic medications, and many others using agents with antidopaminergic properties, have moderately elevated prolactin levels. Drug-related and physiologic conditions resulting in hyperprolactinemia do not always require direct intervention to normalize prolactin levels.

Evaluation

Plasma levels of immunoreactive prolactin are 5 to 27 ng/mL throughout the normal menstrual cycle. Samples should not be obtained soon after the patient awakes or after procedures. Prolactin is secreted in a pulsatile fashion with a pulse frequency ranging from about 14 pulses per 24 hours in the late follicular phase to about 9 pulses per 24 hours in the late luteal phase. There also is a diurnal variation, with the lowest levels occurring in midmorning. Levels rise 1 hour after the onset of sleep and continue to rise until peak values are reached between 5:00 and 7:00 AM (205,206). The pulse amplitude of prolactin appears to increase from early to late follicular and luteal phases (207,208,209). Because of the variability of secretion and inherent limitations of radioimmunoassay, an elevated level should always be rechecked. This sample preferably is obtained midmorning and not after a stressful event, previous venipuncture, breast stimulation, or physical examination, all of which transiently increase prolactin levels.

When prolactin levels are found to be elevated, hypothyroidism and medication use should first be ruled out as a cause. Prolactin and TSH determinations are basic evaluations

in infertile women. Infertile men with hypogonadism also should be tested. Likewise, prolactin levels should be measured in the evaluation of amenorrhea, galactorrhea, amenorrhea with galactorrhea, hirsutism with amenorrhea, anovulatory bleeding, and delayed puberty (Fig. 28.5).

Physical Signs

Elevations in prolactin may cause amenorrhea or galactorrhea. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women (210,211,212). The cessation of normal ovulatory processes resulting from elevated prolactin levels primarily is due to the suppressive effects of prolactin, via hypothalamic mediation, on GnRH pulsatile release (192,210,211,213,214,215,216,217,218,219,220,221). In addition to inducing a hypogonadotropic state, prolactin elevations may secondarily impair the mechanisms of ovulation through a number of actions: causing a reduction in granulosa cell number and FSH binding (222), inhibiting granulosa cell 17β -estradiol production by interfering with FSH action (222,223,224), and causing inadequate luteinization and reduced luteal secretion of progesterone (225,226,227). Other causes of amenorrhea are detailed in Chapter 27.

Although isolated galactorrhea is considered indicative of hyperprolactinemia, prolactin levels are within the normal range in nearly 50% of such patients (228,229,230) (see Fig. 28.5). In such cases, whether because of a prior transient episode of hyperprolactinemia or other unknown factors, the sensitivity of the breast to the lactotrophic stimulus engendered by normal prolactin levels is sufficient to result in galactorrhea. This situation is similar to that observed in breastfeeding mothers in whom milk secretion, once established, continues and even increases despite progressive normalization of prolactin levels. Repeat testing may be helpful in detecting hyperprolactinemia. Approximately one third of women with galactorrhea have normal menses. Conversely, hyperprolactinemia often occurs in the absence of galactorrhea (66%), possibly as a result of inadequate estrogenic or progestational priming of the breast.

In patients with both galactorrhea and amenorrhea (including the syndromes described and named by Forbes, Henneman, Griswold, and Albright in 1951, Argonz and del Castilla in 1953, and Chiari and Frommel in 1985), **approximately two thirds will have hyperprolactinemia; of those, approximately one third will have a pituitary adenoma** (231). In anovulatory women, 3% to 10% of women diagnosed with polycystic ovary disease have coexistent and usually modest hyperprolactinemia (232,233) (Fig. 28.6).

Figure 28.6 Prolactin levels in 235 patients with galactorrhea. Among patients with a tumor, open triangles denote associated acromegaly, and solid circles and solid triangles denote previous radiotherapy or surgical resection, respectively. (From **Kleinberg DL, Noel GL, Frantz AG.** Galactorrhea: a study of 235 cases, including 48 with pituitary tumors. *N Engl J Med* 1977;296:589–600.)

Prolactin and TSH levels should be measured in all patients with delayed puberty.

Pituitary abnormalities, including craniopharyngiomas and adenomas, should be considered in all cases of delayed puberty accompanied by low levels of gonadotropins, regardless whether prolactin levels are elevated. When prolactin-secreting pituitary adenomas are present, the condition of multiple endocrine neoplasia type 1 (MEN-1) syndrome (gastrinoma, insulinoma, parathyroid hyperplasia, and pituitary neoplasia) should be considered, although symptoms of pituitary adenoma are rarely the presenting symptom. Patients who have a pituitary adenoma and a family history of multiple adenomas warrant special attention (234). Prolactinomas are noted in approximately 20% of patients with MEN-1. The *MEN-1* gene

suppressor gene. An inactivating mutation results in development of the tumor. It is thought that prolactin-secreting pituitary adenomas that occur in patients with MEN-1 may be more aggressive than sporadic cases (235).

Once an elevated prolactin level is documented and medications or hypothyroidism excluded as the underlying cause, knowledge of neuroanatomy as well as imaging techniques and their interpretation are required for further evaluation (see Chapter 7).

Pituitary hyperprolactinemia is most often caused a microadenoma, and the results of imaging studies usually are normal. These patients can be reassured that the course of their condition generally is benign. Macroadenomas or juxtaseellar lesions are less common and require more complex evaluation and treatment, including surgery, radiation, or both. Levels of TSH should be measured in all patients with hyperprolactinemia (see Fig. 28.5).

Imaging Techniques

In patients with larger microadenomas and macroadenomas, prolactin levels usually are higher than 100 ng/mL. However, levels lower than 100 ng/mL may be associated with smaller microadenomas, macroadenomas that produce a "stalk section" effect, and suprasellar tumors that may be easily missed on a "coned-down" view of the sella turcica.

Modest elevations of prolactin can, therefore, be associated with microadenomas or macroadenomas, nonlactotroph pituitary tumors, and other central nervous system abnormalities. Imaging of the pituitary gland must be considered in the presence of otherwise unexplained and persistent elevation of prolactin (Table 28.8).

In patients with a clearly identifiable drug-induced or physiologic hyperprolactinemia, imaging is not necessary unless it is accompanied by symptoms suggesting a mass lesion (headache, visual field deficits). **Magnetic resonance imaging of the sella and pituitary gland with gadolinium enhancement appears to provide the best anatomic detail (236) (Fig. 28.7).** The cumulative radiation dose from multiple CT scans may cause cataracts, and the "coned-down" views or tomograms of the sella are very insensitive and likewise expose the patient

to radiation. For patients with hyperprolactinemia who desire future fertility, MRI is indicated to differentiate a pituitary microadenoma from a macroadenoma, as well as to identify other potential sellar or suprasellar masses. Although rare, when pregnancy-related complications of a pituitary adenoma occur, they occur more frequently in the presence of macroadenomas.

Hamartoma (tuber cinereum/hypothalamus)	Rathke's cleft cyst
Histiocytosis	Sarcoidosis
Hyperplasia	
Hypophysitis	

In more than 90% of untreated women, microadenomas do not enlarge over a 4- to 6-year period. For that reason, the argument that medical therapy will prevent a microadenoma from growing is false. Additionally, although prolactin levels correlate with tumor size, both elevations and reductions in prolactin levels may occur without any change in tumor size. If prolactin levels increase significantly or central nervous system symptoms (e. g., headache, visual changes) occur, repeat imaging may be indicated.

Hypothalamic Disorders

Dopamine was the first of many substances demonstrated to be produced in the arcuate nucleus. Dopamine-releasing neurons innervate the external zone of the median eminence. When released into the hypophyseal portal system, dopamine inhibits prolactin

P.1109

release in the anterior pituitary. Lesions that disrupt dopamine release can result in hyperprolactinemia. Such lesions may arise from the suprasellar area, pituitary gland, and infundibular stalk, as well as from adjacent bone, brain, cranial nerves, dura, leptomeninges, nasopharynx, and vessels. Numerous pathologic entities and physiologic conditions in the hypothalamic-pituitary region can disrupt dopamine release and cause hyperprolactinemia (see Table 28.8).

Pituitary Disorders

Microadenoma

Autopsy series reveal that 25% of the U.S. population has microadenomas, and approximately 40% stain positively for prolactin. Clinically significant pituitary tumors requiring some type of intervention affect only 14 per 100,000 individuals.

In more than one third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (less than 1 cm) is found. Release of pituitary stem-cell growth inhibition via activation or loss-of-function mutations results in cell cycle dysregulation and is critical to the development of pituitary microadenomas and macroadenomas. Microadenomas are monoclonal in origin. Genetic mutations are thought to release stem-cell growth inhibition and result in autonomous anterior pituitary hormone production, secretion, and cell proliferation. Additional anatomic factors that may contribute to adenoma formation include reduced dopamine concentrations in the hypophyseal portal system and vascular isolation of the tumor, or both. Recently, the heparin-binding secretory transforming (*HST*) gene has been noted in a variety of cancers as well as in prolactinomas (237). **Patients with microadenomas can generally be reassured of a benign course, and many of these lesions gradually regress spontaneously** (238,239).

Both microadenomas and macroadenomas are monoclonal in origin. Pituitary

prolactinomas or lactotrope adenomas are sparsely or densely granulated histologically. The sparsely granulated lactotrope adenomas have trabecular, papillary, or solid patterns. Calcification of these tumors may take the form of a psammoma body or a pituitary stone. Densely granulated lactotrope adenomas are strongly acidophilic tumors and appear to be more aggressive than sparsely granulated lactotrope adenomas. Unusual acidophil stem-cell adenomas can be associated with hyperprolactinemia with some clinical or biochemical evidence of growth hormone excess.

Microadenomas rarely progress to macroadenomas. Six large series of patients with microadenomas reveal that, with no treatment, the risk of progression for microadenoma to a macroadenoma is only 7% (240). Treatments include expectant, medical, or, rarely, surgical therapy. All affected women should be advised to notify their physicians of chronic headaches, visual disturbances (particularly tunnel vision consistent with bitemporal hemianopsia), and extraocular muscle palsies. Formal visual field testing is rarely helpful unless imaging suggests compression of the optic nerves.

Expectant Management

In women who do not desire fertility, expectant management can be used for both microadenomas and hyperprolactinemia in the absence of an adenoma if menstrual function remains intact. Hyperprolactinemia-induced estrogen deficiency, rather than prolactin itself, is the major factor in the development of osteopenia (241).

Therefore, **estrogen replacement with hormone regimens or hormonal contraceptives is indicated for patients with amenorrhea or irregular menses. Patients with drug-induced hyperprolactinemia can also be managed expectantly with attention to the risks of osteoporosis. In the absence of symptoms of pituitary enlargement,** imaging may be repeated in 12 months and, if prolactin levels remain stable, less frequently thereafter to assess further growth of the microadenoma.

P.1110

Medical Treatment

Ergot alkaloids are the mainstay of therapy. In 1985, *bromocriptine* was approved for use in the United States to treat hyperprolactinemia caused by a pituitary adenoma. These agents act as strong dopamine agonists, thus decreasing prolactin levels. Effects on prolactin levels occur within hours, and lesion size may decrease within 1 to 2 weeks. *Bromocriptine* decreases prolactin synthesis, DNA synthesis, cell multiplication, and overall size of prolactinomas. Treatment results in normal prolactin blood levels or return of ovulatory menses in 80% to 90% of patients.

Because ergot alkaloids such as *bromocriptine* are excreted via the biliary tree, it should be used with caution in the presence of liver disease. The major adverse effects include nausea, headaches, hypotension, dizziness, fatigue and drowsiness, vomiting, headaches, nasal congestion, and constipation. Many patients tolerate *bromocriptine* **when dose is increased gradually, by 1.25 mg (one half tablet) daily each week until prolactin levels are normal or a dose of 2.5 mg twice daily is reached. A proposed regimen is as follows: one half tablet every evening (1.25 mg) for 1 week, one half tablet morning and evening (1.25 mg) during the second week, one half tablet in the morning (1.25 mg) and a full tablet every evening (2.5 mg) during the third week, and one tablet every morning and every evening during the fourth week and thereafter (2.5 mg twice a day).** The lowest dose that maintains the prolactin level in the normal range is continued (1.25 mg twice daily often is sufficient to normalize prolactin levels in individuals with levels <100 ng/mL). Pharmacokinetic studies show peak serum levels occur 3 hours after an oral

dose, with a nadir at 7 hours. Because little detectable *bromocriptine* remains in the serum by 11 to 14 hours, twice-a-day administration is required. Prolactin levels can be checked soon (6–24 hours) after the last dose is taken.

One rare but notable adverse effect of *bromocriptine* is a **psychotic reaction**. Symptoms include auditory hallucinations, delusional ideas, and changes in mood that quickly resolve with discontinuation of the drug (242). Many investigators report no difference in fibrosis, calcification, prolactin immunoreactivity, or the surgical success in patients pretreated with *bromocriptine* compared with those not receiving *bromocriptine* (240).

An alternative to oral administration is the vaginal administration of *bromocriptine* tablets, which is well tolerated and actually results in increased pharmacokinetic measures (243).

Cabergoline, another ergot alkaloid, has a very long half-life and can be given orally twice per week. Its long duration of action is attributable to slow elimination by pituitary tumor tissue, high affinity binding to pituitary dopamine receptors, and extensive enterohepatic recirculation.

Cabergoline, which appears to be as effective as *bromocriptine* in lowering prolactin levels and in reducing tumor size, has substantially fewer adverse effects than bromocriptine. Very rarely, patients experience nausea and vomiting or dizziness with *cabergoline*; they may be treated with intravaginal *cabergoline*, as with *bromocriptine*. Although *cabergoline* appears to be safe to use during pregnancy, more extensive data regarding the use of *bromocriptine* in pregnancy is available; therefore *bromocriptine* is preferred for pregnant patients. A gradually increasing dosage helps avoid the side effects of nausea, vomiting, and dizziness. *Cabergoline* at 0.25 mg twice per week is usually adequate for hyperprolactinemia with values less than 100 ng/mL. If required to normalize prolactin levels, the dosage can be increased by 0.25 mg per dose on a weekly basis to a maximum of 1 mg twice weekly.

When *bromocriptine* or *cabergoline* cannot be used, other medications such as *pergolide* or *methergoline* may be used. In patients with a microadenoma who are receiving *bromocriptine* therapy, a repeat MRI scan may be performed if indicated 6 to 12 months after prolactin levels are normal. Normal prolactin levels and resumption of menses should not be considered absolute proof of tumor response to treatment. Further MRI scans should be performed if new symptoms appear.

P.1111

Discontinuation of *bromocriptine* **therapy after 2 to 3 years may be attempted in a select group of patients in whom normal prolactin levels have been maintained with therapy** (244,245). Discontinuation of *cabergoline* therapy has also been successful in patients treated for 3 to 4 years who have maintained normal prolactin levels (246). In general, recurrence rates are higher for macroadenomas (as compared with microadenomas or hyperprolactinemia without adenoma) after cessation of either bromocriptine or cabergoline, warranting close follow-up with serum prolactin assessment and MRI after cessation of therapy. In patients with macroadenomas, withdrawal of therapy should proceed with caution because tumors may re-expand rapidly.

Macroadenomas

Macroadenomas are pituitary tumors that are larger than 1 cm. *Bromocriptine* is the best initial and potentially long-term treatment option, but transsphenoidal surgery may be required. Evaluation for pituitary hormone deficiencies may be indicated. Symptoms of macroadenoma enlargement include severe headaches, visual field changes and, rarely, diabetes insipidus and blindness.

Medical Treatment

Treatment with *bromocriptine* **decreases prolactin levels and the size of macroadenomas**; nearly one half show a 50% reduction in size, and another one fourth show a 33% reduction after 6 months of therapy. Because tumor regrowth occurs in more than 60% of cases after discontinuation of *bromocriptine* therapy, long-term therapy is usually required.

After stabilization of tumor size is documented, an MRI scan is repeated 6 months later and, if stable, yearly for several years. This examination may be performed earlier if new symptoms develop or if there is no improvement in symptoms. Serum prolactin levels are measured every 6 months. Because tumors may enlarge despite normalized prolactin values, a reevaluation of symptoms at regular intervals (6 months) is prudent. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment.

Surgical Intervention

Tumors that are unresponsive to *bromocriptine* **or that cause persistent visual field loss require surgical intervention**. Some neurosurgeons have noted that a short (2-week) preoperative course of *bromocriptine* increases the efficacy of surgery in patients with larger adenomas (243). Unfortunately, despite surgical resection, recurrence of hyperprolactinemia and tumor growth is common. Complications of surgery include cerebral carotid artery injury, diabetes insipidus, meningitis, nasal septal perforation, partial or panhypopituitarism, spinal fluid rhinorrhea, and third nerve palsy. Periodic MRI scanning after surgery is indicated, particularly in patients with recurrent hyperprolactinemia.

Metabolic Dysfunction and Hyperprolactinemia

Occasionally, patients with hypothyroidism exhibit hyperprolactinemia with remarkable pituitary enlargement caused by thyrotroph hyperplasia. Thyroid replacement therapy can reduce pituitary enlargement and normalize prolactin levels (247).

Hyperprolactinemia occurs in 20% to 75% of women with chronic renal failure. Hemodialysis does not lower prolactin levels, but levels become normal with transplantation (248,249,250). Occasionally, women with hyperandrogenemia also have hyperprolactinemia. Elevated prolactin levels may alter adrenal function by enhancing the release of adrenal androgens such as DHEAS (251).

Drug-induced Hyperprolactinemia

Numerous drugs interfere with dopamine secretion and can therefore be responsible for hyperprolactinemia and its attendant symptoms (see Table 28.7). If medication can be discontinued, resolution of hyperprolactinemia is uniformly prompt. If not,

P.1112

endocrine management should be directed toward replacing estrogen and normalizing menses for those with disturbed or absent ovulation. Treatment with *dopamine agonists* may be utilized if ovulation is desired and the drug inducing hyperprolactinemia cannot be discontinued.

Use of Estrogen in Hyperprolactinemia

In rodents, pituitary prolactin-secreting adenomas occur with high-dose estrogen administration (252). Elevated levels of estrogen, such as those that occur in pregnancy, are responsible for hypertrophy and hyperplasia of lactotrophic cells and account for the progressive increase in prolactin levels in normal pregnancy. The increase in prolactin during pregnancy is physiologic and reversible, however, and adenomas are not fostered by

the hyperestrogenemia of pregnancy. Pregnancy may even have a favorable influence on pre-existing prolactinomas (253,254). Estrogen administration is not associated with clinical, biochemical, or radiologic evidence of growth of pituitary microadenomas or the progression of idiopathic hyperprolactinemia to the status of an adenoma (255,256,257,258). For these reasons, **estrogen replacement or OC use is appropriate for hypoenestrogenic patients with hyperprolactinemia secondary to microadenoma or hyperplasia.**

Monitoring Pituitary Adenomas During Pregnancy

Prolactin-secreting microadenomas rarely create complications during pregnancy. However, monitoring of patients with serial gross visual field examinations and funduscopic examination is recommended. If persistent headaches, visual field deficits, or visual or funduscopic changes occur, MRI scanning is advisable. **Because serum prolactin levels progressively rise throughout pregnancy, prolactin measurements are rarely of value.**

For those women who experience return of spontaneous ovulation and become pregnant while taking *bromocriptine*, discontinuation of *bromocriptine* is recommended.

This does not, however, preclude subsequent use of *bromocriptine* during the pregnancy to treat symptoms (visual field defects, headaches) that arise from further enlargement of the microadenoma (259,260,261,262). *Bromocriptine* has not exhibited teratogenicity in animals, and observational data do not suggest it is harmful to the pregnancy or the fetus in humans.

Pregnant women with previous transsphenoidal surgery for microadenomas or macroadenomas may be monitored additionally with monthly Goldman perimetry visual field testing. Periodic MRI scanning may be necessary in women with symptoms or visual changes. **Breastfeeding is not contraindicated in the presence of microadenomas or macroadenomas** (259,260,261,262). The use of *bromocriptine* and presumably other dopaminergic agents that may cause blood pressure elevation during the postpartum period is contraindicated (263,264,265,266,267).

Thyroid Disorders

Thyroid disorders are 10 times more common in women than men (268).

Approximately 1% of the female population of the United States will develop overt hypothyroidism. Even before the discovery of the long-acting thyroid stimulator (LATS) in women with Graves disease in 1956, numerous investigations demonstrated a link between these autoimmune thyroid disorders and reproductive physiology and pathology (269).

Thyroid Hormones

Iodide is a critical component of the class of hormones known as thyronines, among which the most important are triiodothyronine and thyroxine (T_3 and T_4). Iodide obtained from dietary sources is actively transported into the thyroid follicular cell for synthesis of these

P.1113

hormones. Sodium-iodide symporter (NIS) is a key molecule in thyroid function. It allows the accumulation of iodide from the circulation into the thyrocyte against an electrochemical gradient. Sodium-iodide symporter requires energy that is supplied by Na-K ATPase. Uptake is stimulated by TSH. The enzyme thyroid peroxidase (TPO) then oxidizes iodide near the cell-colloid surface and incorporates it into tyrosyl residues within the thyroglobulin molecule, which results in the formation of monoiodotyrosine (MIT) and

diiodotyrosine (DIT). Triiodothyronine (T_3) and thyroxine (T_4), formed by secondary coupling of MIT and DIT, are also catalyzed by TPO. The membrane-bound, heme-containing oligomer, TPO, is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and on the follicular cell surface. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T_3 and T_4 , and the remainder is present in MIT and DIT or found as unbound iodine. Thyroglobulin provides a storage capacity capable of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The thyroid antimicrosomal antibodies found in patients with autoimmune thyroid disease are directed against the TPO enzyme (270,271).

Thyroid-stimulating hormone regulates thyroidal iodine metabolism by activation of adenylate cyclase. This facilitates endocytosis as a component of iodide uptake, digestion of thyroglobulin-containing colloid, and the release of thyroid hormones T_4 , T_3 , and reverse T_3 . T_4 is released from the thyroid at 40 to 100 times the concentration of T_3 . The concentration of reverse T_3 , which has no intrinsic thyroid activity, is 30% to 50% of T_3 secretion and 1% of T_4 concentration. Of thyroid hormones released, 70% are bound by circulating thyroid-binding globulin (TBG). Although T_4 is present in the circulating storage pool in the highest concentrations, it has a slow turnover rate (about 7 days). Compared with T_4 , the concentration of T_3 is lower and has a higher turnover rate. Approximately 30% of T_4 is converted to T_3 in the periphery. Reverse T_3 participates in regulation of the conversion of T_4 to T_3 . T_3 is the primary physiologically functional thyroid hormone at the cellular level. T_3 binds the nuclear receptor with 10 times the affinity of T_4 . Thyroid hormone effects on cells include increased oxygen consumption, heat production, and metabolism of fats, proteins, and carbohydrates. Systemically, thyroid hormone activity is responsible for the basal metabolic rate. It balances fuel efficiency with performance, much as a carburetor functions in an engine. Hyperthyroid states result in excessive fuel consumption with marginal performance.

Iodide Metabolism

Normal function of the thyroid gland depends on iodine. The present recommended daily allowance by the U.S. National Research Council is 150 to 300 mg/day. Present daily consumption in the United States averages 200 to 600 mg/day and is largely assured by virtue of addition of iodine to many common foodstuffs. Iodine is usually ingested in the form of iodized salt (100 mg of potassium iodine/kg of salt) (272).

In regions where dietary iodine is insufficient, goitrous hypothyroidism among adults and the consequences of inadequate fetal thyroxine are common (endemic goiter and endemic cretinism). Paradoxically, sufficiency of iodine appears to be associated with the development of autoimmune thyroid disorders (273,274) and reduced remission rates in patients treated for Graves disease (275). Animal studies suggest that iodine stimulates immunoglobulin production by B lymphocytes, activates macrophages, and increases the immunogenic potential of thyroglobulin because of the higher iodide content (276,277,278,279).

Risk Factors for Autoimmune Thyroid Disorders

Environmental factors that have been associated with the occurrence of autoimmune thyroid diseases include pollutants (plasticizers, polychlorinated biphenyls, and coal-processing pollutants) (280,281) and antibodies to *Yersinia enterocolitica* (282).

The female hormonal milieu and its effects on immune surveillance undoubtedly play

a role in the increased risk (10-fold) for women to develop autoimmune thyroid disease.

P.1114

The immunoglobulins produced against the thyroid are polyclonal, and the multiple combinations of various antibodies present (stimulating versus blocking, complement fixing, and noncytotoxic) combine to create the clinical spectrum of autoimmune thyroid diseases that may affect reproductive function.

Evaluation

Thyroid Function

Total serum T₄ is measured by radioimmunoassay, and these measurements are indifferent to the fraction of T₄ that is bound to its specific binding protein, TBG. Levels of TBG are variable, and many conditions cause elevations in them (e.g., pregnancy, OC use, estrogen therapy, hepatitis, and genetic abnormalities of TBG). Thus, indirect estimation of the unbound ("free") T₄ or its direct measurement are required for clinical evaluation.

The T₃ resin uptake determines the fractional binding of radiolabeled T₃ that is added to a serum sample in the presence of a resin that competes with TBG for T₃ binding.

The binding capacity of TBG in the sample is inversely proportional to the amount of labeled T₃ bound to the artificial resin. Therefore, a low T₃ resin uptake indicates high TBG T₃ receptor site availability and implies high circulating TBG levels.

The free T₄ index (FTI) is obtained by multiplying the serum T₄ concentration by the T₃ resin uptake percentage, yielding an indirect estimate of the levels of free T₄:

$$\mathbf{T_3 \text{ RU } \% \times T_4 \text{ total} = \text{free } T_4 \text{ index}}$$

A high T₃ resin uptake percentage indicates reduced TBG receptor site availability and high free T₄ index and thus hyperthyroidism, whereas a low T₃ resin uptake percentage is a result of increased TBG receptor site binding and thus hypothyroidism. Equilibrium dialysis and ultrafiltration techniques may be used to determine directly the free T₄. Free T₄ and T₃ may also be determined by radioimmunoassay.

Because levels of TSH are sensitive to excessive or deficient levels of circulating thyroid hormone, and because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland, TSH levels are used to screen for these disorders. Current TSH sandwich immunoassays are extremely sensitive and capable of differentiating low-normal from pathologic or iatrogenically subnormal values and elevations. Thus, TSH measurements provide the best way to screen for thyroid dysfunction (283) and accurately predict thyroid hormone dysfunction in about 80% of cases.

Immunologic Abnormalities

Many antigen-antibody reactions affecting the thyroid gland can be detected. A number of recognized thyroid autoantigens are listed in Table 28.9. Antibody production to thyroglobulin obviously depends on a breach in normal immune surveillance (273,274). The incidence of thyroid autoantibodies in various autoimmune thyroid disorders is shown in Table 28.10.

Antibodies to thyroglobulin are restricted to one minor and two major epitopes. Antibodies

are mainly noncomplement-fixing immunoglobulin G (IgG) polyclonal antibodies (275). **Antithyroglobulin antibodies are found in patients with Hashimoto thyroiditis, Graves disease, acute thyroiditis, nontoxic goiter, and thyroid cancer.** They also appear in normal women.

Antithyroid peroxidase antibodies (anti-TPO antibodies), previously referred to as antimicrosomal antibodies, are directed against TPO and are found in Hashimoto thyroiditis,

P.1115

Graves disease, and postpartum thyroiditis. The antibodies produced are characteristically cytotoxic, complement-fixing IgG antibodies. Antimicrosomal antibodies correlate with the histologic appearance of lymphocytic thyroiditis (259,260). These antibodies can cause artifacts in the measurement of thyroid hormone levels.

<i>Antigen</i>	<i>Location</i>	<i>Function</i>
Thyroglobulin (Tg)	Thyroid	Thyroid hormone storage
Thyroid peroxidase (TPO) (microsomal antigen)	Thyroid	Transduction of signal from TSH
TSH receptor (TSHR)	Thyroid, lymphocytes, fibroblasts, adipocytes (including retro-orbital)	Transduction of signal from TSH
Na⁺/I⁻ symporter (NIS)	Thyroid, breast, salivary or lacrimal gland, gastric or colonic mucosa, thymus, pancreas	ATP-driven uptake of I ⁻ along with Na ⁺

TSH, thyroid-stimulating hormone; ATP, adenosine triphosphate.

Another group of antibodies important in autoimmune thyroid disease binds the TSH receptor. These antibodies often create the signs and symptoms that lead to an evaluation. Thyroid-stimulating hormone receptor antibodies (TSHR-Ab or TRAb) are pathogenic and capable of activating or blocking TSH receptor functions. These antibodies are detected using two approaches—competitive and functional assays. The competition between antibody and TSH for binding to the TSH receptor is the basis for the measurement of TSH-binding inhibitory immunoglobulin (TBII). The functional assay approach is based on the status of the receptor induced by the antibody-receptor interaction. This functional assay measures the production and accumulation of cAMP, thyroid hormone or thyroglobulin secretion, or iodide uptake in thyroid epithelial cells, or Chinese hamster ovary cells transfected with the human TSH receptor. Whereas the competitive assay does not indicate any functional activity of the antibody, the functional assay identifies whether the antibody is agonistic (thyroid-stimulating antibody [TSAb] or antagonistic TSH stimulation-blocking antibody [TSBAbs or TSHBAbs]). Both types of antibodies may be present in the same patient, and the effect is the algebraic sum of the two levels of activity (agonistic and antagonistic) (Fig. 28.8).

Thyroid-stimulating antibody or thyroid-stimulating immunoglobulin (TSI) activates the TSH receptor (Table 28.11). Long-acting thyroid stimulators are monoclonal or limited polyclonal TSAb, which mimic TSH action. They are quantified by their ability to stimulate human thyroid cell cultures to produce cyclic adenosine monophosphate or to release T₃.

Thyroid-stimulating hormone-binding inhibitory immunoglobulin is detectable in two

P.1116

varieties: those that block TSH binding and those that block both pre- and postreceptor processes. Several investigators have detected such blocking antibodies in patients with

primary hypothyroidism who have atrophic thyroid glands (277,278,279). The nomenclature and detection assay of TSH receptor antibodies are listed in Table 28.11.

Table 28.10 Prevalence of Thyroid Autoantibodies and Their Role in Immunopathology

Antibody	General Population	Hypothyroid	
		Autoimmune Thyroiditis	Graves Disease
Antithyroglobulin (anti-Tg)	3%	35%–60%	12%–30%
Antimicrosomal thyroid peroxidase (anti-TPO)	10%–15%	80%–99%	45%–80%
Anti-TSH receptor (anti-TSHR)	1%–2%	6%–60%	70%–100%
Anti-Na ⁺ /I [−] 2symporter (anti-NIS)	0%	25%	20%

TSH, thyroid-stimulating hormone.

Figure 28.8 Types of autoimmune injury found in Hashimoto thyroiditis. A: Complement-mediated cytotoxicity, which can be abolished by inactivating the complement system. **B:** Antibody-dependent cell-mediated cytotoxicity (ADCC) function through killer T cells, monocytes, and natural killer cells that have immunoglobulin G fragment receptors. **C:** Stimulation or blockade of hormone receptors leading to hyperfunction or hypofunction or growth, depending on the types of immunoglobulins acting on the target cell. (TBII, TSH-binding inhibitor immunoglobulin; TGI, thyroid growth-promoting immunoglobulin; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone.) (From **Coulam CB, Faulk WP, McIntyre JA. Immunologic obstetrics.** New York, NY: Norton Medical Books, 1992:658, with permission.)

Thyroid growth-promoting immunoglobulins (TGI) stimulate growth but not hormone release (250,251,252,253,254,255,256,257,258,259). Their immunologic antagonists are the TGI-blocking antibodies that are capable of inhibiting TSH-mediated growth responses in patients who may have had thyroid damage by immune destruction.

Antibodies to the NIS are prevalent in a number of thyroid conditions. Increased expression of NIS protein and NIS mRNA is found in patients with autonomous thyroid adenomas and Graves disease. They are decreased in Hashimoto thyroiditis, cold nodules, and thyroid carcinoma.

Autoimmune Thyroid Disease

The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced (284). **The various antigen-antibody reactions result in the wide clinical spectrum of these disorders.**

Transplacental transmission of some of these immunoglobulins may affect thyroid function in the fetus. The presence of autoimmune thyroid disorders, particularly Graves disease, is associated with other autoimmune conditions: Hashimoto thyroiditis, Addison disease, ovarian failure, rheumatoid arthritis, Sjögren syndrome, diabetes mellitus (type I), vitiligo, pernicious anemia, myasthenia gravis, and idiopathic thrombocytopenic purpura. Other factors associated with the development of autoimmune thyroid disorders include low birth weight, iodine excess and deficiency, selenium deficiency, parity, OC use, reproductive age span, fetal microchimerism, stress, seasonal variation, allergy, smoking, radiation damage to the thyroid, and viral and bacterial infections (285).

Table 28.11 Nomenclature of Anti-TSH Receptor Antibodies

<i>Abbreviation</i>	<i>Term</i>	<i>Assay Used</i>	<i>Refers To</i>
LATS	Long-acting thyroid stimulator	<i>In vivo</i> assay of stimulation of mouse thyroid	Original description of serum molecule able to stimulate mouse thyroid; no longer used
TSHR-Ab, TRAb	TSH receptor antibodies	Multiple	All antibodies recognizing the TSH receptor
TBII	TSH-binding inhibitory immunoglobulin	Competitive binding assays with TSH	Antibodies able to compete with TSH for TSH receptor binding irrespective of biologic activity
TSAb	Thyroid-stimulating antibodies	Bioassays of TSH receptor activation	TSH receptor-stimulating antibodies
TSI	Thyroid-stimulating immunoglobulins	As TSAb	Identical to TSAb
TSBAb, TSHBAb	TSH stimulation-blocking antibodies	Competition with TSH in bioassays of TSH receptor activation	Antibodies able to block activation of the TSH receptor by TSH

TSH, thyroid-stimulating hormone.

Certain groups of individuals, including infertile and pregnant women, should undergo an assessment of thyroid function at least once (286). Testing is also recommended for women with atrial fibrillation, hyperemesis gravidarum, and hyperlipidemia. Periodic assessment of thyroid function is indicated in patients who receive amiodarone and lithium.

Epidemiologists recommend that all women with diabetes be tested annually for thyroid dysfunction. Women with type 1 diabetes are three times more likely to experience postpartum thyroid dysfunction, and it is recommended that all pregnant women with diabetes be screened with TSH in the first trimester. Any woman with a history of postpartum thyroiditis should also be offered annual surveillance of thyroid function. Because there is a high prevalence of hypothyroidism in women with Turner and Down syndrome, an annual check of thyroid function is recommended. Periodic TSH screening in mature women is advisable.

Hashimoto Thyroiditis

Hashimoto thyroiditis or chronic lymphocytic thyroiditis, which was first described in 1912, can manifest as hyperthyroidism, hypothyroidism, euthyroid goiter, or diffuse goiter. High levels of antimicrosomal and antithyroglobulin antibody are usually present. Typically, glandular hypertrophy is found, but atrophic forms are also present. The composition of various antibodies (i.e., TBII, causing the atrophic form and congenital hypothyroidism in some neonates, and TGI, causing the goitrous variety) results in varied physical findings.

Three classic types of autoimmune injury are found in Hashimoto thyroiditis: (i) complement-mediated cytotoxicity, (ii) antibody-dependent cell-mediated cytotoxicity, and (iii) stimulation or blockade of hormone receptors, which results in hypo- or hyperfunction or growth (see Fig. 28.8).

The histologic picture of Hashimoto thyroiditis includes cellular hyperplasia, disruption of follicular cells, and infiltration of the gland by lymphocytes, monocytes, and plasma cells. Occasionally, adjacent lymphadenopathy may be noted. Some epithelial cells are enlarged and demonstrate oxyphilic changes in the cytoplasm (Askanazy cells or Hürthle cells, which are not specific to this disorder). The interstitial cells show fibrosis and lymphocytic infiltration. Graves disease and Hashimoto thyroiditis may cause very similar histologic findings manifested by a similar mechanism of action. Nearly all patients with Hashimoto thyroiditis and about two thirds of patients with Graves disease have sera demonstrating antibody-dependent cell-mediated cytotoxicity. Thyroid antibody positivity is detected in 16.8% of white women and in 10.2% of men in the United States (287).

Clinical Characteristics and Diagnosis of Hashimoto Thyroiditis

Most patients with Hashimoto thyroiditis are relatively asymptomatic with painless goiter and hypothyroidism. The goiter can also involve the pyramidal lobe. At later stages of the disease, hypothyroidism can be found without a goiter. Notable manifestations of hypothyroidism include cold intolerance, constipation, carotene deposition in the periorbital region, carpal tunnel syndrome, dry skin, fatigue, hair loss, lethargy, and weight gain. Hashitoxicosis, the hyperthyroid manifestation of Hashimoto thyroiditis, may represent a variant of Graves disease. This form is estimated to occur in 4% to 8% of patients with Hashimoto thyroiditis. These patients often become hypothyroid during the course of treatment.

In many cases, an elevated serum level of TSH is detected during routine screening. Elevated

serum antithyroglobulin and antimicrosomal antibody elevation confirm the diagnosis.

The sedimentation rate may be elevated, depending on the course of the disease at the time of recognition. Other causes of hypothyroidism should be considered as listed in Table 28.12. In light of the annual risk of hypothyroidism (5%) and the potential adverse

effects on the neuropsychological development of the fetus, most clinicians treat women who have elevated serum TSH concentrations and positive thyroid antibody tests, even in the absence of symptoms (subclinical hypothyroidism) (284). If the serum TSH alone is elevated, in the absence of positive thyroid antibody titers, the annual risk for hypothyroidism drops to less than 3% per year.

Table 28.12 Potential Causes of Hypothyroidism

Primary

Congenital absence of thyroid gland

External thyroid gland radiation

Familial disorders and thyroxine synthesis

Hashimoto thyroiditis

Iodine-131 ablation for Graves disease

Ingestion of antithyroid drugs

Iodine deficiency

Idiopathic myxedema (autoimmune)

Surgical removal of thyroid gland

Secondary

Hypothalamic thyrotropin-releasing hormone deficiency

Pituitary or hypothalamic tumors or disease

Treatment

Thyroxine replacement is initiated in patients with symptomatic hypothyroidism, patients who have a goiter that is cosmetically or physically bothersome and are subclinically hypothyroid, and patients who are undergoing fertility therapy and are subclinically hypothyroid. Regression of gland size usually does not occur, but treatment prevents further growth. All pregnant patients with an elevated TSH level should be treated with *levothyroxine*. Treatment does not slow progression of the disease.

Replacement therapy is monitored by TSH determinations at least 6 weeks after a change in dose. *Aluminum hydroxide* (antacids), *cholestyramine*, iron, and *sucralfate* may interfere with absorption. The half-life of *levothyroxine* is nearly 7 days; therefore, nearly 6 weeks of treatment are necessary before the effects of a dose change can be evaluated.

Hypothyroidism appears to be associated with decreased fertility resulting from ovulatory difficulties and possibly with spontaneous abortion (288,289,290,291). A meta-analysis of case-control and longitudinal studies performed since 1990 reveals a possible association between miscarriage and thyroid antibodies with an odds ratio of 2.73 (2.20–3.40, 95% confidence interval). This association may be explained by a heightened autoimmune state affecting the fetal allograft, or, alternatively, a slightly higher age of women with antibodies compared with those without antibodies (0.7 ± 1 year, $P < 0.001$) (292). Studies also suggest that early subclinical hypothyroidism may be associated with menorrhagia (293).

Severe primary hypothyroidism is associated with amenorrhea or anovulation

(294,295). Enhanced sensitivity of the prolactin-secreting cells to TRH and defective dopamine turnover resulting in hyperprolactinemia associated with a deficiency of thyroid hormone are the apparent explanations for the hyperprolactinemia (296,297,298,299). Hyperprolactinemia-induced luteal phase defects also are associated with less severe forms of hypothyroidism (300,301). Replacement therapy appears to reverse the hyperprolactinemia and correct ovulatory defects (302,303).

Combined thyroxine and triiodothyronine therapy is no more effective than thyroxine therapy alone (304). In patients with Hashimoto thyroiditis and subclinical hypothyroidism, a daily dose of 0.025 to 0.075 mg of levothyroxine is usually adequate to normalize TSH values.

Graves Disease

Graves disease, characterized by exophthalmos, goiter, and hyperthyroidism, was first identified as an association of findings in 1835. A heritable specific defect in immunosurveillance by suppressor T lymphocytes is believed to result in the development of a helper T-cell population that reacts to multiple epitopes of the thyrotropin receptor. This activity induces a B-cell-mediated response (301), resulting in the clinical features of Graves disease. The generic TSAbs bind to conformational epitopes in the extracellular domain of the thyrotropin receptor and are detected in the serum of 90% of patients with Graves disease. The epitopes make up discontinuous areas that overlap the thyrotropin binding site. Human leukocyte antigen (HLA) class II antigens DR, DP, DQ, and DS can present antigens to T cells and are expressed on thyroid epithelial cells. Antibodies to the TSH receptor (TSHR-Ab) are produced when this immunogen (TSH receptor) is presented to helper T lymphocytes with the D locus antigens (302).

P.1120

The class II antigens are upregulated by chronic stimulation of the TSH receptor, reduction in the iodinating capacity of thyroid tissue, viral transformation, and interferon- α (302,303). The clinical use of *interferon- α* has been associated with autoimmune thyroid disease. Graves disease is a complex autoimmune disorder in which several genetic susceptibility loci and environmental factors are likely to play a role in the development of the disease. Human leukocyte antigen and the CTLA-4 gene region have been established as susceptibility loci; however, the magnitude of their contributions seems to vary among patient populations and study groups. Additional loci are likely to be identified by a combination of genome-wide linkage analyses and allelic association analyses of candidate genes. The rate of concordance for Graves disease is only 20% in monozygotic twins and even lower in dizygotic twins, consistent with a multifactorial inheritance pattern highly influenced by environmental factors. Graves disease is associated with polymorphisms of the cytotoxic T-lymphocyte antigen 4 (*CTLA-4*) gene in several populations. Linkage analysis has identified loci on chromosomes 14q31, 20q11.2, and Xq21 that are associated with susceptibility to Graves disease (305).

Clinical Characteristics and Diagnosis

The classic triad of exophthalmos, goiter, and hyperthyroidism in *Graves disease* is **associated with symptoms of hyperthyroidism: frequent bowel movements, heat intolerance, irritability, nervousness, palpitations or tachycardia, tremor, weight loss, and lower extremity swelling**. Physical findings include lid lag, nontender thyroid enlargement (2 to 4 times normal), onycholysis, palmar erythema, proptosis, staring gaze, and thick skin. A cervical venous bruit and tachycardia are usually noted. The tachycardia does not respond to increased vagal tone produced with a Valsalva maneuver. Severe cases may demonstrate acropachy, chemosis, clubbing, dermopathy, exophthalmos with

ophthalmoplegia, follicular conjunctivitis, pretibial myxedema, and vision loss.

Approximately 40% of patients with new onset of Graves disease and many of those previously treated have elevated T_3 and normal T_4 levels. Therefore, assessment of T_4 , T_3 , and TSH values is indicated. The TSH levels are suppressed, and levels may remain undetectable for some time even after the initiation of treatment. This assessment is useful in evaluating medical treatment and prognosis, and anticipating fetal complications such as neonatal thyrotoxicosis. Autonomously functioning, benign thyroid neoplasms that exhibit a similar clinical picture include toxic adenomas and toxic multinodular goiter. Very rare conditions causing thyrotoxicosis include hCG-secreting choriocarcinoma, TSH-secreting pituitary adenomas, and struma ovarii. Factitious ingestion of thyroxine or desiccated thyroid should be considered in patients with eating disorders. Other potential causes of hyperthyroidism are listed in Table 28.13. Smoking appears to be an independent risk factor for relapse after medical therapy and should be considered when planning treatment.

Treatment

Iodine-131 Ablation

Treatment of women with hyperthyroidism of an autoimmune origin presents unique challenges to the physician who must consider the patient's needs and her reproductive plans. Because the drugs used to treat this disorder have potentially harmful effects on the fetus, special attention must be given to the use of contraception and the potential for pregnancy.

A single dose of radioactive iodine-131 (^{131}I) is an effective cure in about 80% of cases and is the most commonly used definitive treatment in nonpregnant women. Any woman of childbearing age should be tested for pregnancy before undergoing diagnostic or therapeutic administration of ^{131}I . Ablation of a second-trimester fetal thyroid gland and congenital hypothyroidism (cretinism) as a result of treatment during the first trimester have been reported (306,307).

Nuclear medicine professionals

P.1121

provide expertise in the administration of the radioactive isotope, and suppressive medical treatment is provided for 6 to 12 weeks after administration of ^{131}I . Medical therapy is the main component of therapy even when radioactive ^{131}I or surgery is eventually planned. Postablative hypothyroidism develops in 50% of patients within the first year after ^{131}I therapy and in more than 2% of patients per year thereafter.

Table 28.13 Potential Causes of Hyperthyroidism

Factitious hyperthyroidism
Graves disease
Metastatic follicular cancer
Pituitary hyperthyroidism
Postpartum thyroiditis
Silent hyperthyroidism (low radioiodine uptake)
Struma ovarii
Subacute thyroiditis
Toxic multinodular goiter
Toxic nodule

Tumors secreting human chorionic gonadotropin (molar pregnancy, choriocarcinoma)

A higher rate of miscarriage has been noted in women treated with ^{131}I therapy in the year preceding therapy, but there has been no reported increase in the rate of stillbirths, preterm birth, low birth weight, congenital malformation, or death after therapy (308). Many thyroidologists and nuclear medicine specialists ascribe the higher rates of miscarriage to unrecognized post ^{131}I induced hypothyroidism and are now more willing to allow pregnancy earlier than 1 year after therapy if patients receive replacement therapy with *levothyroxine*.

Thyroid-stimulating Receptor Antibody in Graves Disease

The level of TSHR–Ab (TBII) grossly parallels the degree of hyperthyroidism as assessed by the serum levels of thyroid hormones and total thyroid volume. Studies suggest that the combination of a small goiter volume (<40 mL) and a low TBII level (<30 units/L) results in a 45% chance of remission during the 5 years after completion of a 12- to 24-month course of antithyroid drug therapy (309). In contrast, the overall rate of relapse exceeded 70% in patients with a large goiter volume (>70 mL) and a higher TBII level (>30 units/L). Thus, the subgroup of patients with larger goiters and higher TBII levels had less than a 10% chance to remain in remission in the 5 years after treatment. Although it is not necessary for the diagnosis of Graves disease, except in some cases of multinodular goiter, a TSHR–Ab measurement may be a useful marker of disease severity. Used in combination with other clinical factors, it may contribute to initial decisions regarding treatment. See Table 28.11 for a review of the nomenclature and assay methods for TSHR–Ab.

Measurements of TSHR–Ab (TBII) during treatment with antithyroid drugs also are predictive of subsequent outcome. In one series, 73% of TBII–negative patients had remission compared with only 28% of TBII–positive patients who had achieved remission after 12 months of antithyroid drug therapy (310). Furthermore, the duration of a course of antithyroid drug therapy can be modified according to the TSHR–Ab status. In patients whose TSHR–Ab status became negative and antithyroid drug therapy was discontinued, the relapse rate was 41% compared with a rate of 92% for those patients who remained TSHR–Ab positive (311). Regardless of the rapidity of the disappearance of TSHR–Ab, it does seem that antithyroid drug therapy should be maintained for 9 to 12 months to minimize the

P.1122

risk of relapse. TSHR–Ab status also appears to determine, in an inverse relationship, the reduction in thyroid volume after radioactive iodine therapy.

Recently, a second generation assay has been developed for assessment of TSHR–Ab using recombinant human TSH receptor (312). This new assay has nearly 100% sensitivity and specificity in the diagnosis of Graves disease. Its utility in monitoring treatment is being evaluated. Many patients with Graves disease have or will develop antineutrophil cytoplasmic antibodies (ANCA), but the significance of this finding is still being studied.

Antithyroid Drugs

Antithyroid drugs of the thioamide class include *propylthiouracil* (PTU) and *methimazole*. Low doses of either agent block the secondary coupling reactions that form T_3 and T_4 from MIT and DIT. At higher doses, they also block iodination of tyrosyl residues in thyroglobulin. *Propylthiouracil* additionally blocks the peripheral conversion of T_4 to T_3 . Approximately one third of patients treated by this approach alone go into remission and become euthyroid (309).

Propylthiouracil causes a reduction of hyperthyroid symptoms at a dose of 100 mg taken every 8 hours over 1 month. Adequate control of thyrotoxic symptoms may require considerably higher doses. *Propylthiouracil* blocks the intrathyroid synthesis of T_3 and the peripheral conversion of T_4 to T_3 but does not cross the placenta as easily as *methimazole*; therefore, it is the drug of choice during pregnancy. Drug efficacy is monitored weekly by evaluation of appetite, emotional lability, insomnia, and tremor. A general rule is to lower the dosage by 50% when thyroid function returns to normal, which frequently correlates with the return to a normal heart rate and, subsequently, normalization of TSH levels. Thyroxine is usually the first value to become normal.

Pruritus affects 3% to 5% of treated patients. Serious adverse reactions include agranulocytosis (occurring 1–2 months after therapy in 0.02%) and a generalized drug eruption accompanied by arthralgia, fever, and sore throat. A complete blood count determination is performed if the patient develops an upper respiratory tract infection. If adverse reactions occur, *methimazole* may be used.

***Methimazole* (10 mg) is given every 8 to 24 hours. Its dosage is reduced in a manner similar to that used with *PTU*. It is not the drug of choice in pregnant women because it does not block peripheral conversion and crosses the placenta more readily than *PTU*.** Its use in pregnancy is associated in some instances with the development of characteristic skin lesions in the fetus, aplasia cutis congenita. It does, however, have fewer adverse reactions, a longer dosing interval, and a lower cost than *PTU*; therefore, it is most often prescribed in nonpregnant women.

Other medical therapies include *iodide* and *lithium*, both of which reduce thyroid hormone release and inhibit the organification of iodine. *Iodide* also leads to the secondary coupling of T_3 and T_4 . These medications are rarely used in women of reproductive age because of their risks to the fetal thyroid and to fetal development (*iodine* causes congenital goiter; *lithium* causes Ebstein's anomaly).

Surgery

A subtotal thyroidectomy is less commonly used primarily but is used routinely if medical treatment fails or if a patient is hypersensitive to medical therapy. Surgery is the most rapid and consistent method of achieving a euthyroid state in Graves disease that avoids the possible long-term risks of radioactive iodine. Children, young women, pregnant women, and patients with coexistent thyroid nodules are potential candidates for thyroidectomy. It is felt to be the treatment of choice for a patient with significant Graves ophthalmology. Patients should be rendered euthyroid before a thyroidectomy. The risks of surgery include postoperative hypoparathyroidism, recurrent laryngeal nerve paralysis, routine anesthetic and surgical risks, hypothyroidism, and failure to relieve thyrotoxicosis.

P.1123

β -Blockers

Propranolol is occasionally used before surgery in patients who prove to be hypersensitive to other medical therapy. It provides relief of symptoms while awaiting a reduction in T_4 caused by *PTU* or *methimazole*.

Thyroid Storm

In severe hypothyroidism, physiologic stress—including childbirth, systemic infection, or surgery

—may provoke a life-threatening spectrum of symptoms. These include diarrhea, vomiting, and fever, with associated dehydration, as well as altered mental status that may proceed to coma. Patients with poorly controlled hyperthyroidism are most susceptible. Beta-blocker agents, glucocorticoids, *PTU* (the action of which includes inhibition T_4 - T_3 conversion), and iodides are key elements of therapy.

Hyperthyroidism in Gestational Trophoblastic Disease and Hyperemesis Gravidarum

Because of the weak TSH-like activity of hCG, conditions with high levels of hCG, such as molar pregnancy, may be associated with biochemical and clinical hyperthyroidism. Symptoms regress with removal of the abnormal trophoblastic tissue and resolution of elevated levels of hCG. In a similar fashion, when hyperemesis gravidarum is associated with high levels of hCG, mild biochemical and clinical features of hyperthyroidism may be seen (313,314). Gestational trophoblastic disease is reviewed in Chapter 37.

Thyroid Function in Pregnancy

High levels of hCG at the end of the first trimester are sufficient to contribute to the thyrotropic effects of TSH, and TSH levels may show transient depression as a result of this phenomenon. Thyroid hormone requirements in pregnancy increase moderately. Patients depending on replacement thyroid hormone require monitoring to determine the need for increases in thyroid hormone replacement (estimated at 30%) commencing in the first weeks of pregnancy. Evidence suggests that optimal fetal and infant neurodevelopmental outcomes may require careful titration of replacement thyroxine that meets the frequently increased requirements of pregnancy (315,316).

Reproductive Effects of Hyperthyroidism

High levels of TSAb in women with Graves disease have been associated with fetal-neonatal hyperthyroidism (317,318). Despite both the inhibition and elevation of gonadotropins seen in thyrotoxicosis (319), most women remain ovulatory and fertile (320). Severe thyrotoxicosis can result in weight loss, menstrual cycle irregularities, and amenorrhea. An increased risk of spontaneous abortion is noted in women with thyrotoxicosis. An increased incidence of congenital anomalies, particularly aplasia cutis, occurs in the offspring of women treated with *methimazole* (321).

Autoimmune hyperthyroid Graves disease may improve spontaneously, in which case antithyroid drug therapy may be reduced or stopped. Nevertheless, TSHR-Ab production may persist for several years after radical radioactive iodine therapy or surgical treatment for hyperthyroid Graves disease. In this circumstance, there is a risk of exposing a fetus to TSHR-Ab. Fetal-neonatal hyperthyroidism is observed in 2% to 10% of pregnancies occurring in mothers with a current or previous diagnosis of Graves disease, secondary to the transplacental passage of maternal TSHR-Ab. This is a serious condition with a 16% neonatal mortality rate as well as a risk of intrauterine fetal death, stillbirth, and skeletal developmental abnormalities, such as craniosynostosis. Caution against overtreatment with antithyroid medication is also warranted as these medications may cross the placenta in sufficient quantities to induce fetal goiter. Guidelines for TSHR-Ab testing during pregnancy in women with previously treated Graves disease are found in Table 28.14. Fetal goiters and the associated fetal hypo- or hyperthyroid status have been diagnosed accurately in mothers with Graves disease using a combination of fetal ultrasonography of the thyroid with Doppler, fetal heart rate monitoring, bone maturation, and maternal TSHR-

Table 28.14 Guidelines for TSHR–Ab Testing During Pregnancy with Previously Treated Graves Disease

1. In the woman with antecedent Graves disease in remission after ATD treatment, the risk for fetal–neonatal hyperthyroidism is negligible, and systematic measurement of TSHR–Ab is not necessary. Thyroid function should be evaluated during pregnancy to detect an unlikely but possible recurrence. In that case, TSHR–Ab assay is mandatory.

2. In the woman with antecedent Graves disease previously treated with radioiodine or thyroidectomy and regardless of the current thyroid status (euthyroidism with or without thyroxine substitution), TSHR–Ab should be measured early in pregnancy to evaluate the risk for fetal hyperthyroidism. If the TSHR–Ab level is high, careful monitoring of the fetus is mandatory for the early detection of signs of thyroid overstimulation (tachycardia, impaired growth rate, oligohydramnios, goiter). Cardiac echography and measurement of circulatory velocity may be confirmatory. Ultrasonographic measurements of the fetal thyroid have been defined from 20 weeks gestational age but require a well–trained operator, and thyroid visibility may be hindered because of fetal head position. Color Doppler ultrasonography is helpful in evaluating thyroid hypervascularization. Because of the potential risks of fetal–neonatal hyperthyroid cardiac insufficiency and the inability to measure the degree of hyperthyroidism in the mother because of previous thyroid ablation, it may be appropriate to consider direct diagnosis in the fetus. Fetal blood sampling through cordocentesis is feasible as early as 25 to 27 weeks gestation with less than 1% adverse effects (fetal bleeding, bradycardia, infection, spontaneous abortion, *in utero* death) when performed by experienced clinicians. ATD administration to the mother may be considered to treat the fetal hyperthyroidism.

3. In the woman with concurrent hyperthyroid Graves disease, regardless of whether it has preceded the onset of pregnancy, ATD treatment should be monitored and adjusted to keep free T₄ in the high–normal range to prevent fetal hypothyroidism. TSHR–Ab should be measured at the beginning of the last trimester, especially if the required ATD dosage is high. If the TSHR–Ab assay is negative or the level low, fetal–neonatal hyperthyroidism is rare. If antibody levels are high (TBII ≥ 40 U/L or TSAb ≥ 300%), evaluation of the fetus for hyperthyroidism is required. In this condition, there is usually a fair correlation between maternal and fetal thyroid function such that monitoring the ATD dosage according to the mother's thyroid status is appropriate for the fetus. In some cases in which a high dose of ATD (>300 mg/d of propylthiouracil [PTU] or >20 mg/d of methimazole) is necessary, there is a risk of goitrous hypothyroidism in the fetus, which might be indistinguishable from goitrous Graves disease. The correct diagnosis relies on the assay of fetal thyroid hormones and TSH, which allows for optimal treatment.

4. In any woman who has previously given birth to a newborn with hyperthyroidism, a TSHR–Ab assay should be performed early in the course of pregnancy.

TSHR–Ab, thyroid–stimulating hormone receptor antibodies; ATD, autoimmune thyroid disease; T₄, thyroxine; TBII, TSH–binding inhibitory immunoglobulin; TSAb, thyroid–stimulating antibody.

Postpartum Thyroid Dysfunction

This clinical entity is much more common than recognized; it is often difficult to diagnose, because its symptoms appear 1 to 8 months postpartum and often are confused with postpartum depression and difficulties adjusting to the demands of the neonate and infant. Following are criteria for the diagnosis of postpartum thyroiditis: (i) no history of thyroid hormonal abnormalities either before or during pregnancy, (ii) documented abnormal TSH level (either depressed or elevated) during the first year postpartum, and (iii) absence of a positive TSH-receptor antibody titer (Graves disease) or a toxic nodule. An incidence of approximately 5% has been documented (323). A number of studies now describe clinical and biochemical evidence of postpartum thyroid dysfunction in 5% to 10% of new mothers (324). These women have a 25% chance of becoming permanently hypothyroid.

Histologically, lymphocytic infiltration and inflammation are found. Antimicrosomal antibodies are also present in this disorder (325,326). Women who are at greatest risk of developing this disorder are those with a personal or family history of the disorder, those with an autoimmune thyroid disorder, or those with an autoimmune disease.

Clinical Characteristics and Diagnosis

Postpartum thyroiditis usually begins with a transient hyperthyroid phase between 6 weeks and 6 months postpartum followed by a hypothyroid phase. However, only one fourth of the cases follow this classic clinical picture, whereas more than one third

P.1125

have either hyperthyroidism or hypothyroidism alone. Individuals with type 1 diabetes are 3 times more likely to develop postpartum thyroiditis, and women with a history of postpartum thyroiditis in a previous pregnancy have nearly a 70% chance of recurrence in a subsequent pregnancy. Numerous case reports demonstrate a possible association between postpartum thyroiditis and other autoimmune disorders. Postpartum thyroiditis appears to be caused by the combination of a rebounding immune system in the postpartum state and the presence of thyroid autoantibodies. Although psychotic episodes are rare, postpartum thyroid dysfunction should be considered in all women with postpartum psychosis. The thyrotoxic phase may be subclinical and overlooked, particularly in areas where iodine intake is low (327). Unlike patients with Graves disease, those with the hyperthyroidism caused by postpartum thyroiditis have a low level of radioactive isotope uptake.

The absence of thyroid tenderness, pain, fever, elevated sedimentation rate, and leukocytosis helps to rule out subacute thyroiditis (de Quervain thyroiditis). Evaluation of TSH, T_4 , T_3 , T_3 resin uptake, and antimicrosomal antibody titer confirm the diagnosis.

Treatment

Most patients are diagnosed during the hypothyroid phase and require 6 to 12 months of T_4 replacement if they are symptomatic. **Because approximately 10% to 30% of women develop permanent hypothyroidism, TSH should be evaluated following discontinuation of replacement therapy.**

Rarely, patients are diagnosed during the hyperthyroid phase (328). Antithyroid medications are not routinely used for these women. *Propranolol* may be used for relief of symptoms. Approximately two thirds of these patients return to a euthyroid state, and one third return to a hypothyroid state.

Antithyroid Antibodies and Disorders of Reproduction

Women who have antithyroid autoantibodies before and after conception appear to be at an increased risk for spontaneous abortion (329,330). Nonorgan-specific antibody production and pregnancy loss are documented in cases of antiphospholipid abnormalities (331). The concurrent presence of organ-specific thyroid antibodies and nonorgan-specific autoantibody production is not uncommon (331,332,333). In cases of recurrent pregnancy loss, thyroid autoantibodies may serve as peripheral markers of abnormal T-cell function and further implicate an immune component as the cause of reproductive failure (334). The clinical implications of these findings in the management of patients with recurrent pregnancy loss is not known. Recurrent pregnancy loss is covered in Chapter 31.

Thyroid Nodules

Thyroid nodules are a common finding on physical examination and are demonstrated by ultrasonography in more than 50% of patients (335). Occasionally such nodules are functional, and clinical and laboratory evaluation should be applied to distinguish these nodules from nonfunctional nodules, which are occasionally malignant. For nonfunctional "cold" nodules, fine-needle biopsy and aspiration are required to rule out malignancy. In the case of indeterminate aspirates, 2% to 20% are malignant; therefore, surgical biopsy often is indicated (336).

Gonadal Dysgenesis and Down Syndrome

Patients with ***gonadal dysgenesis (Turner syndrome***, and other forms of hypergonadotropic hypogonadism associated with abnormalities of the second sex chromosome) exhibit a high prevalence of autoimmune thyroid disorders. Approximately 50% of adult patients with Turner syndrome have antithyroid peroxidase (anti-TPO) and antithyroglobulin (anti-TG) autoantibodies. Of these patients, approximately 30% will develop subclinical or clinical hypothyroidism. The disorder is indistinguishable from Hashimoto thyroiditis. A susceptibility locus for Graves disease is noted on chromosome X (337).

P.1126

Down syndrome, caused by an extra chromosome 21, is characterized by an atypical body habitus, mental retardation, cardiac malformations, an increased risk of leukemia, and a reduced life expectancy. The extra chromosome is almost always of maternal origin. Autoimmune thyroid disorders are more common in patients with Down syndrome than in the general population. The gene for autoimmune polyglandular syndrome I (*APECED*) has been mapped to chromosome 21 and is thought to be a transcription factor involved in immune regulation (AIRE). This gene may play a role in the development of autoimmune thyroid disease in these patients (338). Hashimoto thyroiditis is the most common type of thyroid disease in individuals with Down syndrome. Hypothyroidism develops in as many as 50% of patients older than age 40 with Down syndrome. These clinical syndromes and other evidence suggest part of the genetic susceptibility to Hashimoto thyroiditis may reside on chromosomes X and 21.

29

Endometriosis

Thomas M. D'Hooghe

Joseph A. Hill III

- Endometriosis is diagnosed by visual inspection of the pelvis during laparoscopy, ideally with histological confirmation; positive histology confirms the diagnosis, but negative histology does not exclude it.
- Severe or deeply infiltrating endometriosis should be managed in a facility with the necessary expertise to provide treatment in a multidisciplinary context, including advanced laparoscopic surgery and laparotomy.
- Systems currently available for the classification of endometriosis are subjective and correlate poorly with pain symptoms but may be of value in determining the prognosis and management of infertility.
- Suppression of ovarian function for 6 months reduces pain associated with endometriosis. Hormonal drugs are equally effective in reducing pain but have differing side effects and cost.
- Ablation of endometriotic lesions with laparoscopic uterine nerve ablation (LUNA) in

minimal-to-moderate disease reduces pain associated with endometriosis; however, because LUNA used alone has no effect on dysmenorrhea associated with endometriosis, there is no evidence that LUNA is a necessary component of treatment.

- Ablation of endometriotic lesions plus adhesiolysis in minimal-to-mild endometriosis is more effective than diagnostic laparoscopy alone in improving fertility. Suppression of ovarian function is not effective in improving fertility in patients with endometriosis.

Endometriosis is defined as the presence of endometrial tissue (glands and stroma) outside the uterus. The most frequent sites of implantation are the pelvic viscera and the peritoneum. Endometriosis varies in appearance from a few minimal lesions on otherwise intact pelvic organs to massive ovarian endometriotic cysts that distort tubo-ovarian anatomy and extensive adhesions often involving bowel, bladder, and ureter. It is estimated to occur in 7% of reproductive-age women in the United States and often is associated

P.1138

with pelvic pain and infertility. Considerable progress has been made in understanding the pathogenesis, spontaneous evolution, diagnosis, and treatment of endometriosis.

Etiology

Although signs and symptoms of endometriosis have been described since the 1800s, its widespread occurrence was acknowledged only during the 20th century. Endometriosis is an estrogen-dependent disease. Three theories have been proposed to explain the histogenesis of endometriosis:

- Ectopic transplantation of endometrial tissue.
- Coelomic metaplasia.
- The induction theory.

No single theory can account for the location of endometriosis in all cases.

Transplantation Theory

The transplantation theory, originally proposed by Sampson in the mid-1920s, is based on the assumption that endometriosis is caused by the seeding or implantation of endometrial cells by transtubal regurgitation during menstruation (1). Substantial clinical and experimental data support this hypothesis (2,3). Retrograde menstruation occurs in 70% to 90% of women (4,5), and it may be more common in women with endometriosis than in those without the disease (5). The presence of endometrial cells in the peritoneal fluid, indicating retrograde menstruation, has been reported in 59% to 79% of women during menses or in the early follicular phase (6,7), and these cells can be cultured *in vitro* (7). The presence of endometrial cells in the dialysate of women undergoing peritoneal dialysis during menses supports the theory of retrograde menstruation (8). Endometriosis is most often found in dependent portions of the pelvis—the ovaries, the anterior and posterior cul-de-sac, the uterosacral ligaments, the posterior uterus, and

the posterior broad ligaments (9).

Endometrium obtained during menses can grow when injected beneath abdominal skin or into the pelvic cavity of animals (10,11). Endometriosis has been found in 50% of Rhesus monkeys after surgical transposition of the cervix to allow intra-abdominal menstruation (12).

Increased retrograde menstruation by obstruction of the outflow of menstrual fluid from the uterus is associated with a higher incidence of endometriosis in women (13,14) and in baboons (15). Women with shorter intervals between menstruation and longer duration of menses are more likely to have retrograde menstruation and are at higher risk for endometriosis (16).

Ovarian endometriosis may be caused by either retrograde menstruation or by lymphatic flow from the uterus to the ovary (17). Extrapelvic endometriosis, although rare (1%–2%), potentially may result from vascular or lymphatic dissemination of endometrial cells to many gynecologic (vulva, vagina, cervix) and nongynecologic sites. The latter include bowel (appendix, rectum, sigmoid colon, small intestine, hernia sacs), lungs and pleural cavity, skin (episiotomy or other surgical scars, inguinal region, extremities, umbilicus), lymph glands, nerves, and brain (18).

Coelomic Metaplasia

The transformation (metaplasia) of coelomic epithelium into endometrial tissue has been proposed as a mechanism for the origin of endometriosis. Previously this theory had not been supported by either strong clinical or experimental data. One study evaluating structural and cell surface antigen expression in the rete ovarii and epoöphoron reported little commonality between endometriosis and ovarian

P.1139

surface epithelium, suggesting that serosal metaplasia is unlikely in the ovary (19). In contrast, the results of another study involving the genetic induction of endometriosis in mice suggest that ovarian endometriotic lesions may arise directly from the ovarian surface epithelium through a metaplastic differentiation process induced by activation of an oncogenic *K-ras* allele (20).

Induction Theory

The induction theory is, in principle, an extension of the coelomic metaplasia theory. It proposes that an endogenous (undefined) biochemical factor can induce undifferentiated peritoneal cells to develop into endometrial tissue. This theory has been supported by experiments in rabbits (21,22) but has not been substantiated in women and primates.

Genetic Factors

There is increasing evidence to suggest that endometriosis is at least partially a genetic disease. Recent findings that support this association include evidence of familial clustering in humans and in rhesus monkeys, a founder effect detected in the Icelandic population, concordance in monozygotic twins, a similar age at onset of symptoms in affected nontwin sisters, a 6- to 9-times increased prevalence of endometriosis among first-degree relatives of women compared with the general population, and a 15% prevalence of magnetic resonance imaging (MRI) findings suggestive of endometriosis in the first-degree relatives of women with stage III–IV disease based on the classification of the American Society of Reproductive Medicine (23). **The induction of humanlike endometriosis by genetic activation of an oncogenic *K-ras* allele lends further support to the genetic basis of this disorder (20).**

Population Studies

The risk of endometriosis is 7 times greater if a first-degree relative has been affected by endometriosis (24). Because no specific Mendelian inheritance pattern has been identified, multifactorial inheritance has been postulated. A relative risk for endometriosis of 7.2 has been found in mothers and sisters, and a 75% (6 of 8) incidence has been noted in homozygotic twins of patients with endometriosis (25). In another study of twins, 51% of the variance of the latent liability to endometriosis may be attributable to additive genetic influences (26). Other investigators reported that 14 monozygotic twin pairs were concordant for endometriosis, and 2 pairs were discordant (27). Of these twin pairs, 9 had moderate to severe endometriosis.

A relationship has been shown between endometriosis and systematic lupus erythematosus (28), dysplastic nevi, and a history of melanoma in women of reproductive age (29). Endometriosis also is linked to the presence of individual human leukocyte antigens (30,31,32).

Mutations

In women with endometriosis, no mutations were found in the *TP53* and *RASK* genes (33). No significant differences were observed in *N314D* (galactose-1-phosphate uridylyl transferase) mutation frequency between women with endometriosis (18%) and controls (17%) (34).

Steroid Receptor Genetics

An association of estrogen receptor gene polymorphisms (two-allele and multiallele polymorphism) with endometriosis has been reported (35). Furthermore, various exon-deleted progesterone-receptor messenger RNAs (mRNAs) have been documented in human endometrium and ovarian endometriosis (36).

Aneuploidy

Epithelial cells of endometriotic cysts are monoclonal on the basis of phosphoglycerate kinase gene methylation, but normal endometrial glands are monoclonal (37,38). In a

P.1140

comparison of endometriotic tissue with normal tissue from the endometrium flow, cytometric DNA analysis failed to show aneuploidy (39). However, more recent studies using comparative genomic hybridization (40) or multicolor *in situ* hybridization (41) showed aneuploidy for chromosomes 11, 16, and 17 (41), increased heterogeneity of chromosome 17 aneuploidy (42), and losses of 1p and 22q (50%), 5p (33%), 6q (27%), 70 (22%), 9q (22%), and 16 (22%) of 18 selected endometriotic tissues (40).

Loss of Heterozygosity

Microsatellite DNA assays reveal an allelic imbalance (loss of heterozygosity) in *p16 (Ink4)*, *GALT*, *p53*, and *APOA2* loci in patients with endometriosis, even in stage II of endometriosis (43). Another report (38) found in 28% of endometriotic lesions a loss of heterozygosity at one or more sites: chromosomes 9p (18%), 11q (18%), and 22q (15%).

Immunologic Factors and Inflammation

Although retrograde menstruation appears to be a common event in women, not all and Inflammation women who have retrograde menstruation develop endometriosis.

The immune system may be altered in women with endometriosis, and it has been hypothesized that the disease may develop as a result of reduced immunologic clearance of viable endometrial cells from the pelvic cavity

(44,45). Endometriosis can be caused by decreased clearance of peritoneal fluid endometrial cells resulting from reduced natural killer (NK) cell activity or decreased macrophage activity (46). Decreased cell-mediated cytotoxicity toward autologous endometrial cells has been associated with endometriosis (46,47,48,49,50). However, these studies used techniques that have considerable variability in target cells and methods (51,52). Whether NK cell activity is lower in patients who have endometriosis than in those without endometriosis is controversial. Some reports demonstrate reduced NK activity (53,54,55,56,57), whereas others have found no increase in NK activity, even in women with moderate to severe disease (48,49,50,58). There also is great variability in NK cell activity among normal individuals that may be related to variables such as smoking, drug use, and exercise (51).

In contrast, endometriosis can also be considered a condition of immunologic tolerance, as opposed to ectopic endometrium, which essentially is self-tissue (44). It can be questioned why viable endometrial cells in the peritoneal fluid would be a target for NK cells or macrophages. Autotransplantation of blood vessels, muscles, skin grafts, and other tissues is known to be extremely successful (47,48,49). Furthermore, there is no *in vitro* evidence that peritoneal fluid macrophages actually attack and perform phagocytosis of viable peritoneal fluid endometrial cells. High-dose immunosuppression can slightly increase the progression of spontaneous endometriosis in baboons (59). There is no clinical evidence, however, that the prevalence of endometriosis is increased in immunosuppressed patients. The fact that women with kidney transplants, who undergo chronic immunosuppression, are not known to have increased infertility problems can be considered indirect evidence that these patients do not develop extensive endometriosis.

Substantial evidence suggests that endometriosis is associated with a state of subclinical peritoneal inflammation, marked by an increased peritoneal fluid volume, increased peritoneal fluid white blood cell concentration (especially macrophages with increased activation status), and increased inflammatory cytokines, growth factors, and angiogenesis-promoting substances. It has been reported in baboons that subclinical peritoneal inflammation occurs both during menstruation and after intrapelvic injection of endometrium (57). A higher basal activation status of peritoneal macrophages in women with endometriosis may impair fertility by reducing sperm motility, increasing sperm phagocytosis, or interfering with fertilization (60,61), possibly by increased secretion of cytokines such as tumor necrosis factor- α (TNF- α) (62,63,64). Tumor necrosis factor also may facilitate the pelvic implantation of ectopic endometrium (63,64). The adherence of human endometrial stromal cells to mesothelial cells *in vitro* has been increased by the

P.1141

pretreatment of mesothelial cells with physiologic doses of TNF- α (65). Macrophages or other cells may promote the growth of endometrial cells (66,67,68) by secretion of growth and angiogenetic factors such as epidermal growth factor (EGF) (65), macrophage-derived growth factor (MDGF) (69), fibronectin (70), and adhesion molecules such as integrins (71). After attachment of endometrial cells to the peritoneum, subsequent invasion and growth appear to be regulated by matrix metalloproteinases (MMP) and their tissue inhibitors (72,73).

There is increasing evidence that local inflammation and secretion of prostaglandins (PG) is related to differences in endometrial aromatase activity between women with and without endometriosis. Expression of aromatase cytochrome P450 protein and mRNA was present in human endometriotic implants but not in normal endometrium, suggesting that ectopic endometrium produces estrogens, which may be involved in the tissue growth

interacting with the estrogen receptor (74). Inactivation of 17β -estradiol has been reported to be impaired in endometriotic tissues because of deficient expression of 17β -hydroxysteroid dehydrogenase type 2, which is normally expressed in eutopic endometrium in response to progesterone (75). The inappropriate aromatase expression in endometriosis lesions can be stimulated by prostaglandin E^2 (PGE^2). This reaction leads to local production of E^2 , which also stimulates PGE^2 production, resulting in a positive-feedback system between local inflammation and estrogen-driven local growth of ectopic endometrium (76).

The subclinical pelvic inflammatory status associated with endometriosis is also reflected in the systemic circulation. Increased concentrations of C-reactive protein, serum amyloid A (SAA), TNF- α , membrane cofactor protein-1, interleukin-6, interleukin-8 and chemokine (C-C motif) receptor 1 (CCR1) have been observed in peripheral blood samples of patients with endometriosis when compared with controls (77). This observation can be the basis for the development of noninvasive diagnostic tests.

Environmental Factors and Dioxin

There is an increasing awareness of potential links between reproductive health, infertility, and environmental pollution. Attention has been directed to the potential role of dioxins in the pathogenesis of endometriosis, but the issue remains controversial. A recent meta-analysis concluded that currently there is insufficient evidence in women or in nonhuman primates that endometriosis is caused by dioxin exposure (78).

Human Data

A 1976 explosion of a factory in Seveso (Italy) resulted in the highest levels of dioxin exposure recorded in humans (79), but so far no data have been published. The Seveso Women's Health Study will correlate prospective individual data on exposure to dioxin with reproductive endpoints such as the incidence of endometriosis, infertility, and decreased sperm quality. Thus far, one case-control study has failed to show in the general population an association between endometriosis and exposure to polychlorinated biphenyl and chlorinated pesticides during adulthood. No differences in mean plasma concentrations of 14 polychlorinated biphenyl and 11 chlorinated pesticides were found between women with and those without endometriosis (80). Genetic mechanisms may play a role in dioxin exposure and the development of endometriosis. Transcripts of the *CYP1A1* gene, a dioxin-induced gene, have been reported to be significantly higher (9 times higher) in endometriotic tissues than in eutopic endometrium (81). Other investigators have reported a similar expression of arylhydrocarbon receptor and dioxin-related genes (using semiquantitative reverse transcriptase polymerase chain reaction) in the endometrium from women with or without endometriosis (82). In Japanese women, no association was found between endometriosis prevalence or severity and polymorphisms for arylhydrocarbon receptor repressor, arylhydrocarbon (x2) receptor, and arylhydrocarbon nuclear translocator or *CYP1A1* genes (83). Based on these data, there is insufficient

P.1142

evidence supporting the association between endometriosis and dioxin exposure in humans.

Primates

An initial retrospective case-control study reported that the prevalence of endometriosis was not statistically different (Fisher exact test, $p=0.08$) between monkeys chronically exposed to dioxin during 4 years (11 of 14, 79%) and in nonexposed animals (2 of 6, 33%) after a period of 10 years. However, a positive correlation was found between the severity of endometriosis

and dioxin dose, serum levels of dioxin, and dioxinlike chemicals (84,85). Two prospective studies have evaluated the association between dioxin exposure and development of endometriosis in Rhesus monkeys. In the most recent study (86), monkeys exposed over 12 months to low-dose dioxin (0.71 ng/kg/day) had endometriosis implants with smaller maximal and minimal diameters and similar survival rate when compared with endometriotic lesions in unexposed controls, suggesting no effect of dioxin on endometriosis. However, after 12 months of exposure to high-dose dioxin (17.86 ng/kg/day), larger diameters and a higher survival rate of endometriosis implants were observed in exposed Rhesus monkeys compared with nonexposed controls. The second randomized controlled study performed in 80 Rhesus monkeys compared those with no treatment with those treated with 0, 5, 20, 40, and 80 µg of *Aroclor* (1,254/kg/day) for 6 years. Endometriosis occurred in 37% of controls and in 25% of treated monkeys as determined by laparoscopy and necropsy data (87). No association was observed between endometriosis severity and polychlorinated biphenyl exposure. These data question the importance of dioxin exposure, except at high doses, in the development of endometriosis in primates.

Rodents

Continuous exposure to 2,3,7,8-tetrachlorodibenzo-P-dioxin inhibited the growth of surgically induced endometriosis in ovariectomized mice treated with high-dose estradiol. No correlation was observed between the dose of dioxin and survival of endometrial implants, adhesions, and serum E₂ levels (88). In ovariectomized mice induced with endometriosis, similar stimulating effects of estrone and 4-chlorodiphenyl ether (4-CDE) were observed on survival rates of endometriotic mice, suggesting an estrogenlike effect of 4-CDE (89). Potential mechanisms mediating dioxin action to promote endometriosis in rodents are complex and probably different in rats and mice, not to mention women. The mouse appears to be a better model to elucidate these mechanisms (90,91), but both models have important limitations.

Future Research

The study of endometriosis is compounded by the need to exclude other causes and to assess symptoms within the context of the pelvic condition (i.e., the presence or absence of pathology). The pathogenesis of endometriosis, the pathophysiology of related infertility, and the spontaneous evolution of endometriosis are being investigated. At the time of diagnosis, most patients with endometriosis have had the disease for an unknown period, making it difficult to initiate any clinical experiments that would determine definitely the etiology or progression of the disease (3). Because endometriosis occurs naturally only in women and primates and invasive experiments cannot be performed easily, it is difficult to undertake properly controlled studies. Thus, there is a need for the development of a good animal model with spontaneous endometriosis.

The main advantage of the rat and rabbit animal models used to study endometriosis is their low cost relative to primates. The disadvantages are numerous, however. Rodents lack a menstrual cycle comparable to that of primates and are not subject to spontaneous endometriosis. Whereas the rat ovulates spontaneously, it has a shorter luteal phase than humans. The reproductive pattern of the rabbit lacks a luteal phase. There is a wide phylogenetic gap between these two species and the human. In both rodent models, the

type of lesions appear to be quite different from the variety of pigmented and nonpigmented lesions observed in women (92,93,94).

Primates, conversely, are phylogenetically close to humans, have a comparable menstrual cycle, are afflicted with spontaneous endometriosis, and when induced with endometriosis, develop macroscopic lesions that are similar to those found in human disease (12,95,96,97,98,99). Although the great apes are closest to humans in many anatomic and physiologic aspects of reproduction, they are not practical models for study; therefore, Rhesus and cynomolgus monkeys have been used. Baboons may be a better choice for study because they are continuous breeders, are phylogenetically very close to humans, and have similar reproductive anatomy and physiology with regard to menstrual cycle characteristics and regularity, embryo implantation, and fetal development (95). In addition, spontaneous endometriosis in the baboon has been found to be both minimal and disseminated, similar to the different stages of endometriosis in women (95,100,101). Experimental endometriosis can be successfully induced by the intrapelvic injection of menstrual endometrium (11). In recent years, the baboon has been established in about 30 peer-reviewed articles as an excellent model for endometriosis research (102). Future research on the pathogenesis of endometriosis, using the baboon model, should focus on the early interactions between endometrial and peritoneal cells in the pelvic cavity at the time of menstruation. Proteomic and genomic approaches can detect potential differences between eutopic endometrium and myometrium in women with and without endometriosis. Immunomodulatory drugs inhibiting pelvic inflammation associated with endometriosis may offer new approaches to medical treatment in the future (103).

Prevalence

Endometriosis is predominantly found in women of reproductive age but has been reported in adolescents and in postmenopausal women receiving hormonal replacement (104). It is found in women of all ethnic and social groups. **In women with pelvic pain or infertility, a high prevalence of endometriosis (from a low of 20% to a high of 90%) has been reported (2,105).** **In asymptomatic women undergoing tubal ligation (women of proven fertility), the prevalence of endometriosis ranges from 3% to 43% (5,106,107,108,109,110).** This great variation in the reported prevalence may be explained by several factors. First, it may vary with the diagnostic method used: laparoscopy, the operation of choice for diagnosis, is generally accepted to be a better method than laparotomy for diagnosing minimal to mild endometriosis. Second, minimal or mild endometriosis may be more thoroughly evaluated in a symptomatic patient being given general anesthesia than in an asymptomatic patient during tubal sterilization. Third, the experience of the surgeon is important because there is a wide variation in the appearance of subtle endometriosis implants, cysts, and adhesions. Most studies that evaluate the prevalence of endometriosis in women of reproductive age lack histologic confirmation (5,106,107,110,111,112,113,114,115).

Diagnosis

Clinical Presentation

Endometriosis should be suspected in women with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. However, these symptoms can also be associated with other diseases. Endometriosis may be asymptomatic, even in some women with more advanced disease (ovarian or deeply invasive rectovaginal endometriosis).

Risk factors for endometriosis include short cycle length (116), heavier menstruation, and longer flow duration (16,117), probably related to a higher incidence of retrograde

menstruation. Patient height and weight are positively and negatively, respectively, associated with the risk of endometriosis (118).

Endometriosis can be associated with significant gastrointestinal symptoms (pain, nausea, vomiting, early satiety, bloating and distention, altered bowel habits).

A characteristic motility change (ampulla of Vater–duodenal spasm, a seizure equivalent of the enteric nervous system), along with bacterial overgrowth, has been documented in most women with the disease (119). Women of reproductive age with endometriosis are not osteopenic (120).

The average delay between onset of pain symptoms and surgically confirmed endometriosis is quite long: ± 8 years in the United Kingdom and ± 9 to 12 years in the United States (121). Similar durations have been observed in Scandinavia (122) and in Brazil (123). A delay in diagnosis of endometriosis of 6 and 3 years in women with pain and women with infertility, respectively, has been reported. Over the past two decades, there has been a steady decrease in the delay in diagnosis and a decline in the prevalence of advanced endometriosis at first diagnosis (124). Concurrently, patient awareness of endometriosis has increased. For many patients, quality of life is affected by pain, emotional impact of subfertility, anger about disease recurrence, and uncertainty about the future regarding repeated surgeries or long-term medical therapy and its side effects. Therefore, **endometriosis should be perceived as a chronic disease, at least in a subset of highly symptomatic women, and quality-of-life issues should be evaluated using reliable and valid questionnaires** (125).

Pain

In adult women, dysmenorrhea may be especially suggestive of endometriosis if it begins after years of pain-free menses. Dysmenorrhea often starts before the onset of menstrual bleeding and continues throughout the menstrual period. In adolescents, the pain may be present after menarche without an interval of pain-free menses. The distribution of pain is variable but most often is bilateral.

Local symptoms can arise from rectal, ureteral, and bladder involvement, and lower back pain can occur. **Most studies have failed to detect a correlation between the degree of pelvic pain and the severity of endometriosis** (108). Some women with extensive disease have no pain, whereas others with only minimal disease may experience severe pelvic pain. Severe pelvic pain and dyspareunia may be associated with deep infiltrating subperitoneal endometriosis (105,115,126). The character of pelvic pain is related to the anatomic location of deeply infiltrating endometriotic lesions (127).

Possible mechanisms causing pain in patients with endometriosis include local peritoneal inflammation, deep infiltration with tissue damage, adhesion formation, fibrotic thickening, and collection of shed menstrual blood in endometriotic implants, resulting in painful traction with the physiologic movement of tissues (115,128).

In rectovaginal endometriotic nodules, a close histologic relationship has been observed between nerves and endometriotic foci and between nerves and the fibrotic component of the nodule (129).

Subfertility

An association between endometriosis and subfertility is generally accepted, but most of the studies suggesting this link have been based on retrospective or cross-sectional analysis

(130). **When endometriosis is moderate or severe, involving the ovaries and causing adhesions that block tubo-ovarian motility and ovum pickup, it is associated with subfertility** (131). This effect has also been shown in primates, including cynomolgus monkeys and baboons (98,132). Although numerous mechanisms (ovulatory dysfunction, luteal insufficiency, luteinized unruptured follicle syndrome, recurrent abortion,

altered immunity, and intraperitoneal inflammation) have been proposed (133), the association between fertility and minimal or mild endometriosis remains controversial (130,131).

Infertility

Based on the number of asymptomatic women who are found to have endometriosis during tubal ligation, it would appear that the prevalence of endometriosis is not necessarily higher in infertile than in fertile women with endometriosis (5). **In fertile women, endometriosis has been reported to be minimal or mild in 80% and moderate or severe in 20%** (5,106,107,108,109,110).

In women with mild disease, some studies have reported a lower spontaneous monthly fecundity rate (MFR), which is the total number of pregnancies divided by the number of months of pregnancy exposure (i.e., 5%–11% compared with 25% in a normally fertile population) (133). Other studies using artificial insemination with donor semen have reported that the MFR in women with minimal and mild endometriosis is either reduced (4%) or normal (20%) (134,135,136,137). Fertility is not reduced in baboons with spontaneous minimal endometriosis (132,138). In one study, the fecundity rate (probability of becoming pregnant in the first 36 weeks after laparoscopy and carrying the pregnancy to 20 weeks or more) was 18% in infertile women with minimal to mild endometriosis and 23.7% in women with unexplained infertility (no significant difference). None of these women had been surgically treated for endometriosis during the diagnostic laparoscopy. However, 10% of women in each group had been treated with intrauterine insemination, *in vitro* fertilization (IVF), or cystectomy–myomectomy (139). **It remains unclear whether the mere presence of peritoneal endometriosis directly correlates with infertility.**

Spontaneous Abortion

A possible association between endometriosis and spontaneous abortion has been suggested in mostly uncontrolled or retrospective studies. Some controlled studies evaluating the association between endometriosis and spontaneous abortion have important methodologic shortcomings: heterogeneity between cases and controls, analysis of the abortion rate before the diagnosis of endometriosis, and selection bias of study and control groups (140,141,142). **Based on controlled prospective studies, there is no evidence that endometriosis is associated with (recurrent) pregnancy loss (143), or that medical or surgical treatment of endometriosis reduces the spontaneous abortion rate** (144,145).

Endocrinologic Abnormalities

Endometriosis has been associated with anovulation, abnormal follicular development with impaired follicle growth, reduced circulating E₂ levels during the preovulatory phase, disturbed luteinizing hormone (LH) surge patterns, premenstrual spotting, the luteinized unruptured follicle syndrome, and galactorrhea and hyperprolactinemia (146). Increased incidence and recurrence of the luteinized unruptured follicle syndrome has been reported in baboons with mild endometriosis, but not in primates with minimal endometriosis or a

normal pelvis (147). Luteal insufficiency with reduced circulating E₂ and progesterone levels, out-of-phase endometrial biopsies, and aberrant integrin expression has been reported in the endometrium of women with endometriosis by some researchers (146,148), but these findings have not been confirmed by other investigators (149). Therefore, no convincing data exist to conclude that the incidence of these endocrinologic abnormalities is increased in women who have endometriosis.

Extrapelvic Endometriosis

Extrapelvic endometriosis, although often asymptomatic, should be suspected when symptoms of pain or a palpable mass occur outside the pelvis in a cyclic pattern. Endometriosis involving the intestinal tract (especially colon and rectum) is the most common site of extrapelvic disease and may cause abdominal and back pain, abdominal distention, cyclic rectal bleeding, constipation, and obstruction. Ureteral involvement can

P.1146

lead to obstruction and result in cyclic pain, dysuria, and hematuria. Pulmonary endometriosis can manifest as pneumothorax, hemothorax, or hemoptysis during menses. Umbilical endometriosis should be suspected when a patient has a palpable mass and cyclic pain in the umbilical area (18).

Clinical Examination

In many women with endometriosis, no abnormality is detected during the clinical examination. The vulva, vagina, and cervix should be inspected for any signs of endometriosis, although the occurrence of endometriosis in these areas is rare (e.g., episiotomy scar). Other possible signs of endometriosis include uterosacral or cul-de-sac nodularity, lateral or cervical displacement caused by uterosacral scarring (150), painful swelling of the rectovaginal septum, and unilateral ovarian (cystic) enlargement. In more advanced disease, the uterus is often in fixed retroversion, and the mobility of the ovaries and fallopian tubes is reduced. Evidence of deeply infiltrative endometriosis (deeper than 5 mm under the peritoneum) in the rectovaginal septum with cul-de-sac obliteration or cystic ovarian endometriosis should be suspected by clinical documentation of uterosacral nodularities during menses, especially if CA125 serum levels are higher than 35 IU/mL (151,152,153).

The clinical examination may have false-negative results. Therefore, the diagnosis of endometriosis should be confirmed by biopsy of suspicious lesions that are obtained laparoscopically.

Imaging and Endometriosis

The presence of filling defects (presence of hypertrophic or polypoid endometrium) detected by hysterosalpingography (154) has a significant positive correlation with endometriosis. The positive predictive value of this finding is 84% and negative predictive value is 75%.

Gynecologic transvaginal (155) or transrectal ultrasonography (156) is an important diagnostic tool (157) in the assessment of ovarian endometriotic cysts (differentiation from other adnexal masses) and of rectovaginal endometriosis (sensitivity, 97%; specificity, 96%).

Other imaging techniques, including computed tomography (CT) and MRI, can be used to provide additional and confirmatory information, but they cannot be used for primary diagnosis (158,159). These techniques are more costly than ultrasonography, and their added value is not clear.

CA125

There is no blood test available for the diagnosis of endometriosis. Levels of CA125, a marker found on derivatives of the coelomic epithelium and common to most nonmucinous epithelial ovarian carcinomas, have been found to be significantly higher in women with moderate or severe endometriosis and normal in women with minimal or mild disease (160,161). During menstruation, an increase in CA125 levels has been shown in women with and without endometriosis (162,163,164,165,166). Other studies have not found an increase during menses (167,168) or have found an increase only with moderate to severe endometriosis (169,170). The levels of CA125 vary widely, not only in patients without endometriosis (8–22 U/mL in the nonmenstrual phase) but also in those with minimal to mild endometriosis (14–31 U/mL in the nonmenstrual phase) and in those with moderate to severe disease (13–95 U/mL in the nonmenstrual phase). **Compared with laparoscopy, measurement of serum CA125 levels has no value as a diagnostic tool** (171).

P.1147

The reason CA125 levels are increased in moderate to severe endometriosis is unclear. It has been hypothesized that endometriosis lesions contain a greater amount of CA125 than normal endometrium and that the associated inflammation could lead to an increased shedding of CA125 (161).

The specificity of CA125 has been reported to be higher than 80% in most studies. This high level of specificity is achieved in selected women with infertility or pain who are known to be at risk for endometriosis. The low level of sensitivity of CA125 (20%–50% in most studies) poses limitations for the clinical use of this test for diagnosis of endometriosis. Theoretically, the sensitivity might increase during the menstrual period, when the increase in CA125 levels is more pronounced in women who have endometriosis. However, studies using cutoff levels of 35 U/mL (169,170) or 85 U/mL (172) have not found a significant improvement in sensitivity. A sensitivity of 66% was found when CA125 was determined during both the follicular phase and the menstrual phase in each patient and when the ratio of menstrual versus follicular values (≥ 1.5) was used instead of one CA125 level (170). More recent studies reported that the value of CA125 in diagnosis of endometriosis is limited but higher for moderate to severe disease, especially if serum CA125 concentrations are measured during the midfollicular phase (171,173).

Serial CA125 determinations may be useful to predict the recurrence of endometriosis after therapy (174,175). CA125 levels decrease after combined medical and surgical therapy or during medical treatment of endometriosis with *danazol*, gonadotropin-releasing hormone (GnRH) analogues, or *gestrinone*, but not with *medroxyprogesterone acetate* (MPA) or placebo (176,177,178). Levels of CA125 have been reported to increase to pretreatment levels as early as 3, 4, or 6 months after the cessation of therapy with *danazol*, GnRH analogs, or *gestrinone* (166,177,178,179,180,181). Posttreatment increases in CA125 levels have been reported to correlate with endometriosis recurrence (165,175,182). However, other studies have not substantiated a correlation between posttreatment CA125 levels and disease recurrence (176,179,183).

Laparoscopic Findings

Unless disease is visible in the vagina or elsewhere, laparoscopy is the standard technique for visual inspection of the pelvis and establishment of a definitive diagnosis (159). During diagnostic laparoscopy, the pelvic and abdominal cavity should be systematically investigated for the presence of endometriosis. This examination should include

a complete inspection and palpation, in a clockwise or counterclockwise fashion with a blunt probe, of the bowel, bladder, uterus, tubes, ovaries, cul-de-sac, and broad ligament (Fig. 29.1.). The type, location, and extent of all lesions and adhesions should be documented in the operative notes; ideally, the findings should be recorded on video or DVD (159). There is insufficient evidence to justify performing the laparoscopy at a specific time in the menstrual cycle, but to avoid underdiagnosis, it should not be performed during or within 3 months of hormonal treatment (159).

Characteristic findings include typical ("powder-burn" or "gunshot") lesions on the serosal surfaces of the peritoneum. These lesions are black, dark brown, or bluish nodules or small cysts containing old hemorrhage surrounded by a variable degree of fibrosis (Fig. 29.2.). Endometriosis can appear as subtle lesions (Fig. 29.3.), including red implants (petechial, vesicular, polypoid, hemorrhagic, red flamelike), serous or clear vesicles, white plaques or scarring, yellow-brown discoloration of the peritoneum, and subovarian adhesions (93,94,95,184,185). Histologic confirmation of the laparoscopic impression is essential for the diagnosis of endometriosis (186), not only for subtle lesions but also for typical lesions reported to be histologically negative in 24% of cases (187). **In the presenc**

P.1148

of ovarian endometrioma (greater than 3 cm in diameter) and deeply infiltrating disease, histology should be obtained to identify endometriosis and to exclude rare instances of malignancy (159).

Figure 29.1 Pelvic localization of endometriosis.

Mild forms of deep endometriosis may only be detected by palpation under an endometriotic lesion or by discovery of a palpable mass beneath visually normal peritoneum, most notably in the posterior cul-de-sac (152) (Fig. 29.4.). At laparoscopy, deeply infiltrating endometriosis

may have the appearance of minimal disease, resulting in an underestimation of disease severity (188). Reduced Douglas depth and volume in women with deep endometriosis suggests that such lesions develop not in the rectovaginal septum but intraperitoneally and that burial of anterior rectal wall adhesions creates a false bottom, giving an erroneous impression of extraperitoneal origin (189). **The diagnosis of ovarian endometriosis is facilitated by careful inspection of all sides of both ovaries, which may be difficult when adhesions are present in more advanced stages of disease** (Fig. 29.5.). With superficial ovarian endometriosis, lesions can be both typical and subtle. Larger ovarian endometriotic cysts (endometrioma) are usually located on the anterior surface of the ovary and are associated with retraction, pigmentation, and adhesions to the posterior peritoneum. These ovarian endometriotic cysts often contain a thick, viscous dark brown fluid ("chocolate fluid") composed of hemosiderin derived from previous intraovarian hemorrhage. Because this fluid may also be found in other conditions, such as in hemorrhagic corpus luteum cysts or neoplastic cysts, biopsy and preferably removal of the ovarian cyst for histologic

P.1149

P.1150

P.1151

confirmation are necessary for the diagnosis in the revised endometriosis classification of the American Society for Reproductive Medicine. If that is not possible, **the presence of an ovarian endometriotic cyst should be confirmed by the following features: cyst diameter of less than 12 cm, adhesion to pelvic sidewall or broad ligament, endometriosis on surface of ovary, and tarry, thick, chocolate-colored fluid content** (190). Ovarian endometriosis appears to be a marker for more extensive

P.1152

pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having mostly extensive pelvic or intestinal endometriosis (191).

Histologic Confirmation

Histologic confirmation is essential in the diagnosis of endometriosis. In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 36%, but histologic confirmation was obtained in only 18%. This approach resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77% (192).

Microscopically, endometriotic implants consist of endometrial glands and stroma, with or without hemosiderin-laden macrophages (Fig. 29.6.). It has been suggested, however, that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis (2). Furthermore, problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands (193). The presence of stromal endometriosis, which contains endometrial stroma with hemosiderin-laden macrophages or hemorrhage, has been reported in women (186,187) and in baboons (101) and may represent a very early event in the pathogenesis of endometriosis. Isolated endometrial stromal cell nodules, immunohistochemically positive for vimentin and estrogen receptor, can be found in the absence of endometrial glands along blood or lymphatic vessels (194).

Different types of lesions may have different degrees of proliferative or secretory glandular activity (193). Vascularization, mitotic activity, and the three-dimensional structure of endometriosis lesions are key factors (195,196,197). Deep endometriosis has been described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue (115). However, smooth muscles are

P.1153

P.1154

also frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uterosacral ligaments (198).

(photographs kindly donated by Dr Christel Meuleman, Leuven University Fertility Center, Leuven University Hospitals, Leuven, Belgium). **A:** Extensive endometriosis with deep nodule at the right uterosacral ligament, masked by adhesions. **B:** Deep nodule still present in dense adhesion between rectum and uterosacral ligaments. **C:** Cul-de-sac after resection of deep nodule with CO² laser.

Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is believed to be important in the histogenesis of endometriosis and its recurrence after treatment (199,200). The clinical relevance of microscopic endometriosis is controversial because it has not been observed uniformly. Using undefined criteria for what constitutes normal peritoneum, peritoneal biopsy specimens of 1 to 3 cm were obtained during laparotomy from 20 patients with moderate to severe endometriosis (200). Examination of the biopsy results with low-power scanning electron microscopy revealed unsuspected microscopic endometriosis in 25% of cases not confirmed by light microscopy. Peritoneal endometriotic foci have been demonstrated by light microscopy in areas that show no obvious evidence of disease (201). **In serial sections of laparoscopic biopsies of normal peritoneum, 10% to 15% of women were shown to have microscopic endometriosis, and endometriosis was found in 6% of those without macroscopic disease** (185,202,203).

In contrast, other studies have been unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum (92,204,205,206). Examination of larger samples (5–15 mm) of visually normal peritoneum has revealed microscopic endometriosis in only 1 of 55 patients studied (207). Similarly, a histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic endometriosis is a rare occurrence (208). **Therefore, it appears that macroscopically appearing normal peritoneum rarely contains microscopic endometriosis** (207).

Classification

The current classification system of endometriosis by the American Society of Reproductive Medicine is the former American Fertility Society (AFS) system (see

P.1155

Fig. 29.5.), which has been revised without major changes (131). It is based on the appearance, size, and depth of peritoneal and ovarian implants; the presence, extent, and type of adnexal adhesions; and the degree of cul-de-sac obliteration. **In the new classification system, the morphology of peritoneal and ovarian implants should be categorized as red (red, red-pink, and clear lesions), white (white, yellow-brown, and peritoneal defects), and black (black and blue lesions)..**

Patient's Name _____ Date _____
 Stage I (Minimal) - 1-5
 Stage II (Mild) - 6-15
 Stage III (Moderate) - 16-40
 Stage IV (Severe) - >40

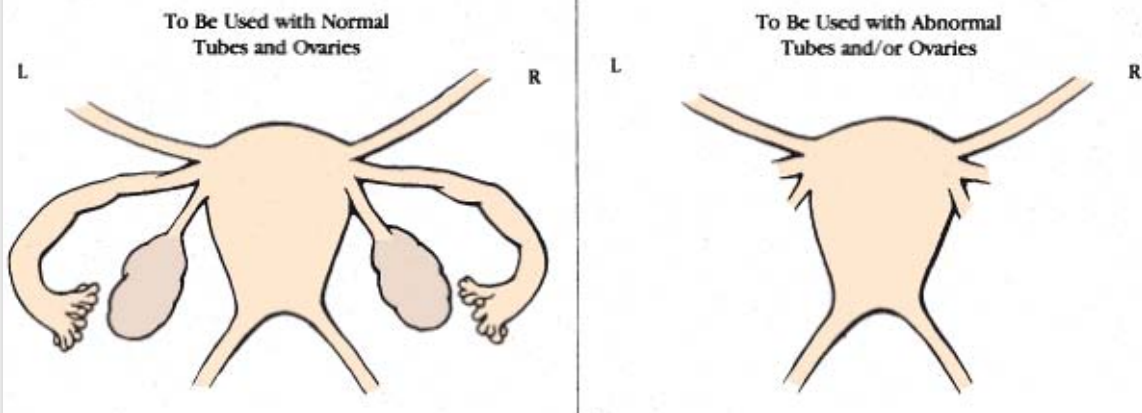

Figure 29.5 Revised American Society for Reproductive Medicine Classification. (From the American Society for Reproductive Medicine. Revised American Society for Reproductive Medicine classification of endometriosis. *Am Soc Reprod Med* 1997;5:817-821.).

This system reflects the extent of endometriotic disease but has considerable intraobserver and interobserver variability (209,210). Because the revised classification of endometriosis is the only internationally accepted system, it appears to be the best available tool to describe objectively the extent of endometriosis and relate it to spontaneous evolution and to therapeutic outcomes (pain relief, enhancement of fertility).

Figure 29.6 Histologic appearance of endometriosis: endometrial glandular epithelium, surrounded by stroma in typical lesion and clear vesicle..

The classification system has also been criticized because several investigators failed to find a correlation between it and endometriosis-related pain or infertility. This topic will be reviewed in "Results of Surgical Treatment."

Spontaneous Evolution

Endometriosis appears to be a progressive disease in a significant proportion (30%–60%) of patients. During serial observations, deterioration (47%), improvement (30%), or elimination (23%) was documented over a 6-month period (211). In another study, endometriosis progressed in 64%, improved in 27%, and remained unchanged in 9% of patients over 12 months (212). A third study of 24 women reported 29% with disease progression, 29% with disease regression, and 42% with no change over 12 months. Follow-up studies in both baboons and women (213,214,215) with spontaneous endometriosis over 24 months have demonstrated disease progression in all baboons and in 6 of 7 women. Several studies have reported that subtle lesions and typical implants may represent younger and older types of endometriosis, respectively. In a cross-sectional study, the incidence of subtle lesions decreased with age (216). This finding was confirmed by a 3-year prospective study that reported that the incidence, overall pelvic area involved, and volume of subtle lesions decreased with age, but in typical lesions, these parameters and the depth of infiltration increased with age (105). Remodeling of endometriotic lesions (transition between typical and subtle subtypes) has been reported to occur in women and in baboons, indicating that endometriosis is a dynamic condition (217,218). Several studies in women, cynomolgus monkeys, and rodents have shown that endometriosis is ameliorated after pregnancy (218,219,220,221).

The characteristics of endometriosis are variable during pregnancy, and lesions tend to enlarge during the first trimester but regress thereafter (222). Studies in baboons have revealed no change in the number or surface area of endometriosis lesions during the first two trimesters of pregnancy (223). These results do not exclude a beneficial effect that potentially may occur during the third trimester or in the immediate postpartum period. Establishment of a "pseudopregnant state" with exogenously administered estrogen and progestins was based on the belief that symptomatic improvement may result from decidualization of endometrial implants during pregnancy (224). This hypothesis, however, has not been substantiated.

Treatment

Treatment must be individualized, taking into consideration the clinical problem in its entirety, including the impact of the disease and the effect of its treatment on quality of life (159). Pain may persist despite seemingly adequate medical or surgical treatment of the disease. In such circumstances, a multidisciplinary approach involving a pain clinic and counseling should be considered early in the treatment plan (159). It also is important to involve the woman in all decisions, to be flexible in considering diagnostic and therapeutic approaches, and to maintain a good relationship with the patient. It may be appropriate to seek advice from more experienced colleagues or to refer the woman to a center with the necessary expertise to offer all available treatments in a multidisciplinary context, including advanced laparoscopic surgery and laparotomy (159). Because the management of severe or deeply infiltrating endometriosis is complex, referral is strongly recommended if disease of such severity is suspected or diagnosed (159).

Prevention

No strategies to prevent endometriosis have been uniformly successful. Although a reduced incidence of endometriosis has been reported in women who engaged in aerobic activity from an early age (16), the possible protective effect of exercise has not been investigated thoroughly. There also is insufficient evidence that oral contraceptive use offers protection against the development of endometriosis. In contrast, a recent report (225) showed an increased risk for endometriosis development in a select population of women taking oral contraceptives.

Regardless of the clinical profile (subfertility, pain, asymptomatic findings), treatment of endometriosis may be justified because endometriosis appears to progress in 30% to 60% of patients within a year of diagnosis and because it is not possible to predict in which patients it will progress (212). **Unfortunately, elimination of the endometriotic implants by surgical or medical treatment often provides only temporary relief. Therefore, in addition to eliminating the endometriotic lesions, the goal should be, more importantly, to treat the sequelae (pain and subfertility) often associated with this disease.**

Surgical Treatment

In most women with endometriosis, preservation of reproductive function is desirable. Therefore, the least invasive and least expensive approach that is effective should be used. Depending on the severity of disease, diagnosis and removal of endometriosis should be performed simultaneously at the time of surgery provided preoperative consent has been obtained (159,226,227,228,229). **The goal of surgery is to excise all visible**

endometriotic lesions and associated adhesions—peritoneal lesions, ovarian cysts, deep rectovaginal endometriosis—and to restore normal anatomy. In most women, laparoscopy can be used, and this technique decreases cost, morbidity, and the possibility of recurrence of adhesions postoperatively. **Laparotomy should be reserved for patients with advanced—state**

P.1158

disease who cannot undergo a laparoscopic procedure and for those in whom fertility conservation is not necessary.

Peritoneal Endometriosis

Endometriosis lesions can be removed during laparoscopy by surgical excision with scissors, bipolar coagulation, or laser methods (CO₂ laser, potassium–titanium–phosphate laser, or argon laser). Although some surgeons claim that the CO₂ laser is superior because it causes only minimal thermal damage, no evidence is available to show the superiority of one technique over another. Comparable cumulative pregnancy rates have been reported after treatment of mild endometriosis with laparoscopic excision and electrocoagulation (230).

Ovarian Endometriosis

Superficial ovarian lesions can be vaporized. Small ovarian endometrioma (<3 cm in diameter) can be aspirated, irrigated, and inspected with ovarian cystoscopy for intracystic lesions; their interior wall can be vaporized to destroy the mucosal lining of the cyst (231). Large (>3 cm in diameter) ovarian endometrioma should be aspirated, followed by incision and removal of the cyst wall from the ovarian cortex. To prevent recurrence, the cyst wall of the endometrioma must be removed, and normal ovarian tissue must be preserved..

Although as little as one tenth of an ovary is enough to preserve function and fertility (232), there is increasing concern that ovarian cystectomy with concomitant removal or destruction of primordial follicles may reduce ovarian volume and reserve and diminish fertility. A recent study reported reduced follicular response in natural and clomiphene citrate–stimulated cycles, but not in gonadotropin–stimulated cycles, in women younger than 35 years of age who underwent cystectomy compared with controls of similar age with normal ovaries (233). Therefore, it has been proposed to replace cystectomy by fenestration and coagulation of the inner wall of the endometriotic ovarian cyst. In one study, cumulative clinical pregnancy rates and recurrence rates were comparable in women treated with cystectomy and with fenestration and coagulation after 36 months, but conception occurred more quickly in the fenestration and coagulation group (234). A more recent case–control study in 231 patients reported a lower cumulative reoperation rate in the cyst excision group than in the fenestration and coagulation group after 18 (6% versus 22%) and 42 (24% versus 59%) months of follow-up (235). A randomized controlled trial demonstrated that pain and subfertility caused by ovarian endometrioma were improved more by cystectomy than by fenestration and coagulation (236). A reduced recurrence of pain after 2 years (odds ratio [OR], 0.2; confidence interval [CI], 0.05–0.77), an increased pain–free interval after operation (19 months versus 9.5 months), and an increased pregnancy rate (67% versus 23%) were found in the cystectomy group when compared with the fenestration and coagulation group (236). In another recent study (237), coagulation or laser vaporization of endometriomas without excision of the pseudocapsule was associated with a significantly increased risk of cyst recurrence. Laparoscopic cystectomy for ovarian endometriomas greater than 4 cm diameter improves fertility compared with drainage and coagulation (238,239).

Therefore, based on the current evidence, **ovarian cystectomy appears to be the method**

of choice..

Adhesiolysis

The removal of endometriosis-related adhesions (adhesiolysis) should be performed carefully. Routine use of pharmacologic or liquid agents to prevent postoperative adhesions after fertility surgery cannot be recommended based on evidence from randomized controlled trials (240).

Preoperative Hormonal Treatment

In patients with severe endometriosis, it has been recommended that surgical treatment be preceded by a 3-month course of medical treatment to reduce vascularization and nodular size (152). However, **a recent randomized study comparing 3 months of preoperative treatment with GnRH and no treatment in 75 women with moderate to severe endometriosis failed to show a significant difference in ease of surgery between the two groups** (241).

P.1159

Deep Rectovaginal and Rectosigmoidal Endometriosis

The surgical excision of deep rectovaginal and rectosigmoidal endometriosis is difficult and can be associated with major complications. Postoperative bowel perforations with peritonitis have been reported in 2% to 3% of cases (242).

Preoperative investigations, including gynecologic ultrasonography, intravenous pyelography (to exclude ureteral endometriosis), and colon contrast radiography (to exclude transmural rectosigmoidal endometriosis), are essential, and MRI may be useful in specific cases. Preoperative laxatives, starch-free diet, and full bowel preparation are needed to allow perioperative bowel suturing, if needed. To allow complete excision of rectovaginal endometriosis, 6% of patients needed bowel wall resection, and 14% required partial resection of the posterior vaginal fornix (242). Segmental rectosigmoid resection can be performed by laparotomy, laparoscopy with intracorporeal suturing, or by laparoscopically assisted vaginal technique (243). The latter technique appears to be faster than laparoscopy with intracorporeal suturing and cheaper than laparotomy because of decreased hospital stay and lower operating room charges (243), but more studies are needed to confirm this impression. Ureter stents may be required before excision of peritoneal endometriosis surrounding the ureter. A multidisciplinary approach involving gynecologic and gastroenterologic surgeons and urologists is desirable. More long-term follow-up after surgery for colorectal endometriosis is needed to document complications, recurrences, and long-term effects on pain and fertility.

Oophorectomy and Hysterectomy

Radical procedures such as oophorectomy or total hysterectomy are indicated only in severe situations and can be performed either laparoscopically or, more commonly, by laparotomy. However, it is important to note that women aged 30 years or younger at the time of hysterectomy for endometriosis-associated pain are more likely than older women to have residual symptoms, to report a sense of loss, and to report more disruption from pain in different aspects of their lives (244). If a hysterectomy is performed, bilateral salpingo-oophorectomy should be considered as well (245), and all visible endometriotic tissue should be removed at the same time (246).

Postoperative Hormone Therapy

Postoperative hormone therapy with estrogen is required after bilateral oophorectomy, and there is a negligible risk for renewed growth of residual endometriosis (247). To reduce this risk, hormone therapy should be withheld until 3 months after surgery. The addition of progestins to this regimen protects the endometrium. However, the decision to start hormone therapy with a combination of estrogen and progestin should be balanced against the increased risk of breast cancer and heart disease associated with hormone therapy.

Some cases of adenocarcinoma have been reported, presumably arising from endometriosis lesions remaining in women treated with unopposed estrogen (232).

Results of Surgical Treatment

Pain

The outcome of surgical therapy in patients with endometriosis and pain is influenced by many psychological factors relating to personality, depression, and marital and sexual problems. **There is a significant placebo response to surgical therapy: diagnostic laparoscopy without complete removal of endometriosis may alleviate pain in 50% of patients** (248,249,250). Similar results have been reported using oral placebos (251). Although some reports have claimed pain relief with laser laparoscopy in 60% to 80% of patients with very low morbidity, none was prospective or controlled and, thus, did not allow a definitive conclusion regarding treatment efficacy (152,252,253,254,255).

Endometriosis Stage and Pain Relief after Surgery

In patients with pain, the endometriosis stage was not related to pain symptoms in several studies (256,257).

P.1160

However, more recent studies reported a positive correlation between endometriosis stage and endometriosis-related dysmenorrhea or chronic pelvic pain (258,259).

In a prospective, controlled, randomized, double-blind study, surgical therapy (ablation of endometriotic lesions and laparoscopic uterine nerve ablation [LUNA]) was shown to be superior to expectant management 6 months after treatment of mild and moderate endometriosis (248). In women with mild and moderate disease treated with laser, 74% achieved pain relief. Treatment was least effective in women with minimal disease. There were no reported operative or laser complications (248). There is no evidence that LUNA is a necessary part of this treatment (260) because LUNA by itself has no effect on dysmenorrhea associated with endometriosis (237). One year later, symptom relief was still present in 90% of those who responded initially (213,248). Patients with severe disease were not included (248) because it had previously been shown that surgery resulted in pain relief in 80% of patients who did not respond to medical therapy (261).

These results suggest that laser laparoscopy may be effective for the treatment of pain associated with mild to severe endometriosis. In women with minimal endometriosis, laser treatment may limit progression of disease.

Effect of Preoperative and Postoperative Treatment

Hormonal therapy before surgery improves endometriosis scores, but there is insufficient evidence that it has any effect on pain relief after the operation (262).

Some evidence from randomized controlled trials supports the postoperative medical treatment of pain associated with endometriosis for 6–12 months. Postoperative GnRH treatment resulted in reduced pain scores and in a delay of pain recurrence for more than 12 months if the agonists were given for 6 months but not if they were only administered for 3 months (263,264,265). Similarly, postoperative hormonal treatment with *danazol*, 100 mg/day (low dose), for 12 months after surgery for moderate to severe endometriosis resulted in a significantly lower pain score in the treated group when compared with the placebo group. In contrast, postoperative high-dose *danazol*, 600 mg/day for 3 months, was not superior to expectant management with respect to pain recurrence in an identical patient population (266). According to a recent Cochrane review (262), compared with surgery alone or surgery plus placebo, postoperative hormonal treatment does not reduce pain recurrence at 12 or 24 months and has no effect on disease recurrence 263–266, 268, 270, 271, 273.

Subfertility

Advanced Endometriosis and Pregnancy Outcome after Surgery

When endometriosis causes mechanical distortion of the pelvis, surgery should be performed to achieve reconstruction of normal pelvic anatomy. **Laparoscopic cystectomy for ovarian endometriomas greater than 4 cm diameter improves fertility compared with drainage and coagulation** (238,239).

The success of surgery in relieving infertility is probably related to the severity of endometriosis. A recent retrospective multicenter analysis (271) reported cumulative pregnancy rates of 39%, 31%, 30%, and 25% in patients with endometriosis stages I, II, III, and IV, respectively, 12 months after surgical treatment. Although there appeared to be a negative correlation between stage of endometriosis and fertility outcome, no significant difference was found between the four groups in this study. However, the study had many limitations, including retrospective design, lack of well-defined definition of male factor infertility as potential bias, multicenter data with significant interobserver variability, inclusion of only a limited number of patients with substantial adhesive disease, variable infertility treatment after 6 months of follow-up, and absence of a control group.

P.1161

A somewhat higher cumulative intrauterine pregnancy rate has been reported in 30 women with deep uterosacral endometriosis after surgery: 48% after 12 months (47% for AFS stages I to II and 46% for AFS stages III to IV) (276). A cumulative pregnancy rate of 24% was reported in patients 9 months after undergoing reoperation for stage III to IV endometriosis (277).

Other investigators reported a negative correlation between stage of endometriosis and fertility after surgical treatment. In an older study, using an older classification system, a significant decrease in fecundability was seen in women with severe or extensive endometriosis compared with women with mild or moderate disease (278,279). In a more recent study (280), the negative correlation between the stage of endometriosis and the spontaneous cumulative pregnancy rate after surgical removal of endometriosis was statistically significant. Other studies have reported a significant negative correlation between endometriosis stage and pregnancy rate and decreased pregnancy rates when the

revised scores exceeded 70 (281,282).

Preoperative and Postoperative Medical Treatment

Preoperative medical treatment with *danazol*, GnRH agonists, or progestins may be useful to reduce the extent of endometriosis in patients with advanced disease. **Postoperative medical treatment is rarely indicated because it does not work based on randomized trials, because it prevents pregnancy, and because the highest pregnancy rates occur during the first 6 to 12 months after conservative surgery** (264,265). If pregnancy does not occur within 2 years of surgery, there is little chance of subsequent fertility (283).

Minimal to Mild Endometriosis and Fertility after Surgery

Surgical management of infertile women with minimal to mild endometriosis is controversial. The cumulative pregnancy rate after 5 years without therapy has been reported to be as high as 90% in women with minimal or mild endometriosis (284). This is comparable to the 93% rate reported in women who do not have endometriosis. Laparoscopic destruction of endometriosis has been reported to improve fertility in patients with minimal to mild disease (285,286,287), but not all investigators share this conclusion (288,289,290). It has been hypothesized that the MFR is higher during the first 6 to 12 months after laparoscopic surgery than with expectant management (291,292).

Two randomized controlled studies have evaluated the effect of surgical treatment of endometriosis on fertility parameters (144,145). **One study** (144) **reported that laparoscopic surgery enhanced fecundity in infertile women with minimal or mild endometriosis.** They studied 341 infertile women, 20 to 39 years of age, with minimal or mild endometriosis. During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They were followed for 36 weeks after the laparoscopy or, for those who became pregnant during that interval, for up to 20 weeks of pregnancy. The study objects were recruited among infertile women scheduled for diagnostic laparoscopy with strict eligibility criteria. The women in the study had no previous surgical treatment for endometriosis and no medical treatment for endometriosis in the previous 9 months and no other medical or surgical treatment for infertility in the previous 3 months. They had no history of pelvic inflammatory disease and no severe pelvic pain precluding expectant management. The diagnosis of endometriosis required the presence of one or more typical bluish or black lesions. The stage of endometriosis was determined according to the revised American Society of Reproductive Medicine classification. **During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They found that resection or ablation of minimal and mild endometriosis increased the likelihood of pregnancy in infertile women.** In the treated group, 31% of the patients became pregnant, compared with 18% in the nontreated group ($p=0.006$).

P.1162

In a multicenter study in Italy, a similar study design was used to compare the effect of diagnostic laparoscopy with surgical resection and ablation of visible endometriosis (on fertility parameters) in infertile women with minimal to mild endometriosis (145). Eligible patients were women aged less than 36 years who were trying to conceive and had a laparoscopically confirmed diagnosis of minimal or mild endometriosis. None of the women had had therapy for endometriosis or infertility. Treatment was randomly allocated during laparoscopy. There was a follow-up period of 1 year after the laparoscopy. **The results of this study did not show a beneficial effect of surgery regarding fertility.** During the

follow-up period after laparoscopy, no statistically significant differences in conception and live-birth rates were observed in the treated group (24% and 20%, respectively) and in the control group (29% and 22%, respectively).

Prognosis with Surgical Treatment

Based on the aforementioned studies, and taking into account the larger patient population in the Canadian multicenter study, **surgical treatment of minimal to mild endometriosis appears to offer a small but significant benefit with regard to fertility outcome** (130,159,289). Furthermore, the surgical removal of peritoneal endometriosis may also be important to prevent progression of endometriosis. However, care is needed to prevent adhesion formation that could result as a consequence of overenthusiastic excision of minimal to mild endometriosis.

Medical Treatment

Empirical Treatment

If the patient desires treatment of pain symptoms suggestive of endometriosis in the absence of a definitive diagnosis, a therapeutic trial of a hormonal medication to reduce menstrual flow is appropriate. Empirical treatment for pain presumed to be due to endometriosis in the absence of a definitive diagnosis includes counseling, analgesia, nutritional therapy, progestins, or combined oral contraceptives.

It is unclear whether combined oral contraceptives should be taken in a conventional, continuous, or tricycle regimen. A GnRH agonist may be taken, but this class of drug is more expensive and associated with more side effects and concerns about bone density than oral contraceptives (159).

Dysmenorrhea

Generally, women suffering from dysmenorrhea are treated with analgesics; many women treat themselves with over-the-counter oral analgesics. **In a recent systematic Cochrane review evaluating the use of nonsteroidal anti-inflammatory drugs (NSAIDs) for primary dysmenorrhea** (290), primary dysmenorrhea was described as menstrual pain without organic pathology (see Chapter 15). Exclusion of pelvic pathology was based on physical examination alone. It can be argued that some of these women with so-called primary dysmenorrhea probably in fact had endometriosis. **It was concluded that NSAIDs, except *niflumic acid*, were more effective than placebo for pain relief** (290), **but there was insufficient evidence to suggest whether any individual NSAID was more effective than another.** In another review, selective cyclo-oxygenase-2 inhibitors *rofecoxib* and *valdecoxib* were found to be as effective as *naproxen* and more effective than placebo for the treatment of primary dysmenorrhea (291). However, concerns have been raised about the safety of these medications, and its manufacturers have recently withdrawn *rofecoxib* from the market.

According to a systematic review (292) based on two relatively small randomized controlled trials comparing *paracetamol* and *co-proxamol* with placebo, respectively, *co-proxamol* (*paracetamol* 650 mg and *dextropropoxyphen* 65 mg) but not *paracetamol*

(500 mg 4 times daily) was more effective than placebo in reducing pain. This observation can possibly be explained by the suboptimal dosage of *paracetamol* used.

Pain

Considering that endometriosis is a chronic inflammatory disease, anti-inflammatory drugs would appear to be effective for treatment (see Chapter 15). **Nonsteroidal anti-inflammatory drugs may be effective in reducing endometriosis associated pain** (159,293,294,295). Although NSAIDs have been used extensively and have often been the first line therapy for reduction of endometriosis-related pain, the analgesic effect of NSAIDs has not been studied extensively. Only one small, double-blind, placebo-controlled, four-period, crossover clinical study has been published (294). This study showed complete or substantial pain relief of endometriosis-related dysmenorrhea in 83% of cases treated with *naproxen* compared with 41% in cases treated with placebo. Women who received *naproxen* needed significantly fewer supplemental analgesics compared to women taking placebo.

Endometriosis-related pain is nociceptive (296), but persistent nociceptive input from endometriotic lesions leads to central sensitization manifested by somatic hyperalgesia and increased referred pain. The effectiveness of NSAIDs in the reduction of endometriosis-related pain may be explained by both a local antinociceptive effect and a reduced central sensitization in addition to the anti-inflammatory effect. However, NSAIDs have significant side effects, including gastric ulceration and possible inhibition of ovulation. Prostaglandins also are involved in the follicle rupture mechanism at ovulation, which is why women who wish to become pregnant should not take NSAIDs at the time of ovulation (297).

Nonhormonal Medical Therapy

Modulation of Cytokines

In rats with experimental endometriosis, recombinant human TNF- α -binding protein can reduce 64% of the size of endometriosis-like peritoneal lesions (298). Similarly, a recent prospective randomized placebo- and drug-controlled study in baboons showed that recombinant human TNF- α -binding protein effectively inhibits the development of endometriosis and endometriosis-related adhesions (57) and is effective in the treatment of spontaneous endometriosis in baboons (299).

In mice with experimental endometriosis, a placebo-controlled double-blind study showed that intraperitoneal or subcutaneous injection of recombinant interferon- α 2b resulted in smaller endometriotic lesions when compared with the placebo control group (300). In rats with experimental endometriosis, regression of endometrial explants was observed after treatment with immune-enhancing modulators *loxoribine* and *levamisole* (301).

Anti-inflammation

In the future, leukotriene receptor antagonists could be of use in patients with endometriosis who do not respond to prostaglandin synthetase inhibitors (302). In humans, a randomized placebo-controlled trial of oral *pentoxifylline*, 800 mg/day for 12 months, reported after life-table analysis a similar overall pregnancy rate in treated patients (31%) and in controls (18.5%) (303).

Inhibition of Matrix Metalloproteinase

In nude mice, suppression of MMPs by progesterone or by a natural inhibitor slows the establishment of ectopic lesions by human endometrium (304). Thus far, no clinical reports

have been published.

New Developments

Many substances potentially capable of modulating immunologic or inflammatory mechanisms involved in the onset or progression of the disease could be the targets for future research in endometriosis (305,306).

P.1164

Hormonal Medical Treatment

Because estrogen is known to stimulate the growth of endometriosis, hormonal therapy has been designed to suppress estrogen synthesis, thereby inducing atrophy of ectopic endometrial implants or interrupting the cycle of stimulation and bleeding. Implants of endometriosis react to gonadal steroid hormones in a manner similar but not identical to normally stimulated ectopic endometrium. Ectopic endometrial tissue displays histologic and biochemical differences from normal ectopic endometrium in characteristics such as glandular activity (proliferation, secretion), enzyme activity (17 β -hydroxysteroid dehydrogenase), and steroid (estrogen, progestin, and androgen) hormone receptor levels.

There is strong evidence that suppression of ovarian function for 6 months reduces pain associated with endometriosis. Combined oral contraceptives *danazol*, *gestrinone*, *medroxyprogesterone acetate*, and GnRH agonists are all equally effective but their side-effect and cost profiles differ (159,306,307,308,309).

The use of *diethylstilbestrol*, *methyltestosterone*, or other androgens is no longer advocated because they lack efficacy, have significant side effects, and pose risks to the fetus if pregnancy occurs during therapy. A new generation of aromatase inhibitors, estrogen receptor modulators, and progesterone antagonists may offer new hormonal treatment options in the future. Recent progress in the understanding of the pathogenesis of endometriosis has led to the expectation that new pharmaceutical agents affecting inflammation, angiogenesis, and MMP activity may prevent or inhibit the development of endometriosis.

Oral Contraceptives

Continuous Administration

Manipulation of the endogenous hormonal milieu is the basis for the medical management of endometriosis. The treatment of endometriosis with continuous low-dose monophasic combination contraceptives (one pill per day for 6–12 months) was originally used to induce pseudopregnancy caused by the resultant amenorrhea and decidualization of endometrial tissue (224). Kistner was the first to introduce the concept of an adynamic endometrium through elimination of the normal cyclic hormonal changes characteristic of the menstrual cycle (310). **This induction of a pseudopregnancy state with combination oral contraceptive pills has been shown to be effective in reducing dysmenorrhea and pelvic pain.** In addition, the subsequent amenorrhea induced by oral contraceptives could potentially reduce the amount of retrograde menstruation (one of the risk factors proposed in the etiology of endometriosis), decreasing the risk for disease progression. Pathologically, oral contraceptive use is associated with decidualization of endometrial tissue, necrobiosis, and possibly absorption of the endometrial tissue (311). Unfortunately, there is no convincing evidence that medical therapy with oral

contraceptives offers definitive therapy. Instead, the endometrial implants survive the induced atrophy and, in most patients, reactivate after termination of treatment.

Any low-dose combination oral contraceptive containing 30 to 35 µg of ethinyl estradiol used continuously can be effective in the management of endometriosis.

The objective of the treatment is the induction of amenorrhea, which should be continued for 6 to 12 months. Symptomatic relief of dysmenorrhea and pelvic pain is reported in 60% to 95% of patients (312,313). After a first-year recurrence rate of 17% to 18%, a 5% to 10% annual recurrence rate has been observed. In addition, a posttreatment pregnancy rate of up to 50% can be expected. Although oral contraceptives are effective in inducing a decidualized endometrium, the estrogenic component in oral contraceptives may potentially stimulate endometrial growth and increase pelvic pain in the first few weeks of treatment. The long-term significance of this effect remains to be determined. **Oral contraceptives are less costly than other treatments and may be helpful in the short-term management of endometriosis with potential long-term benefits in some women.**

P.1165

Cyclic Administration

There is no convincing evidence that cyclic use of combination oral contraceptives provides prophylaxis against either the development or recurrence of endometriosis. Estrogens in oral contraceptives potentially may stimulate the proliferation of endometriosis. The reduced menstrual bleeding that often occurs in women taking oral contraceptives may be beneficial to women with prolonged, frequent menstrual bleeding, which is a known risk factor for endometriosis (16). Further research is warranted to assess the effect of low-dose oral contraceptives in preventing endometriosis and in treating associated pain. In a randomized controlled study, a cyclic 21-day oral contraceptive (*ethinyl estradiol* 20 µg plus *desogestrel* 0.15 mg) combined with very-low-dose *danazol* (50 mg/day) was less effective in relief of dysmenorrhea than depot *medroxyprogesterone* acetate (150 mg every 3 months) (314).

Progestins

Progestins may exert an antiendometriotic effect by causing initial decidualization of endometrial tissue followed by atrophy. They can be considered as the first choice for the treatment of endometriosis because they are as effective as *danazol* or GnRH analogues and have a lower cost and a lower incidence of side effects than these agents (315).

There is no evidence that any single agent or any particular dose is preferable to another. The effective doses of several progestins are summarized in Table 29.1. In most studies, the effect of treatment has been evaluated after 3 to 6 months of therapy. *MPA* has been the most studied agent. It is effective in relieving pain starting at a dose of 30 mg/day and increasing the dose based on the clinical response and bleeding patterns (316,317). However, a recent randomized placebo-controlled study reported a significant reduction

P.1166

in stages and scores of endometriosis in both the placebo group and the group treated with *MPA*, 50 mg/day, and placebo at laparoscopy within 3 months after cessation of therapy (318). These findings raise questions about the need for medical therapy.

Table 29.1 Medical Treatment of Endometriosis–Associated Pain: Effective Regimens (Usual Duration: 6 Months)

	<i>Administration</i>	<i>Dose</i>	<i>Frequency</i>
Progestogens			
<i>Medroxyprogesterone acetate</i>	PO	30 mg	Daily
<i>Megestrol acetate</i>	PO	40 mg	Daily
<i>Lynoestrenol</i>	PO	10 mg	Daily
<i>Dydrogesterone</i>	PO	20–30 mg	Daily
Antiprogestins			
<i>Gestrinone</i>	PO	1.25 or 2.5 mg	Twice weekly
<i>Danazol</i>	PO	400 mg	Daily
Gonadotropin–Releasing Hormone			
<i>Leuprolide</i>	SC	500 mg	Daily
	IM	3.75 mg	Monthly
<i>Goserelin</i>	SC	3.6 mg	Monthly
<i>Buserelin</i>	IN	300 µg	Daily
	SC	200 µg	Daily
<i>Nafarelin</i>	IN	200 µg	Daily
<i>Triptorelin</i>	IM	3.75 mg	Monthly

PO, oral; SC, subcutaneous; IM, intramuscular; IN, intranasal.

Medroxyprogesterone acetate (150 mg) given intramuscularly every 3 months is also effective for the treatment of pain associated with endometriosis, but it is not indicated in infertile women because it induces profound amenorrhea and anovulation, and a varying length of time is required for ovulation to resume after discontinuation of therapy. *Megestrol acetate* has been administered in a dose of 40 mg/day with good results (319). Other treatment strategies have included *dydrogesterone* (20 to 30 mg/day, either continuously or on days 5 to 25) and *lynestrenol* (10 mg/day). The effectiveness of natural progesterone has not been evaluated.

Side effects of progestins include nausea, weight gain, fluid retention, and breakthrough bleeding caused by hypoestrogenemia. Breakthrough bleeding, although common, is usually corrected by short-term (7-day) administration of estrogen. Depression and other mood disorders are a significant problem in about 1% of women taking these medications.

Intrauterine Progesterone Treatment

Local progesterone treatment of endometriosis–associated dysmenorrhea with a *levonorgestrel*-releasing intrauterine system for 12 months has resulted in a significant reduction in dysmenorrhea, pelvic pain, and dyspareunia; a high degree of patient satisfaction; and a significant reduction in the volume of rectovaginal endometriotic nodules (320,321). These promising results have been confirmed in other studies (322), even after 3 years of treatment (323). This type of local treatment may become a more important option if a long-term medical suppression of endometriosis is needed.

Progesterone Antagonists

Progesterone antagonists and progesterone receptor modulators may suppress endometriosis based on their antiproliferative effects on the endometrium, without the risk for hypoestrogenism

or bone loss that occurs with GnRH treatment. These products are soon to be introduced in the United States, but their clinical effectiveness remains to be proved.

Mifepristone

Mifepristone (RU-486) is a potent antiprogestagen with a direct inhibitory effect on human endometrial cells and, in high doses, an antiglucocorticoid action (324). The recommended dose for endometriosis is 25 to 100 mg/day. In uncontrolled studies, *mifepristone*, 50 to 100 mg/day, reduced pelvic pain and induced 55% regression of the lesions without significant side effects (325,326). In an uncontrolled pilot study, *mifepristone*, 5 mg/day, resulted in pain improvement, but there was no change in endometriosis lesions, suggesting that this dosage is probably too low (327).

Onapristone

Progesterone antagonists *onapristone* (ZK98299) and ZK136799, used in the treatment of rats with surgically induced endometriosis, resulted in a remission in 40% to 60% of treated animals. In animals with persistent endometriosis, growth inhibition was obtained in 48% and 85% of endometriotic lesions after therapy with *onapristone* and ZK136799, respectively (328).

Other Progesterone Antagonists

The chemical synthesis and pharmacologic characterization of a highly potent progesterone antagonist, ZK230211, have been reported, with little or no other endocrinologic effects. ZK230211 is active on both progesterone receptors A and B (329). In primates, this drug has been reported to block ovulation and menstruation at all effective doses (330), whereas another progesterone antagonist, ZK137316, allowed ovulation but blocked menstruation in a dose-dependent fashion. All progesterone antagonist-treated animals maintained normal follicular phase concentration

P.1167

of estradiol and returned to menstrual cyclicity within 15 to 41 days after treatment (330). Both progesterone antagonists block unopposed estrogen action on the endometriosis through their antiproliferative effect.

Gestrinone

Gestrinone is a 19-nortestosterone derivative with androgenic, antiprogestagenic, antiestrogenic, and antigonadotropic properties. It acts centrally and peripherally to increase free testosterone and reduce sex hormone-binding globulin levels (androgenic effect), reduce serum estradiol values to early follicular phase levels (antiestrogenic effect), reduce mean LH levels, and obliterate the LH and follicle-stimulating hormone (FSH) surge (antigonadotropic effect). *Gestrinone* causes cellular inactivation and degeneration of endometriotic implants but not their disappearance (331). Amenorrhea occurs in 50% to 100% of women and is dose dependent.

Resumption of menses generally occurs 33 days after discontinuing the medication (332,333). An advantage of gestrinone is its long half-life (28 hours) when given orally. The standard dose has been 2.5 mg twice a week. Although it has been reported that 1.25 mg twice weekly is equally effective (334), a more recent randomized study demonstrated in women with mild to moderate endometriosis that 2.5 mg *gestrinone*, twice weekly for 24 weeks, is more effective and has a better effect on bone mass (+7% versus -7%) when compared with 1.25 mg *gestrinone*, 2 times weekly for 24 weeks (335).

The clinical side effects of gestrinone are dose dependent and similar to but less intense than those caused by *danazol* (332). They include nausea, muscle cramps, and androgenic effects such as weight gain, acne, seborrhea, and oily hair and skin.

In a multicenter, randomized, double-blind study, *gestrinone* was as effective as GnRH for the treatment of pelvic pain associated with endometriosis (336). However, *gestrinone* has fewer side effects and has the added advantage of twice-weekly administration. Pregnancy is contraindicated while taking gestrinone because of the risk for masculinization of the fetus.

Danazol

Danazol is not more effective than other available medications to treat

endometriosis. Recognized pharmacologic properties of *danazol* include suppression of GnRH or gonadotropin secretion, direct inhibition of steroidogenesis, increased metabolic clearance of estradiol and progesterone, direct antagonistic and agonistic interaction with endometrial androgen and progesterone receptors, and immunologic attenuation of potentially adverse reproductive effects (337,338). The multiple effects of *danazol* produce a high-androgen, low-estrogen environment (estrogen levels in the early follicular to postmenopausal range) that does not support the growth of endometriosis, and the amenorrhea that is produced prevents new seeding of implants from the uterus into the peritoneal cavity.

The immunologic effects of danazol have been studied in women with endometriosis and adenomyosis and include a decrease in serum immunoglobulins, a decrease in serum C3, a rise in serum C4 levels, decreased serum levels of autoantibodies against various phospholipid antigens, and decreased serum levels of CA125 during treatment (165,166,178,179,180,181,339,340). *Danazol* inhibits peripheral blood lymphocyte proliferation in cultures activated by T-cell mitogens but does not affect macrophage-dependent T-lymphocyte activation of B lymphocytes (338). *Danazol* inhibits interleukin-1 and TNF production by monocytes in a dose-dependent manner, and suppresses macrophage- and monocyte-mediated cytotoxicity of susceptible target cells in women with mild endometriosis (341,342). These immunologic findings may be important in the remission of endometriosis with danazol treatment and may offer an explanation of the effect of *danazol* in the treatment of a number of autoimmune diseases, including hereditary

P.1168

angioedema (343), autoimmune hemolytic anemia (344), systemic lupus erythematosus (345), and idiopathic thrombocytopenic purpura (346,347). Doses of 800 mg/day are frequently used in North America, whereas 600 mg/day is commonly prescribed in Europe and Australia. It appears that the absence of menstruation is a better indicator of response than drug dose. A practical strategy for the use of *danazol* is to start treatment with 400 mg daily (200 mg twice a day) and increase the dose, if necessary, to achieve amenorrhea and relieve symptoms (333).

The significant adverse side effects of *danazol* are related to its androgenic

and hypoestrogenic properties. The most common side effects include weight gain, fluid retention, acne, oily skin, hirsutism, hot flashes, atrophic vaginitis, reduced breast size, reduced libido, fatigue, nausea, muscle cramps, and emotional instability. Deepening of the voice is another potential side effect that is nonreversible. Although *danazol* can cause increased cholesterol and low-density lipoprotein levels and decreased high-density lipoproteins levels, it is unlikely that these short-term effects are clinically important. *Danazol* is contraindicated in patients with liver disease because it is largely metabolized in the liver and may cause hepatocellular damage. *Danazol* is also contraindicated in patients with hypertension, congestive heart failure, or impaired renal function because it can cause fluid retention. The use of danazol is contraindicated in pregnancy because of its androgenic effects on the fetus.

Because the many side effects of oral *danazol* limit its use, alternative routes of administration have been studied. In an uncontrolled pilot study, local *danazol* treatment using a vaginal *danazol* ring (1,500 mg) has been shown to be effective for pain relief in deeply infiltrative endometriosis. This treatment did not cause the classic *danazol* side effects or detectable serum *danazol* levels, and it allowed ovulation and conception to occur (348).

Gonadotropin-releasing Hormone Agonists

Gonadotropin-releasing hormone agonists bind to pituitary GnRH receptors and stimulate LH and FSH synthesis and release. However, the agonists have a much longer biologic half-life (3–8 hours) than endogenous GnRH (3.5 minutes), resulting in the continuous exposure of GnRH receptors to GnRH agonist activity. This exposure causes a loss of pituitary receptors and downregulation of GnRH activity, resulting in low FSH and LH levels. Consequently, ovarian steroid production is suppressed, providing a medically induced and reversible state of pseudomenopause. A direct effect of GnRH agonists on ectopic endometrium is also possible, because expression of the GnRH receptor gene has been documented in ectopic endometrium and because direct inhibition of endometriosis cells has been shown *in vitro* (349). Furthermore, in rat models used to study surgical adhesion formation and endometriosis, GnRH agonist therapy decreased activity of plasminogen activators and matrix MMPs and increased the activity of their inhibitors, suggesting potential GnRH agonist-regulated mechanisms for reducing adhesion formation (350).

Various GnRH agonists have been developed and used in treating endometriosis. These agents include *leuprolide*, *buserelin*, *nafarelin*, *histrelin*, *goserelin*, *deslorelin*, and *triptorelin*. These drugs are inactive orally and must be administered intramuscularly, subcutaneously, or by intranasal absorption. The best therapeutic effect is often associated with an *estradiol* dose of 20 to 40 pg/mL (75–150 pmol/L). These so-called depot formulations are attractive because of the reduced frequency of administration and because nasal administration can be complicated by variations in absorption rates and problems with patient compliance (333). The results with GnRH agonists are similar to those with *danazol* or progestin therapy. **Treatment for 3 months with a GnRH agonist is effective in improving pain for 6 months** (263).

Although GnRH agonists do not have an adverse effect on serum lipids and lipoproteins levels, their side effects are caused by hypoestrogenism and include hot flashes, vaginal

P.1169

dryness, reduced libido, and osteoporosis (6%–8% loss in trabecular bone density after 6 months of therapy). Reversibility of bone loss is equivocal and therefore of concern (351,352), especially because treatment periods of longer than 6 months may be required. The goal is to suppress endometriosis and maintain serum estrogen levels of 30 to 45 pg/mL. More extreme estradiol suppression will induce bone loss (351). The dose of daily GnRH agonist can be regulated by monitoring estradiol levels, by the addition of low-dose progestin or estrogen-progestin in an add-back regimen, or by draw-back therapy. **The goal of add-back therapy is to treat endometriosis and endometriosis-associated pain effectively while preventing vasomotor symptoms and bone loss related to the hypoestrogenic state induced by GnRH analogues.** Add-back therapy can be achieved by administering progestins only, including *norethisterone*, 1.2 mg, and *norethindrone acetate*, 5 mg, but bone loss is not prevented by *medrogestone*, 10 mg/day (352,353,354). Add-back therapy can also be achieved by *tibolone*, 2.5 mg/day (353,356) or by an estrogen-progestin combination (i.e., *conjugated estrogens*, 0.625 mg, combined with *medroxyprogesterone acetate*, 2.5 mg, or with *norethindrone acetate*, 5 mg, *estradiol*, 2 mg, and *norethisterone acetate*, 1 mg) (353,354,355,356,357). However, some concern remains about the long-term effects of GnRH analogues on bone loss. In one report, bone mineral

density reduction occurred during long-term GnRH agonist use and was not fully recovered up to 6 years after treatment (358). Use of add-back therapy (2 mg *estradiol* and 1 mg *norethisterone acetate*) did not affect this process (358). Therefore, **GnRH agonists should not be prescribed to girls who have not yet attained their maximal bone density.**

Draw-back therapy has been suggested as an alternative in a study showing that 6 months of intake of 400 µg/day of *nafarelin* was as effective as a draw-back regimen consisting of 1 month of intake of 400 µg/day of *nafarelin* followed by 5 months of 200 µg/day of *nafarelin*, with similar estradiol levels (30 pg/mL) but less loss of bone mineral density (359).

Aromatase Inhibitors

Treatment of rats with induced endometriosis using the nonsteroidal aromatase inhibitor *fadrozole hydrochloride* (360) or *YM511* (361) resulted in a dose-dependent volume reduction of endometriosis transplants. In one case report (362), treatment of severe postmenopausal endometriosis with an aromatase inhibitor, *anastrozole*, 1 mg/day, and elemental *calcium*, 1.5 g/day for 9 months, resulted in hypoestrogenism, pain relief after 2 months, and after 9 months a 10-fold reduction in the 30-mm diameter size of red, polypoid vaginal lesions, along with remodeling to gray tissue. In a pilot study (363), preliminary data were generated suggesting a potential future use of this drug, but randomized controlled trials are needed to confirm these data.

Selective Estrogen Receptor Modulators

In animal models, *raloxifene* therapy resulted in regression of endometriosis. The effect was seen in both a surgically prepared, rat uterine explant model and in Rhesus macaques diagnosed with spontaneous endometriosis before exposure (364).

Efficacy of Medical Treatment

Pain

Medical treatment with progestins, *danazol*, *gestrinone*, or GnRH agonists is effective in treating pain associated with endometriosis, as shown in several prospective, randomized, placebo-controlled double-blind studies (211,250,365,366). Based on published studies, *medroxyprogesterone acetate*, *danazol*, *gestrinone*, and GnRH agonists have similar efficacy in resolution of the laparoscopically documented disease and in pain alleviation (332). **Postoperative medical therapy may be required in patients with**

P.1170

incomplete surgical resection and persistent pain. Treatment should be continued at least 3 to 6 months, and pain relief may be of short duration, presumably because endometriosis recurs. Disadvantages of medical therapy over surgical therapy include the high cost of hormone preparations, the high prevalence of side effects, and the higher recurrence rate of endometriosis.

Subfertility

Conception is either impossible or contraindicated during medical treatment of endometriosis. There is no evidence that medical treatment of minimal to mild endometriosis leads to better chances of pregnancy than expectant management (211,280,365,366,367,368,369,370,371).

Adolescent Endometriosis

The incidental finding of minimal to mild endometriosis in a young woman without immediate interest in pregnancy is a common clinical problem. Seventy percent of girls with chronic pelvic pain unresponsive to oral contraceptives or NSAIDs are affected by endometriosis (372). Mild disease can be treated by surgical removal of implants at the time of diagnosis, followed by continuous administration of low-dose combination oral contraceptives to prevent recurrence. More advanced disease can be treated medically for 6 months, followed by continuous oral contraceptives to prevent progression of disease. Gonadotropin-releasing hormone agonists with add-back therapy can be considered for adolescents older than 16 years of age who have completed pubertal maturation (372).

Recurrence

Endometriosis tends to recur unless definitive surgery is performed. The recurrence rate is about 5% to 20% per year, reaching a cumulative rate of 40% after 5 years. The rate of recurrence increases with the stage of disease, the duration of follow-up, and the occurrence of previous surgery (373,374,375,376,377). The likelihood of recurrence appears to be lower when endometriosis is located only on the right side of the pelvis than when the left side is involved (378).

In a recent randomized controlled trial, postoperative low-dose cyclic oral contraceptive use resulted in a significantly lower cumulative recurrence rate after 1 year, but not after 2 to 3 years (271). In women treated with a second operation for recurrent endometriosis, the cumulative recurrence rate was comparable to those rates after laparoscopy or laparotomy (379).

The recurrence rates reported in women 5 years after therapy with various GnRH agonists were 37% for minimal disease and 74% for severe disease (373). In women treated with GnRH agonists or *danazol* for endometriosis associated with pelvic pain, the recurrence rates of endometriosis were similar, and associated pain symptoms usually returned after cessation of therapy (380). **Pain recurs within 5 years in about one in five patients with pelvic pain treated by complete laparoscopic excision of visible endometriotic lesions (381).**

Assisted Reproduction and Endometriosis

The treatment of endometriosis-related infertility is dependent on the age of the woman, the duration of infertility, the stage of endometriosis, the involvement of ovaries, tubes, or both in the endometriosis process, previous therapy, associated pain symptoms, and the priorities of the patient, taking into account her attitude toward the disease, the cost of treatment, her financial means, and the expected results. Assisted reproduction—including controlled ovarian hyperstimulation with intrauterine insemination, IVF, and gamete intrafallopian transfer—may be options for infertility treatment in addition to surgical reconstruction and expectant management. IVF is the method of choice when distortion of the tubo-ovarian anatomy

P.1171

contraindicates the use of superovulation with intrauterine insemination or gamete intrafallopian transfer.

Intrauterine Insemination

Endometriosis-associated infertility can be successfully treated with intrauterine insemination, but only if it is done in combination with ovarian stimulation (382). A randomized study (382) compared controlled ovarian hyperstimulation

with FSH and intrauterine insemination with no treatment during 311 cycles in 103 couples with minimal to mild endometriosis as the only infertility factor. In this study, a significantly higher live-birth rate per cycle was reported in the treated group (11%) than in the control group (2%) (OR, 5.6; 95% CI, 1.8–17.4). However, **there is clear evidence that the pregnancy rate in an insemination program is lower in women with endometriosis than in women with unexplained infertility** (383,384). A recent meta-analysis of 5,214 cycles by stepwise logistic regression (385) evaluated the effectiveness of ovulation induction and intrauterine insemination in the treatment of persistent infertility. The odds ratio for pregnancy associated with endometriosis was 0.45 (95% CI, 0.27–0.76) and for male factor was 0.48 (95% CI, 0.37–0.61).

In Vitro Fertilization

Based on several retrospective studies (141,146), investigators have suggested that the pregnancy rate after IVF may be lower in women with endometriosis than in women without the disease. In earlier studies, this finding had been attributed to lower oocyte quality and decreased fertilization rate in women with endometriosis. However, these findings were not confirmed in **more recent studies that reported a normal fertilization rate but a reduced implantation rate per embryo transferred in women obtaining oocytes from donors with endometriosis** (386,387). This reduced implantation rate could be related to increased interleukin-6 levels in follicular fluid of women with endometriosis when compared with controls (388). A more recent case-control study in an IVF egg-donation program compared oocyte receptors in patients with endometriosis stage III or IV (cases) with oocyte receptors in patients without endometriosis (controls). Similar rates of implantation, miscarriage, and pregnancy were observed in cases and controls, suggesting that there is no endometrial implantation problem in women with endometriosis stage III or IV treated with IVF (389). **In another case-control study, the cumulative pregnancy rate and live-birth rates were comparable after five cycles of IVF in women with ovarian endometriosis and those with tubal infertility.** The cumulative pregnancy rates were 63% and 63%, respectively, and the cumulative live-birth rates were 47% and 51%, respectively, but women with ovarian endometriosis had poorer responses and needed higher doses of gonadotropin therapy (390).

When endometriosis was assigned a stage, the pregnancy rate after IVF was decreased in patients with stage IV endometriosis but normal in women with less advanced disease (381,391,392,393,394,395,396). However, some studies have been unable to demonstrate a significant negative correlation between either the presence or stage of endometriosis and the pregnancy rate per cycle (397,398). **The best evidence probably is provided by a recently published meta-analysis (399) showing that IVF pregnancy rates are lower in patients with endometriosis than in those with tubal infertility, even when women with minimal to mild endometriosis were analyzed separately.** The use of *danazol*, *gestrinone*, or GnRH agonists in women with endometriosis before IVF has been reported to improve the pregnancy rate by some (396,400,401) but not all investigators (398). Prolonged treatment with a GnRH agonist before IVF in moderate to severe endometriosis can be considered and discussed with patients; although improved pregnancy rates have been reported (402,403), the long duration of treatment may limit the practical application of this treatment.

Laparoscopic ovarian cystectomy is recommended if an ovarian endometrioma 4 cm or more in diameter is present to confirm the diagnosis histologically. This procedure

may reduce the risk of infection, improve access to follicles, and possibly improve ovarian response (159). The woman should be counseled regarding the risks of reduced ovarian

function after surgery (404) and the loss of the ovary.

Intracytoplasmic Sperm Injection

A recent well-controlled study in patients undergoing intracytoplasmic sperm injection (ICSI) (400) reported a reduced number of oocytes recovered after ovarian aspiration but a normal fertilization rate, implantation rate, and pregnancy rate in women with endometriosis when compared with controls. These normal fertilization, implantation, and pregnancy rates also were reported in another recent study of ICSI (405).

Gamete Intrafallopian Transfer

The use of gamete intrafallopian transfer in patients with endometriosis is reported to result in a higher monthly fecundity rate (25%) than with IVF (14%). This difference may be related to selection bias because less severe forms of endometriosis may have been more likely to be treated with gamete intrafallopian transfer, reserving IVF for more advanced stages of disease (288). In one study, the gamete intrafallopian transfer pregnancy rate in patients with a primary diagnosis of endometriosis (32.5%) was lower than in matched controls (406).

The current evidence suggests that patients with endometriosis have a poorer ovarian response and need a higher dose of gonadotropin therapy in IVF or ICSI programs, but endometrial implantation is not reduced. Future studies evaluating the association between endometriosis and reproductive outcome after assisted reproduction should be prospective and should include the following components (142): .

- Accurate and recent laparoscopic description of the stage of endometriosis.
- Date, number of procedures, and interval between surgical procedures.
- Ultrasonographic evidence of endometriosis, confirmed by cytology or histology when endometriotic cysts are aspirated during oocyte aspiration.
- Effectiveness of interim suppressive therapy between diagnosis and treatment with assisted reproduction.
- Reliability and date of negative diagnosis.
- Clear definition of implantation rate, pregnancy rate, abortion rate, and live-birth rate per started cycle, per oocyte aspiration, and per embryo transfer.

Coping with Disease

Coping with endometriosis as a chronic disease is an important component of management. According to guidelines for the management of endometriosis (159), evidence from two systematic reviews suggests that high frequency transcutaneous electrical nerve stimulation (TENS), acupuncture, vitamin B¹, and magnesium may help to relieve dysmenorrhea (407). Whether such treatments are effective in endometriosis-

associated dysmenorrhea is unknown. Many women with endometriosis report that nutritional and complementary therapies such as reflexology, traditional Chinese medicine, herbal treatments, and homeopathy improve pain symptoms. Although there is no evidence from randomized controlled trials to support the effectiveness of these treatments in endometriosis, they should not be ruled out if the woman feels they work in conjunction with more traditional therapies or that they could be beneficial to her overall pain management and quality of life. Patient self-help groups

P.1173

can provide invaluable counseling, support, and advice. The Web site <http://www.endometriosis.org/support.html> provides a comprehensive list of all the self-help groups in the world (159).

Infertility

Richard O. Burney

Daniel J. Schust

Mylene W. M. Yao

• **The physician's initial encounter with the infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. Factors**

from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment..

- The main causes of infertility include male factor, decreased ovarian reserve, ovulatory disorders (ovulatory factor), tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions), uterine factors, systemic conditions (including infections or chronic diseases such as autoimmune conditions or chronic renal failure), cervical and immunologic factors, and unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions)..
- The basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency..
- Male factor is the only cause of infertility in 20% of infertile couples, but it may be a contributing factor in as many as 30% to 40% of cases. Treatment of reversible endocrine or infectious causes of subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious. Intrauterine insemination (IUI) is the best studied and most widely practiced of all the insemination techniques. Intracytoplasmic sperm injection (ICSI) has allowed couples with male factor infertility to achieve assisted reproductive technology (ART) pregnancy outcomes that are comparable with those of couples with non-male factor infertility using conventional *in vitro* fertilization (IVF) treatment..
- An association between the age of the woman and reduced fertility has been well documented. The decline in fecundability begins in the early 30s and accelerates during the late 30s and early 40s..

Disorders of ovulation account for about 30% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and most treatable causes of infertility..

- **The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is polycystic ovarian syndrome (PCOS)..**
- **Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Cervical factor is estimated to be a cause of infertility in no more than 5% of infertile couples. Uterine pathologies constitute the etiologic factor in infertility in as many as 15% of couples seeking treatment and are diagnosed in as many as 50% of infertile patients. Leiomyomas have not been shown to be a direct cause of infertility..**
- **All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined..**
- **Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications..**
- **Fortunately, recent studies have not shown an increased risk for breast, uterine, or ovarian cancer secondary to medications used for superovulation in the treatment of infertility..**
- **Information on the Society for Assisted Reproductive Technology (SART) and registered ART clinics are accessible by the public at <http://www.sart.org>..**

Infertility is defined as 1 year of unprotected intercourse without pregnancy. This condition may be further classified as *primary infertility*, in which no previous pregnancies have occurred, and *secondary infertility*, in which a prior pregnancy, although not necessarily a live birth, has occurred. *Fecundability* is the probability of achieving pregnancy within a single menstrual cycle, and *fecundity* is the probability of achieving a live birth within a single cycle. The fecundability of a normal couple has been estimated at 20% to 25% (1). On the basis of this estimate, about 90% of couples should conceive after 12 months of unprotected intercourse..

Epidemiology

Infertility affects about 10% to 15% of reproductive-age couples in the United States. Data from the U.S. National Survey of Family Growth indicate that the prevalence of infertility among women who had not been surgically sterilized was 13.3% in 1965, 13.9% in 1982, and 13.7% in 1988 (2). In 1990, about 1 in 3 women in the United States reported 12 consecutive months of unprotected coitus without pregnancy at some time in her life (3). A number of demographic variables, including age and socioeconomic status, have been associated with infertility. As a result of the delay in childbearing in the United States population, more older reproductive-age women are attempting to conceive. **Thus, although the overall prevalence of infertility in the United States has not changed since 1965, the percentage of women with primary infertility has increased significantly.** In 1965, only one of six infertile women was nulliparous, whereas in 1988, more than half of infertile women had never been pregnant (4).

P.1187

Although the prevalence of infertility has been stable, the demand for infertility care has increased significantly over the past few decades. Between 1968 and 1984, the number of office visits for infertility increased nearly threefold to 1.6 million visits annually (5). In 1995, it was estimated that about 2% of women (1.2 million) had a medical visit related to their infertility, whereas 13% (7.6 million) had sought medical attention for infertility in their lifetime (6). The increase in the use of infertility medical care stems from many factors, including a heightened awareness that infertility is a medical condition that may be treated in many cases, and sociologic changes that have led to delayed childbearing. Still, despite an increased awareness of available therapies, only 43% of infertile couples seek treatment, and only 24% seek specialized care. Fewer than 2% use *in vitro* fertilization (IVF) or other forms

of assisted reproductive technology (ART) (7). Although infertility is more prevalent among women of relatively low socioeconomic status, patients seeking treatment for infertility are predominantly of high socioeconomic status (4). The women most likely to obtain specialized treatment are 30 years of age or older, white, married, and of relatively high socioeconomic status (7). Familiarity with and access to infertility services among the affluent and better-educated patients probably account for their greater use of these medical resources.

Initial Assessment

The physician's initial encounter with the infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. The male partner should be present at this first visit because his history is a key component in the selection of diagnostic and therapeutic plans. It cannot be overemphasized that infertility is a problem of the couple. The presence of the male partner, beginning with the initial evaluation, involves him in the therapeutic process. This essential involvement demonstrates that the physician is receptive to the male partner's needs as well as to those of the female partner and allows the male partner an opportunity to ask questions and to voice any concerns.

The physician should obtain a complete medical, surgical, and gynecologic history from the woman. Specifically, information regarding menstrual cyclicity, pelvic pain, and previous pregnancy outcomes is important. Risk factors for infertility, such as a history of pelvic inflammatory disease (PID), intrauterine device use, or pelvic surgery, should be reviewed. A history of intrauterine exposure to *diethylstilbestrol* (DES) is significant. In addition, a review of systems relevant to pituitary, adrenal, and thyroid function is useful. Questions regarding galactorrhea, hirsutism, and changes in weight are particularly relevant. A directed history, including developmental defects such as undescended testes, past genital surgery, infections (including mumps orchitis), previous genital trauma, and medications should be obtained from the male partner. A history of occupational exposures that might affect the reproductive function of either partner is also important, as is information about coital frequency, dyspareunia, and sexual dysfunction. Finally, information should be obtained on any family history of infertility, premature ovarian failure, congenital or developmental defects, mental retardation, and hereditary conditions relevant to preconceptional planning, such as cystic fibrosis, thalassemia, and Tay Sachs disease.

The initial interview provides the physician with the opportunity to assess the

to emphasize the emotional support available to the couple as they proceed with the diagnostic evaluation and suggested treatments. In some cases, referral to a trained social worker or psychologist may be beneficial.

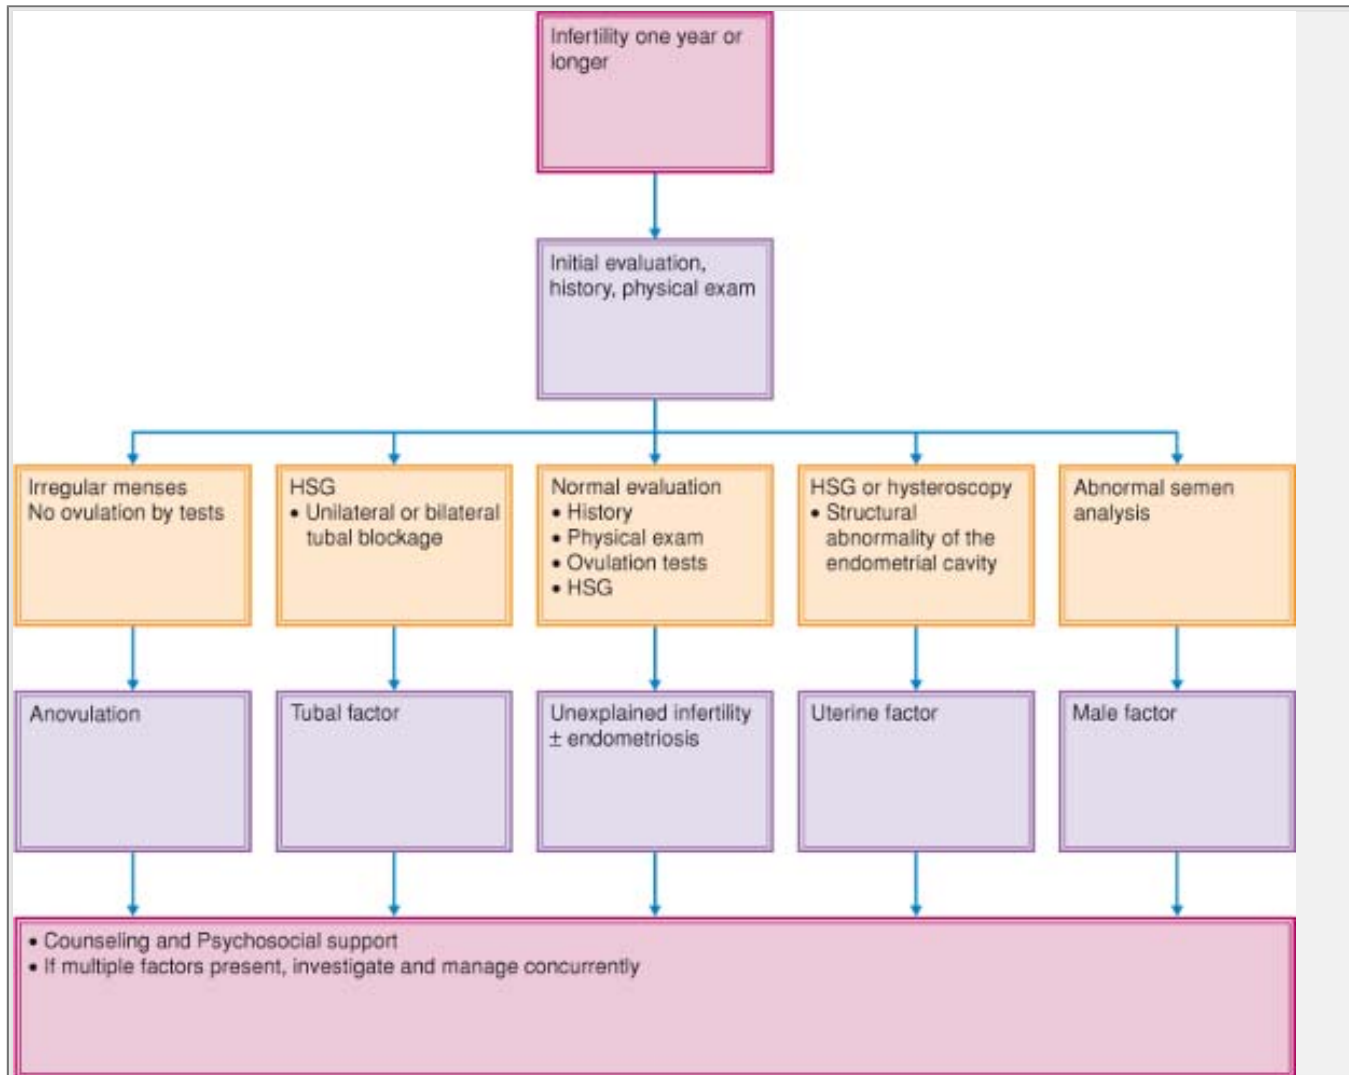

Figure 30.1 Diagnostic and treatment algorithm: infertility. HSG, hysterosalpingography. (From Yao M. Clinical management of infertility. Washington, DC: The Advisory Board: 2000, with permission.)

The physical examination of the woman should be thorough, with particular attention given to height, weight, body habitus, hair distribution, thyroid gland, and pelvic examination. Referral of the man to a urologist for examination often is beneficial if historic information or subsequent evaluation suggests an abnormality. This initial encounter also provides an opportunity to outline the general causes of infertility and to discuss subsequent diagnostic and treatment plans (Figs. 30.1–30.3).

Causes of Infertility

The main causes of infertility include:

- **Male factor.**
- **Decreased ovarian reserve.**
- **Ovulatory disorders (ovulatory factor).**

P.1189

P.1190
- **Tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions).**
- **Uterine factors.**
- **Systemic conditions (including infections or chronic diseases such as autoimmune conditions or chronic renal failure).**
- **Cervical and immunologic factors.**
- **Unexplained factors (including endometriosis with no evidence of tubal or**

peritoneal adhesions).

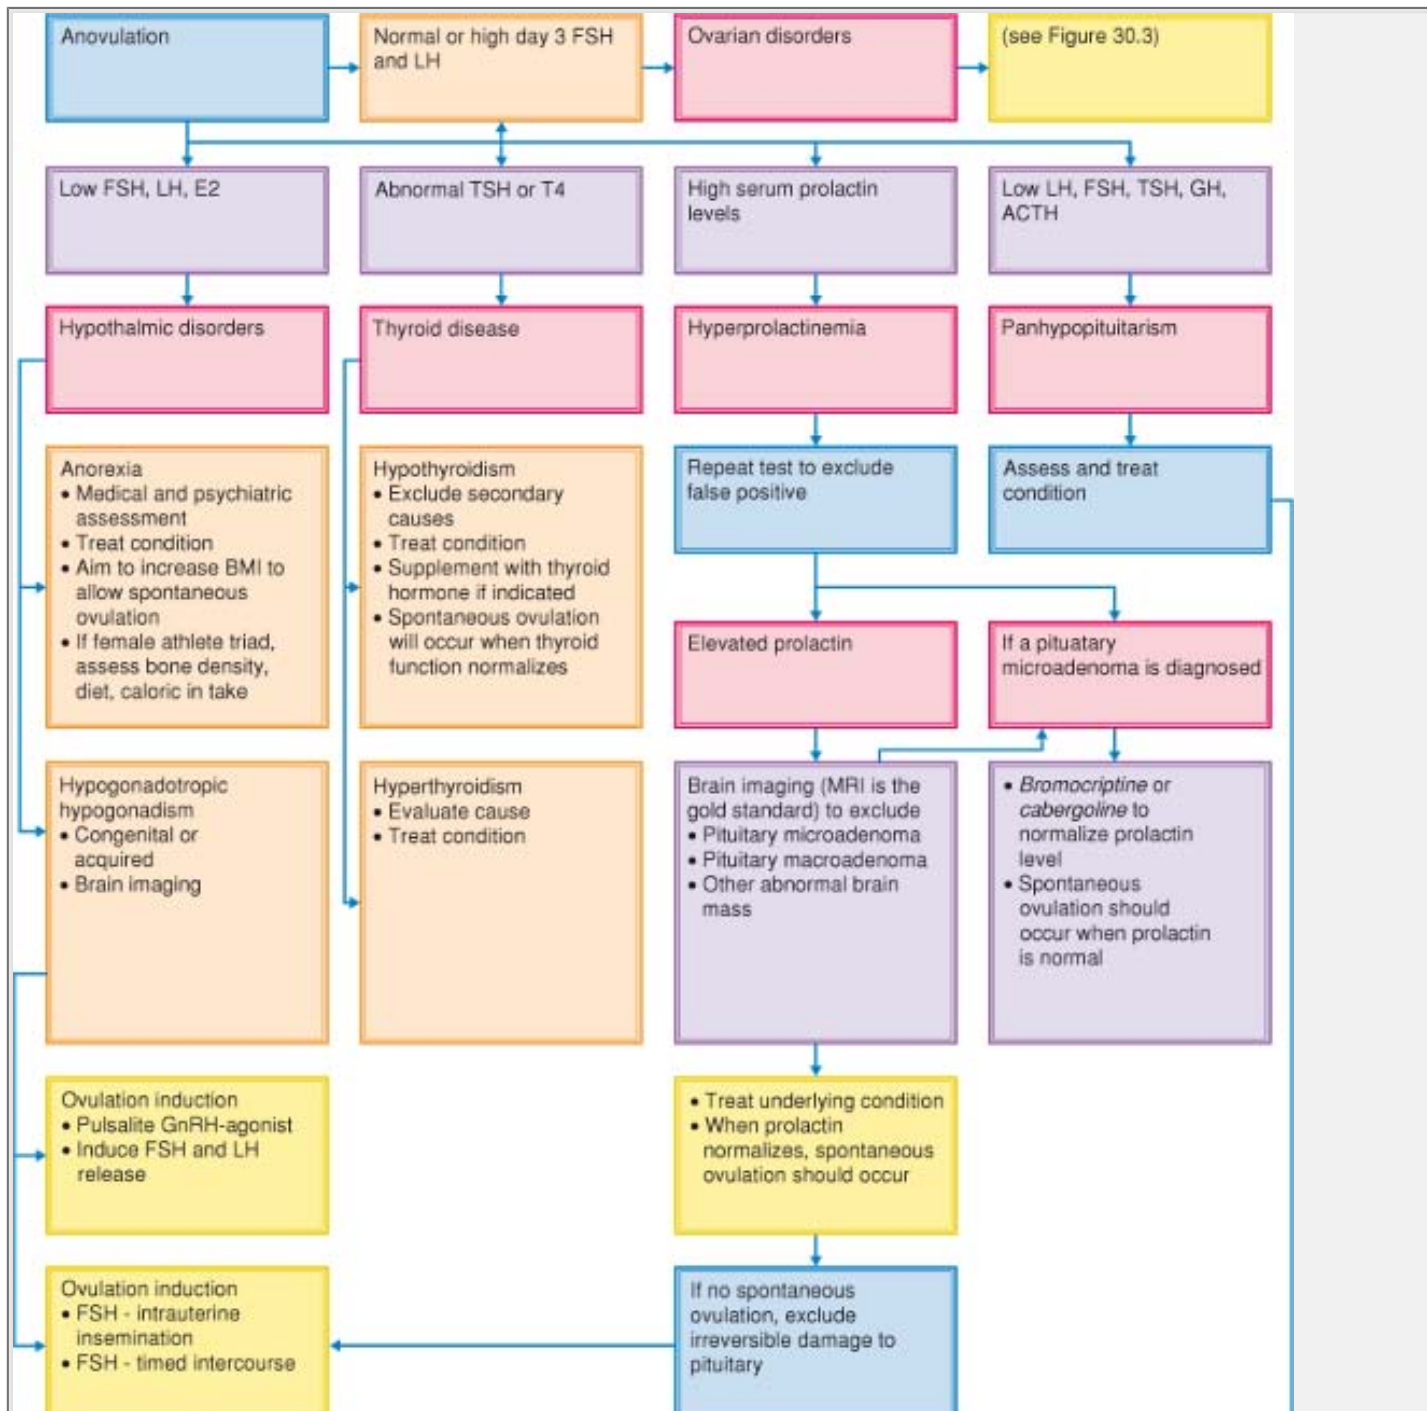

Figure 30.2 Diagnostic and treatment algorithm: anovulation. FSH, follicle-stimulating hormone; LH, luteinizing hormone; E2, estradiol; TSH, thyroid-stimulating hormone; T4, thyroxine; GH, growth hormone; ACTH, adrenocorticotrophic hormone; BMI, body mass index; MRI, magnetic resonance imaging; GnRH, gonadotropin-releasing hormone. (From Yao M. Clinical management of infertility. Washington, DC: The Advisory Board: 2000, with permission.)

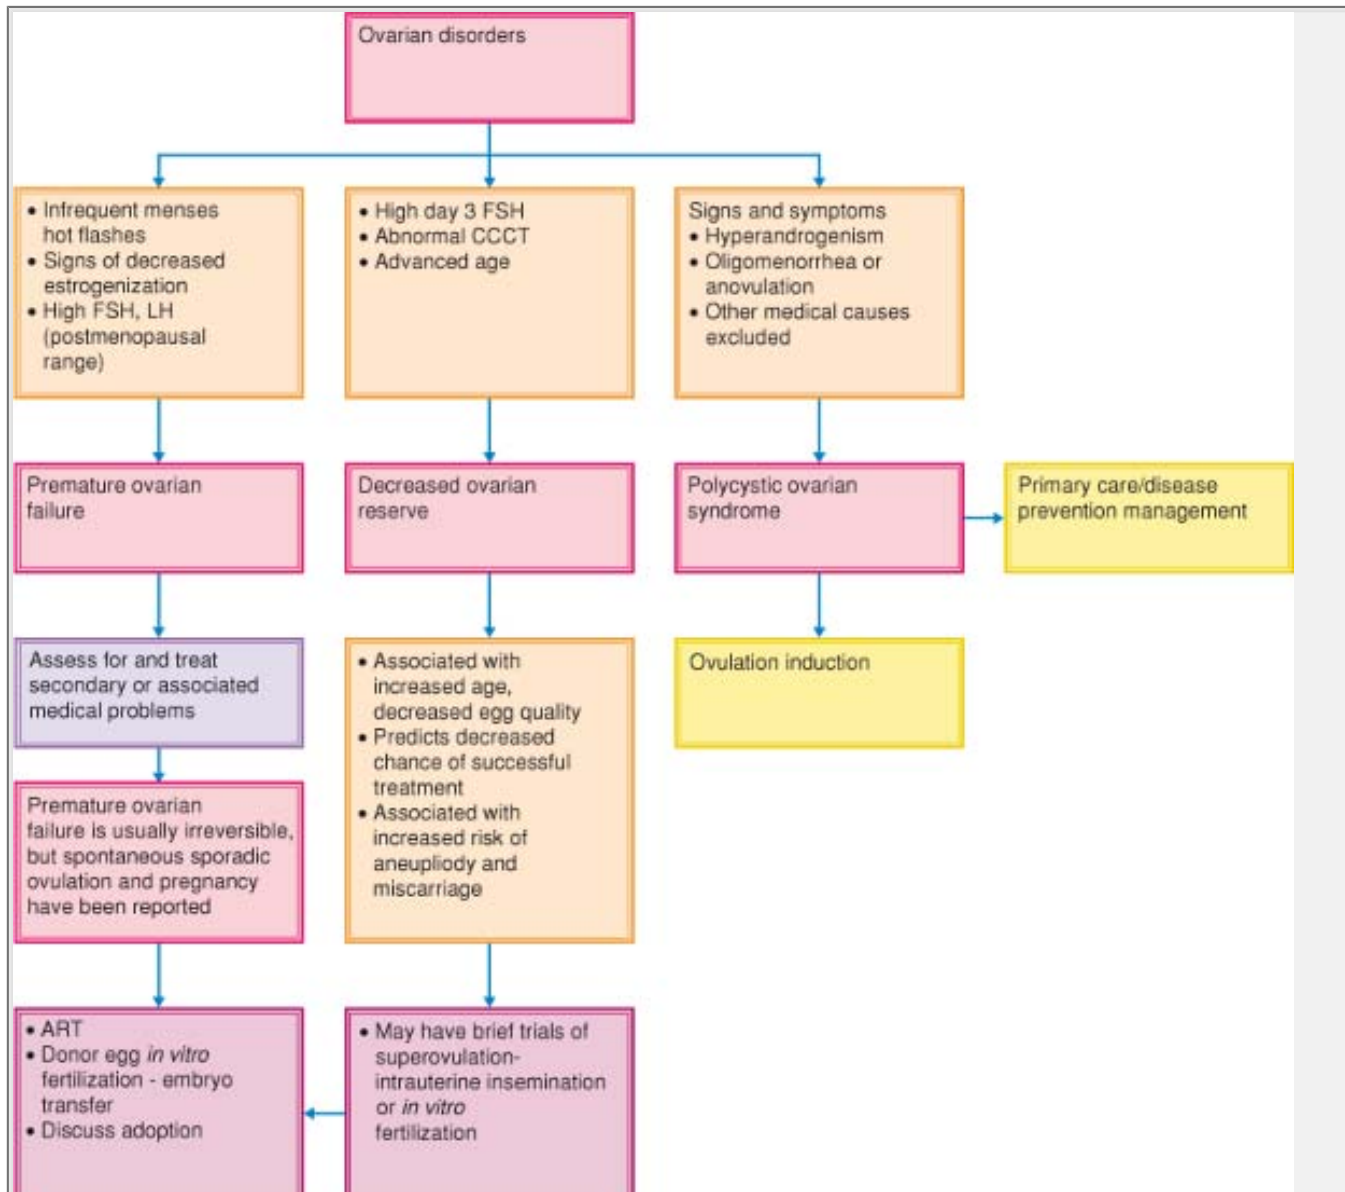

Figure 30.3 Diagnostic and treatment algorithm: ovarian disorders. FSH, follicle-stimulating hormone; LH, luteinizing hormone; CCCT, clomiphene citrate challenge test ART, assisted reproductive technology. (From **Yao M.** Clinical management of infertility. Washington, DC: The Advisory Board: 2000, with permission.)

Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment. The relative prevalence of the different causes of infertility varies widely among patient populations (Table 30.1). In many cases, no specific cause is detected despite a thorough evaluation, and the couple's infertility is categorized as unexplained.

Table 30.1 Causes of Infertility

Relative prevalence of the etiologies of infertility (%)	
Male factor	25–40
Both male and female factors	10
Female factor	40–55
Unexplained infertility	10
Approximate prevalence of the causes of infertility in the female (%)	
Ovulatory dysfunction	30–40
Tubal or periotoneal factor	30–40
Unexplained infertility	10–15
Miscellaneous causes	10–15

Very few couples have absolute infertility, which can result from congenital or acquired irreversible loss of functional gametes in either partner or the absence of reproductive structures in either partner. In these specific instances, couples should be counseled regarding their options of adoption, the use of donor gametes, or surrogacy. However, most couples that have difficulty conceiving have subfertility. According to this fundamental concept, most couples could conceive spontaneously in time, but because of known or unidentifiable causes, their spontaneous fecundity rate is so low that medical management is warranted. Another reason to seek medical attention, particularly among

older women, is that as time passes with unsuccessful spontaneous attempts, fecundability will be compromised further by increasing age and concomitantly decreasing ovarian reserve. Although identification of apparent causes of subfertility (such as anovulation or oligospermia) allows treatment to be targeted, effective empiric treatments also greatly increase the chance of a pregnancy even when no distinct cause is identified. Overall, these treatments aim at increasing the probability of conception and implantation by optimizing gamete (sperm and oocyte) and uterine factors.

The basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency. Some treatments, especially ART, are indicated for more than one diagnosis and are discussed in greater detail. Often, more than one cause is identified in a couple. For this reason, multiple approaches to investigation and treatment may be undertaken simultaneously.

Male Factor

Male factor is the only cause of infertility in 20% of infertile couples, but it may be a contributing factor in as many as 30% to 40% of cases (8). However, the combined effects of our increased understanding of genetic causes in male factor infertility and the efficacy of intracytoplasmic sperm injection (ICSI) in ART have revolutionized modern treatment of male factor infertility. For men, semen analysis is inexpensive and noninvasive, and remains fundamental to the infertility evaluation. The value and interpretation of the semen analysis and other tests for male infertility should be considered within the context of male reproductive physiology.

Physiology

The male reproductive tract consists of the testis, epididymis, vas deferens, prostate, seminal vesicles, ejaculatory duct, bulbourethral glands, and urethra. The testes contain two cell types: the Sertoli cells, which line the seminiferous tubules (the site of spermatogenesis), and the Leydig cells (the site of androgen synthesis). In the man, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which act on the testes. The former (LH) stimulates the synthesis and secretion of testosterone by the Leydig cells, and the latter (FSH) stimulates the Sertoli cells to secrete inhibin. Both FSH and testosterone act on the seminiferous tubules to stimulate spermatogenesis. In humans,

the development from spermatogonia stem cells to the mature sperm cells takes about 75 days. Spermatogonia undergo mitotic division to give rise to spermatocytes. These spermatocytes subsequently undergo meiosis to produce spermatids, which contain 23 (rather than 46) chromosomes. Upon maturation, spermatids become spermatozoa, which enter the epididymis, where they continue to mature and become progressively more motile during the 12 to 21 days that is required to traverse this tortuous structure.

During ejaculation, mature spermatozoa are released from the vas deferens along with fluid from the prostate, seminal vesicles, and bulbourethral glands. The semen released is a gelatinous mixture of spermatozoa and seminal plasma; however, it thins out 20 to 30 minutes after ejaculation by a process called *liquefaction*. Liquefaction occurs secondary to the presence of proteolytic enzymes within the prostatic fluid. The released spermatozoa are not usually capable of fertilization. Instead, a series of complex biochemical and electrical events, termed *capacitation*, must take place within the sperm's outer surface membrane before fertilization can occur. Normally, capacitation occurs in the cervical mucus; however, it can occur in physiologic media *in vitro*. Finally, as part of fertilization, the sperm must undergo the acrosome reaction, in which the release of enzymes of the inner acrosomal membrane results in the breakdown of the outer plasma membrane and its fusion with the outer acrosomal membrane (9). The acrosome reaction and binding of sperm and ovum surface proteins are important for the penetration of the ovum's zona pellucida and subsequent fusion between the ovum and sperm. As the sperm penetrates the egg, it initiates a hardening of the zona pellucida (cortical reaction), which prevents penetration by additional sperm (9,10).

The concept of a global decline in sperm counts needs to be reassessed (11,12). A number of recent analyses reported no decrease in sperm counts over time (13,14,15). Geographic differences in the results of semen analyses do seem to exist, but a global trend toward decreasing semen quality does not (16,17,18). Furthermore, the rate of male factor infertility has not increased significantly in recent decades. Thus, even if semen characteristics are changing, these changes do not appear to be having a dramatic clinical effect. Nevertheless, exposures to environmental toxins may certainly be harmful to sperm, and the incidence of some exposures (e.g., phytoestrogens) may be on the rise. Marijuana and cocaine use can reduce sperm concentration (19,20). Certain drugs may reduce sperm count or function or cause ejaculatory dysfunction (Table 30.2). Finally, **consumption of**

caffeine, alcohol, and smoking has been associated with diminished semen quality or fecundity in a dose-related fashion (21,22).

Table 30.2 Drugs that Can Impair Male Fertility

Impaired spermatogenesis— *sulfasalazine, methotrexate, nitrofurantoin, colchicine, chemotherapy*

Pituitary suppression— *testosterone injections, gonadotrophin-releasing hormone analogues*

Antiandrogenic effects— *cimetidine, spironolactone*

Ejaculation failure— *α blockers, antidepressants, phenothiazines*

Erectile dysfunction— *β blockers, thiazide diuretics, metoclopramide*

Drugs of misuse— *β anabolic steroids, cannabis, heroin, cocaine*

Semen Analysis

The basic semen analysis measures **semen volume, sperm concentration, sperm motility, and sperm morphology**. In addition, many laboratories measure pH, fructose levels, and white blood cell counts within the semen. Normal values suggested by the World Health Organization (WHO) are listed in Table 30.3 (23). These values represent only general guidelines, and normal values should be established by individual andrology laboratories.

Specimen Collection

The method used for semen specimen collection is important to the achievement of accurate results. **The optimal period of abstinence before semen collection is unknown; however, because a decrease in sperm concentration is associated with frequent ejaculation, a period of 2 to 3 days usually is recommended.** The specimen should be obtained by masturbation and collected in a clean container. Because of the presence of spermicidal agents, collection into condoms is generally unacceptable, although special sheaths that do not contain spermicides are available for semen collection. All semen specimens should be kept at body temperature and taken to the laboratory within one-half to one hour of collection. Even when the specimen is obtained under optimal circumstances, interpretation of the results of the semen analysis is complicated by variability within the same individual, wide differences in normal semen parameters, and their relativity to

the minimum parameters required for conception (11). Semen parameters also may vary widely from one man to another and among men with proven fertility. In many circumstances, several specimens are necessary to verify an abnormality.

Table 30.3 Semen Analysis Terminology and Normal Values

Semen analysis terminology

Normozoospermia—all semen parameters normal

Oligozoospermia—reduced sperm numbers

Mild to moderate: 5–20 million/mL of semen

Severe: <5 million/mL of semen

Asthenozoospermia—reduced sperm motility

Teratozoospermia—increased abnormal forms of sperm

Oligoasthenoteratozoospermia—sperm variables all subnormal

Azoospermia—no sperm in semen

Aspermia (anejaculation)—no ejaculate (ejaculation failure)

Leucocytospermia—increased white cells in semen

Necrozoospermia—all sperm are non-viable or non-motile

Normal seminal fluid analysis (World Health Organization, 2002)

Volume>2 mL

Sperm concentration>20 million/mL

Sperm motility>50% progressive or >25% rapidly progressive

Morphology (strict criteria)>15% normal forms

White blood cells>1 million/mL

Immunobead or mixed antiglobulin reaction testa <10% coated

^aTests for the presence of antibodies coating the sperm

From **Hirsh A**. Male infertility. *BMJ* 2003;327:669–672, with permission.

Sperm Volume

The normal ejaculated volume of semen is 1.5 to 5 mL. Volumes may be abnormally low in cases of retrograde ejaculation, and high volumes usually reflect relatively long periods

of abstinence or inflammation of the accessory glands. Absence of fructose or high pH may be associated with ejaculatory tract obstruction or seminal vesicle dysfunction.

Sperm Concentration

Sperm concentration or density is defined as the number of sperm per milliliter in the total ejaculate. Establishing a lower limit of normal for sperm concentration is difficult.

Historically, cutoffs of 60 million sperm per milliliter for normal fertility have been advocated, but most WHO laboratories recognize the value of 20 million sperm per milliliter as a lower limit of normal (24).

Sperm Motility

An equally important parameter in the semen analysis is sperm motility, which is defined as the percentage of progressively motile sperm in the ejaculate. Lower limits of normal vary considerably and depend on the local laboratory's experience. A reduction in sperm motility is referred to as *asthenozoospermia*. The WHO and many laboratories use a cutoff of 50% motility as the lower limit of normal, whereas others use less than 40% motility as a criterion for defining asthenospermia (25). Computer-assisted semen analysis, in which computer-generated images of sperm specimens quantitate both sperm counts and sperm motility, may yield results very different from those of nonautomated semen analyses. Regardless of how motility is assessed, the interpretation of sperm motility—as with sperm concentration—is hampered by both significant variability among repeat samples obtained from a single individual and poor correlation between values for normal motility and fertility potential.

Sperm Morphology

An abnormality of sperm morphology is known as *teratozoospermia*. The WHO uses a fairly permissive visual assessment of sperm within a semen specimen to assess morphology value, with greater than 30% normal forms defined as acceptable. More stringent criteria have evolved from other sources. **The strict Tygerberg criteria were introduced by Kruger et al. in 1986 to assess sperm morphology (26).** Using this system, the entire spermatozoon—including the head, midpiece, and tail—is assessed, and even mild abnormalities in head forms are classified as abnormal. Most sperm from normal men exhibit minor abnormalities when subjected to Tygerberg standards. One advantage of these strict criteria, however, is that the Tygerberg classification correlates with prognosis in

IVF treatment. For example, greater than 14% normal morphology is associated with normal rates of fertilization in IVF programs; 4% to 14% normal morphology is associated with a "good prognosis." Values of less than 4% normal sperm morphology are associated with poor prognosis for fertilization and pregnancy in IVF (27). In some studies, this sperm morphology classification has also been found to be predictive of pregnancy outcomes after intrauterine insemination (IUI) treatment, especially when the total motile sperm count is less than 1×10^6 (23). The disparity in criteria for assessment of semen morphology mandates that to interpret semen analysis results properly, the clinician must thoroughly understand the methodology used by the local andrology laboratory.

White Blood Cells

Although measurements of semen volume, sperm concentration, sperm motility, and sperm morphology make up the standard semen analysis, some laboratories also report numbers of round cells. These cells, which may be lymphocytes, can signify the presence of prostatitis or, alternatively, may actually be immature germ cells.

These two cell types can be distinguished by an immunoperoxidase–staining technique that identifies leukocytes (Endtz test) (28). The WHO views ejaculates with more than 5 million round cells per milliliter or more than 1 million leukocytes per milliliter as abnormal (29).

However, the prognostic significance of leukocytes in the semen is controversial. The presence of immature sperm cells in the ejaculate suggests a defect in spermatogenesis and, therefore, may signify a relatively poor prognosis for fertilization (30).

P.1195

Although the standard semen analysis and associated tests provide a fairly reasonable picture of semen quality, they yield little information about sperm function. These specialized tests may be pursued to assess sperm viability, fertilization potential (zona–free hamster oocyte test), the presence of antisperm antibodies, and the effect of cervical mucus on sperm viability and function (postcoital test). In general, these tests are not currently considered part of the standard assessment because their prognostic value and impact on management are limited by poor specificity, poor reproducibility, or controversial interpretation of the results (31,32).

Further Evaluation

If abnormalities in the semen are detected, further evaluation of the male partner by a urologist is indicated to diagnose the defect (31). Table 30.4 lists the differential diagnoses for male factor infertility (33). Several groups have attempted to assess the distribution of male infertility diagnoses; two such distributions are shown in Table 30.5 (34,35). The first is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (35). The figures include data from cases in which the male partner was normal and the presumed

P.1196

cause of the couple's infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (34). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently.

<i>Pretesticular</i>	<i>Testicular</i>
<i>Endocrine</i>	<i>Genetic</i>
Hypogonadotropic hypogonadism	Klinefelter's syndrome

Treatment

Significant deviations from the normal range of sperm count, concentration, motility, and morphology indicate the presence of male factor infertility. Treatment of male factor infertility may be classified as medical, surgical, or ART-related therapies. The diagnosis and treatment of azoospermia (no sperm on semen analysis) will be discussed separately from other forms of male factor infertility.

Treatment of reversible endocrine or infectious causes of subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious.

However, medical therapies for other causes of male factor infertility are severely limited. *Clomiphene citrate*, an estrogen agonist and partial antagonist, has often been used to treat male infertility of idiopathic origin. *Clomiphene citrate* acts on the hypothalamic-pituitary axis and, in men, increases serum levels of LH, FSH, and testosterone (36). Most studies have shown that *clomiphene citrate* treatment yields little improvement in semen parameters and no improvement in pregnancy rates (37), whereas treatment with pure FSH during ART has resulted in significant increases in fertilization rates (38).

Varicocele

A varicocele is an abnormal dilation of the veins within the spermatic cord.

Varicoceles nearly always occur on the left side, presumably because of the direct insertion of the spermatic vein into the renal vein on that side.

The pathophysiologic effects of varicocele on testicular function are uncertain but appear to be mediated by an associated rise in testicular temperature or a reflux of toxic metabolites from the left adrenal or renal veins (39). In either event, the effect on sperm production is bilateral. Understanding of the role of varicoceles in infertility is complicated by the prevalence of varicoceles in fertile men and the efficacy of varicocele repair in infertile men.

P.1197

One WHO study found varicocele to be present in 25.4% of men with abnormal semen analyses, as opposed to 11.7% of men with normal semen (40). This study failed to demonstrate a difference in the frequency of spontaneous pregnancies among couples in which the men had varicoceles versus those who did not. When compared with fertile men with or without varicoceles, however, infertile patients with varicoceles have higher levels of FSH, smaller testes, and lower sperm concentration and motility (41).

Varicocele repair, which involves interruption of the internal spermatic vein, is commonly performed in the 40% of infertile men with clinically evident varicoceles. Currently, it is

performed as an outpatient procedure and may involve laparoscopy, open surgery, or the injection of embolizing agents. **Despite its widespread use, the therapeutic benefits of varicocele repair remain controversial.** Two multicenter trials have shown that pregnancy rates are significantly increased after varicocelectomy (42,43). However, the validity of the control groups in each of these trials has been criticized (44). A more recent meta-analysis of four randomized, controlled trials involving a total of 385 patients failed to demonstrate significantly altered pregnancy rates after varicocelectomy (44,45,46,47,48).

Artificial Insemination

Artificial insemination encompasses a variety of procedures. All involve the placement of whole semen or processed sperm into the female reproductive tract, which permits sperm-ovum interaction in the absence of intercourse. The placement of whole semen into the vagina as a mode of fertility treatment is now rarely performed except in cases of severe coital dysfunction. Currently, all of the common forms of artificial insemination involve processed sperm obtained from the male partner or a donor. **Artificial insemination has mainly been used to treat unexplained infertility (usually combined with superovulation) and male factor infertility.** The efficacy of each type of insemination method should be assessed separately for each of these two diagnoses.

Types of Insemination for Unexplained Infertility

Many techniques for artificial insemination have been described, but only intracervical and intrauterine insemination have been routinely employed. **Intrauterine insemination is the best studied and most widely practiced of all the insemination techniques.** It involves placement of about 0.3 to 0.5 mL of washed, processed, and concentrated sperm into the intrauterine cavity by transcervical catheterization. In contrast with IUI, intracervical insemination may be performed either with unwashed or with processed specimens. The success rates with intracervical insemination are consistently lower than those with IUI and are further discussed under "Unexplained Infertility" (49).

Processing Semen

Two important issues regarding the use of artificial insemination procedures are the mode of semen processing and the number and timing of inseminations. Many protocols have been developed for sperm preparation. Seminal fluid usually is prevented

from reaching the intrauterine cavity and intra-abdominal space by the cervical barrier. The introduction of seminal fluid past this barrier may be associated with severe uterine cramping or anaphylactoid reactions, possibly mediated by seminal factors such as prostaglandins. Thus, protocols for processing whole semen include the washing of specimens to remove seminal factors and to isolate pure sperm. Some semen preparation methods attempt to further enhance sperm motility or morphology by using additional separation protocols. These methods include centrifugation through density gradients, sperm migration protocols, and differential adherence procedures. Finally, phosphodiesterase inhibitors, such as pentoxifylline, have been used during semen processing in an attempt to enhance sperm motility, fertilization capacity, and acrosome reactivity for IVF procedures (50).

Intrauterine Insemination as Treatment for Male Factor Infertility

Studies of the efficacy of IUI in the treatment of male factor infertility have been difficult to assess

P.1198

because of variations in inclusion criteria and the limitations of sperm function tests. Considering these limitations, **the benefits of IUI in male factor infertility have been accepted because IUI appears to result in higher pregnancy rates than natural intercourse or intracervical insemination (OR 2.20, 95% CI, 1.43–3.39) (51). However, the IUI pregnancy rates are generally lower in couples with male factor infertility than in couples with unexplained infertility (4.8% versus 11.6%) (51).** A retrospective analysis of 1,841 couples undergoing 4,056 cycles of IUI for male factor infertility found that pregnancy rates were related to total motile sperm count. Optimal pregnancy rates (>8.2% per cycle) were reached with initial total motile sperm counts of greater than or equal to 5.0×10^6 . Higher counts did not necessarily yield higher pregnancy rates. The minimal total motile sperm count that resulted in a pregnancy was 1.6×10^6 (52). Some couples with male factor infertility do not achieve pregnancy with artificial insemination, whereas others have initial semen parameters that make insemination a suboptimal approach. In these couples, the use of ART, especially with ICSI, may be superior treatment options. Because ICSI is highly effective and requires only that viable sperm be present, almost all cases of male factor infertility can be treated successfully. Because the IUI success rates are extremely low if the total motile sperm count is less than 0.5×10^6 , ICSI should be considered in such cases (53). Finally, ICSI should be recommended after a maximum of three IUI cycles have failed in a couple with male factor infertility.

Azoospermia: Classification and Treatment

Azoospermia is the absence of spermatozoa in the ejaculate. Azoospermia is found on semen analysis in about 5% of all couples being investigated for infertility (54), and its incidence is 1% in all men and 10% to 15% among infertile men (55,56).

The classification of azoospermia reflects the etiology, prognosis, and treatment and differentiates the causes as pretesticular, testicular, and posttesticular (57).

Pretesticular Azoospermia

Pretesticular azoospermia represents those conditions in which the hypothalamic– pituitary axis fails to stimulate spermatogenesis within the testis. Congenital, acquired, and idiopathic etiologies of hypogonadotropic hypogonadism are included in this category. A full endocrine history, including information on puberty and growth and a review of endocrine systems, should guide the physician in the evaluation of the patient with hypogonadotropic hypogonadism. Laboratory investigations of particular benefit in this population include measurement of serum LH, FSH, testosterone, and prolactin levels and imaging of the pituitary gland. Low levels of gonadotropins (LH and FSH) and low serum levels of testosterone are characteristic of hypogonadotropic hypogonadism.

Hormonal treatment of hypogonadotropic hypogonadism is effective. Administration of pulsatile *gonadotropin-releasing hormone* (GnRH) therapy is both conceptually indicated and effective in infertile men with hypothalamic dysfunction (58), including those patients with Kallmann syndrome. Infertile males with hypogonadotropic hypogonadism secondary to panhypopituitarism also may respond to GnRH therapy (59). An alternative treatment uses *human chorionic gonadotropin* (hCG), 1,000–2,500 IU twice a week, with the dose titrated to maintain serum testosterone and estradiol levels within the normal range. Treatment with hCG is then combined with *human menopausal gonadotropin* (hMG), which is given at a dose of 150 IU three times weekly (60,61). Spermatogenesis and pregnancy can be achieved in as many as 80% to 88% of patients after 1 year of therapy (60,61).

Testicular Azoospermia

Gonadal failure is the hallmark of testicular azoospermia. Causes of this condition may be congenital or genetic (e.g., Klinefelter syndrome, microdeletion of Y chromosome), acquired (e.g., radiation therapy, chemotherapy, testicular torsion, or mumps orchitis), or

developmental (e.g., testicular maldescent). The latter disorder may be associated most closely with male factor infertility in the absence of complete testicular azoospermia. A large observational cohort study suggested that infertility was, in fact, associated with congenital bilaterally maldescended testes, but that men with congenital unilaterally maldescended testes did not have decreased fertility when compared with controls (62).

Men with hypergonadotropic hypogonadism (elevated levels of LH and FSH with low serum levels of testosterone) **generally have primary gonadal failure**. A karyotype should be obtained in such cases to detect chromosomal abnormalities such as *Klinefelter syndrome* (47,XXY). Acquired causes of primary gonadal failure are usually evident based on the history, but the diagnosis should be confirmed by assessment of the serum hormonal profile and biopsy. If the diagnosis of gonadal failure is confirmed on biopsy, endocrine therapy is contraindicated.

It is becoming increasingly evident that some cases of male factor infertility that have previously been categorized as idiopathic are actually the result of genetic defects on the Y chromosome (Table 30.6). The two most commonly implicated candidate gene families are the RNA-binding motif (*RBM*) and the "deleted in azoospermia" (*DAZ*) families, but microdeletions at various loci on the Y chromosome have been described. For example, microdeletions in Yq11.23 can occur in one or more of three regions: *AZFa* (proximal), *AZFb* (central), and *AZFc* (distal). Microdeletions in the Y chromosome have been identified in 10% to 20% of men with idiopathic azoospermia or severe oligospermia (63,64) and in 7% of 200 infertile men (65). Semen analyses in affected men varied between oligospermia and azoospermia. Microdeletions in the Y chromosome occur in 2% of fertile men. These microdeletions can be transmitted to the male offspring, who may then suffer from infertility. Therefore, screening for genetic causes is indicated in nonacquired cases of testicular azoospermia so that genetic counseling can be provided before treatment. Testicular azoospermia is treated by surgical retrieval of spermatozoa with subsequent fertilization of the oocyte by ICSI.

Intracytoplasmic Sperm Injection

This micromanipulation technique is performed to increase the fertilization rate of oocytes retrieved during ART by direct injection of a live sperm into the oocyte, thereby theoretically bypassing limitations imposed by sperm motility, defective capacitation or acrosome reaction, and sperm binding the zona pellucida.

This technique was first reported to result in human pregnancies in 1992 (66). The

procedure involves stripping the aspirated cumulus complex of all

surrounding granulosa cells so that micromanipulation can be performed on the egg itself. A viable sperm is then inserted into the cytoplasm of the egg (ooplasm).

<i>Clinical diagnosis</i>	<i>Genetic tests</i>	<i>Most common defects</i>	<i>Incidence (%)</i>
Congenital bilateral absence of vas deferens (CBAVD)	Cystic fibrosis (CFTR gene)	ΔF508, R117H	66
Non-obstructive azoospermia	Karyotype	47, XXY AZFa, AZFb ^a , AZFc	15–30 10–15
Severe (<5M/mL) oligozoospermia	Karyotype Y chromosome microdeletions	47, XXY Translocation Partial AZFb, AZFc	1–2 0.2–0.4 7–10

CFTR = cystic fibrosis transmembrane conductance regulator; AZF, azoospermia factor; ^aAZFb the most severe (DAZ gene—deleted in azoospermia) causes the most severe defects of spermatogenesis; AZFc causes the mildest defects of spermatogenesis
From **Hirsh A**. Male infertility. *BMJ* 2003;327:669–672, with permission.

In general, ICSI has allowed couples with male factor infertility to achieve ART pregnancy outcomes that are comparable with those of couples with non-male factor infertility using conventional IVF treatment. The indications of ICSI have evolved since its introduction and will continue to evolve as more is learned about its risks and benefits. One absolute indication for ICSI is severe male factor infertility as demonstrated by total progressively motile sperm counts ($0.5 \times 10^6/\text{mL}$ and $<3\%$ normal morphology according to strict Tygerberg criteria) (53). Sperm counts of less than $0.5 \times 10^6/\text{mL}$ are associated with poor fertilization rates in IVF, and this finding alone is also an indication for ICSI (67). Other indications for ICSI include the sole presence of spermatozoa lacking an acrosome or those that are completely immotile, as well as the use of surgically recovered epididymal or testicular sperm. Other absolute indications for ICSI are non-male factor-related and include a history of fertilization failure with conventional IVF and the fertilization of oocytes

before preimplantation genetic diagnosis (68). The benefit of combined IVF/ICSI in ART for unexplained infertility also is described under "Unexplained Infertility."

Micromanipulation is a highly skilled technique. When performed by specially trained embryologists, the immediate risk for damaging the manipulated oocyte is less than 10% (53). Because the particular spermatazoa used for ICSI might otherwise be incapable of fertilization, concerns have been voiced regarding possible increased risks for congenital abnormalities among ICSI offspring. Several large series have followed 1,987, 1,139, and 730 children born after ICSI (69). Each has reported no increase in major or minor congenital malformations among offspring produced by ICSI when compared with the general population (69,70,71) and when adjusted for multiple gestation (70). However, an increased incidence of sex chromosome karyotypic abnormalities (69,72) and hypospadias (70) has been suggested. Because the prevalence of sex chromosome karyotypic abnormalities and other genetic factors is increased in infertile men with severe oligospermia or azoospermia, genetic counseling should be offered before treatment with ART (73).

Posttesticular Azoospermia

In posttesticular azoospermia, the hypothalamic–pituitary axis and spermatogenesis are normal. No sperm appear in the ejaculate secondary to congenital absence or obstruction of the vas deferens or ejaculatory ducts, acquired obstruction of these ducts, or ductal dysfunctions, including retrograde ejaculation. Although low seminal pH (6.7–8.0) or low seminal fructose may signal the congenital absence or obstruction of the vas deferens, the diagnosis is confirmed by vasography. In some cases, testicular biopsy may be indicated to differentiate between primary testicular damage and outflow obstruction. Congenital bilateral absence of the vas deferens (CBAVD) is found in 1% to 2% of infertile men and 95% of men with cystic fibrosis (74). Common mutations of the cystic fibrosis transmembrane conductance regulator gene (*CFTR*), which encodes a cyclic adenosine monophosphate (cAMP)–regulated chloride channel, can be found in some infertile men with CBAVD, despite the absence of clinical symptoms of cystic fibrosis. Therefore, screening for mutations in the *CFTR* gene is indicated if men with CBAVD plan to undergo sperm retrieval and ICSI to conceive using their own sperm. One cost–effective screening method addressing this problem involves screening the female partner for the three most common mutations in the *CFTR* gene. If negative, the couple has a risk of less than 1 in 1,500 for conceiving a child with cystic fibrosis, regardless of the paternal genotype (33).

Prior vasectomy is probably the most common cause of posttesticular azoospermia

one study, vas deferens patency was obtained in 86% of cases, and pregnancy was

achieved in 52% of cases after primary procedures (75). Rates of patency and pregnancy vary inversely with the length of time from vasectomy. For those patients with azoospermia 3 months after the reversal procedure, either the reanastomosis has failed or the epididymis is obstructed. However, repeat vasovasostomy is associated with patency rates of 75% and pregnancy rates of 43% (75).

Epididymal obstruction is diagnosed by finding normal spermatogenesis on testicular biopsy. Vasography can be used to determine the level of obstruction, but because of its risk of increased scarring, it is done only if reconstructive surgery is performed with the procedure. Alternatively, transrectal ultrasonography (TRUS) findings, in conjunction with the presence of large numbers of sperm in the seminal vesicle aspiration, strongly suggest ejaculatory duct obstruction without the high risk of scarring (76).

There are two approaches to the treatment of posttesticular obstruction if the use of donor sperm is not being considered. Epididymal aspiration proximal to the obstruction may be used to obtain sperm for use in ART in cases of epididymal or vas deferens obstruction. Alternatively, microsurgical vasoepididymostomy is associated with patency rates of 70% and postoperative pregnancy rates of 44% at 1 year if no other infertility factor is present (77).

Some men with reduced semen volume may have **retrograde ejaculation**, in which sperm is propelled into the bladder during ejaculation rather than through the urethra. **This diagnosis can be confirmed by examination of a urine specimen that is obtained by voiding after ejaculation or catheterization.** This condition occurs in rare cases of patients with diabetes mellitus, in certain neurologic conditions, and after bladder or prostatic surgery. For subfertile men with retrograde ejaculatory dysfunction, α -adrenergic agonists such as *phenylephrine* have been reported to strengthen internal urethral sphincter tone (78). Sperm may also be isolated from the neutralized urine of men with retrograde ejaculation and processed for insemination or for ART (79).

Surgical Sperm Recovery for Intracytoplasmic Sperm Injection

Among the many surgical methods for sperm recovery, the most widely described

are **microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), testicular sperm extraction (TESE), and percutaneous testicular sperm fine-needle aspiration (TESA, also called *fine-needle aspiration*, or FNA)** (80). The choice of surgical sperm recovery method depends on the underlying diagnosis, whether the goal of the procedure is diagnostic or therapeutic, and whether isolated sperm will be used immediately or will be cryopreserved.

In cases of posttesticular azoospermia, in which spermatogenesis is expected to be normal, all four methods give successful sperm recovery greater than 90% (81). Both MESA and TESE are open surgical procedures performed with an operating microscope and general or regional anesthesia, whereas TESA and PESA are noninvasive, blind aspiration procedures that are performed with 19- to 21-gauge needles. Alternatively, a 14-gauge Trucut needle, which gives a higher sperm yield, can be used in these procedures (82). Because MESA allows for diagnosis and possibly reconstruction, and usually yields very large numbers of sperm, cryopreservation and avoidance of repeat surgery may be possible (83). Although PESA and TESA appear less invasive, there is increased risk of bleeding, epididymal injury, and postsurgical fibrosis, which can lead to failure of sperm recovery in repeat procedures (84,85).

A meta-analysis found no difference in the rates of fertilization, implantation, or ongoing pregnancy between epididymal and testicular sperm for patients with the same diagnosis (86). Fertilization and implantation rates have been reported to be similar in a retrospective analysis comparing TESA with open biopsy using TESE (81). Further, cryopreservation of spermatozoa within testicular tissues for use in subsequent ICSI treatment

P.1202

cycles has been reported (87). Fresh and frozen-thawed epididymal (88) or testicular spermatozoa (89) appear to have comparable fertilization and ongoing pregnancy rates when used for ICSI.

In contrast to posttesticular azoospermia, patients with testicular azoospermia require the use of TESE or TESA, and possibly multiple biopsies, for sperm retrieval (90). The use of TESE followed by ICSI has resulted in ongoing pregnancies, even for patients with 47,XXY Klinefelter syndrome (91,92). However, the sperm recovery rate with TESE is only about 50% and is even lower with TESA. Further, ICSI after TESE has variable clinical outcomes in patients with testicular azoospermia.

Following ICSI, fertilization and pregnancy rates are significantly lower with

testicular azoospermia than with posttesticular azoospermia (86,93). Moreover, embryos derived from testicular sperm retrieved from men with testicular azoospermia have higher aneuploidy rates and lower developmental competence (94). In comparison with patients who have normal testicular histology, all measures of success are lower in the presence of an associated histologic diagnosis of testicular aplasia, Sertoli cell-only syndrome, or spermatogenesis arrest (92,95,96). Despite these findings, the histologic diagnosis alone should not be used to exclude patients from ICSI treatment because 15% of cases with no sperm identified on histology were found to have sperm on retrieval (97). Among patients with testicular azoospermia, surgically recovered sperm may be at various stages of maturation arrest (i.e., round spermatid, elongated spermatid, and motile and immotile spermatozoa). Although sperm at all stages have been used to establish successful pregnancies using ICSI (53,98), the fertilization and pregnancy rates associated with maturation-arrested spermatid are very low, and couples should be counseled regarding their prognosis and alternative options (99,100,101).

Donor Insemination

For men with azoospermia, couples with significant male factor infertility who do not desire ART, or women without a male partner who are seeking pregnancy, therapeutic donor insemination offers an effective option. A number of important issues surround the use of this form of artificial insemination. First, despite reports that the use of fresh donor semen is associated with higher pregnancy rates than the use of frozen specimens (102), both the Centers for Disease Control and Prevention and the American Society for Reproductive Medicine recommend the use of frozen samples (103). This recommendation stems from the increasing incidence of human immunodeficiency virus (HIV) infection in the general population and the lag time between HIV infection and seroconversion. **Currently, semen donors are screened for HIV infection, hepatitis B, hepatitis C, syphilis, gonorrhea, chlamydia, and cytomegalovirus infections, all of which may be transmitted through semen. All cryopreserved samples are quarantined for 6 months, and the donor is retested for HIV before clinical use of the specimen.** Donors are likewise questioned about any family history of genetically transmitted disorders, including both mendelian (e.g., hemophilia, Tay-Sachs disease, thalassemia, cystic fibrosis, congenital adrenal hyperplasia, Huntington disease) and polygenic-multifactorial conditions (e.g., mental retardation, diabetes, heart malformation, spina bifida). Those with a positive family history of these conditions are eliminated as donor candidates.

A second issue surrounding the use of therapeutic donor insemination—that which is most

important to the patient—is the success rate of treatment. **In patients younger than 30 years of age who have no other infertility factors, conception rates approach 62% after 12 cycles of treatment with frozen sperm (104). In several prospective randomized or crossover trials, IUI was superior to intracervical insemination for donor insemination.** Overall, the cycle fecundity rates ranged from 9.7% to 24% for IUI, to 3.9% to 17.9% for intracervical insemination (105,106,107,108,109,110,111). A meta-analysis concluded that IUI had a significantly higher cycle fecundity rate when compared with ICSI (OR 2.4, 95% CI, 1.5–3.8) (112). Moreover, the concomitant use of *clomiphene citrate* or gonadotropin

P.1203

(hMG) for controlled ovarian hyperstimulation (COH) did not result in higher fecundity rates (112). In addition, the length of recommended treatment also should be considered. When frozen donor semen is used, more than 80% of subsequent pregnancies will occur during the first 12 months of treatment (113). Thus, patients who do not conceive within 6 to 12 months should be assessed for female factors and encouraged to terminate treatment or proceed with alternative forms of therapy.

Last, but not least, one must consider the psychosocial aspects of pregnancies involving donor gametes. Among patients without a male partner, the potential repercussions of becoming a single mother and the issue of telling others about the father of the child should be considered. If the couple is married, it is imperative that the husband is aware of the process of using donor gametes. Most programs require that the husband sign a consent form. A skilled infertility social worker or psychologist can be immeasurably helpful in addressing these concerns.

Age and Decreased Ovarian Reserve

An association between the age of the woman and reduced fertility has been well documented. The decline in fecundability begins in the early 30s and accelerates during the late 30s and early 40s. **Chronologic age is the strongest determinant of reproductive success in both spontaneous and ART cycles because it is a predictor of ovarian reserve (114,115). However, age has traditionally not been regarded as a cause of infertility per se, likely because it represents a physiologic rather than a pathologic progression.**

In rural Senegal, where each woman gives birth to an average of 7.9 children, fertility rates peak at 25 years of age and decline steeply after 35 years of age (116). Similarly, among the Hutterites, a communal sect living in the Dakotas and Montana that practiced no contraception and had large families, fertility peaked by 25 years of age, and one third of women were no

longer fertile by 40 years of age (117). In one study, the fecundability of women who underwent donor insemination because of azoospermia in their husbands provided insight into the effects of age on their fertility. It was found that fertility rates began to drop after 30 years of age. The pregnancy rate after 1 year of inseminations was 74% in women aged 30 years and younger, 62% in women aged 30 to 35 years, and 54% in women older than 35 years of age (118).

Oocyte donation programs provide insight into the physiology of declining fertility in older women (Fig. 30.4.). **When embryos produced from oocytes retrieved from younger women were transferred into older women, the pregnancy rates among the older women approximated those of the younger women** (119), **and variations in pregnancy rates were directly dependent on the age of the donors rather than that of the recipients** (119,120,121). In fact, among 260 egg donors (mean age of 30 years) who underwent COH with exogenous gonadotropins, the number of oocytes retrieved per cycle decreased steadily at the rate of 0.24 oocyte per year of increasing age (121). In another study, the use of oocytes from young donors provided cycle fecundity rates of 50% per cycle. The accumulated pregnancy and live birth rates in this investigation reached 95% and 89%, respectively, after up to four cycles of ART (122). **These observations strongly support that it is the age of the oocyte, rather than the age of the endometrium, that accounts for the age-related decline in female fertility.** This oocyte-related decline in fertility is also known as *decreased ovarian reserve*.

Ovarian reserve refers to the size of the nongrowing, or resting, primordial follicle population, which presumably determines the number of growing follicles and the "quality" or reproductive potential of their oocytes. Ovarian reserve is thought to affect how the ovaries respond to pharmacologic doses of exogenous gonadotropins in terms of follicle count, oocytes produced, serum estradiol levels, duration of stimulation, and the quantity of exogenous gonadotropins required. Although age is the best predictor of

ovarian reserve, approximately 10% of women have an accelerated loss of ovarian reserve by their mid-30s, whereas others respond well to COH and achieve pregnancies despite their advanced age. Because of this imperfect correlation between chronological age and ovarian biological age, assays have been developed to assist in the prediction of ovarian responsiveness to COH.

Figure 30.4 Live births per embryo transfer comparing use of a patient's own versus donor oocytes. (From CDC Reproductive Health. 2000 Assisted Reproductive Technology Success Rates. National Summary and Fertility Clinic Reports. <http://www.cdc.gov/nccdphp/drh/art.htm>.)

Screening tests used in the prediction of ovarian responsiveness to COH include assessments of serum day 3 FSH, serum inhibin B, serum mullerian-inhibiting substance (MIS), the *clomiphene citrate* challenge test (CCCT), and transvaginal ultrasound parameters such as antral follicle count and mean ovarian volume measurement (123,124,125). Measurement of day 3 FSH is based on evidence that small increases in basal serum FSH levels correlate with the decreased fecundability seen among women in their late 30s. For IVF treatment following pituitary desensitization, basal FSH assessment proved to be a better predictor of ovarian response than age (126). *Clomiphene citrate* is thought to have antiestrogenic effects on the hypothalamic-pituitary axis, resulting in a decrease in the suppression of FSH production by the pituitary. The CCCT involves the measurement of serum FSH and estradiol on day 3, and again on day 10 after administration of *clomiphene citrate* (100 mg orally each day) from days 5 to 9.

Because FSH levels vary by the assay used and by the population screened, it is recommended that each ART center set its own reference range for evaluating the FSH levels. In a general infertility patient population, the incidence of an abnormal CCCT rises from less than 10% in patients younger than 35 years of age to 26% in patients older than 40 years of age (127). Basal day 3 FSH testing has a sensitivity of 8% in identifying women who will not conceive with subsequent IVF treatment, and the addition of the CCCT to a day 3 FSH only increases the sensitivity of this prediction to 26% (128,129,130). Both day 3 FSH and CCCT results display high specificity (96%) in the prediction of IVF outcome. In one study, 5% of 435 women beginning their first IVF cycle had a day 3 FSH level greater than 15 IU/L (131). These women proved 3.9 times

P.1205

more likely to have an unsuccessful treatment cycle. Similarly, among 175 IVF cycles involving women older than 40 years of age, no pregnancies resulted when testing revealed a day 3 FSH greater than 11.1 mIU/mL or a day 10 FSH greater than 13.5 mIU/mL after CCCT (132). Although it is reasonable to advise women with advanced age (greater than 40 years) and abnormal basal day 3 FSH or CCCT results to limit the number of IVF cycle attempts based on their overall poor prognosis, abnormal day 3 FSH and CCCT tests are more difficult to interpret in women younger than 40 years of age with regular menstrual cycles. One retrospective study demonstrated an ongoing pregnancy rate of 47% in women with regular cycles who had FSH levels ranging from 10 to 15 IU/L and 28% in those with FSH levels greater than 15 IU/L (133). These results indicate that high basal FSH values should not be used as the sole basis for excluding women from consideration for ART.

Given the imperfect nature of FSH as a screening test before COH, the search for other assays has intensified. Serum inhibin B is secreted by ovarian granulosa cells starting at the preantral follicle stage (134). **Inhibin B secretion increases during the luteal-follicular transition between menstrual cycles (135), and reflects the overall granulosa cell function of the cohort of follicles that is recruited to undergo gonadotropin-dependent growth. This finding provided the impetus to investigate the potential use of inhibin B as a prognostic marker for ovarian responsiveness in ART cycles.** Inhibin B suppresses the production of FSH by the pituitary gland. In the CCCT, the main mechanism for suppression of FSH is inhibin B production by granulosa cells. Although the use of basal inhibin B levels as a predictor of pregnancy outcomes is debatable (114), several studies have shown the value of stimulated inhibin B in the management of COH cycles. The largest of these studies evaluated the inhibin B level after 4 days of gonadotropin stimulation in 54 patients undergoing IVF (136). Patients with serum inhibin B levels less than 400 pg/mL

had significantly lower numbers of follicles and oocytes. This threshold indicates that stimulated inhibin B yielded a positive predictive value of 86.7% in the prediction of ovarian response to exogenous gonadotropins.

Recently, MIS, also known as antimullerian hormone (AMH), has been investigated as a marker for ovarian reserve and for ovarian responsiveness to stimulation. This substance is produced by the granulosa cells of preantral and small antral follicles and inhibits the initiation of primordial follicle growth (137). The serum level of MIS in women with normal cycles declines with age and becomes undetectable by the time of menopause (138). As the ovarian primordial follicle count decreases, the serum MIS concentration also decreases, making this hormone an ideal candidate for the early detection of ovarian reserve depletion. Decreased levels of MIS in the early follicular phase correlate with poor ovarian response in ART cycles (139). A retrospective study comparing normal and poor responders with gonadotropin stimulation established a threshold value of 8.1 pmol/L, which predicted poor ovarian response during a subsequent IVF cycle with a sensitivity of 80% and a specificity of 85% (140).

The ideal marker for ovarian reserve is one that can be performed in a basal state with high sensitivity and specificity for identifying patients who will have live pregnancy outcomes. Ongoing efforts to identify such a prognostic test are warranted so patients can be counseled regarding various treatment options.

Spontaneous Abortion

Another factor contributing to decreased fecundity among older reproductive-age women is the increased risk of spontaneous abortion in this population. A large study based on the Danish national registry estimated the rates of clinically recognized spontaneous abortion for various age groups to be 13.3% (12–19 years), 11.1% (20–24 years), 11.9% (25–29 years), 15.0% (30–34 years), 24.6% (35–39 years), 51.0% (40–44 years), and 93.4% (greater than 45 years) (141). In addition, using sensitive hCG assays in women during their reproductive years, 22% of all pregnancies were found to be lost before they

could be clinically diagnosed (142). This proportion is thought to be increased among older women attempting pregnancy, making subclinical spontaneous pregnancy loss a significant consideration among older women who are thought to be having difficulty conceiving.

One major cause for the increase in spontaneous losses among older women is

their increased incidence of chromosomally abnormal conceptuses. A cytogenetic analysis of 750 spontaneous abortions revealed that the increase in chromosomally abnormal conceptuses seen with increased maternal age was mainly due to an increase in the incidence of chromosomal trisomies. In particular, the incidence of trisomies 16, 21, 22, 18, and 20 were significantly increased, with 18 and 20 being the most dramatic. In contrast, the risk for monosomy X and polyploidy did not increase with advanced maternal age (143). In conclusion, an increased spontaneous loss rate, coupled with a reduced conception rate, significantly decreases the chance of a live birth among women older than 40 years of age.

Age of Male Partner

There is little doubt that increasing age is accompanied by reduced female fecundity. However, the age-related decline in fecundity for men is more controversial. Male fertility peaks at about 35 years of age and declines sharply after 45 years of age. Yet, men have reportedly fathered children into their 80s (4). Studies using chromosome-specific probes on ejaculated sperm reveal a slight but statistically significant increase in aneuploid sperm with advanced paternal age greater than 55 years (144,145). However, it is not known whether this finding corresponds to an increase in liveborn aneuploidy. Several studies describe an increase in the rate of autosomal recessive disorders among the progeny of men 35 years of age and older (146,147). More recently, advancing paternal age has been associated with an increased incidence of several autosomal dominant diseases, Apert syndrome and achondroplasia, and an increased incidence of schizophrenia (148,149). These findings suggest an age-related decline in gamete quality among men, albeit one that is subtler than that observed in women/E.

Ovulatory Factor

Disorders of ovulation account for about 30% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and most treatable causes of infertility. The normal length of the menstrual cycle in reproductive-age women varies from 25 to 35 days, and most women have cycle lengths of 27 to 31 days. Figure 30.5 shows the fluctuations of estradiol, progesterone, FSH, and LH in a normal, 28-day ovulatory cycle. Women who have regular monthly menses (about every 4 weeks) with minimal symptoms, such as premenstrual breast swelling and dysmenorrhea, almost invariably have ovulatory cycles. Because ovulation is prerequisite to conception, ovulation must be documented as part of the basic assessment of the infertile

...among women with ovulatory factor infertility may include anovulation (complete absence of ovulation) or oligo-ovulation (infrequent ovulation).

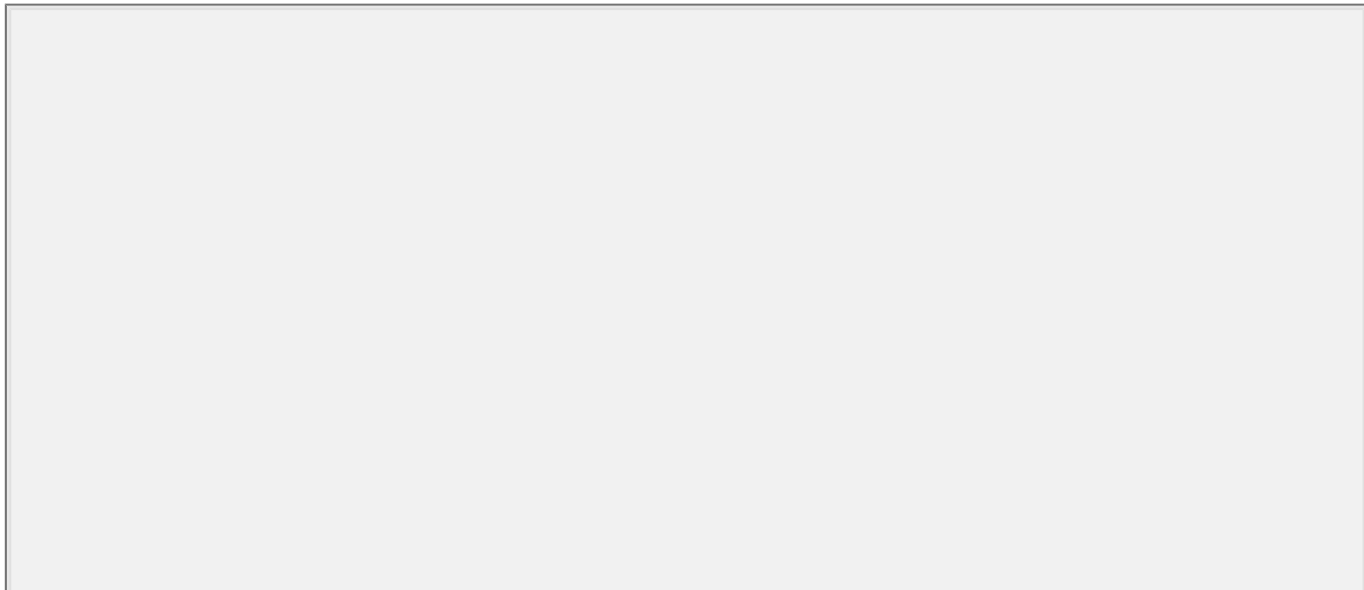

Methods to Document Ovulation

Luteinizing Hormone Monitoring

Documentation of the LH surge represents a remarkably reproducible method of predicting ovulation. Ovulation occurs 34 to 36 hours after the onset of the LH surge and about 10 to 12 hours after the LH peak (150,151). Commercially available kits for documenting the LH surge are generally accurate, quick, convenient, and relatively inexpensive enzyme-linked immunosorbent assays (ELISA) using 40 mIU/mL as the threshold for detection (152,153). The positive and negative predictive values of these kits have been described to be 90% and 96%, respectively

P.1207

(154). A 100% correlation between urinary LH prediction of ovulation and transvaginal ultrasound diagnosis of ovulation has further confirmed the value of urine LH detection kits for home ovulation detection (155). Still, this ELISA test cannot detect urinary LH in up to 5% to 10% of women, probably either because of failed recognition by the antibody used or because their peak urinary LH concentration does not rise above the threshold set by the kit manufacturers. Serum LH measurements may be necessary to predict ovulation in such cases.

Figure 30.5 Relative hormonal fluctuations in a normal, ovulatory, 28-day menstrual cycle..

Basal Body Temperature

The least expensive method of confirming ovulation is for the patient to record her temperature each morning on a basal body temperature (BBT) chart. The oral or rectal temperature should be determined before the patient arises, eats, or drinks. Smoking is forbidden before temperature measurement, and irregular sleep patterns can interfere with the test results. Patients monitoring their BBT record their temperature daily as well as times when they have coitus. Use of a BBT thermometer is preferred over use of a conventional thermometer because of the instrument's precision in the temperature range under consideration. The principle behind temperature charting as a means to document ovulation is based on the thermogenicity of progesterone. Significant progesterone secretion by the ovary generally occurs only after ovulation. The secretion of progesterone causes a temperature increase of about 0.58°F over the baseline temperature of 97° to 98.8°F typically recorded during the follicular phase of the menstrual cycle. Charting of daily BBTs produces a characteristic biphasic pattern in women with ovulatory cycles. Frequently, a nadir

in charted BBT is noted at the time of the LH surge, but this finding is inconsistent. A normal luteal phase is characterized by a documented temperature elevation lasting at least 10 days.

Charting BBT to document ovulation, although simple, has several drawbacks.

Presumptive ovulation can be identified only retrospectively (i.e., the test merely confirms rather than predicts ovulation). Even retrospectively, the exact time of ovulation is difficult to determine using BBTs, although in most instances, it is probably 1 day before documented temperature elevation. An unequivocal temperature rise generally occurs 2 days after the LH surge and correlates with serum progesterone levels of 0.4 ng/mL (156). In a small percentage of patients, BBT charts are monophasic, despite the documentation of

P.1208

ovulation by other methods. Furthermore, BBT charting is correlated with transvaginal ultrasound evidence of ovulation in only 30.4% of cases (155). Despite its limitations, for many patients, BBT charting is a simple way to document ovulation, and unequivocal biphasic cycles are almost certainly ovulatory. Patients with monophasic cycles require confirmation of ovulation using alternative methods.

Midluteal Serum Progesterone

Elevations in serum levels of progesterone constitute indirect evidence of ovulation.

When used to document ovulation, serum progesterone measurement should coincide with peak progesterone secretion in the midluteal phase (typically on days 21–23 of an ideal 28-day cycle). The lower limit of progesterone levels in the luteal phase varies among laboratories, but a level above 3 ng/mL (10 nmol/L) typically confirms ovulation. However, interpretation of isolated luteal-phase measurements of serum progesterone is complicated by the frequent pulses that characterize the secretion of this hormone (157). Although ovulatory levels are often considerably higher than 3 ng/mL, low midluteal serum levels of progesterone are not necessarily diagnostic of anovulation.

Ultrasound Monitoring

Ovulation can also be documented by monitoring the development of a dominant follicle by ultrasound until ovulation takes place. Ovulation is characterized both by a decrease in the size of a monitored ovarian follicle and by the appearance of fluid in the cul-de-sac (158). It most often occurs when follicular size reaches about 21 to 23 mm, although it may occur with follicles as small as 17 mm or as large as 29 mm (159,160). Because of

the inconvenience and expense of serial measurements, routine use of ultrasound for documenting ovulation is discouraged. Instead, its use should be confined to the monitoring of ovulation induction or superovulation.

Follow-up Tests

If test results confirm that a patient is anovulatory or oligo-ovulatory, the differential diagnoses of hypothalamic-pituitary disorder, hypothyroidism, anorexia nervosa, polycystic ovarian syndrome (PCOS), and premature ovarian failure should be considered. In addition to history and physical examination, the basic investigations typically used to assess these potential diagnoses further include serum FSH, prolactin, and thyroid-stimulating hormone (TSH) testing. These three investigations are often sufficient to guide the initial management plan.

Polycystic Ovarian Syndrome

The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is PCOS. The diagnosis of PCOS is determined by exclusion of other medical conditions *and* the presence of two of the following conditions (161):.

- **Oligo-ovulation or anovulation (manifested as oligomenorrhea or amenorrhea).**
- **Hyperandrogenemia (elevated levels of circulating androgens).**
- **Hyperandrogenism (clinical manifestations of androgen excess).**
- **Polycystic ovaries detected by ultrasonography.**

The exclusion of pregnancy, hypothalamic-pituitary disorders, or other causes of hyperandrogenism (e.g., androgen-secreting tumors or nonclassical congenital adrenal hyperplasia) may be indicated in some patients presenting with presumptive ovulatory disorders and infertility. However, once other causes of oligo-ovulation or anovulation have been

excluded, biochemical evidence consistent with PCOS—including elevated serum LH:FSH ratios and hyperinsulinemia—is not required before initiation of infertility treatment. Before initiating therapeutic changes in such women, differential diagnoses should be reviewed and endocrinologic investigations repeated if necessary. **Because oligomenorrheic women with PCOS are at risk for endometrial hyperplasia, it may**

be prudent to perform an endometrial biopsy before beginning ovulation induction therapy.

Ovulation Induction in Women with Polycystic Ovarian Syndrome

Despite the use of similar medications, the indications and goals of ovulation induction should be distinguished from those of superovulation. **Ovulation induction refers to the therapeutic restoration of the release of one egg per cycle in a woman who either has not been ovulating regularly or has not been ovulating at all.** Although it is usually acceptable for ovulation induction to result in the release of two eggs, one should avoid the ovulation of more than two eggs in an effort to minimize the risk of ovarian hyperstimulation syndrome (OHSS) and multiple gestation. **In contrast, superovulation is indicated for the treatment of unexplained infertility in women who have been unable to conceive despite regular, monthly ovulation. The explicit goal of superovulation is to cause more than one egg to be ovulated, thereby increasing the probability of conception..**

Ovulation induction can be achieved either medically or surgically in women with PCOS. There is no fixed protocol on how to approach ovulation induction in these patients, although it is reasonable to progress from the least to the most invasive therapies. Appropriate patient selection for various therapies can be a significant determinant of the success of ovulation induction among PCOS patients.

Regardless of which treatment is employed, one important concept to convey to couples is that pregnancy is a cumulative probability. Once ovulation has been documented for a particular treatment, patients should be mentally prepared to continue with that regimen for at least three cycles because, for most treatments, the rate of a pregnancy occurring per therapeutic cycle is the same for each of the first three cycles. **When counseling patients, it is often helpful to remind them that even a couple with no fertility problems has a fecundity rate of only 20% to 25% per cycle (1).** A good rule of thumb involves review of

the patient management plan at least once every 2 to 3 cycles and more frequently if side effects are present. This plan should be discussed explicitly with patients, thereby promoting education, communication, and informed compliance.

Weight Loss

A body mass index (BMI) above 27 kg/m² is considered excessive; moreover, an increase in BMI is associated with an increased risk for insulin resistance. There are several excellent reasons for recommending weight loss for infertile patients who are overweight. Weight loss of 20 kg (mean pretreatment weight, 77 kg) through the use of hypocaloric diets in one study and 10 kg (mean pretreatment BMI, 32 kg/m²) in another study resulted in a decrease in plasma testosterone, androstenedione, LH, and fasting insulin levels (162,163). Significant improvement in these parameters, which are thought to play a role in the pathogenesis of PCOS, helps restore spontaneous ovulation in many patients. In a study of 67 overweight women who had a mean weight loss of 10.2 kg/m², spontaneous ovulation and pregnancy occurred in 90% and 30%, respectively (164).

Obese patients are at increased risk for medical conditions such as diabetes, hypertension, and cardiovascular disease. Because obesity also is a risk factor for obstetric complications, there should be tremendous incentive for infertile patients to lose weight (165). As with any other lifestyle change, promotion of weight loss can be difficult and frustrating for both patient and practitioner. Weight loss often requires multidisciplinary efforts, including the involvement of an experienced dietician and promotion of an effective exercise program. However, because weight loss is a gradual process, and other factors may be contributing to infertility concomitantly, it is reasonable to pursue medical options in conjunction with lifestyle changes.

Clomiphene Citrate

Traditionally, *clomiphene citrate* (*Clomid*, *Serophene*) has been the first-line intervention for medical induction of ovulation in PCOS patients.

Clomiphene citrate is a weak synthetic estrogen that mimics the activity of an estrogen antagonist when given at typical pharmacologic doses for the induction of ovulation. A functional hypothalamic-pituitary-ovarian axis is required for appropriate *clomiphene*

citrate activity. More specifically, *clomiphene citrate* is thought to bind and block estrogen receptors in the hypothalamus for prolonged periods, thereby decreasing the normal ovarian–hypothalamic estrogen feedback loop (166). This blockade increases GnRH pulse amplitude in some anovulatory women (167). Increased GnRH levels lead to increased pituitary secretion of gonadotropins, which promotes ovarian follicular development. *Clomiphene citrate* also may affect ovulation through direct action on the pituitary or the ovary (168,169). Unfortunately, the antiestrogenic effects of *clomiphene citrate* at the level of the endometrium or the cervix may have adverse effects on fertility in a minority of individuals (170,171).

Use of *clomiphene citrate* for ovulation induction is generally associated with excellent outcomes. In fact, in some populations, 80% to 85% of treated women will ovulate and 40% will conceive (172,173). Discrepancies between ovulatory rates and conception rates are most likely associated with the number of cycles attempted or are secondary to the presence of additional, nonovulatory infertility factors among treated women. Most pregnancies resulting from induction of ovulation with *clomiphene citrate* occur during the first 6 months of therapy (172). Side effects of *clomiphene citrate* therapy include infrequent OHSS, vasomotor flushes, nausea, pelvic discomfort, and breast pain (174). In the presence of visual abnormalities, *clomiphene citrate* should be discontinued promptly. Use of *clomiphene citrate* is associated with a 35% to 60% incidence of multiple follicular recruitments (175). However, the incidence of multiple gestation with this agent is only about 5% to 8%. Most of these multiple gestations are twin pregnancies, and triplet pregnancies occur infrequently. Rates of spontaneous abortion and teratogenicity in humans are not increased with the use of *clomiphene citrate* (176).

Clomiphene *citrate* is typically used for ovulation induction in the following manner:

- **The drug is supplied in 50–mg tablets; the usual starting dosage is 50 mg/day. A baseline transvaginal ultrasound should be performed on days 1 to 3 to confirm the absence of ovarian cysts before treatment.** Therapy is typically begun within the first 5 days after the onset of a spontaneous or progesterone–induced menses and is continued for 5 days (i.e., treatment on days 2–6, 3–7, or 5–9 of the menstrual cycle) (177). Some patients respond to a dosage as low as 25 mg/day.

- **Ovulation should be documented using a home urine LH kit in conjunction with ultrasound monitoring of follicular development or confirmation by serum progesterone**

at approximately 7 days following the LH surge. This information is valuable for future therapeutic planning because failure to conceive despite successful ovulation has different implications than failure to conceive because of failed ovulation induction. If ovulation does not occur at the initial dosage of *clomiphene citrate*, the dosage is increased in each subsequent cycle by 50 mg/day. The U.S. Food and Drug Administration recommends a maximum dosage of 100 mg/day; however, in patients who ovulate as a result of *clomiphene citrate* treatment, 11.8% do so only at doses of 150 mg/day or more (172). Considerable clinical experience with *clomiphene citrate* indicates that a dosage of up to 250 mg/day is safe.

- **Ovulation is expected to occur 5 to 10 days after the last day of therapy; thus, with standard *clomiphene citrate* regimens, ovulation testing should begin on day 12 or 13 and continue daily until results are positive. Once a pattern is established, ovulation testing can be confined to a better defined 5–day**

P.1211

period in subsequent months. Daily intercourse for 3 days beginning on the day of a positive urine LH test may maximize the chance of a pregnancy..

- **Ultrasound monitoring can be used to determine the number and size of follicles that are developing.** If a dominant follicle develops, but there is no spontaneous LH surge, hCG (*Profasi* 10,000 units given intramuscularly, or *Ovidrel* 250 µg given subcutaneously) can be used to induce final follicular maturation and ensure that ovulation is timed optimally with respect to follicular growth and timed intercourse or IUI. The number of *clomiphene citrate*–treated and ovulatory cycles should not exceed six. The maximum cumulative pregnancy rate should be achieved by the six–cycle mark, and further treatment with *clomiphene citrate* is of minimal predicted benefit at that point.

Despite the high therapeutic success rates of *clomiphene citrate* in most anovulatory women, treatment has relatively low success in inducing ovulation in women with PCOS and insulin resistance in whom obesity or elevated BMI also is evident. There is increasing evidence that insulin sensitizers are particularly effective in inducing ovulation in women with PCOS who are insulin resistant..

Insulin Sensitizers

The etiology of PCOS is currently viewed as multifactorial, with contributions from different genetic causes and environmental factors (see Chapter 28) (178). **Insulin resistance is thought to play a central role in the pathogenesis of PCOS in the subset of patients who have increased BMI, hyperinsulinemia, and significant hyperandrogenism** (Table 30.7) (178). **It is also thought that a different form of insulin resistance intrinsic to PCOS is part of the underlying disease mechanism in thin women with PCOS** (179,180).

Therefore, the therapeutic roles of insulin sensitizers, *metformin* and *rosiglitazone*, in ovulation induction have been extensively investigated.

Metformin is an oral biguanide that is approved for the treatment of non-insulin-dependent diabetes. *Metformin* acts by several mechanisms, including inhibition of gluconeogenesis in the liver and an increase in the uptake of glucose in the periphery (181).

When women with PCOS, hyperandrogenism, and hyperinsulinemia are treated with *metformin* for 12 weeks, their fasting insulin and total testosterone levels, free testosterone index, BMI, waist-to-hip ratio, hirsutism, and acne all decrease significantly (182). Moreover, among women who have PCOS, a BMI greater than 28 kg/m², and hyperandrogenemia, 89% ovulate after treatment with a combination of *metformin* and *clomiphene citrate* (182). This rate is significantly higher than the 12% of patients who ovulated with combined *clomiphene citrate* and *placebo* treatment (183). A meta-analysis of studies involving ovulation induction of PCOS patients by *metformin* versus placebo, *metformin* versus *clomiphene citrate*, and *metformin* plus *clomiphene citrate* versus placebo plus *clomiphene citrate* showed that the combined regimen of *metformin* and *clomiphene citrate* increased the success of ovulation induction by three- to fourfold when compared with *clomiphene citrate* alone (184).

Table 30.7 Clinical Findings that Suggest Insulin Resistance and Hyperinsulinemia

Physical findings associated with insulin resistance

Body mass index >27 kg/m²

Waist-to-hip ratio >0.85

Waist >100 cm

Numerous achrochordons (skin tags)

From **Barbieri RL**. Induction of ovulation in infertile women with hyperandrogenism and insulin resistance. *Am J Obstet Gynecol* 2000;183:1412-1418, with permission.

Similarly, *rosiglitazone*, an insulin sensitizer belonging to the class of thiazolidinediones, has been shown to induce ovulation within 2 months of treatment in obese, *clomiphene citrate*-resistant patients with PCOS at a rate of 33% when used alone and 77% when combined with *clomiphene citrate* (185). Furthermore, *rosiglitazone* significantly decreases fasting insulin and glucose levels, total testosterone, free testosterone, and dehydroepiandrosterone sulfate (DHEAS) and increases sex hormone-binding globulin (SHBG) (186). Because BMI is not improved by treatment, its ovulation induction effects are presumed to be the result of improved insulin resistance and ovarian androgen profiles (186). The use of *metformin* or *rosiglitazone* alone has been shown to induce ovulation and improve androgen levels in PCOS patients who have normal BMI and insulin sensitivity profiles, although there is no added benefit to combining *metformin* and *rosiglitazone* (187). Thus, the use of insulin sensitizers is not restricted to obese and insulin-resistant PCOS patients. It is anticipated that ongoing investigations in the next few years will further guide patient selection for *clomiphene citrate*, *metformin*, *rosiglitazone*, or combined regimens involving these medications.

Unlike *troglitazone*, which was withdrawn from the market because of its risk of fatal liver failure (1 in 50,000), this newer generation of thiazolidinediones, including *rosiglitazone* and *pioglitazone*, have good safety profiles, especially with respect to liver toxicity (188,189,190). *Metformin* also has an excellent safety profile, but gastrointestinal symptoms are common side effects, and isolated cases of fatal lactic acidosis have been reported in patients with underlying renal compromise. *Metformin* typically is discontinued once pregnancy has been established; however, it is a category B drug, and its administration during pregnancy is not known to confer specific risk to the fetus. Prospective, nonrandomized studies have reported that the continuation of *metformin* in pregnancy appeared safe and may decrease the risk of gestational diabetes (191,192). However, these findings need to be confirmed by a prospective, randomized trial with neonatal and pediatric outcomes before this practice is widely adopted (193).

A typical treatment regimen using *metformin*, with or without *clomiphene citrate*, for ovulation induction in PCOS patients follows (179):.

Select PCOS patients. Failure of ovulation induction with *clomiphene citrate* alone is

an indication but not a requirement for the use of metformin..

- **Confirm normal liver and renal function.** Serum hCG testing to exclude pregnancy, followed by a progestin withdrawal–induced menses, can be undertaken if indicated.

- **Start *metformin* therapy as follows:**

- **Metformin, 500 mg once a day with breakfast for 4 days.**

- **Metformin, 500 mg twice a day with breakfast and dinner for 4 days.**

- **Metformin, 500 mg with breakfast and 1,000 mg with dinner for 4 days.**

- **Thereafter, *metformin*, 1,000 mg twice a day (at breakfast and dinner)..**

- **If a trial of *metformin* alone is chosen, evaluate single serum progesterone levels weekly to detect the occurrence of ovulation.** It may take up to 2 months of therapy for spontaneous ovulation to occur.

- **If *metformin* plus *clomiphene citrate* is the desired regimen, add *clomiphene citrate* at the usual starting dosage of 50 to 100 mg once a day from days 5 to 9 when the full dose of *metformin* has been reached if spontaneous ovulation has not occurred.** Home LH detection kits can then be used to predict ovulation and time intercourse.

P.1213

- ***Clomiphene citrate* can be increased incrementally by 50 mg once a day in subsequent cycles if ovulation still does not occur. Once ovulation occurs, the ovulatory dosage of *clomiphene citrate* can be used in combination with *metformin* for as many as 3 to 6 cycles (in conjunction with ovulation detection and timed intercourse or inseminations)..**

If the combination of *metformin* and *clomiphene citrate* fails to induce ovulation, the diagnosis should be reviewed. Alternatively, the aromatase inhibitor *letrozole* has been reported to be efficacious in inducing ovulation in *clomiphene citrate*-resistant patients (194). In patients who have elevated serum DHEAS, *dexamethasone*, 0.5 mg/day at bedtime, combined with typical *clomiphene citrate* regimens may induce ovulation (195). At this low dosage, *dexamethasone* therapy is associated with minimal adverse effects. Other treatment options, including gonadotropin therapy and surgical ovarian diathermy, may be considered.

Gonadotropin Therapy for Polycystic Ovarian Syndrome Patients

Anovulatory PCOS patients who fail to ovulate or conceive after medical treatment with antiestrogen or insulin sensitizing agents should be considered for ovulation induction with gonadotropin therapy, either alone or in combination with *clomiphene citrate* or *letrozole*. This treatment involves daily injection of gonadotropins, close monitoring of serum estradiol levels and monitoring of follicular development by transvaginal ultrasound. Intrauterine insemination often is recommended in conjunction with ovulation induction to optimize the chances of pregnancy. It is important to remember that PCOS patients tend to have a high number of small antral follicles in the unstimulated state. These follicles can potentially be stimulated by exogenous gonadotropin therapy. This effect could be problematic because the goal of gonadotropin therapy in these patients, unlike that in ovulatory patients with unexplained infertility, is not to produce many eggs but rather to induce the release of only 1 to 2 oocytes. Treatment should be monitored by an experienced physician because the risks of OHSS and multiple gestation are significantly increased when using gonadotropins in this patient population.

Surgical Treatment

Pathophysiologic changes in the polycystic ovary have been the subject of many years of intense investigation. As early as 1935, with the initial description of the syndrome, ovarian surgical treatment of PCOS was considered (196). **Initially, surgical management of PCOS involved wedge resection of the ovaries in an effort to reduce the volume of androgen-producing tissue and thereby alleviate hyperandrogenic abnormalities. In fact, ovarian wedge resection does decrease circulating levels of testosterone (197), and this therapy is associated with resumption of menses in 91% of treated**

PCOS patients (198). Unfortunately, many patients treated with ovarian wedge resection suffer from postoperative intrapelvic adhesions, often leading to iatrogenic tubal factor infertility (198,199).

Laparoscopic techniques for treating PCOS appear to be associated with less adhesion formation in the pelvis than noted after ovarian wedge resection by laparotomy (200,201), while maintaining similar improvements in hormonal profiles (202,203). **Compared with controls, patients undergoing laparoscopic ovarian diathermy (or ovarian drilling) have higher rates of subsequent ovulation and a lower resistance to standard ovulation induction agents** (204,205). In further support of this concept, 112 women with PCOS and anovulatory infertility in whom previous ovulation induction attempts using *clomiphene citrate* (up to 200 mg once a day) were unsuccessful were treated with laparoscopic ovarian diathermy. This surgical therapy resulted in a significant decrease in serum levels of LH, testosterone, DHEAS, and androstenedione as well as in the LH:FSH ratio (206). Furthermore, 73% of these patients ovulated spontaneously, 24% ovulated with *clomiphene citrate* therapy, and 1.8% required gonadotropin use alone. The cumulative probabilities of pregnancy were 54%, 68%, and 82% at 12, 18, and 24 months of follow-up, respectively. The median time to conception was 10.2 months. Thus,

P.1214

laparoscopic ovarian diathermy may have particular application in ovulation induction among PCOS patients who are resistant to treatment with *clomiphene citrate*.

Laparoscopic ovarian diathermy appears to affect IVF outcomes as well. In a prospective trial comparing IVF outcomes in PCOS patients with and without prior surgical intervention, both a higher ongoing pregnancy rate and lower peak estradiol levels were documented in those who had prior laparoscopic ovarian diathermy (207). If these results are interpreted as an indication that laparoscopic ovarian diathermy favorably alters the response of PCOS patients to COH with gonadotropin therapy, then its effect on reducing the risk for OHSS among PCOS patients treated with these medications warrants further investigation. It is of interest that laparoscopic ovarian diathermy has been linked to a decrease in the elevated rates of spontaneous abortions documented in PCOS patients (206,207).

A variety of techniques have been described for laparoscopic destruction of ovarian tissue in the treatment of PCOS, including the use of laser, unipolar cautery, and bipolar cautery. Although no single technique has been proved superior using randomized studies, recent reports have advocated diathermy by electrocautery (206,207,208). In this technique, the ovary is immobilized, and an insulated

needle is inserted into the ovary in a direction perpendicular to the ovarian surface using a short duration of cutting current at 100 W. Coagulating current at 40 W is then applied for about 2 seconds. The needle is withdrawn, and the process is repeated at up to 15 puncture sites per ovary. At the end of the procedure, the ovaries are lavaged with copious amounts of normal saline (206).

In addition to the usual risks associated with laparoscopic surgery, laparoscopic ovarian diathermy involves the rare but potential risk of surgically induced premature ovarian menopause via inadvertent disruption of ovarian vascular supply. More common, however, is the possible formation of adnexal adhesions, which may further compromise fertility..

Of patients who had second-look laparoscopy after laparoscopic ovarian diathermy, 19% had adhesions (201). In a series of 112 PCOS patients (206), filmy adhesions confined to the ovarian surface were reported in 4 of 15 women who had not conceived at 1 year and who underwent second-look laparoscopy. At present, the impact of postsurgical adhesion formation on subsequent fertility and defined indications for use of second-look laparoscopy in treated patients is undetermined.

Ovulation Induction for Other Anovulatory Disorders

Hyperprolactinemia

Hyperprolactinemia can be associated with ovulatory factor infertility. After exclusion of a pituitary macroadenoma or other intracranial pathology, correction of the hyperprolactinemic state with *bromocriptine* is followed by restoration of ovulation in 90% of patients (209). *Cabergoline* has similarly high efficacy, but it has the advantage of a twice-weekly dosing schedule. More controversial is the use of bromocriptine alone or the addition of *bromocriptine* to *clomiphene citrate* therapy in non-galactorrheic patients with normal or minimally elevated serum prolactin levels. Such therapy has, however, been associated with improved pregnancy rates among normoprolactinemic women with unexplained infertility and galactorrhea (210).

Hypogonadotropic Hypogonadism

Anovulation in the presence of low serum LH, FSH, and estradiol levels defines hypogonadotropic hypogonadism and reflects dysfunction within

the hypothalamic–pituitary axis. Causes of hypogonadotropic hypogonadism, including craniopharyngiomas, pituitary adenomas, arteriovenous malformations, or other central space–occupying lesions, should be excluded using magnetic resonance imaging..

Low BMI is thought to cause anovulation and infertility in women, possibly by disrupting hypothalamic function (211). Examples of conditions characterized by low BMI include anorexia nervosa, rigorous athletic training, and malnutrition. In recent years, the female athlete triad, which consists of secondary amenorrhea, eating disorder or disordered eating, and osteopenia or osteoporosis, has become more widely recognized (212). It is important to understand that the female athlete triad is not restricted to professional athletes, but affects women who train for recreational purposes also. In most patients with this condition, weight gain is the ideal treatment for ovulatory dysfunction, thus avoiding the use of ovarian stimulatory medications and their complications. Other health benefits, including the reduction of pregnancy complications such as intrauterine growth restriction and osteoporosis, can result from correction of an abnormally low BMI. In one study, increased caloric intake and weight gain alone resulted in the resumption of menses in 90% patients with amenorrhea related to low BMI, with 73% conceiving spontaneously (213). In another study, a mean weight gain of 3.6 kg was sufficient to promote the resumption of spontaneous ovulation (214).

There is now increasing evidence linking genetic and physiologic mechanisms to the regulation of body fat content, caloric intake, and hypothalamic control of reproduction. In humans, abnormalities in leptin receptor function lead to early-onset morbid obesity and the absence of pubertal development, presumably secondary to defective hypothalamic function (215). Further, in women with hypothalamic amenorrhea secondary to strenuous exercise or low BMI, daily administration of recombinant human leptin increased LH pulse frequency and mean LH levels within 2 weeks and successfully induced follicular growth or ovulatory cycles within 3 months (216). Leptin, produced by peripheral adipocytes and reflects energy stores, and its receptor have critical functions in body mass regulation, glucose homeostasis, and reproductive function at the level of the hypothalamus (215).

Other conditions of hypothalamic dysfunction, such as congenital hypothalamic failure (*Kallmann syndrome*), can be treated using pulsatile GnRH therapy if the pituitary–ovarian axis is intact. Gonadotropin therapy should be chosen for patients

with pituitary dysfunction, such as those with empty sella syndrome. Each of these treatment modalities is discussed in greater detail under "Gonadotropin Therapy."

Hypothyroidism

The prevalence of abnormal TSH levels in the general infertility population has been reported to be 6.3%, 4.8%, 2.6%, and 1.5% for women in couples diagnosed with anovulatory infertility, unexplained infertility, tubal infertility, and male infertility, respectively (217). This diagnosis is significant in the management of infertility. For instance, one study reported that among 171 women with hypothyroidism, 23% had irregular menses, likely resulting from anovulation (218). Spontaneous ovulatory cycles typically resume when euthyroid status is achieved using *thyroxine* supplementation.

In contrast to the causal relationship between hypothyroidism and anovulation, the association between hypothyroidism or thyroid antibodies and spontaneous abortion is still unclear. Although hypothyroidism has been associated with increased fetal wastage in some studies (219,220), the association between thyroid antibody status and recurrent pregnancy loss or success rates in ART is controversial (221,222,223,224). In any case, because even very mild or subclinical hypothyroidism can have adverse effects on fetal brain development and subsequent intelligence quotient, it is prudent to screen and treat women with thyroid hormone abnormalities before commencing infertility treatment (225).

Tubal, Paratubal, and Peritoneal Factors

Tubal and peritoneal factors account for 30% to 40% of cases of female infertility.

Tubal factors include

P.1216

damage or obstruction of the fallopian tubes and usually are associated with previous PID or previous pelvic or tubal surgery. Peritoneal factors include peritubal and periovarian adhesions, which generally result from PID, surgery, or endometriosis. The risk of infertility after a single episode of PID is significant and increases rapidly with subsequent episodes. In fact, the incidence of tubal infertility has been reported to be 12%, 23%, and 54% after one, two, and three episodes of PID, respectively (226). Still, about one half of patients with documented tubal damage have no identifiable risk factors for tubal disease (227). Most of these women are presumed to have had subclinical chlamydial infections.

Hysterosalpingography

The initial diagnostic test used to assess tubal patency, hysterosalpingography (HSG) has a sensitivity of 85% to 100% in identifying tubal occlusion. The specificity of HSG in identifying PID-related tubal occlusion approaches 90% (228,229). Other causes of apparent tubal blockage include salpingitis isthmica nodosa, benign polyps within the tubal lumen, tubal endometriosis, tubal spasm, and intratubal mucous debris (230). Bilateral tubal pathology documented on HSG is associated with significantly reduced fecundity rates and warrants further evaluation using fallopscopy, selective salpingography, or laparoscopy.

HSG usually is performed between cycle days 6 and 11. During menses, HSG should be avoided because there is increased incidence of vascular intravasation caused by dilatation of periuterine veins. Additionally, there is the theoretical risk of retrograde dispensation of menstrual endometrium into the peritoneum with attendant risk of infection and endometriosis. The risk of infectious sequelae after HSG is 0.3% to 1.3%; in high-risk populations, this incidence can be as high as 3% (231,232). Therefore, known hydrosalpinges, current PID or cervicitis, and palpable adnexal masses or tenderness on bimanual examination all constitute contraindications to HSG. **Because there is a high prevalence of current or past chlamydial infection among infertile women and complications of HSG-associated pelvic infection could further compromise fertility, it is reasonable to prescribe antibiotic prophylaxis to patients scheduled for HSG.** A recommended prophylactic regimen consists of *doxycycline*, 100 mg twice daily, beginning the day before HSG and continuing for 3 to 5 days. Other rare complications of HSG include cervical laceration, uterine perforation, hemorrhage, vasovagal reaction, and allergic response to the contrast dye. The procedure often causes uterine cramping; prophylaxis with a nonsteroidal anti-inflammatory medication taken 30 minutes before the procedure may minimize this discomfort.

The performance of the HSG procedure is fairly straightforward. After vaginal cleansing, an acorn (Jarcho) cannula or other injection device is introduced into the uterine cervix. A paracervical anesthetic block is not routinely necessary, but may be used in selected patients. Either a water-soluble or a low-viscosity oil-based (i.e., Ethiodol) dye is used for the procedure. Water-soluble contrast material is more rapidly absorbed than oil-based dyes and does not carry the risk for either lipid embolism caused by dye extravasation or lipid granuloma formation. Conversely, oil-based dyes are associated with less uterine cramping, better resolution of tubal architecture, and a higher postprocedure pregnancy rate (233). In a randomized controlled trial of oil versus water-soluble dye, there was a 33% pregnancy rate with oil and a 17% pregnancy rate with water-soluble dye within nine ovulatory cycles after HSG (234). A meta-analysis found that the use of oil-soluble media to flush the tubes during

HSG significantly increases subsequent pregnancy rates (OR 1.8, 95% CI, 1.29–2.50) (235). Most pregnancies occurred within 7 months of the HSG. A potential mechanism to explain this therapeutic benefit entails flushing of inspissated mucus and debris from the tubal lumen, which allows fertilization to occur. Careful and slow initial injection of 3 to 4 mL of contrast media should give a clear outline of the uterine cavity. Further injection of about 5 to 10 mL of contrast media usually is sufficient to demonstrate bilateral tubal patency or tubal obstruction.

It is not unusual for unilateral tubal fill and spill to occur at the time of HSG. If the tube that fills and spills demonstrates normal architecture and prompt spillage, then it is

P.1217

possible that the hydrostatic dye column is following the path of least resistance out of the open tube. Additionally, unilateral or bilateral proximal occlusion may be secondary to procedure-related spastic constriction of the fallopian tubal lumen, which would result in a misdiagnosis of tubal nonpatency. To alleviate the potential for tubal spasm, premedication with diazepam 30 minutes before the procedure has been advocated. If proximal spasm is suspected during the procedure, subcutaneous terbutaline in the amount of 0.25 mg can be administered.

Successful evaluation of proximal tubal obstruction using selective *salpingography* has been described. Based on techniques derived from coronary angioplasty, salpingography uses a small guidewire to permit selective tubal cannulation and radiographic visualization under fluoroscopy.

Other Diagnostic Modalities

Fallopscopy is based on principles similar to selective salpingography but allows direct fiberoptic visualization of tubal ostia and intratubal architecture. **Fallopscopy allows the visual identification of tubal ostial spasm, abnormal tubal mucosal patterns, and even intraluminal debris causing tubal obstruction.** In fact, a tubal disease scoring system based on falloposcopic examination has been suggested to identify patients with poor prognoses for spontaneous conception (236). Complications associated with fallopscopy include a 5.1% rate of pinpoint perforations of the tube.

Alternatively, **sonohysterography with contrast media offers a much less invasive method of diagnosing fallopian tubal obstruction while maintaining a sensitivity and specificity similar to that of laparoscopic chromotubation** (237). Further prospective evaluation and cost analyses are necessary to determine the utility of tubal

cannulation and sonohysterography with contrast media.

Laparoscopy

The most thorough technique for diagnosing tubal and peritoneal disease is laparoscopy. It allows visualization of all pelvic organs and permits detection of intramural and subserosal uterine fibroids, peritubal and periovarian adhesions, and endometriosis. Abnormal findings on HSG can be validated by direct visualization on laparoscopy. Chromopertubation involves the transcervical installation of a dye, such as methylene blue or indigo carmine. Tubal patency is assessed by direct laparoscopic visualization of the dye extruding through the fimbrial openings of the tubes. **Unlike HSG, laparoscopy allows careful assessment of the external architecture of the tubes and, in particular, visualization of the fimbria. Identified abnormalities, including tubal obstruction, pelvic adhesions, and endometriosis, can be treated at the time of diagnosis..**

Treatment of Tubal Factor Infertility

Therapies that directly correct tubal factor infertility are entirely surgical and include (i) correction of periadnexal disease; (ii) correction of proximal, distal, or combined tubal disease; and (iii) correction of iatrogenic tubal abnormalities (e.g., tubal sterilization). **As success rates for ART continue to improve, the indications for surgical approaches in the treatment of tubal factor infertility have become increasingly limited.** Still, many of the principles underlying surgical management remain important. Surgical treatment of periadnexal disease distorting tubo-ovarian relationships has been proved to be effective, regardless of whether the approach is by laparotomy or laparoscopy (238). Adhesion prevention, however, becomes particularly vital when surgery is used to treat prior adhesive disease causing infertility. The relative value of laparotomy versus laparoscopy for the treatment of tubal infertility has received considerable attention, as have their respective effects on postoperative adhesion formation. For example, one study comparing laparoscopy and laparotomy for the treatment of ectopic pregnancy demonstrated that adhesion formation occurred more frequently after laparotomy, even when meticulous technique was maintained during all procedures (239). **Although many adjuncts for**

postoperative adhesion prevention have been proposed, none has consistently deterred postoperative adhesion formation. Thus, the microsurgical principles of

careful hemostatic technique, minimization of tissue trauma, and judicious use of the laparoscopic approach are essential in the surgical management of tubal factor infertility

Proximal Tubal Occlusion

Tubal spasm, temporary mucous plugging, and underfilling of the tube may cause a false-positive finding by HSG when proximal obstruction is demonstrated. The false-positive rate for proximal tubal obstruction may be as high as 15%.

Consequently, confirmation of proximal occlusion by repeat HSG or laparoscopic chromopertubation should be considered. Salpingitis isthmica nodosa, the pathologic sequelae of inflammation in the fallopian tube, accounts for 23% to 60% of histologically confirmed cases of proximal occlusion (240,241). **Proximal tubal occlusion can be corrected at the time of diagnosis by HSG.** Selective salpingography performed under fluoroscopy may be used to inject contrast media directly into the tubal lumen in an attempt to overcome obstruction resulting from mucous plugging. **If selective salpingography fails to recreate tubal patency, proximal tubal cannulation can be performed using a guidewire under radiologic guidance.** Proximal tubal cannulation has a reported success rate of 85% in establishing tubal patency. Reocclusion occurs in 30% of cases. The risk for tubal perforation with cannulation ranges from 3% to 11%, but tubal damage is usually mild and heals spontaneously (230). The ongoing pregnancy rates for selective salpingography and fluoroscopic tubal cannulation in studies averages 26% (230,242,243,244,245,246).

Microsurgical tubocornual anastomosis is the primary surgical approach, with postsurgical ongoing pregnancy rates averaging 47.4% in five reported series involving 175 patients (230,247,248,249,250). Hysteroscopic cannulation appears to have similar efficacy, with a 48.9% ongoing pregnancy rate among 133 patients treated in four series (230,251,252,253,254). **Although ongoing pregnancy rates with microsurgical tubocornual anastomosis and hysteroscopic cannulation appear comparable, cannulation is significantly less invasive and has fewer complications.**

Microsurgery, however, provides access to other pelvic structures, allowing the surgeon to assess the distal fimbriae and to lyse any periadnexal adhesions that may be compromising normal tubo-ovarian relationships. The success of the surgical approach is enhanced by the possibility of subsequent pregnancies without additional treatment. In a study of 102 patients who underwent microsurgical treatment for proximal tubal disease, nearly one half of the women who wanted a second child succeeded over a 2-year period (255).

Distal Tubal Occlusion and Hydrosalpinx

Distal tubal disease and occlusion can be secondary to a variety of inflammatory conditions including infection, endometriosis, or prior abdominal or pelvic surgery. Because of the secretory capacity of cells lining the oviductal lumen, fluid can accumulate within the occluded fallopian tube. The deleterious impact of a hydrosalpinx extends beyond mere blockage of the fallopian tube. The fluid within such a hydrosalpinx may contain substances that are directly embryotoxic or that impede efficient embryo implantation. **A meta-analysis of 14 studies and 1,004 patients with hydrosalpinx concluded that IVF pregnancy rates were significantly lower in cases of hydrosalpinx (256).**

Patients should be selected carefully for surgical correction of distal tubal disease via fimbrioplasty or neosalpingostomy. Fimbrioplasty is the lysis of fimbrial adhesions or the dilation of fimbrial phimosis, whereas salpingostomy (also known as salpingoneostomy) involves the creation of a new tubal opening in an occluded fallopian tube (257). The efficacy of neosalpingostomy or fimbrioplasty as treatment for distal tubal occlusion depends on the extent of tubal and peritubal disease as assessed by HSG and laparoscopy. Poor prognostic factors for successful pregnancy after tubal corrective surgery include hydrosalpinx greater than 30 mm in diameter, thickened tubal walls, absence of visible fimbriae, and dense pelvic or adnexal adhesions (258). The appearance of the tubal

P.1219

mucosa has added prognostic significance for the fertility outcome of laparoscopic tuboplasty for distal tubal occlusion (259). Patients with both proximal and distal tubal disease represent the poorest candidates for surgical management of tubal infertility (260). A study of a series of 194 cases of laparoscopic fimbrioplasty and neosalpingostomy resulted in an intrauterine pregnancy rate of 27.3% and an ectopic pregnancy rate of 4.1% (261). Patients younger than 35 years of age with mild distal tubal disease, normal tubal mucosa, and absent or minimal pelvic adhesions may be considered for corrective microsurgery. Otherwise, the extent of disease may render surgery less effective than ART, and the patient should be considered for IVF treatment.

Given the deleterious impact of hydrosalpinges on IVF outcome, the paradoxical situation is presented whereby tubal removal or proximal interruption may actually improve fertility. Removal of a hydrosalpinx that is visualized on transvaginal ultrasound before IVF treatment has been shown to significantly improve outcomes. In a randomized trial of 204 women with ultrasonographic findings consistent with a hydrosalpinx,

the live birth rate was 29% in women who had salpingectomy before IVF and 16% in women who underwent IVF alone (262). A subsequent Cochrane review of three randomized studies confirmed that salpingectomy for hydrosalpinx significantly increases IVF pregnancy rates (263). A technically simpler alternative to salpingectomy is proximal tubal occlusion via cauterization or clip device. **Comparative studies indicate that tubal occlusion is as effective as salpingectomy for improving IVF pregnancy rates in patients with hydrosalpinx** (264).

Sterilization Reversal

About 0.2% of women who choose surgical tubal sterilization request reversal procedures (265,266). The success of tubal reanastomosis depends on the method of sterilization, the site of anastomosis, and the presence of other infertility factors. **Pregnancy rates are lowest (49%) after the reversal of sterilization procedures involving unipolar electrocautery. In contrast, postprocedure pregnancy rates rose to 67% when the sterilization technique involved Fallope rings or spring-loaded clips and 75% when Pomeroy tubal ligation was employed.** The prognosis is best when anastomotic sites have no significant differences in tubal diameter (e.g., isthmic-isthmic or cornual-isthmic anastomoses). Tubal length is also an important prognostic consideration: Final anastomosed tubal lengths of less than 4 cm are associated with low pregnancy rates (267). Pregnancy rates higher than 40% have been reported after microsurgical fimbriectomy correction (268). Laparoscopy to assess surgical prognostic factors, such as potential final tubal length, site of reanastomosis, method of sterilization (if not previously known), and presence of associated pelvic pathology, is often performed before microsurgical fallopian tubal reanastomosis by laparotomy.

Historically, all sterilization reversal procedures have involved laparotomy. More recently, excellent pregnancy rates have been reported after laparoscopic tubal anastomosis. In one study of 186 patients followed after laparoscopic tubal anastomosis with a two-layer closure, cumulative postprocedure pregnancy rates were 60.3%, 79.4%, and 83.3% at 6, 12, and 18 months, respectively (269). In another study, laparoscopic tubal reanastomosis was performed on 102 women, of whom 70% conceived and 65% had ongoing intrauterine pregnancies during the 15-month follow-up period (270). Rates of ectopic pregnancy were similar (3% and 7%) in both series (269,270). The surgical time of laparoscopic tubal reanastomosis depended on the surgeon's experience as well as the number of layers involved in tubal closure.

has been reported. The reported procedures had a mean duration of 159 ± 33.8 minutes and were performed solely using robotic arms that were remotely controlled by surgeons with previous extensive experience with microsurgical tubal anastomosis by laparotomy. The reported postprocedure tubal patency rate was 89% at 6 weeks, and the ongoing pregnancy rate was 50% (271). **Despite advances in surgical technology, however, IVF**

P.1220

should be considered for patients with prior sterilization and poor prognostic characteristics. Likewise, IVF is indicated for those patients whose tubal reanastomoses have not yielded a pregnancy by 12 to 18 months postoperatively.

Cervical and Immunologic Factors

Postcoital Test

Cervical factor is estimated to be a cause of infertility in no more than 5% of infertile couples. The classic test for evaluation of the potential role of cervical factor in infertility is the postcoital test (PCT). The PCT is designed to assess the quality of cervical mucus, the presence and number of motile sperm in the female reproductive tract after coitus, and the interaction between cervical mucus and sperm. The test does not yield sufficient information on sperm count, motility, or morphology to allow assessment of semen quality. The PCT should be performed 1 to 2 days before the anticipated time of ovulation because sufficient estrogenization of the cervical mucus is critical to the interpretation of the results. Intercourse after 2 days of abstinence and about 2 to 12 hours before the PCT should be sufficient for testing purposes. Inexpensive and easily performed, the PCT involves both gross assessment of the cervical mucus and microscopic assessment of the sperm–mucus interaction. A small amount of cervical mucus is withdrawn by means of oval forceps or via an angiocatheter syringe. Cervical mucus is assessed for clarity and for spinnbarkeit (i. e., stretchability), with normal estrogen–stimulated mucus stretching 8 to 10 cm when pulled from the cervix. The mucus is placed on a glass slide and covered with a cover slip. A small trail of mucus may be left to dry outside the cover slip so that ferning can be assessed. Estrogenized mucus is clear and watery with a characteristic ferning pattern, whereas progesterone results in mucus that is opaque, thick, and lacking ferning. The presence of sperm, number per high–power field, and motility are assessed by the examination of several microscopic fields. Although the number of motile sperm per high–power field should be documented, normal values have not been established. Some authors suggest that virtually any number of motile sperm seen on the PCT is normal (272), whereas others require greater

than 20 sperm per high-power field (273).

There are several potential causes for an abnormal PCT. The most common is incorrect timing of the test within the menstrual cycle, leading to the production of cervical mucus that is suboptimal for sperm penetration. Other causes of poor mucus quality include anovulation, anatomic factors (e.g., prior cervical conization or cryotherapy), infection, and use of certain medications. *Clomiphene citrate* may exert detrimental effects on cervical mucus by its antiestrogenic action on cervical glands. Poor PCT results may, of course, reflect suboptimal mucus-sperm interactions. The observation of shaking or uniformly dead sperm on PCT may suggest the presence of antisperm antibodies.

Although there is a plausible biologic rationale for the PCT, this test has been accepted without critical review of its prognostic value or of its impact on the overall management plan of the subfertile couple. **The PCT lacks reproducibility, standard methodology, and uniform criteria for assessment. These factors, in conjunction with poor correlation between PCT results and pregnancy outcome, argue against the use of PCT as a standard investigational tool in infertility patients** (273,274,275,276). For example, one study reported no difference in pregnancy outcomes among women whose cervical mucus contained 0 to 11 motile sperm per high-power field (274), whereas another reported abnormal PCTs in 20% of fertile couples (273). A review of the world's English-language literature challenged the validity of the PCT, and found the sensitivity (the ability to detect infertility) of the test to be 9% to 71% and the specificity (the ability to identify fertility) to be 62% to 100% (275). The PCT has no bearing on the management of patients with unexplained infertility because the accepted treatment of superovulation with IUI bypasses

P.1221

the cervical mucus. In a prospective, randomized controlled study, couples who underwent PCT as part of their infertility evaluation had cumulative pregnancy rates identical to those of a control group not undergoing PCT after 24 months of therapy (277). **These findings indicate that PCT testing has no effect on treatment outcomes.**

Antisperm Antibodies

Both men and women have the capability to mount a humoral response to sperm. Either allogenic or autoimmune response could, in turn, adversely affect fertility. Antisperm antibodies (ASA) are most commonly limited to immunoglobulin G (IgG), IgM, and IgA isotypes, and each subclass has characteristic anatomic localization. Systemically produced IgG molecules may be found in serum as well as in cervical mucus and semen. Agglutinating antibodies of the IgA class

are typically found in cervical mucus and seminal plasma. The larger IgM antibodies have difficulty traversing the genital tract mucosa and therefore are found exclusively in serum. Antisperm antibodies have also been detected in ovarian follicular fluid (278). In addition to subclassification by isotype, antisperm antibodies can be free, agglutinating, bound to sperm that is motile, or bound to sperm that is immobilized. Further complexity arises in that sperm-bound antisperm antibodies can bind to different parts of the outer sperm plasma membrane, including the head, body, or tail. One major challenge in understanding antisperm antibodies is to determine the relative importance of each of these factors with respect to disease pathogenesis, impact on fertility, and prognosis. Though ASA are present in up to 9% to 12.8% of infertile couples (279), they are also found in up to 2.5% of fertile men (280) and 4% of fertile women (281). These findings would indicate that these antibodies may contribute to subfertility rather than result in absolute infertility.

Many causes have been proposed to explain the formation of antisperm antibodies (271). In women, coital trauma that disrupts the vaginal epithelium could theoretically expose immune effector cells to sperm antigens, thereby leading to antisperm antibody formation. However, it remains unclear why most women, who are repeatedly exposed to millions of spermatozoa, do not exhibit this immune response. In men, the blood-testis barrier normally shields the serum from exposure to sperm and their antigens. Conditions that cause breaks in this barrier could activate autoimmunity. Testicular trauma or torsion, occlusion of the vas deferens secondary to childhood inguinal herniorrhaphy or cystic fibrosis, vasectomy reversal, and genital tract infections have been suggested to elicit antisperm antibody formation.

The mechanisms by which antisperm antibodies might adversely affect fertility remain a subject of debate and ongoing investigation. One or more of these mechanisms could be involved in a particular infertile couple. Adverse antibody-mediated effects on semen quality (either before ejaculation or upon contact of ejaculate with the female reproductive tract) present obvious potential for subfertility. Other purported mechanisms include antisperm antibody-mediated interference with capacitation, acrosome reaction, sperm-egg fusion, and cleavage of the early embryo (282). A recent comprehensive review of the English language literature identified 20 trials examining the effect of ASA on fertilization (32). Of these trials, 14 showed a decrease in fertilization rate, two showed equivocal effect, and four showed no effect.

A number of assays, both indirect and direct, are available for the detection of antisperm antibodies. Sperm agglutination tests (Kibrick's or Franklin-Dukes) and sperm complement-dependent immobilization tests (Isojoma's) have largely been replaced by the immunobead or mixed agglutination tests. The immunobead test uses commercially

available anti-IgG-, anti-IgA-, or anti-IgM-coated polyacrylamide beads. Washed spermatozoa are exposed to the labeled beads, and sperm binding is assessed. The test yields specific information on both the immunoglobulin class of the antisperm antibody and the site of binding to the involved sperm (283). In the mixed agglutination reaction, human red blood cells sensitized with human IgG are mixed with the male's semen. The presence of antibody-coated spermatozoa results in the formation of mixed agglutinates with the red

blood cells (284). A comparison of these two methods demonstrates good correlation of results. However, the mixed agglutination test is easier to perform (279). Though useful in detecting the binding of ASA to various locations on sperm, these tests are not yet capable of determining the antigenic specificities of these antibodies. Until the antigenic specificity is revealed, the exact role of ASA in the impairment of fertilization will remain speculative.
