Developing and maintaining assisted breech delivery skills

With the increasing use of CS, most practice for assisted breech will come from use of a model pelvis and doll. I personally prefer a bony or plastic pelvis to the covered mannequins as it lets you see the diameters correctly. The manoeuvres should be practised over and over again by every MRCOG candidate until they are second nature. When delivering a breech at CS, it is also possible to use similar manoeuvres (although it's more akin to a breech extraction), and this is an ideal way to rehearse the motor skills in safe handling of a vaginal breech (but remember no traction in the latter). Labour suites should organise regular 'skills drills' where the whole team manage an unexpected breech birth together. Courses widely available in the UK such as ALSO, MOET and PROMPT also include breech delivery skills.

KEY POINTS

- Breech affects 3 per cent of babies at term and 20 per cent at 28 weeks, and can be a siren for later development problems.
- Ultrasound can be used to assess the cause of breech which may direct subsequent management e.g. placenta praevia, fetal anomaly.
- Caesarean section has become the favoured recommendation in most circumstances, on the basis of research evidence and guidelines based on better early neonatal outcomes, but these are still subject to debate and

further analysis as longer-term infant outcomes seem no different yet the risks to mothers are higher.

- Routine CS is not currently advised for preterm breech babies in labour.
- Twins in labour may benefit from CS where the first twin is breech as for singleton pregnancies, but not so where only the second twin is breech.
- Vaginal breech delivery skills should be practised until they are intuitive on birth simulators, and standard manoeuvres for minimisation of risks, for the situations where vaginal breech is still inevitable.
- Evidence and RCOG guidelines around breech should be critically appraised and form a vital part of MRCOG preparation and subsequent Continuing Professional Development.

CONCLUSION

The research on vaginal breech has borne fruit which remains ripe for debate around evidence quality, the ethics of choice and service provision, and most of all the apprenticed skill of the obstetrician in counselling, enabling informed choice and safely conducting external cephalic version or an assisted vaginal breech birth and minimising the chance of complications. This is a rich seam of gold for the aspiring MRCOG candidate to explore and demonstrate their excellence in the Membership exam, and beyond into a lifetime of practicing the craft.

Chapter 58 Perineal trauma

Lucy Kean

MRCOG standards

Theoretical skills

- Have a clear understanding of the impact of severe vaginal trauma and be able to counsel women about vaginal delivery following third-degree or fourth-degree tears.
- Have completed the programme of FGM e-modules developed by Health Education England.
- Be able to identify and refer women in antenatal clinic who have undergone female genital mutilation.
- Have attended a course on repair of third- and fourth-degree perineal trauma.

Practical skills

- Be able to recognise and grade the degree of perineal trauma, including recognition of the degree of anal sphincter damage.
- Be able to repair second- and third-degree perineal trauma.
- Be able to repair fourth-degree trauma under supervision.
- Have attended skills drills on obstetric collapse.
- Be able to recognise and manage paravaginal haematomas.

In addition, we suggest the following.

Theoretical skills

- Revise your knowledge of pelvic anatomy.

INTRODUCTION

Perineal trauma is a common event in first labours, affecting up to 90 per cent of first-time mothers. It is a cause for concern for many women and in some countries has led to a large increase in the numbers of women requesting elective

caesarean section. Considerable postnatal morbidity and occasionally mortality can be attributed to this, and therefore a clear understanding of the best management of perineal trauma is mandatory for every clinician working in obstetrics.

ANATOMY OF THE PELVIC FLOOR AND DEFINITIONS OF TRAUMA

In order to understand the pathophysiology of perineal trauma, an understanding of the anatomy of the pelvic floor is required.

First-degree trauma is defined as injury to the perineal skin alone. Second-degree trauma involves injury to the perineum including the perineal muscles but not involving the anal sphincter. Figure 58.1 shows the muscles of the perineum and the usual extensions of mediolateral and midline episiotomy.

Third-degree extensions involve any part of the anal sphincter complex (external and internal sphincters) and fourth-degree encompasses extension into the rectal mucosa.

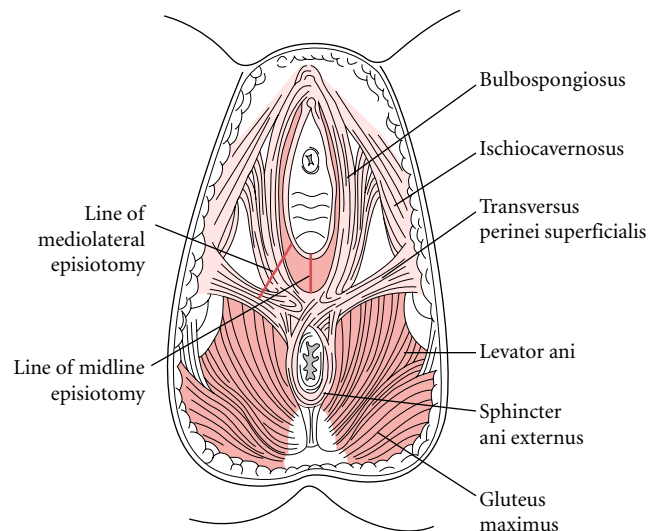

Fig. 58.1 Muscles of the perineum

RCOG recommends classifying anal sphincter damage as follows:¹

- 3a: less than 50 per cent of the external anal sphincter (EAS) is torn;
- 3b: more than 50 per cent of the external anal sphincter is torn;
- 3c: tear involving the internal anal sphincter (almost always involves complete disruption of the external sphincter);
- 4th degree: injury to the both the external and internal anal sphincter complex and anal epithelium.

FIRST- AND SECOND-DEGREE PERINEAL TRAUMA

In a first pregnancy, perineal trauma affects up to 90 per cent of women, with episiotomy rates of 40–60 per cent being common in many countries. Following delivery the perineum is often the source of much discomfort and pain for many women. Morbidity to the perineum may persist for weeks to years post-delivery. This can result in a cascade of events such as dyspareunia, psychosexual dysfunction, maladjustment to motherhood and relationship breakdown. Minimising the risk of perineal trauma should therefore be at the forefront of care during labour.

RISK FACTORS FOR PERINEAL TRAUMA

It is recognised that perineal trauma is associated with:

- larger infants;
- prolonged labour;
- instrumental delivery.

Instrumental delivery and forceps delivery in particular increase the risk of extended trauma, with as many as 60 per cent of women experiencing ultrasonographically visible anal sphincter defects in research studies.² Long second stage also appears to contribute to perineal damage. Malposition of the fetal head in labour is a risk factor for long labour and instrumental delivery and thus perineal trauma.

REDUCING THE RISK OF PERINEAL TRAUMA

Perineal massage

Perineal massage antenatally appears to slightly reduce the need for episiotomy in first-time mothers and reduce pain at three months in women who have had a baby before. Fifteen women need to undertake this to avoid one case of trauma, but this is a simple technique that women can be taught in parent education classes and has no harm [A].³ Also the application

of warm compresses during the second stage has been shown to reduce the incidence of third- and fourth-degree tears. The physiology behind this is very unclear, but as women find this acceptable, there is no reason not to use this [A].⁴

The role of episiotomy

Liberal use of mediolateral episiotomy does not appear to reduce the incidence of third-degree tears. In the most recent Cochrane evaluation, eight studies involving 5541 women were examined. In the routine episiotomy group, 75 per cent of women had episiotomies; in the restrictive episiotomy group 28 per cent did.

Combining trials of restrictive policy for episiotomy compared with standard care gives the following results:

- less severe perineal trauma (RR 0.67, 95% CI 0.49–0.91);
- more anterior perineal trauma (RR 1.84, 95% CI 1.61–2.10);
- less suturing (RR 0.71, 95% CI 0.61–0.81);
- fewer healing complications (RR 0.69, 95% CI 0.56–0.85);
- no difference in:
 - severe vaginal/perineal trauma (RR 0.92, 95% CI 0.72–1.18);
 - dyspareunia (RR 1.02, 95% CI 0.90–1.16);
 - urinary incontinence (RR 0.98, 95% CI 0.79–1.20);
 - pain scores.

Midline episiotomy certainly increases the risk of extended trauma, with a reported OR of 4.5–6 for third-degree or fourth-degree tears [A].⁵

NICE has recommended that:

- There is considerable high-level evidence that the routine use of episiotomy (trial mean 71.6%, range 44.9–93.7%) is not of benefit to women either in the short or longer term, compared with restricted use (trial mean 29.1%, range 7.6–53.0%) [A].
- Where an episiotomy is performed, the recommended technique is a mediolateral episiotomy originating at the vaginal fourchette and usually directed to the right side. The angle to the vertical axis should be between 45 and 60 degrees at the time of the episiotomy [A].⁶

This final point is an important practice point, as a common error made by inexperienced practitioners is to angle the episiotomy too vertically. Perineal stretching at crowning makes the perineum appear broader and therefore a much more horizontal angle of incision is required than would be expected. In a prospective case–control study there was a 50 per cent relative reduction in risk of sustaining third-degree tear observed for every 6 degrees away from the perineal midline that an episiotomy was cut. Recent data from Scandinavia have shown that education of practitioners regarding the mechanism of birth and the correct angle of episiotomy (and also using a hands-on approach) led to a reduction in extended trauma of 50 per cent. These data are not randomised and so we must be careful in using this in practice, but good education regarding birth and how to perform episiotomy is vital.

Conduct of normal birth

The conduct of delivery has also been examined in three studies. Changing established practice is obviously difficult, in one study there was only 73 per cent compliance in the 'hands poised' group (vs 95 per cent in 'hands on').⁷ Across the three relevant studies the rates of perineal trauma were similar in both groups: 29 per cent first-degree trauma and 37 per cent second-degree trauma. Thus, conduct of the delivery in terms of a hands-on or -off approach showed no advantage of one method over the other.

The use of Lidocaine spray has been evaluated and shown to have no effect on pain, but possibly a small reduction in trauma rates [B].⁶

Birth position in women without an epidural does not influence perineal trauma rates (increased spontaneous trauma but reduced episiotomy rates in women who were not supine). Non-supine positions were also associated with higher rates of bleeding but fewer fetal heart rate abnormalities, a marginally shorter second stage (by 4.28 mins) and less pain [A].⁶

Mode of delivery

Mode of delivery has a large impact on rates of perineal trauma. Of course, elective CS prevents damage to the perineum from labour-related events, and reducing the rates of instrumental vaginal delivery will reduce the incidence of perineal trauma.

Ventouse delivery appears to be associated with less perineal trauma (see Chapter **). Ventouse delivery (risk difference 0.06, 95% CI 0.10, 0.02) and spontaneous birth (0.11, 95% CI 0.18, 0.04) causes less anal sphincter trauma than forceps delivery. However, at 5-year follow-up there is no difference in reported symptoms in women delivered by either ventouse or forceps. Therefore, given that the highest rates of severe perineal damage occur in women for whom two instruments are needed to achieve delivery, the first choice must be the instrument most likely to deliver the baby safely and with which the obstetrician is experienced.

Episiotomy has been recommended when instrumental vaginal delivery is performed. This is not based on any randomised evidence.⁸ Ventouse delivery in a multiparous woman may not require any episiotomy, and an intact perineum may result. However, a forceps delivery in a nulliparous woman is likely to require episiotomy and a good technique with a correct angle of cut will minimise the risk of extended trauma [C].⁹

Prolonged second stage and epidural analgesia

The issue of epidural analgesia and instrumental delivery are closely linked and trials that attempt to divide the two are difficult to perform. Epidural analgesia has been shown to be associated with an increased risk of instrumental vaginal

delivery, with the attendant perineal morbidity [A]. There is an association between long second stage and perineal trauma, with increased risk of severe trauma in women experiencing long second stages. However, it has been shown that allowing a passive second stage in nulliparae with continuous epidural analgesia reduces the incidence of difficult instrumental delivery (RR 0.79, 95% CI 0.66–0.95). Spontaneous delivery is also slightly more likely among women who delay pushing (RR 1.09, 95% CI 1.00–1.18).¹⁰ NICE recommends that consideration should be given to the use of oxytocin, with the offer of regional analgesia, for nulliparous women if contractions are inadequate at the onset of the second stage. NICE guidance is clear that for nulliparous women:

- Birth would be expected to take place within 3 hours of the start of the active second stage in most women.
- A diagnosis of delay in the active second stage should be made when it has lasted 2 hours and women should be referred to a healthcare professional trained to undertake an operative vaginal birth if birth is not imminent.

And for multiparous women:

- Birth would be expected to take place within 2 hours of the start of the active second stage in most women.
- A diagnosis of delay in the active second stage should be made when it has lasted 1 hour and women should be referred to a healthcare professional trained to undertake an operative vaginal birth if birth is not imminent.⁶

This has involved a culture change for many units where recourse to instrumental delivery if birth is not imminent after an hour of pushing has been normal practice.

REPAIR TECHNIQUES FOR FIRST-DEGREE AND SECOND-DEGREE TRAUMA

Adequate lighting, analgesia and any necessary assistance are mandatory before attempting to repair a tear or episiotomy. It is unacceptable to perform a perineal repair with inadequate anaesthesia just as performing a CS without adequate anaesthesia would be considered unacceptable.

Before commencing a repair, a full examination should take place. The vaginal apex must be identified and the anal sphincter inspected. If the practitioner is inexperienced in the examination of the anal sphincter, someone with experience should be called at this stage. One study has shown that when the practitioner is uncertain, re-examination by a trained person identifies significantly more anal sphincter ruptures.

Minor first-degree trauma that is not bleeding and where the skin edges are opposed does not need closure; however, a careful examination should be undertaken to ensure no damage to the perineal muscles has occurred.

Women should be advised that second-degree trauma should be sutured, as this leads to faster healing and less gaping of the perineum.

It is vital to ensure that the apex of the vaginal component is secured, as paravaginal haematoma formation can occur if the apex is missed. When individual bleeding arteries are identified, they should be ligated separately. Once the repair is complete, it is important to perform the following.

- 1 Remove any vaginal tampon placed to aid visualisation.
- 2 Count swabs and ensure none is retained.
- 3 Count and dispose carefully of any needles.
- 4 Inspect the repair to ensure vascular haemostasis.
- 5 Perform a rectal examination to ensure no sutures have breached the rectal mucosa and to palpate the anal sphincter to ensure it is intact.
- 6 Prescribe analgesia.
- 7 Document the repair, using a diagram if necessary.
- 8 Document that the swab and needle count is correct.

Retained swab is now seen as a 'never event' by the national patient safety agency (NPSA) and all units must have procedures in place for the counting of swabs and the recording of any that are placed within the vagina to aid visualisation. A particular area of danger is when a swab is placed into the vagina and then the patient moved to the operating theatre.

Evidence for suture technique

The Cochrane Review showed that continuous suture techniques compared with interrupted sutures for perineal closure (all layers or perineal skin only) are associated with:

- reduction in analgesia use associated with the continuous subcutaneous technique vs interrupted stitches for repair of perineal skin (RR 0.70, 95% CI 0.59–0.84);
- reduction in suture removal in the continuous suturing groups vs interrupted (RR 0.56, 95% CI 0.32–0.98);
- no difference in long-term pain.

Using a two-stage method where the skin is left unsutured but approximated is associated with very slightly less pain at 14 days (RR 0.86, 95% CI 0.76–0.98), and interestingly a slight reduction in the need for re-suturing, despite more reported gaping at 7–10 days [A].¹⁰

Evidence for suture material

In modern practice synthetic sutures are used. Comparisons between rapidly absorbable and medium absorbable sutures show there is little difference, but a slight increase in the need for suture removal if medium absorbable sutures are used.

Braided sutures have not been compared with monofilament sutures.

Follow-up

In general, most first-degree and second-degree perineal repairs will heal without problems. Important issues relate to

the failure to identify anal sphincter damage, which may only become apparent later. Women who have experienced difficult vaginal deliveries may value the opportunity to discuss their delivery at a later date.

The ideal setting for follow-up for women experiencing persistent problems after delivery is a dedicated clinic. Where this is not available a team approach involving obstetricians and physiotherapists, with access to appropriate investigative techniques such as endo-anal ultrasound and manometry, is important. Urinary problems are amenable to biofeedback techniques, and physiotherapy input is vital to ensure that these are appropriately taught and reinforced.

The incidence of childbirth-related perineal wound dehiscence is unknown; figures of 0.1 per cent to 4.6 per cent have been reported, dependent on the degree of the initial trauma. Wound breakdown, when it occurs, happens remarkably quickly, with most women presenting at 4–5 days. It is devastating and can lead to depression and impaired breastfeeding.

Because of the association of breakdown with infection, many units have advocated allowing healing by secondary intention. This can take many weeks and women often request primary re-closure. There are only a few small trials examining this, of which only two are randomised. Women in the early suturing arm resumed sexual intercourse more quickly, but no other differences were seen. These trials did not include satisfaction or depression in their outcomes. All women received antibiotics [B].¹¹

Clearly this is an area in which further research is urgently needed. In the meantime an open-minded approach is probably best, and the adoption of the view that healing by secondary intention is best should be re-evaluated.

THIRD-DEGREE AND FOURTH-DEGREE TRAUMA

Incidence

Internal anal sphincter incompetence results in insensible faecal incontinence, whereas external anal sphincter incompetence is associated with faecal urgency. Third-degree tears are reported in approximately 2.8 per cent of primigravidae and 0.4 per cent of multigravidae. The reported rates will vary amongst units with different rates of instrumental delivery. New-onset symptoms of faecal incontinence are reported in 10 per cent of primigravidae undergoing instrumental vaginal delivery at 10 months, and in 3 per cent of primigravidae undergoing spontaneous vaginal delivery. Some of these new symptoms are attributable to pudendal neuropathy, as 5 per cent of women report new symptoms after emergency CS, whereas new-onset bowel symptoms are very uncommon after elective CS. Some degree of faecal urgency probably related to occult anal sphincter damage is much more common, with 44 per cent of women reporting this at 5 years following instrumental delivery of their first baby.

Ultrasonographically visible anal sphincter defects are apparent in 82 per cent of women undergoing forceps delivery and in 48 per cent of ventouse deliveries. However, most women report infrequent problems, and there is no difference in long-term follow-up between forceps and ventouse delivery.¹²

Research studies investigating anal sphincter damage have demonstrated sphincter defects visible on ultrasound in 36 per cent of women after vaginal delivery of their first baby, though two thirds of these will be asymptomatic. The much higher incidence of problems demonstrated in research studies underlines two important facts:

- 1 women are embarrassed about faecal problems after childbirth;
- 2 ultrasonographically demonstrated lesions do not translate into confirmed problems of faecal continence.

Anal sphincter damage is mainly limited to first deliveries, whereas pudendal nerve damage can be cumulative. Pudendal nerve damage occurs during labour as the nerve becomes compressed and stretched. Delivery late in first stage or second stage by CS does not prevent this. It has also been shown that ultrasonographically visible anal sphincter defects can be demonstrated in women who were demonstrated to have an intact anal sphincter at the time of delivery. The mechanism for this late disruption is unclear. It may be related to infection or haematoma formation, or possibly to partial unrecognised sphincter ruptures.

Women who have undergone a primary repair of a third- or fourth-degree tear have a 10 per cent risk of wound breakdown and a 0.3–0.4 per cent risk for fistula formation.

Risk factors for third-degree and fourth-degree tears

The risk factors for third-degree and fourth-degree tears are shown in Table 58.1.

Risk factors are cumulative, and in some cases the risks may be greater than the sum of two individual risks; for instance

Table 58.1 Factors associated with increased risk of third-degree tears

Factor	Odds ratio
Primigravida	2–7
Second stage of labour of .60 minutes (including passive second stage)	2
Instrumental vaginal delivery	1.7–7
Midline episiotomy	5–11
Macrosomia (>4 kg)	2.9
Persistent occipito-posterior position	1.7
Epidural analgesia	1.5
Prior third-degree tear	4
Induction of labour	2
Shoulder dystocia	4

the risk of severe trauma when two instruments are needed is much greater than the summed risks for each individual instrument.

Repair

Identification of extent of damage

All women sustaining perineal trauma should be carefully examined to assess the severity of damage to the perineum, vagina and rectum. All staff performing perineal repair must be confident in their ability to diagnose anal sphincter injury. It is imperative to examine carefully for rectal extension, as **small buttonhole tears** can be overlooked and lead to fistula formation.

When disrupted, the anal sphincter retracts, forming a dimple on either side of the anal canal. Rupture of the rectal mucosa will almost always involve damage to both the internal and external anal sphincters.

A good repair of the sphincter is imperative, as this is the factor most strongly associated with future faecal continence.

Conduct of the repair

The most recent Cochrane review of techniques used to repair the EAS included six eligible trials, of variable quality, involving 588 women. There was considerable heterogeneity in the outcome measures, time points and reported results. In one of the six trials all of the repairs were carried out by one of two practitioners only. In the others experienced practitioners within the department undertook the repairs.

Comparing the overlap technique with an end-to-end repair the results showed:

No statistically significant difference in:

- perineal pain (RR 0.08, 95% CI 0.00–1.45, one trial, 52 women);
- dyspareunia (average RR 0.77, 95% CI 0.48–1.24, two trials, 151 women);
- flatus incontinence (average RR 1.14, 95% CI 0.58–2.23, three trials, 256 women) between the two repair techniques at 12 months;
- quality of life;
- flatus incontinence at 36 months follow-up (average RR 1.12, 95% CI 0.63–1.99, one trial, 68 women);
- faecal incontinence at 36 months (average RR 1.01, 95% CI 0.34–2.98, one trial, 68 women).

Lower incidence of:

- faecal urgency (RR 0.12, 95% CI 0.02–0.86, one trial, 52 women);
- lower anal incontinence score (standardised mean difference [SMD] 0.70, 95% CI 1.26 to –0.14 [author check], one trial, 52 women) in the overlap group;
- deterioration of anal incontinence symptoms over 12 months (RR 0.26, 95% CI 0.09–0.79, one trial, 41 women) [A].¹³

For partial thickness EAS tears the new RCOG guidance recommends an end to end technique, avoiding figure of eight sutures. If the EAS tear is full thickness, either an overlap or end to end technique is acceptable with equal outcomes.

Whichever method is used it is important to ensure that the muscle is correctly approximated with long-acting sutures so that it is given adequate time to heal. In the case of 3b tears some practitioners advocate cutting the remaining fibres to perform an overlap repair.

The repair must be performed or directly supervised by a practitioner trained in the repair of third-degree and fourth-degree trauma. There must be adequate analgesia. In practice, this means either a regional or general anaesthetic, as local infiltration does not allow enough relaxation of the sphincter to allow a satisfactory repair. The lighting must be adequate and an assistant is usually needed. This means in practice that repair should usually be undertaken in the operating theatre, though if the prerequisites are met, repair in the room, after senior discussion is also reasonable.

Repair of the rectal mucosa should be performed first. 2:0 polyglycolic acid interrupted sutures with the knots placed on the mucosal side are commonly used and are less irritant than PDS sutures. Next, the layers of the internal sphincter should be replicated across the defect with interrupted sutures of 2:0 or 3:0 Vicryl or PDS. The torn external sphincter is then repaired. This should be re-approximated with either three or four figure-of-eight sutures, or an overlap technique.

A 2.0 or 3.0 polydioxanone suture (PDS) is ideal. Polyglycolic acid is also used. A single study comparing the two showed no difference in outcomes at 12 months [B]. However, the longer tensile retention of PDS and its monofilament characteristics make it especially suitable. Short half-life treated polyglactin sutures (Vicryl Rapide™) are not acceptable as they do not have a long enough half-life to ensure muscle healing. Also, non-absorbable sutures should not be used in the acute setting as these can form a focus for infection, requiring removal. The knots should be buried beneath the superficial perineal muscles, to minimise knot migration.

The remainder of the perineal repair is undertaken as for second-degree trauma. It is imperative to ensure that a good repair of the perineal muscles is performed, as a short or deficient perineum makes injury in future deliveries more likely.

Retention of urine secondary to the anaesthesia or repair is common and a urinary catheter should be inserted until spontaneous voiding is achieved.

Postoperative precautions

It is common practice after delayed anal sphincter repair to use a constipating regimen to allow the repair to heal before stools are passed. This is difficult in recently delivered women who have very different needs from those of the surgical patient. Constipative regimens have been compared with stool-softening regimens. It is concluded that constipative management leads to more pain and a longer postoperative

stay compared to stool-softening regimens, but with no difference in repair success. Lactulose and a bulk agent such as Fybogel are recommended for 5–10 days.

It is common sense to give a broad-spectrum antibiotic. There is only one randomised trial on this which showed a large reduction in wound breakdown. It is important to include an antibiotic that will cover possible anaerobic contamination, such as metronidazole. This should be prescribed orally rather than per rectum [C].

Adequate oral analgesia should be prescribed. Paracetamol, NSAIDs and opioid analgesia are acceptable. However, opioids used alone can exacerbate constipation, and thus the former should be used first. A laxative should be prescribed, but bulking agents avoided as they can exacerbate urgency.

Re-evaluate the thrombosis risk and provide appropriate thromboprophylaxis.

Before the mother goes home:

- ensure that she has had a chance to discuss the delivery with a senior member of the team;
- prescribe necessary analgesia and stool softeners;
- advise on perineal hygiene;
- counsel that 60–80 per cent of women will be asymptomatic following healing of the repair;
- provide a contact number in case problems occur;
- make an initial plan for short-term management with a physiotherapist;
- counsel that sutures occasionally migrate and fragments may be passed per vaginum or, occasionally, per rectum; help should be sought if there are concerns;
- give an appointment for follow-up at 6–12 weeks.

DOCUMENTATION

Clear written or electronic notes in black ink must be made following any perineal trauma. These must include:

- clear record of the extent of trauma (measurements are helpful);
- type of analgesia/anaesthesia;
- comprehensive notes of the procedure undertaken and suture material used (including evidence of anal sphincter examination);
- documentation of a swab and needle count before and after the procedure with the name of the second checker;
- estimated blood loss (measured ideally);
- post-operative instructions covering all aspects (fluid replacement, extra monitoring, antibiotics, thromboprophylaxis, stool softeners);
- pre-discharge instructions as necessary;
- follow-up needs.

The notes must be signed, with the date and time. The operator's name should be printed and a contact or pager number given if possible.

FOLLOW-UP

All women who have sustained a third-degree or fourth-degree tear should be offered follow-up by someone interested in this field. A team approach as outlined earlier is best. Physiotherapy should include augmented biofeedback, as this has been shown to improve continence.

At 6–12 weeks, a full evaluation of the degree of symptoms should take place. This must include careful questioning with regard to faecal and urinary symptoms. A standard questionnaire for women to complete before attending is helpful in precisely delineating the degree of symptoms. Symptomatic women should be offered investigation, including endo-anal ultrasound and manometry [C].

Asymptomatic women with low squeeze pressures and a demonstrable sphincter defect of more than a quadrant should be counselled regarding the pros and cons of future deliveries. Women with ongoing severe symptoms should be considered for secondary surgery. As pudendal neuropathy can take at least 6 months to improve, any further surgical intervention is best deferred until at least this time; however, in exceptional cases in which sphincter disruption is demonstrated and faecal incontinence is debilitating, surgery may be required earlier.

Women with mild symptoms should be advised to avoid gas-producing foods and bulking agents, and constipating agents and biofeedback offered.

Counselling about subsequent delivery

Women can be divided into one of three or four groups with regard to their next delivery.

Previous third-/fourth-degree tear, no ongoing symptoms

These women should be counselled that there is approximately a 5–7 per cent risk of further anal sphincter damage in a subsequent vaginal delivery. This recurrence is not predictable antenatally. Women who were transiently incontinent after their first delivery are particularly at risk of worsening of symptoms, and 17–24 per cent may develop worsening symptoms after subsequent delivery.¹⁴

When women opt for subsequent vaginal delivery, every effort should be made to avoid instrumental vaginal delivery. There is no evidence that episiotomy prevents muscle damage, and most women appreciate an intact perineum if that can be achieved. The second stage should not be prolonged. Women need careful counselling about epidural analgesia with reference to both the type of delivery and length of second stage. Where anal sphincter damage does not occur, new-onset symptoms are usually attributable to pudendal neuropathy, which usually improves with time. Transient flatus incontinence is reported by 10 per cent of women delivered without further sphincter damage.

Women who continue to be symptomatic

The majority of these women will have a demonstrable defect on ultrasound. There is a risk of worsening of symptoms,

which may then make life much more difficult. Women should be carefully counselled with regard to the additional effects of worsening pudendal damage and the small risk of further muscle damage. The majority of women in this group may opt for CS, but for those choosing vaginal delivery, every effort should be made to avoid operative vaginal delivery and lengthy second stage.

Women who have undergone a secondary anal sphincter repair

The consensus is that these women should be delivered by CS [E]. However, there are no data to advise women who wish to try for a vaginal delivery. Again, instrumental delivery and long second stage should be avoided where possible.

Women who are asymptomatic but have demonstrable anal sphincter defects or abnormal manometry on testing

This is a difficult group to manage, as there are few data to advise management. These women are at risk of new symptoms following subsequent delivery. Those at most risk appear to be women with a full quadrant defect, and these women may wish to choose CS next time [C].¹⁴

The plan for delivery must be clearly documented in the case notes.

PERINEAL TRAUMA AND FEMALE GENITAL MUTILATION

Female genital mutilation (FGM) is defined as all procedures involving partial or total removal of the external female genitalia or other injury to the female genital organs, whether for cultural or other non-therapeutic reasons. The practice of FGM is very common in parts of the Middle East and Africa but also to some extent in India and Indonesia. Somalia, Egypt and Sudan are the countries with the highest rates of FGM. It is important to note that the practice is not limited to particular cultural or religious groups and all women from areas of risk must be sensitively questioned and examined.

For most women, the procedure will have been undertaken when they were children. Some women may not have any recollection of the procedure, and for some women it will be seen by them as a normal thing to have happened. Many women experience physical and psychological damage for many years following FGM.

It is vital that questioning is undertaken with sensitivity. It is usually easier to refer to the practice as ‘cutting’ as most women understand what is meant by this.

The practice involves removal of parts of the female genital organs, including the labia minora, infundibulum, clitoris and, in some cases, the labia majora. It is important to

ascertain the extent of the FGM as complications are more likely with type III FGM.

Classification of types of FGM procedures (WHO) is as follows:

- Type I. Partial or total removal of the clitoris and/or the prepuce (clitoridectomy);
- Type II. Partial or total removal of the clitoris and the labia minora, with or without excision of the labia majora (excision);
- Type III. Narrowing of the vaginal orifice with creation of a covering seal by cutting and appositioning the labia minora and/or the labia majora, with or without excision of the clitoris (infibulation).
- Type IV. All other harmful procedures to the female genitalia for non-medical purposes e.g. pricking, piercing, incising, scraping and cauterising.

Piercing is part of this WHO classification and is classed at type 4 FGM. This is reportable to HSCIC (see below).

Ninety per cent of women who have undergone FGM will have types I, II or IV.

Under the 1985 and 2003 Acts in England and the Prohibition of Female Genital Mutilation (Scotland) Act 2005 it is illegal to perform FGM for traditional or ritual reasons, and is punishable by imprisonment for up to 14 years. It is also illegal to remove an individual to another country for the purposes of FGM. Interestingly, responsibility for decisions regarding surgical reduction of the labia for cosmetic/comfort reasons has been derogated to doctors. It is advised that where a doctor is unsure of the legal position of any request an ethical committee and a legal opinion should be sought and compliance with the FGM acts ensured.

If the unborn child, or any other child in the family, is considered to be at risk of FGM then reporting to social services or the police must occur.

FGM in a woman under 18 must be reported to the police within a month of detection, and if there is a family history of FGM, this must be recorded in the personal child health record (Red book) of the baby.

In the main, the issues seen with FGM are those related to the sequelae of the procedure. Type III is most often associated with physical problems, but all women are at risk of the psychological problems related to FGM.

Physical problems include:

- UTI;
- chronic inflammation and scarring;
- epidermoid and sebaceous cysts (which can become infected);
- fistulae;
- risk of blood born viruses (HIV, Hep B and C).

Psychological problems are common with one third to one half of women displaying symptoms of PTSD, depression, fear of childbirth and other anxiety states.

Obstetric complications are more likely with the more severe types of FGM. An increase in the rates of CS, PPH,

neonatal resuscitation and stillbirth are seen with types II and III FGM, with type III posing the highest risk.

In settings where high-quality intrapartum care is available FGM does not appear to lead to a longer second stage, but perineal tears and the need for episiotomy are much more common.

Additional screening for hepatitis C should be offered in early pregnancy.

De-infibulation pre-conceptually is the best option where this is likely to be needed.¹⁵

When women who are likely to have undergone FGM are seen in antenatal clinic it is vital that they are sensitively questioned and examined and that a careful plan of management is made for delivery. Psychological support should be offered. A discussion regarding whether de-infibulation is advised antenatally or intrapartum should be undertaken by a senior professional with experience in this area, and all women should be referred to the local specialist team.

Examination in clinic can determine whether de-infibulation is indicated. If the introitus is sufficiently open to permit vaginal examination and if the urethral meatus is visible, then de-infibulation is unlikely to be necessary. Usually a midline anterior episiotomy (division of the labia) is required. A catheter may need to be passed to identify the urethra when the anterior episiotomy is performed. A carefully placed posterior mediolateral episiotomy will be needed if there is rigid scar tissue. Great care must be taken when performing the posterior mediolateral episiotomy, as the presence of the scar tissue can lead to extensive tears if not appropriately managed.

Women should be informed that re-infibulation will not be undertaken under any circumstances. Perineal repair should be undertaken as for a woman without FGM.

Postnatal care should include regular inspection of the perineum to ensure healing, as poor or delayed healing is common.

Women who have had defibulation performed during pregnancy or delivery should be re-examined in any future pregnancy, as reinfibulation between pregnancies is not uncommon.

In response to the paucity of prosecutions since the law was enshrined, there has been a recent intercollegiate document produced to improve the awareness and understanding of responsibilities regarding women and children who have undergone, or who are at risk of, FGM.¹⁶ The nine recommendations are:

- 1 Treat it as child abuse. FGM is a severe form of violence against women and girls. It is child abuse and must be integrated into all UK child safeguarding procedures in a systematic way.
- 2 Document and collect information. The NHS should document and collect information on FGM and its associated complications in a consistent and rigorous way.
- 3 Share that information systematically. The NHS should develop protocols for sharing information about girls at risk of – or girls who have already undergone – FGM with other health and social care agencies, the Department for Education and the police.

- 4 Empower frontline professionals. Develop the competence, knowledge and awareness of frontline health professionals to ensure prevention and protection of girls at risk of FGM. Also ensure that health professionals know how to provide quality care for girls and women who suffer complications of FGM.
- 5 Identify girls at risk and refer them as part of child safeguarding obligation. Health professionals should identify girls at risk of FGM as early as possible. All suspected cases should be referred as part of existing child safeguarding obligations. Sustained information and support should be given to families to protect girls at risk.
- 6 Report cases of FGM. All girls and women presenting with FGM within the NHS must be considered as potential victims of crime, and should be referred to the police and support services.
- 7 Hold frontline professionals accountable. The NHS and local authorities should systematically measure the performance of frontline health professionals against agreed standards for addressing FGM and publish outcomes to monitor the progress of implementing these recommendations.
- 8 Empower and support affected girls and young women (both those at risk and survivors). This should be a priority public health consideration; health and education professionals should work together to integrate FGM into prevention messages (especially those focused on avoiding harm e.g. NSPCC 'Pants' Campaign, Personal, Social and Health Education, extracurricular activities for young people).
- 9 Implement awareness campaign. The government should implement a national public health and legal awareness publicity campaign on FGM, similar to previous domestic abuse and HIV campaigns.

Following this document there is now a legal requirement to report every case of FGM to the Health and Social Care information Centre via the enhanced dataset. This requires notifying of the patient in an identifiable form and must be discussed with the woman. There is also a legal requirement to inform the police and social care of FGM in any minor (under 18).

ACUTE HAEMATOMA

Incidence

The reported incidence of puerperal haematomas varies widely, ranging from 1 in 309 to 1 in 1500. However, large and clinically significant haematomas complicate between 1 in 1000 and 1 in 4000 deliveries.

Aetiological factors

Aetiological factors include:

- Episiotomy (85–90 per cent of cases);
- Instrumental vaginal delivery;
- Primiparity;
- Hypertensive disorders;
- Older mothers.

Multiple pregnancy, vulval varicosities, macrosomic infants and prolonged second stage have all been implicated, but their contribution is probably small.

In two thirds of haematomas, failure to achieve perfect haemostasis at the time of repair, particularly at the upper end of the incision, has been implicated. However, haematomas can occur without any perineal laceration, due to stretching and avulsion of vessels during delivery.

The anatomy of the perineum and vagina plays an important part in the limitation or extension of haematoma formation. Infralevator haematomas, most commonly associated with vaginal delivery, are limited superiorly by the levator ani, medially by the perineal body and from extension onto the thigh by Colles fascia and the fascia lata. These may extend into the ischioanal fossa. They usually arise from small vulvar or labial vessels, branches of the inferior rectal, inferior vesical or vaginal branch of the uterine arteries. They usually present as vulval pain out of proportion to that expected from an episiotomy, with an ischioanal mass and discoloration. Continued bleeding or urinary retention may also occur.

In contrast, supralelevator haematomas have no fibrous boundaries. They may be paravaginal or supravaginal. They arise from branches of the uterine artery, the inferior vesical and pudendal artery. Bleeding can track into the broad ligament, the retroperitoneal and presacral spaces. Thus they present as rectal pain and pressure, an enlarging rectal or vaginal mass or with hypovolaemic shock.

Broad ligament haematomas will cause upward and lateral displacement of the uterus. The uterus feels well contracted and there may be little revealed vaginal bleeding. As these haematomas are above the pelvic diaphragm; they are more rarely associated with vaginal delivery, although they can occur if genital trauma extends into the fornices or if a cervical tear is sustained. They may also occur in cases of uterine rupture or scar dehiscence.

Following delivery, the vulvar and paravaginal tissues are loose and oedematous. They can accommodate large amounts of blood before a haematoma becomes obvious and gives rise to symptoms (500–1500 mL). Blood loss estimation is therefore extremely difficult and it is usually grossly underestimated.

Presenting symptoms

Infralevator haematomas

- Vaginal swelling;
- Continued vaginal bleeding;
- Severe rectal/vaginal pain;
- Urinary retention.

If postpartum blood loss was moderate, bleeding into the haematoma may produce signs of shock.

Suprlevator haematomas

- Cardiovascular collapse;
- Uterine displacement;
- Abdominal or rectal pain;
- Continued vaginal bleeding.

Urgent MRI or CT scanning may help in the identification of supravaginal haematomas.

Management

Small, non-expanding haematomas of less than 3 cm can be managed conservatively. Larger or expanding haematomas require surgical management to prevent pressure necrosis, septicæmia, haemorrhage and death. Full maternal resuscitation in conjunction with anaesthetic colleagues is vital. Blood loss is likely to be significantly underestimated and early recourse to transfusion is necessary. As for repair of genital trauma, adequate analgesia, assistance and lighting are needed.

If the haematoma lies beneath a repair, this should be taken down. If no repair was made, an incision in the inferior portion of the mass near the introitus should be made. Clot is evacuated and the area involved is irrigated with saline. Individual bleeding points should be ligated, although it is more common to find diffuse ooze from very friable haemorrhagic paravaginal tissue. If the tissues allow, a layered closure or primary closure should be undertaken; however, the tissues are generally very difficult to place sutures into, as they are extremely friable. If sutures appear to be tearing out, closing the defect over a soft suction drain such as a Jackson–Pratt drain with a tight pack in the vagina for 12–24 hours may achieve the necessary reduction of dead space and control of bleeding. A urethral catheter will be needed, both to allow effective bladder emptying and to monitor urinary output. Prophylactic broad-spectrum antibiotics should be given, as the risk of subsequent infection is reasonably high and late problems are often attributable to infection. There must be a high index of suspicion if repeated symptoms occur, as the risk of recurrence in the first 12–48 hours is high (approximately 10 per cent). Special vigilance after pack removal is particularly important.

Large paravaginal and supravaginal haematomas can be much more complicated. Extension into the retroperitoneal space or broad ligament can be life threatening. The cervix should be carefully examined to assess cervical lacerations. This is best accomplished by grasping the cervix with a sponge holder, starting at 12 o'clock. A second sponge holder is placed at 2 o'clock and the cervix examined between the two. If intact, the first holder is moved to 4 o'clock. By working around the cervix in this way the whole circumference can be examined and tears identified. Tears must be repaired with full-thickness interrupted sutures, ensuring that the apex is identified. A combined vaginal and abdominal approach may be needed to evacuate clot, identify bleeding and secure haemostasis. An abdominal approach is always needed for tears of the cervix or upper vagina where the apex cannot be identified and

bleeding is occurring. **Ureteric injury can result from blindly placed deep sutures in the fornix.**

Internal iliac artery ligation, hysterectomy and radiological embolisation techniques have all been described to control intractable bleeding.

Careful observation in a high-dependency area is required for 12–24 hours, as recurrence of the haematoma may occur in up to 10 per cent of cases. These women are likely to have lost very large amounts of blood and the strategy for major obstetric haemorrhage should be followed. Early recourse to surgery, antibiotics and transfusion has improved maternal mortality in this life-threatening situation.

It is important that measures to reduce thromboembolism are not ignored in these women, as they have a high risk of thrombosis. Whilst many surgeons may wish to defer heparins until the risk of recurrence is lessened, other measures such as full-length thromboembolic stockings, compression boots and leg exercises can all be safely implemented without increasing the risk of recurrence.

KEY POINTS

- Episiotomy does not prevent third-degree and fourth-degree tears. Midline episiotomy increases the risk of such trauma.
- Perineal massage antepartum reduces the risk of third-degree and fourth-degree trauma in primiparae by a small amount.
- There are higher rates of ultrasonographically visible anal sphincter defects after forceps compared with ventouse, but no difference in maternal symptoms at 5 years.
- Leaving the perineal skin approximated but not closed is associated with less perineal dysaesthesia. If the skin is sutured, a subcuticular suture causes less short-term pain.
- A loose continuous repair without locking the vaginal component is associated with less short-term pain.
- Overlap is probably marginally superior to end-to-end approximation of the anal sphincter in repair of third-degree tears.
- FGM is illegal and the national guidance is that all cases should be reported. Local guidelines will exist as to how this is done.

Chapter 59 Perinatal asphyxia

Andrew Currie

MRCOG standards

- Candidates are expected to have undergone training in basic resuscitation.
- They are also expected to have undertaken training in counselling after perinatal loss.
- A full understanding of perinatal asphyxia, its causes and natural history, is expected.

INTRODUCTION

Perinatal asphyxia is an important cause of death and disability in the term neonate. Although the pathophysiology of the asphyxial process is understood, there are currently few interventions available that preserve brain function and few treatment modalities have been subject to RCTs. Mild therapeutic hypothermia has recently shown positive results and is discussed later in the chapter.

A number of clinical, biochemical and radiological markers of hypoxic–ischaemic damage are available, but their use in predicting outcome requires caution.

Perinatal asphyxia can lead to the neonatal condition called ‘hypoxic–ischaemic encephalopathy’ (HIE). Neonatal encephalopathies are a heterogeneous group of disorders clinically defined by a disturbance in the neurological function of the neonate in the early days of life. They are the result of a number of causes including hypoxic–ischaemic insults, metabolic disorders, sepsis, drug exposure, intracranial bleeds, neurological malformations, etc. Neonatal encephalopathies are usually grouped into mild, moderate or severe (or alternatively stage I, II and III) depending on the severity of symptoms and signs. These range from mild hyperalertness in very mild cases through to stupor, severe hypotonia, seizures and respiratory embarrassment in severe cases.

The most common single cause for neonatal encephalopathy is HIE, secondary to some perinatal asphyxial process. However, it is important to understand both from a clinical point of view and a medico-legal perspective that not all neonatal encephalopathies are the result of hypoxia or asphyxia and other causes should be ruled out, especially when the

clinical history is ambiguous. Thus, it is more appropriate to use the term ‘neonatal encephalopathy’ without ascribing a particular cause until appropriate investigations have been undertaken.

DEFINITION

The terms ‘birth asphyxia’ and ‘perinatal asphyxia’ are widely used to describe an intrapartum hypoxic–ischaemic insult in a term infant. However, the precise clinical definition varies, making interpretation of data on incidence, clinical manifestations and outcome difficult.

It is unclear if premature infants, with their immature CNS, exhibit the same responses to hypoxic–ischaemic insults as term infants. Preterm infants are of course at higher risk of cerebral insults outside the intrapartum period.

INCIDENCE OF HYPOXIC–ISCHAEMIC INJURY

The incidence varies depending on the definition used and whether preterm infants are included. The incidence appears to be higher in developing countries, although preterm infants are often included in published data. With improvements in antenatal and intrapartum monitoring, the incidence appears to have fallen in some published UK studies, from 6.0 per 1000 live births in the early 1980s¹ to 1.0 per 1000 live births in the mid-1990s. Subsequently, population surveys in the UK show the rates appear to have stabilised over recent years at around 1.2 per 1000 live births [C].²

PREVENTION

In order to prevent brain injury caused by hypoxia–ischaemia, there needs to be awareness as to when and under what conditions the injury might occur. Most available information relates to the detection of problems during the intrapartum period. However, it is clear that not all hypoxic–ischaemic

insults occur intrapartum and that many occur prior to labour and delivery [C].³ In recent years, major advances in antenatal assessment have been made and a number of tools for the antenatal assessment of fetal wellbeing are now widely used, including monitoring fetal movements, fetal heart rate, biophysical profiles, fetal growth and blood flow velocity in umbilical and fetal blood vessels (see Chapter 37, Tests of fetal wellbeing).

One group at particular risk of hypoxic–ischaemic brain injury is the preterm fetus. As well as the traditional methods of improving outcome delivered in the peripartum period (i.e. the administration of maternal betamethasone), there is increasing evidence that the maternal administration of a loading dose of intravenous magnesium sulphate (followed by a maintenance dose) significantly reduces long-term neurodevelopmental morbidity (RCOG Scientific Opinion Paper, No. 29, 2011).

The aim of intrapartum monitoring is to detect ‘fetal compromise’; this is often used as a marker for hypoxia–ischaemia. Detection of fetal compromise does not help in timing the hypoxic insult, as it may reflect the infant’s inability to mount a normal physiological response to an earlier hypoxic event. Intrapartum assessments of fetal wellbeing/fetal compromise include:

- monitoring of fetal heart rate, either intermittently or continuously;
- assessment of fetal acid–base status;
- passage of meconium *in utero*.

It should be noted that the detection of fetal compromise is a poor predictor of HIE or later cerebral palsy.

Once concerns have been raised regarding the wellbeing of the infant, in order to ensure optimum resuscitation, it is vital that communication is made to neonatal staff prior to delivery. It is essential that staff attending the delivery are appropriately trained in neonatal resuscitation and are given any relevant details in the maternal history that may affect resuscitation; for example, placental abruption, for which the infant may require blood during the resuscitation.

PATHOPHYSIOLOGY OF BRAIN INJURY

Perinatal asphyxia occurs when a lack of oxygen and acidosis cause organ impairment. Deprivation of oxygen to the brain can occur in two ways:

- 1 **hypoxaemia** – a reduction in the amount of oxygen in the blood;
- 2 **ischaemia** – a reduction in the amount of blood perfusing the brain.

Although brain injury occurs at the time of the hypoxic–ischaemic insult, it is now well established that neuronal damage is an ongoing process which starts at the time of the primary injury and following a ‘latent’ period continues, despite resuscitation, into the recovery phase (secondary injury).

This is supported clinically by the delay of up to 24–48 hours before typical signs of encephalopathy are observed, with further delays before radiological changes are seen on either ultrasound or MRI [C].⁴

Following a hypoxic–ischaemic insult, cell death occurs in two phases. The mechanisms involved are different and are influenced by the severity and nature of the original insult. The neuronal injury resulting from hypoxic–ischaemic insult in a term infant is ‘selective neuronal necrosis’. It is unaffected by resuscitation and occurs 5–30 minutes after the onset of ischaemia. Primary neuronal death predominantly affects the watershed areas of the cerebral cortex, is bilateral and usually symmetrical. Many neurons do not die during this primary phase; they do, however, appear vulnerable to further injury and death as a result of severe cerebrovascular dysfunction. This appears to trigger a series of biochemical events resulting in secondary neuronal death as a result of apoptosis. Evidence from animal and early clinical studies indicates that a therapeutic window exists between the primary and secondary phases when intervention may prevent secondary neuronal death and subsequently improve neurological outcome.⁵

AETIOLOGY

Perinatal asphyxia may be the result of an acute event or may occur as a result of chronic hypoxia (Box 59.1). It is important to note that in many cases no single factor is identified and that asphyxia may be caused by several antenatal factors or antenatal and intrapartum factors coexisting. It is difficult accurately to quantify the timing of hypoxic–ischaemic insults, as reported studies differ widely in their definitions, methodologies and inclusion criteria. It has been estimated that approximately 20 per cent of insults occur antenatally, 35 per cent occur intrapartum and, in a further 35 per cent, there are both antenatal and intrapartum factors involved.³ In the remaining cases, the timing is difficult to define. It is clear that despite differences in definition, intrapartum events contribute to a significant proportion of cases.

Box 59.1 Causes of and associations with perinatal asphyxia

Impaired maternal oxygenation

Maternal cardiovascular disease

Impaired uterine blood flow

Vascular disturbance, pre-eclampsia, diabetes

Maternal hypotension/hypovolaemia

Impaired placental function

Placental infarction

Abruption

Post-maturity

Infection

Impaired blood flow to cord, e.g. cord compression/prolapse

Abnormal fetal haemoglobin

Rhesus haemolytic disease

Twin-twin transfusion

Feto-maternal transfusion

Maternal drugs

Cocaine

Failure to establish adequate cardiopulmonary circulation after birth

Meconium aspiration

Congenital cardiorespiratory disease

CLINICAL FEATURES AND MANAGEMENT OF HIE

Despite the subjective nature of the scoring system, the universal method employed to assess an infant's wellbeing at birth is the Apgar score. Infants who have been exposed to a hypoxic insult will invariably have low Apgar scores beyond 1 minute; however, other factors not associated with asphyxia can also lower the Apgar score e.g. anaesthetic agents and prematurity. Despite this, there is good evidence that prolonged depression of the Apgar score is associated with death or major neurological disability [C].⁶

It is essential that personnel trained in neonatal resuscitation are present prior to the delivery of an asphyxiated infant. Resuscitation should establish a secure airway, ensure adequate oxygenation and restore circulation. Some severely affected infants will require endotracheal intubation and ventilation in the delivery room; however, others will require little in the way of initial resuscitation, but will deteriorate after the first 24 hours. Intravenous fluids, and in particular colloid, should be used with caution in restoring the circulation in severe asphyxia, the exception being where there is a clear history of antepartum haemorrhage or placental abruption; in such cases, O-negative blood should be administered in the delivery room.

If, despite appropriate resuscitation, there is no spontaneous cardiac output by 10 minutes or respiratory activity by 30 minutes, the outlook for both term and preterm infants is poor.

Post-resuscitation management

Infants who have experienced an asphyxial insult develop the clinical syndrome known as HIE. After resuscitation, the infant may be flaccid and unresponsive. The clinical signs progress over the first 24–48 hours before gradual improvement is seen. The severity of HIE can be graded clinically as mild, moderate or severe, as shown in Table 59.1.¹ The management after hypoxia–ischaemia is crucial, as the affected infant is still at risk of reperfusion injury.⁵ Transfer to a neonatal intensive care unit with facilities for cerebral and systemic monitoring is of the utmost importance. Full supportive care is required, with great attention to detail. As well as general intensive care, specific neurological monitoring and care should also be given.

General management

During episodes of hypoxia, blood flow is distributed in order to preserve blood supplies to vital organs, namely the brain, heart and adrenals. This leaves other organs, particularly the kidney, liver and gut, prone to ischaemic damage. With this in mind, blood pressure should be continuously monitored and hypotension avoided in order to ensure cerebral perfusion and to prevent further underperfusion of other organs. Hypotension is common and usually due to myocardial dysfunction rather than hypovolaemia. It should be treated promptly with volume expansion and/or inotropes as clinically indicated. Care should be taken not to overload infants with fluid, as acute tubular necrosis and inappropriate anti-diuretic hormone release are common sequelae. Maintenance fluids should be restricted by 25 per cent for the first 48 hours or so, based on regular clinical assessment of hydration, serum and urinary electrolytes, urine output and specific gravity and the infant's weight.

Asphyxiated infants are at risk of developing necrotising enterocolitis and therefore oral feeds should be introduced with caution. Prevention of tissue catabolism is important and thus nutritional support should be provided by parenteral nutrition until feeds are established.

Respiratory support with endotracheal intubation should only be undertaken if hypercapnia develops, if the infant has prolonged or frequent convulsions, or if there is coexisting respiratory disease. Hyperventilation is not recommended, as hypocapnia reduces cerebral perfusion and may compound the ischaemic insult. Respiratory support is guided by regular

Table 59.1 Clinical grading for HIE⁷

Grade I (mild)	Grade II (moderate)	Grade III (severe)
Irritability	Lethargy	Comatose
Mild hypotonia	Marked abnormalities in tone	Severe hypotonia
Poor suck	Requires tube feeds	Failure to maintain spontaneous respiration
Hyperalert	Seizures	Prolonged seizures

arterial blood gas analysis. Hypoxia should be avoided and the PaO₂ kept between 8 and 12 kPa (60–90 mmHg).

Neonatal meningitis may present in a similar way to HIE and therefore if there is any doubt, a lumbar puncture should be performed and treatment commenced. Routine antibiotics have no part to play in the treatment of HIE.

Disseminated intravascular coagulation is not uncommon in severe cases of HIE, and therefore regular assessments of clotting status should be made. Treatment includes additional vitamin K, platelets, cryoprecipitate and/or fresh frozen plasma infusions.

Neurological management

Much of the management after hypoxic–ischaemic insults has not been subject to RCTs. Probably the one major exception to this is the series of recent multicentre studies investigating mild hypothermia as a neuroprotective measure (see below under Therapeutic hypothermia for treatment of HIE).

In severe HIE, cerebral oedema and raised intracranial pressure (ICP) are commonly observed. Management strategies to lower ICP have included the administration of hyperosmolar agents and lowering PaCO₂. There is no evidence that hyperventilation and the ensuing hypocarbia are beneficial in reducing ICP, and therefore accepted practice is to maintain the PaCO₂ within the normal range [E].

The use of hypertonic saline has been shown to be beneficial in lowering ICP in animal models and in adults. Its use has not been evaluated in the neonate and it cannot be recommended. There is no evidence for the use of mannitol, furosemide or steroids in the treatment of cerebral oedema in neonates.⁷

Seizures are a salient feature of HIE. Frequent and prolonged clinically evident seizures should be treated promptly with anticonvulsant(s). Phenobarbital is the drug of choice, as recent evidence suggests that the use of phenytoin, diazepam or chloral hydrate confers no benefit [A].⁷ Anticonvulsants can be stopped once seizures are controlled. The use of early prophylactic phenobarbital as a ‘neuroprotector’ in HIE has been subject to a meta-analysis, which concluded that routine use is not recommended in perinatal asphyxia [A].⁸

Glucose metabolism in HIE has been extensively studied and yet is still not fully understood. Normoglycaemia should be maintained, as there is evidence that both hypoglycaemia and hyperglycaemia may worsen brain injury.

New neuroprotective strategies

A number of new neuroprotective strategies have evolved in recent years.^{5,7} Most have been used in animal models, with only a few trials in the human neonate. The rationale behind these interventions is in the prevention of reperfusion injury. Interventions have included magnesium sulphate, calcium channel blockers, allopurinol as a free radical scavenger, the Chinese herb *Salvia miltiorrhizae*, naloxone and hypothermia. Of these alternatives, selective hypothermia is the only strategy that has shown positive results.

Therapeutic hypothermia for treatment of HIE

As mentioned earlier, neuronal cell death is the result of a combination of primary and secondary cellular energy failure. There is little that can be done to prevent primary neuronal cell death; however, between these two phases there is a latent period of several hours which may serve as a therapeutic window to prevent the secondary energy failure.

There is clear evidence that fever on top of HIE results in a worse outcome.⁹ In addition, a number of animal studies have shown that cooling ameliorated the delayed energy failure and inhibited neuronal cell apoptosis. As a result, over recent years, a number of large clinical trials have taken place studying the effects of therapeutic hypothermia in HIE. A recent meta-analysis of these studies has concluded that induced mild hypothermia to a core temperature of 33.5°C resulted in a reduction in the combined outcome of mortality and neurodevelopmental disability at 18 months in term infants with moderate or severe HIE. As a result of this and a more recent multicentre clinical study confirming these results, it is generally agreed that therapeutic hypothermia should be offered in cases of moderate and severe HIE.

The treatment is primarily a preventative strategy treatment, so it is important that cooling is commenced as soon as HIE is suspected, and ideally within 6 hours of birth before clinical evidence of secondary neuronal cell death (such as seizures) appears.

INVESTIGATIONS

Continuous integrated single-channel EEG monitoring is now in widespread use and is very useful both from a clinical treatment point of view and prognostically.

The value of neuroimaging is limited in the first 24–48 hours of life. Ultrasound evidence of lesions in the thalami and basal ganglia, focal infarctions and changes in periventricular white matter are usually seen after the first 48 hours of life. Their presence before this suggests an antenatal insult.

MRI is useful in asphyxiated infants. Early scans characteristically show brain swelling and abnormal signal intensity within the basal ganglia, periventricular white matter, subcortical white matter and cortex. Late MRI findings associated with poor outcome include delayed myelination as a marker for neuronal loss and extensive white matter changes.

OUTCOME

Determining the outcome after perinatal asphyxia is difficult for a number of reasons:

- the definition of asphyxia varies;
- there is variation in the outcomes assessed – mortality, motor, behavioural, etc.;
- there is varied inclusion/exclusion of preterm infants;
- the age at time of assessment varies.

What is clear, however, is that the neurological outcome depends on the severity of the insult. It is well recognised that term infants with grade I HIE (mild) have no long-term developmental problems, whereas severe HIE is associated with a poor outcome. It is more difficult to predict the outcome of moderate HIE as there are few readily available reliable markers of long-term impairment. One early predictor of adverse outcome is the severity of the neurological abnormalities found on clinical examination, particularly in association with discontinuous activity on EEG. Severe acidosis associated with poor Apgar scores, multi-organ failure and encephalopathy immediately after birth are also markers of poor outcome [C].¹⁰

The major neurological sequelae in surviving infants are motor deficits and, in particular, spastic quadriplegia and dyskinetic cerebral palsy. There may also be associated visual or intellectual impairment or epilepsy. It is important to note that not all cerebral palsy is the result of perinatal asphyxia and not all asphyxiated infants develop cerebral palsy [C].¹¹

SUMMARY

- Phenobarbital is the drug of choice for convulsions secondary to HIE.
- There is as yet no evidence to support routine seizure prophylaxis in infants with HIE.
- Most infants with severe HIE will develop neurological sequelae. Most infants with mild HIE will have no long-term sequelae. Infants in the moderate category remain the most difficult in whom to predict outcome.
- Therapeutic hypothermia has been proven to improve outcomes in HIE and should be offered as early as possible as part of these infants' intensive care.

KEY POINTS

- Most cases of HIE have an intrapartum element.
- However, not all infants with HIE develop cerebral palsy, and not all children with cerebral palsy demonstrate HIE.
- Damage due to HIE occurs in two phases: the initial insult and then further reperfusion injury (primary and secondary cellular energy failure).
- Damage is usually symmetrical and affects watershed areas.
- A persistently depressed Apgar score is generally associated with poor outcomes.
- Mild therapeutic hypothermia is now recognised as an important part of the management of moderate to severe HIE.

ACKNOWLEDGEMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of Sandie Bohin to the chapter on this topic in the previous edition of the book.

Chapter 60 Neonatal resuscitation

Andrew Currie

MRCOG standards

Candidates are expected to:

- have a full understanding of how labour impacts on neonatal condition at birth, including maternal drugs;
- have detailed knowledge of neonatal resuscitation;
- be able to initiate basic resuscitation;
- have attended a course or training session on neonatal resuscitation.

INTRODUCTION

Health professionals involved with childbirth should be capable of providing life support to the newly born when the need arises.

To facilitate this, various professional bodies have been developed, including the UK Resuscitation Council, the European Resuscitation Council and the International Liaison Committee on Resuscitation (ILCOR).¹⁻³ Each professional body has produced guidelines and training programmes to improve resuscitation practices.

Much of resuscitation procedure is based on 'best practice', with very little evidence-based medicine to support it. This is hardly surprising given the ethical dilemmas that would be created by trying to perform RCTs of resuscitation techniques.

This chapter concentrates on the essential steps required to provide safe and appropriate resuscitation to the newborn. It draws on recommendations from the above resuscitation bodies and, where possible, the evidence is reviewed.

INCIDENCE

Most studies show that approximately 90–95 per cent of all births require no resuscitation. The other 5–10 per cent need some form of respiratory support, with possibly up to 1–2 per cent requiring full cardiopulmonary resuscitation.⁴

PHYSIOLOGICAL CHANGES

Many physiological adaptations occur to the infant at birth.⁵ The most important involve the cardiovascular system, respiratory system and thermoregulatory mechanisms.

Respiratory

In utero, the lungs are full of fluid (30–35 mL/kg in term infants). Pulmonary pressures are suprasystemic, thus reducing blood flow to the fetal lung. To adapt to extrauterine life, lung fluid production reduces near term. In addition, the mechanics of birth include the birth canal exerting an immense extrathoracic pressure on the infant during its descent, squeezing lung fluid from the trachea and upper airways. With delivery, a natural 'recoil' of the airways (along with the infant's first respiratory efforts) helps to inflate the lungs. Subsequent breaths become progressively easier, due to development of a functional residual capacity and improving lung compliance. Dispersal of surfactant to form a monolayer within the alveolar system further improves lung mechanics by lowering surface tension and ensuring alveoli remain open, even in expiration.

Cardiovascular

Major features of the fetal cardiovascular system include high pulmonary pressures and a series of three anatomical right-to-left shunts.

- 1 The ductus venosus carries blood from the placenta back to the fetus (effectively connecting the umbilical vein to the inferior vena cava).
- 2 The foramen ovale is important in diverting blood from the right atrium to the left, thus bypassing the lungs.
- 3 The ductus arteriosus diverts blood from the pulmonary artery to the aorta.

Following birth, the pulmonary pressures fall. This is as much to do with changes at a cellular level (including the effects of cytokines, prostaglandins and the influence of endogenous nitric oxide) as with the mechanics of lung inflation.

The ductus venosus closes soon after clamping of the umbilical cord, with establishment of the normal venous circulation. The fall in pulmonary pressures allows greater blood flow into the pulmonary circulation. This increases the blood volume returning to the left atrium, with consequent closure of the foramen ovale and increased systemic pressures; these in turn reverse the shunting across the ductus arteriosus. The ductus arteriosus subsequently closes under the influence of increasing oxygen concentrations and prostaglandins. As a result, the normal neonatal circulation is established. The conversion of the fetal to the neonatal circulation may take several days to complete.

Thermoregulation

The infant is born naked and wet into a hostile environment. Immature thermoregulatory mechanisms can lead to cold stress with serious morbidity, such as acidosis, hypoglycaemia and respiratory distress. Equally, pyrexia may be as dangerous, studies showing that it worsens cerebral hypoxic injury.⁶ Hence an essential part of neonatal resuscitation is maintenance of a normal body temperature.

AETIOLOGY

Many causes have been associated with a potentially compromised infant at birth. These can be divided into maternal, fetal and intrapartum. A list of the more common is shown in Box 60.1.

Box 60.1 Common causes for a compromised newborn infant

Maternal

Chronic ill-health
Drug ingestion (legal and illegal)
Hypertension
Diabetes mellitus
Anatomical abnormalities
Placenta praevia

Fetal

Multiple pregnancies
Prematurity
Post-term (>42/52)
IUGR
Congenital abnormalities
Liquor disturbances (oligohydramnios/polyhydramnios)
Hydrops
Isoimmunisation
Intrauterine infection

Intrapartum

Fetal distress
Abnormal presentation
Prolapsed cord
Antepartum haemorrhage
Prolonged rupture of membranes
Thick meconium
Instrumental deliveries

MANAGEMENT OF THE RESUSCITATION

Basic principles (fundamental to optimise patient outcome)

- As with any resuscitation, the ABC (airway, breathing, circulation) approach is the most appropriate. The vast majority of neonatal 'arrests' are primarily due to respiratory problems. Hence, heavy emphasis is placed on ensuring an adequate airway and efficient ventilation delivery to the child.
- Good preparation is essential to optimise clinical management.
- Resuscitation of the newborn is a team approach. Clear communication is essential.
- The ability to assess a situation and act accordingly on a regular basis is crucial. The ability to use basic knowledge in a safe, logical and adaptive manner makes resuscitation of the patient a more rewarding process.

Preparation

Good preparation is as important to a successful outcome as the actual resuscitation itself. Preparation involves more than getting equipment ready.

Medical history

Accurate medical information is invaluable. Although a detailed medical history is ideal, time is often against this. It is vital to establish key facts quickly.

Useful questions that may influence the actual resuscitation process include the following:

- How many infants should we expect? This will dictate numbers of personnel and amount of equipment, as well as help inform likelihood of complications.
- What is the gestation? While the basics of resuscitation remain the same, priorities and expectations will differ and may influence the approach taken.
- Are there any congenital anomalies (e.g. congenital diaphragmatic hernia)? Specific conditions do influence the approach taken to resuscitation.

- Has the mother had any relevant medication in the last few hours (e.g. opiates)? This may affect the infant's response to resuscitation.
- Has there been any meconium prior to delivery? Again, this will influence the approach taken to the resuscitation procedure (see below under Meconium).

Personnel

All workers involved in birth should be able to provide basic neonatal life support, and regular updates of skills should be undertaken. Ideally, somebody trained in advanced neonatal life support should also be readily available.

Resuscitation is a team event. Individuals should understand their roles. Ideally, two to three people make an effective team: one to look after the airway, one to look after the cardiovascular circulation and the third to assist with drugs, fluids and additional equipment. One person should take the role of leader; this ensures clarity of the roles and efficient team working.

Other important tasks that may be delegated in the acute situation include informing neonatal unit staff who will be looking after the infant following resuscitation and communicating with the parents, who need to be informed of events as early and fully as possible.

Communication and documentation

Often, the source of mishaps and complaints is poor communication. In addition, poor documentation makes post-hoc reviews very difficult. The importance of accurate information gathering, documentation and communication cannot be emphasised enough. Accurate timing must be recorded and all records (midwifery, obstetric and neonatal) should be consistent. In the acute situation, if sufficient staff are available, one team member should be asked to keep a record of times and procedures.

Environment

A brightly lit, warm and draft-free room is ideal. As well as reducing morbidity due to heat loss, an appropriate environment ensures that attendants can see and assess the infant.

The infant's temperature should be kept in the normothermic range. Hyperthermia is associated with increased neuronal damage in cases of perinatal hypoxia. In the normal situation hypothermia is equally associated with increased morbidity, particularly in the premature infant. However, multicentre trials in recent years have shown that induced mild hypothermia in the early hours after birth is neuroprotective in term infants with moderate or severe perinatal asphyxial hypoxia.⁷ These studies managed infants with core temperatures at 33.5°C for up to 72 hours.

It is speculative to relate these studies to the acute resuscitation when often the clinical picture is unclear; however, it has become accepted practice to turn off the radiant heater on the resuscitaire as a means of passively cooling a term infant in the

presence of possible perinatal hypoxia. Despite this it should be the case that for most situations the recommendation remains that during the acute resuscitation of the newborn maintenance of normothermia, and certainly prevention of hyperthermia, should be the rule [E].⁷

Equipment

Having the right equipment, which is reliable, is paramount to a successful resuscitation. Box 60.2 shows a list of essential equipment.

Within the hospital setting, all essential equipment is found on a resuscitaire – best described as a mobile, open cot. The heat and warmth sources are located above a firm, flat surface. A clock is attached. There are usually two sources of oxygen (piped and cylinders), with two outlets. Air supplies should also be available on resuscitaires. Studies have indicated that resuscitation with air is as effective as oxygen⁸ in term infants [A]. There is also increasing concern about the detrimental effects of hyperoxia to the lungs and eyes in the preterm infant. Thus, it is now felt that the initial approach to resuscitation of the newborn should be with the use of air and only if there is a poor response to this should introduction of oxygen be considered. The availability of an air/oxygen blender to better manage the concentration of oxygen used is considered to be a better approach.

Box 60.2 Essential equipment for neonatal resuscitation

Equipment

Light source
 Source of warmth (heater and/or warmed linen)
 Flat surface (±firm mattress)
 Clock
 Suction apparatus (able to deliver suction up to 100 mmHg)
 Suction catheters
 Oxygen supply
 Ventilation system (either 'bag-valve-mask' or 'facemask and T-piece', or both)
 Oxygen saturation monitor
 Endotracheal tubes (various sizes from 2.5 to 4.0 mm internal diameter)
 Introductory stylet
 Fixation kit for endotracheal tube
 Laryngoscopes (with straight blades and spare bulbs)
 Oropharyngeal airways
 Nasogastric tubes
 Umbilical venous catheters
 Scalpel
 Intravenous cannulae
 Intraosseous cannula
 Syringes and needles
 Fluids and medications

Suction apparatus is intrinsic in the resuscitaire. The rest of the equipment should be readily available, stored in various drawers mounted on the resuscitaire.

The resuscitaire should be situated in the delivery room. Fluids and medications may or may not be stored with the resuscitaire. If not, they should be in a readily accessible place for emergency use.

It is the responsibility of the individuals using equipment for resuscitation to ensure that they are competent with its use and that it is working properly. All resuscitation equipment should be checked daily, as well as before and after each use.

THE RESUSCITATION PROCESS

This section assumes birth is taking place in a maternity suite with a resuscitaire; however, the principles can be applied to any setting.

Fig. 60.1 shows a step-by-step approach. Each step is explained in more detail below.

Step 1

With the birth of the whole baby, the clock is started and the infant is transferred to the resuscitaire. The infant is placed with the head in the 'neutral position', towards the resuscitator. The neutral position involves the head being placed so that the eyes are looking directly upward. This position helps maintain airway patency.

The infant should be kept warm. For the term infant and larger preterm infant, this may be achieved by drying with a warm towel. A vigorous, not aggressive, rub with the towel serves the dual purpose of drying the infant and stimulating breathing. The infant is then wrapped in a second warm towel. Evidence indicates that for the premature infant in the delivery suite (less than 30 weeks' gestation) heat loss is best managed

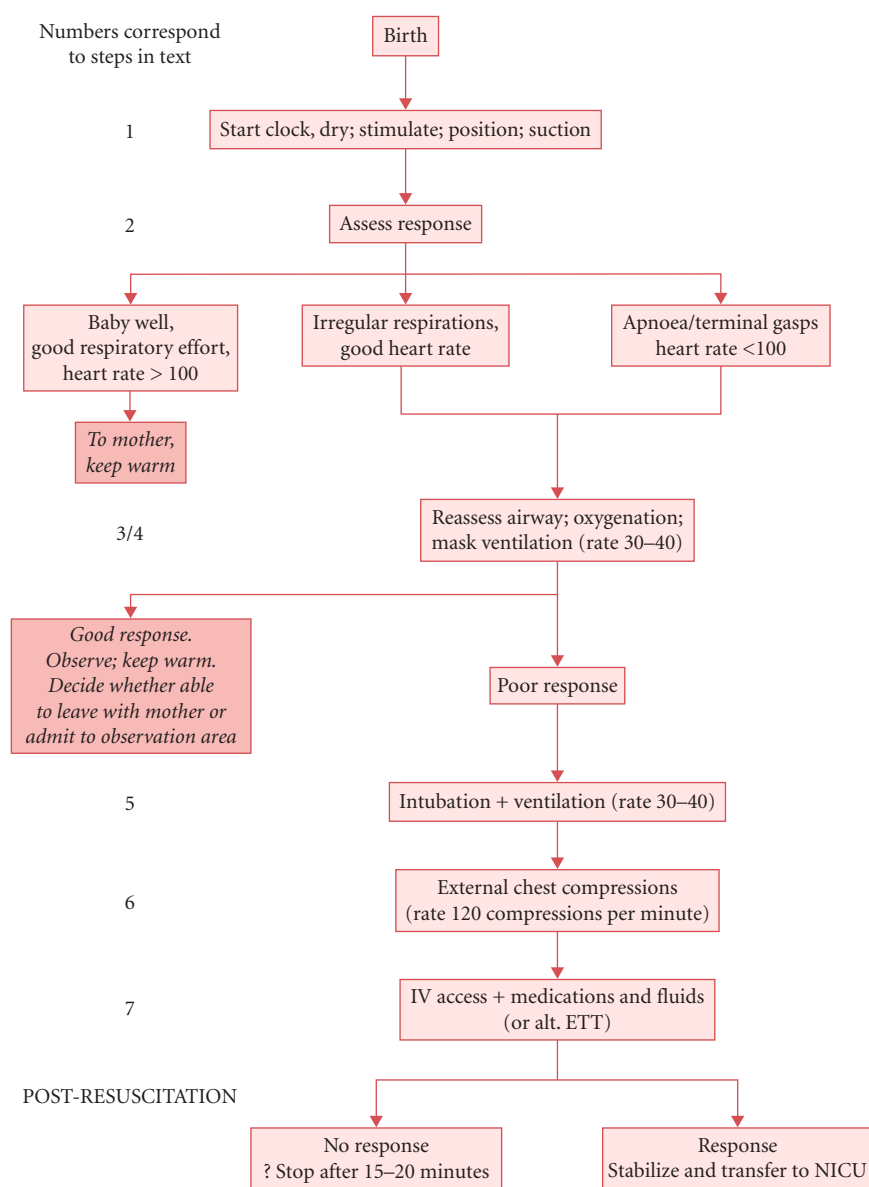

Fig. 60.1 Neonatal resuscitation in the delivery room. ETT, endotracheal tube.

by placing it directly into a plastic bag, without drying, under a radiant heat source.

The airway must be correctly positioned and also needs to be clear. Babies have secretions in their oropharynx at birth. Assuming these are not copious and the infant is vigorous, the infant will clear them independently. Routine oropharyngeal suctioning is to be avoided [E].

Infants with excessive secretions, or those with thick meconium (see below under Special situations) and/or blood, need suctioning. A suction catheter can be placed in the oropharynx; care must be taken not to push the catheter too far back, and some authorities advocate not inserting it further than 5 cm. A suction pressure of 100 mmHg is appropriate. Excessive toileting of the oropharynx causes reflex bradycardia and laryngospasm.

These initial steps should take no more than 20–30 seconds.

Step 2

The infant is then assessed. Initial assessment should include heart rate, respiratory effort and colour. This should have occurred by 30 seconds of age.

Assessment (and reassessment) is vital to a successful outcome. Many workers use the Apgar score (Table 60.1) to aid them. This was originally described by Virginia Apgar, an anaesthesiologist, in 1953. Whilst this is a useful tool, it has its limitations. Apgar scores are carried out at 1 minute and 5 minutes of life. Further scores may be done at 5-minute intervals depending on subsequent progress. It is an internationally recognised assessment tool, giving an indication of the neonate's condition after birth. However, it would be inappropriate to delay resuscitating an apnoeic infant with a profound bradycardia at birth, while waiting for a low 1-minute Apgar score.

From the initial assessment, the infant will fall into one of three groups.

- 1 Well, healthy and vigorous. The child has a good respiratory effort, is pink centrally, and the heart rate is >100 bpm. This infant can be wrapped up and given to the parents.

- 2 Cyanosed, poor respiratory effort, with or without a heart rate <100 bpm. This infant needs further intervention.
- 3 White, apnoeic or terminal gasps, with absent heartbeat or profound bradycardia (<60 bpm). This infant needs full intensive resuscitation.

If the child's condition is still a cause for concern, the previous interventions should be checked.

- Is the airway clear and positioned correctly?
- Has the child responded to stimulation?

Step 3

The person resuscitating the infant must ensure the airway is patent before proceeding, as without this any further resuscitation steps will be futile. Manoeuvres which are useful to learn include the one-person or two-person jaw thrust. Both of these are used to lift the tongue up and help open the oropharynx by lifting the lower jaw forward (with the infant lying supine) so it juts just above the upper jaw. Remember the most common cause for an obstructed airway in the newborn is loss of muscle tone and the tongue falling backward.

Another useful technique is the use of a Guedel airway. The easiest way of selecting the right size airway is by measuring the Guedel from the angle of the jaw to the middle of the jaw. This is then placed in the mouth using a laryngoscope blade to lift the lower jaw and tongue and passing the Guedel airway over the blade.

Once the operator is happy the infant's airway is patent, the infant's response should be reassessed. If there is still concern with their breathing, ventilation should be commenced.

Indications for ventilation are:

- an apnoeic infant, or one with gasping respirations despite the above interventions;
- an infant that remains cyanosed despite adequate oxygen delivery.

At this stage in the resuscitation, the infant should be no more than 1 minute of age. This is time enough to know if simple interventions are going to work, without causing further insult by undue delay.

Ventilation is performed either with a bag–valve–mask (bvm) apparatus or a facemask plus T-piece connector.

- The bvm is attached to a gas supply (air plus oxygen) and should have a reservoir bag attached. This helps to increase the concentration of oxygen to near 100 per cent if needed. (In practice it is probably nearer 60–80 per cent with a refill bag, as opposed to 30–40 per cent without; 100 per cent oxygen concentration is difficult to achieve with bvm devices due to leakage at various points.) It is recommended that 500 mL bags be used to aid efficient delivery of ventilatory breaths. These devices have a 'pop-off' valve, which is set to between 20 and 30 cmH₂O. (The 'pop-off'

Table 60.1 Apgar scoring system

Parameter	Score		
	0	1	2
Heart rate	0	<100	>100
Breathing	Apnoeic	Irregular	Good
Colour	White	Blue	Pink
Muscle tone	Floppy	Some movement	Active
Reflex response	None	Grimace	Cough, cry, sneeze

valve reduces the risk of excessive peak pressures, which could cause overinflation.) The facemask is applied over the nose and mouth. For neonates, a circular facemask forms the best seal. Positive pressure is applied by squeezing the bag fully, then allowing it to reinflate before the next breath.

- The facemask plus T-piece is also attached to an appropriate air and oxygen supply. Again the facemask is applied over the nose and mouth to form a seal. Above the facemask is a hole over which the resuscitator's thumb is applied to create a positive pressure. The peak pressure can be set using a pressure gauge.

Both techniques are easily learnt, although the T-piece plus facemask probably results in more reliable delivery of a set positive pressure compared to the bvm technique. Certain types of T-piece plus facemask apparatus can also deliver positive end-expiratory pressure (PEEP), which is advantageous in helping to create and maintain a functional residual capacity.

When starting ventilation, five 'rescue' breaths should be administered. These are more sustained breaths, designed to overcome the high airways resistance present in the lungs of the infant who has not breathed. This is much easier to achieve using the T-piece plus facemask technique, in which the thumb can be applied for 1–2 seconds at a set pressure. With the bvm technique, prolonged breaths are difficult to achieve, but higher pressures can be applied by locking the 'pop-off' valve (NB: this should only be done by an experienced operator).

Following these initial rescue breaths, the infant's response should be assessed. If there is still concern regarding respiration, regular ventilation should be commenced. This is delivered at a rate of 30–40 breaths per minute, with each breath lasting approximately 0.5 seconds. The peak pressure should be set to achieve adequate lung expansion without overdistension. Clinically, this can be assessed by chest movement, breath sounds, colour and heart rate, as well as improving spontaneous respiratory effort. Ventilation should be stopped once good, spontaneous, respiratory effort is achieved.

Step 4

Next, use of supplementary oxygen may be considered.

Studies in recent years looking at use of air vs oxygen for resuscitation have questioned the previously long-accepted 'best practice' of using 100 per cent oxygen for resuscitation. Animal and clinical trials indicate that resuscitation with air in the term infant is as effective as 100 per cent oxygen and may even be advantageous [C].⁹ Concerns exist relating to the effects of oxygen on the respiratory centres, as well as its direct effects on lungs by means of free radical production. Such effects are even more contentious in the preterm infant. As a result it has become accepted practice to commence resuscitation using air and then add oxygen if there is a poor response. It is important to ensure the airway is patent and good ventilation technique is being applied before using oxygen.

To help with this step, application of an oxygen saturation monitor to the right hand in the newborn can be very helpful.

Remember the oxygen saturations in the well newborn term infant will gradually rise from approximately 60 per cent at birth to over 90 per cent by 10 minutes of age without the use of supplemental oxygen.

Recent guidelines from ILCOR and the UK Resuscitation Council have emphasised the importance of adequate airway and ventilation, leaving the decision to use oxygen to be considered depending on the clinical situation [E].³

Step 5

After another 30–60 seconds of facemask ventilation, if there is still inadequate response, endotracheal intubation for more efficient ventilation should be considered.

Indications for intubation include:

- poor respiratory effort despite appropriate interventions as above;
- thick meconium at delivery;
- anticipated need for long-term ventilatory support.

Intubation is achieved using a straight-bladed laryngoscope held in the left hand and an endotracheal tube held in the right hand. The laryngoscope blade size can be chosen to suit the infant. Thus a size 1 blade is suitable for term infants, whereas a size 0 is better suited to preterm infants. A size 00 is available for extremely premature infants with small mouths.

The blade is inserted into the mouth in the midline and the laryngoscope is pulled forward and upward, thus bringing the lower jaw and tongue up and forward until the uvula is visible. At this point it may be necessary to suction the oropharynx using a suction catheter in the right hand. The blade is then advanced over the back of the tongue into the venecular and pulled forward. This elevates the epiglottis, revealing the glottis and vocal cords. It should be remembered that the larynx in the newborn is more 'floppy' than in adults, hence to aid vision, external downward pressure over the cricoid cartilage may be needed to help bring the vocal cords into view. An alternative technique is to place the laryngoscope in the oropharynx as far as it will go, pull the lower jaw and tongue forward and upward to maximise vision and then gradually withdraw the laryngoscope until the epiglottis slips into view, with the vocal cords visible below. This is quicker, but can be more traumatic if not performed carefully.

Once the vocal cords are visualised, the endotracheal tube can be inserted. There is a choice between a straight-sided and a shouldered endotracheal tube (Coles tube). The shouldered tube is stiffer, to help intubation. An introductory stylet can be used to help stiffen whichever endotracheal tube is used.

For resuscitation purposes, oropharyngeal intubation is best practised [E], as this is simpler and quicker than nasopharyngeal intubation – a technically more demanding skill.

Once the endotracheal tube has been positioned, the ventilatory circuit can be attached and ventilatory breaths delivered. Adequate air entry should be confirmed (equal chest movement, breath sounds, appropriate colour and heart rate). If there is any doubt about whether the tube is in the correct

position, it should be removed and the infant ventilated with a facemask system whilst the situation is reassessed.

The act of intubation should take no longer than 20–30 seconds from the time of inserting the laryngoscope blade in the mouth until the endotracheal tube is attached to the ventilatory circuit. While performing this action, the infant is effectively being asphyxiated, thus undue delay is unacceptable.

Endotracheal intubation should not be attempted by inexperienced practitioners without appropriate supervision.

Ventilation breaths are delivered at a rate of 30–40/minute, the same as for mask ventilation. Slightly higher rates (up to 60 breaths/minute) may be used for premature infants.

Once intubation has been established, the practitioner must be alert to potential complications, such as a blocked or displaced endotracheal tube, equipment failure and pneumothorax.

Step 6

Once the airway and breathing have been addressed, the next step is to assess the circulation. The heart rate and pulses should be checked. Useful sites include the base of the umbilical cord or brachial pulse, as other pulses can be difficult to elicit. Infants with a heart rate of <60 bpm which have not responded to appropriate ventilation require external chest compressions. This is performed by depressing the lower half of the sternum by one third of the antero-posterior diameter of the chest. In practice, for most infants this equates to 1–2 cm.

Chest compressions can be performed either using both thumbs over the lower sternum, with the hands wrapped around the chest, or by placing the index and middle fingers over the lower sternum. It is more important that appropriate sternal compressions are performed, regardless of which technique is preferred. A rate of 120 chest compressions per minute (two per second) should be attained. If ventilation is being undertaken at the same time, a ratio of three chest compressions to one breath is appropriate. Chest compressions should be stopped once the cardiac rate is >60–80 bpm.

Step 7

This step involves vascular access, use of medication and volume expansion.

- Vascular access may be needed for advanced resuscitation. Use of the umbilical vein is the quickest and most effective means of achieving access. An umbilical catheter, primed with 0.9 per cent saline, should be inserted to a depth of approximately 5 cm. Alternative forms of access include the use of peripheral intravenous cannulae (but only if a peripheral vein is readily accessible) or an intraosseous needle. The endotracheal tube can also be used for quick access for certain medications (e.g. adrenaline).
- Medication:

- Adrenaline (epinephrine) is probably the most important medication available. It can be given via any route, most commonly intravenous or endotracheal. The recommended dose is 0.1–0.3 mL/kg of 1:10,000 solution (or 10–30 µg/kg). Following administration, 1–2 minutes of ventilation and chest compressions are performed. This dose may be repeated every 1–2 minutes. Higher doses (i.e. 100–300 µg/kg or 0.1–0.3 mL/kg of 1:1000 solution) are no longer recommended as there is no evidence that this is beneficial and, indeed, some studies suggest higher doses of adrenaline may be detrimental to the infant [B].³
- Sodium bicarbonate remains controversial. It may be useful in prolonged resuscitations when sustained cellular acidosis may affect myocardial contractility. If used, administration should be limited to a 4.2 per cent solution in aliquots of 1.0–2.0 mL/kg intravenously. The aim is to improve acidic conditions in the heart and thus improve myocardial contractility, as well as facilitating the beneficial effects of adrenaline.
- Naloxone may be used in the infant with respiratory depression as a result of maternal intrapartum opiate analgesia. The dose is 200 µg intramuscularly. Naloxone is not a substitute for appropriate resuscitation, which should always take precedence. Also, it is best avoided in infants of drug-dependent mothers, as it can result in a severe withdrawal state in these infants. Finally, the caregiver should note that naloxone has a shorter half-life than most opiates and doses may need to be repeated.
- Dextrose. Hypoglycaemia is a major problem in prolonged resuscitations. Hence, small aliquots of dextrose may be required. A dose of 2–3 mL/kg of 10 per cent dextrose should be adequate.
- Use of volume replacement.
- Blood. If there is any suggestion of haemorrhage, O-negative blood should be used: 10–20 mL/kg can be given as a bolus and the response assessed.
- For other causes of circulatory disturbance, volume replacement with a crystalloid or colloid can be useful in the resuscitation scenario. The dose is again 10–20 mL/kg. Following a Cochrane review¹⁰ that found the use of albumin to be detrimental, most authorities recommend crystalloids, such as 0.9 per cent saline [A].

Glucose solutions must not be used for volume replacement.

POST-RESUSCITATION

Continuing care

Once the infant has been successfully resuscitated, it is essential that provision for ongoing care be provided. This may simply involve handing a well infant to the mother to keep

warm and feed, with attendants available to ensure there is no deterioration, or transfer of the sick infant to a NICU for ongoing intensive care.

Before any transfer, the infant should be reassessed clinically. All lines, including endotracheal tubes, intravenous cannulae, nasogastric tubes and monitoring leads, should be secured. The need for ongoing medication and fluids should be considered.

Comprehensive documentation, including interventions, responses and subsequent management plans, should be completed and signed legibly. The family should be fully informed of events.

Discontinuing care

Unfortunately, not all resuscitation attempts are successful and the decision to stop resuscitative attempts can be extremely difficult. As a guide, it is appropriate to consider discontinuing attempts if there is no spontaneous circulation by 15 minutes [E].

Non-initiation of resuscitation

This can also be a contentious issue and it is important that units develop guidance in this area. Most practitioners would accept that it is inappropriate to routinely attempt resuscitation in infants less than 23 weeks' gestation or 400 g birth-weight. Equally, it is ethically acceptable not to resuscitate infants with lethal anomalies, such as anencephaly or trisomy 13 and 18.

In cases of uncertainty, an alternative approach is to commence resuscitation, and withdraw intensive care only once more information is available. However, it should be remembered that both withdrawal and withholding of intensive care are ethically equivalent.

With such decisions, the family should be fully informed and involved, as they will have to live with the consequences.

SPECIAL SITUATIONS

Extreme prematurity

These infants have much greater difficulties due to their immature physiology. Their lungs are poorly developed, lack surfactant and have poor lung compliance. They thus experience greater degrees of respiratory distress. Many infants less than 30 weeks' gestation require early ventilation, with administration of surfactant. Indeed, some practitioners advocate 'elective' intubation of all infants less than 28 weeks. This has become contentious with greater awareness of the damage caused by barotrauma and oxygen toxicity.

Premature infants have a much greater surface area to body mass ratio, and thus lose heat much more quickly than term infants. Their cardiovascular systems are also immature, with

poor autoregulation of the cerebral circulation. Care should be exercised when administering volume expanders.

The major practical differences in the approach to resuscitation of a premature infant include: use of a sterile plastic bag and a radiant heat source instead of drying with warm towels; consideration of elective early intubation and administration of surfactant to minimise lung injury; and special attention to avoid excessively high oxygen concentrations. Oxygen saturation monitors can help with the aim of keeping oxygen saturations below a maximum of 95 per cent.

Meconium

Whereas it was previously taught that all infants with meconium present prior to delivery should have their airway viewed and suctioned under direct vision, it is now accepted that this approach can be detrimental in the majority of cases [A].¹¹ As a rule, infants born in good condition with good respiratory effort do not require airway visualisation or oropharyngeal suctioning. Infants with depressed respiratory effort at birth should have their airway inspected and cleared prior to any other resuscitative efforts. The aim of this is to prevent inhalation of any meconium into the lungs of the compromised infant, as this can cause mechanical problems with breathing, as well as a chemical pneumonitis.

Hydrops

The main problem at birth, regardless of the cause, is the presence of large effusions (pleural, pericardial and peritoneal). These often need draining as a matter of urgency at delivery. Probably the quickest method is the use of an 18 or 20 FG cannula attached to a syringe. This can be advanced into the effusion to be drained, while maintaining gentle negative pressure on the syringe. As soon as fluid is aspirated, the cannula should be advanced over the needle, which is removed. In this way, the cannula can act as a temporary drain until a more permanent one can be inserted.

Congenital diaphragmatic hernia

At birth, the major concerns relate to the degree of lung hypoplasia and amount of bowel and other abdominal content in the chest. Early control of the infant's ventilation in addition to preventing the infant swallowing air and thus inflating the stomach in the chest is generally felt to be best practice. To this end, the infant may be best managed with early intubation and muscle relaxation soon after birth. A large-bore nasogastric tube is inserted to keep the bowel empty.

Owing to lung hypoplasia, caution with positive pressure ventilation must be exercised to prevent pneumothorax.

Nitric oxide ventilation and extracorporeal membrane oxygenation can be used for intensive care and should be considered early in management, depending on the infant's response.

Congenital cardiac disease

Management depends on the lesion. There are too many to discuss in this chapter, except to say that infants with duct-dependent lesions should be commenced on a low-dose prostaglandin infusion early after birth. Otherwise, for the purposes of early neonatal resuscitation, there is no need for other special measures.

Polyhydramnios

The main difference over the usual resuscitation process in this circumstance is to exclude a possible oesophageal atresia by inserting a large-bore nasogastric tube.

SUMMARY

This chapter briefly discusses the process of resuscitating the newborn infant. It emphasizes the ABC approach, with a need for continual appraisal of a situation. It should be stressed that the vast majority of infants require no, or minimal, intervention. Equally, for those who do need help, most problems are related to the respiratory system, and attention to detail with regard to the airway and ventilation will be all that is required.

- Resuscitation should initially start with managing temperature control and ensuring a patent airway [E].
- In the term baby, air is as good as 100 per cent oxygen for resuscitation and may have additional benefits [B].
- High doses of adrenaline are no longer recommended as they confer no additional advantage and may be detrimental [C].

KEY POINTS

- The vast majority of infants need nothing more active than keeping warm at birth.
- Nearly all neonatal resuscitations involve respiratory failure as the primary event.
- Optimizing airway patency is the most important part of neonatal resuscitation.
- Always remember the ABC approach.
- Do not forget to keep the infant warm.

ACKNOWLEDGEMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of Sandie Bohin to the chapter on this topic in a previous edition of the book.

Chapter 61 Common neonatal problems

Andrew Currie

MRCOG standards

There are no defined standards relevant to this topic. However, a candidate would be expected to know the following:

- How to examine a healthy newborn infant, and thus distinguish between this and a sick infant.
- How to give simple advice regarding feeding regimens.
- What to expect from a well newborn infant in the early days of life.
- How to proceed when faced with a non-life-threatening problem in the term infant.

INTRODUCTION

Most babies are born healthy and remain so throughout their lives. However, they can develop a number of common problems which, while not necessarily life threatening, may nonetheless cause significant morbidity and parental anxiety.

This chapter introduces the reader to the most common problems encountered at or shortly after birth, concentrating in the main on those relating to the term fetus/neonate.

At the end of this chapter, there is a brief summary of the more complicated problems associated with prematurity.

INCIDENCE

There are no reliable figures relating to how often paediatricians are asked to review infants for anything other than a newborn check.

Infants requiring paediatric input fall into two main groups. The first group comprises those that require acute care. These infants are primarily seen within the delivery suite

shortly after birth. Paediatricians are called either to the resuscitation or for acute problems such as ‘the grunting infant’.

The other group comprises infants seen on the postnatal wards. They are usually several hours of age, and any concern is less acute. Table 61.1 summarises an audit of common, non-life-threatening problems seen within one unit during a one-year period, and gives an indication of the concerns paediatricians are asked to respond to on the postnatal wards. The birth population was approximately 5500 births per year. Routine newborn examinations and acutely ill infants have been excluded.

It can be seen from this table that many common problems in the newborn period are not serious health issues, but nonetheless can cause considerable morbidity and anxiety.

Table 61.1 Numbers of infants presenting with common problems on the postnatal wards over a 12-month period, in a birth population of 5500 per year

Clinical condition(s)	Total number
Hips	213

Skin lesions	31

COMMON NEONATAL COMPLICATIONS PRESENTING IN THE FIRST 24 HOURS

Respiratory/grunting (transient tachypnoea of the newborn)

One of the most common problems that paediatricians review is acute respiratory embarrassment. Tachypnoea and 'grunting' are the most common concerns. 'Grunting' is the descriptive term given to the noise made by forced expiration against a closed glottis. It is essentially a sign of alveolar disease: the alveoli do not open adequately, hence the infant tries to open them by increasing his or her intrathoracic pressure. Most commonly, 'grunting' and tachypnoea are caused by excess lung fluid, which has not fully cleared following birth. These signs usually appear within the first few hours after birth and settle within 24–48 hours. The infant is otherwise well and observation is usually all that is required. This condition is often referred to as transient tachypnoea of the newborn (TTN). It must be remembered that this is a diagnosis of exclusion. More serious conditions, such as sepsis, aspiration, pneumothorax or respiratory distress syndrome, should be excluded. The signs of acute respiratory embarrassment are the same for many aetiologies;¹ thus, such infants should be seen by a paediatrician. If the signs are not settling quickly (i.e. within a few hours), if they worsen or if there are other risk factors in the history, the infant should be admitted to a neonatal unit for further investigation and management. This complication is common among babies delivered by elective caesarian section (CS), with as many as 15 per cent of neonates being affected [B].¹

Hypoglycaemia

This subject causes much anxiety and continues to generate much controversy.² It is now accepted that many newborn infants go through a period of relatively low blood glucose levels shortly after birth. Assuming they are otherwise well, they can utilise alternative fuel sources, such as ketones and lactate, in the short term. This means that for term infants of average birthweight, it is unnecessary to monitor blood glucose and start invasive treatments. They should be left alone to establish breast- or bottlefeeding normally. The importance of hypoglycaemia is to identify and treat the 'at-risk' infant. Examples include:

- preterm infants (<36 weeks);
- growth-restricted babies;
- the infants of diabetics;
- infants with perinatal asphyxia;
- septic infants;
- infants with inborn errors of metabolism.

In these groups, a blood glucose <2.6 mmol/L is generally accepted to indicate hypoglycaemia [E]. Any infant presenting with low blood glucose must be carefully examined for

the underlying cause and treated accordingly. The treatment of hypoglycaemia involves the administration of glucose. In the well infant, feeding with milk should be the first-line treatment. If this is not successful, or if there are indicators to suggest the infant is unwell, intravenous dextrose may be needed (a 10 per cent solution should be used initially). It may be necessary to give intravenous bolus doses (small boluses of 2–3 mL/kg of 10 per cent dextrose, followed by an infusion). All infants requiring additional glucose should be admitted to a neonatal unit.

Hypothermia

This can be defined as a rectal temperature <36°C. It is most commonly seen in growth-restricted and preterm small infants, or as part of the clinical picture in the sick infant. Newborn infants are born exposed and wet, and can lose heat very quickly if not dried and covered adequately. Hypothermia can cause significant morbidity; infants are lethargic and feed poorly. More seriously, hypothermia is associated with hypoglycaemia, metabolic acidosis and respiratory distress.

The septic infant may also present with hypothermia rather than pyrexia. Hence, when dealing with the cold newborn, the first concern is to look for the underlying cause. Once this has been dealt with, specific measures to warm the child include a warm environment (this may seem obvious, but it is often found that delivery rooms are environmentally unfriendly for the newborn infant), drying the infant adequately and dressing him or her in warm clothes (including skin-to-skin contact with the mother and warm towels and covers), and the use of a radiant heater or warming mattresses. For extreme hypothermia, more invasive measures, such as reheating with warmed plasma expanders or exchange transfusions with warmed blood, have been used. However, it is debatable whether these convey any benefit over the use of a radiant heater and warming mattress.

Fractures

These are not common. Fracture of the clavicle is the most frequently seen, followed by the humerus, femur and skull bones. Fractures usually result from traumatic deliveries, for example in association with shoulder dystocia and difficult instrumental deliveries [D].³ However, this is not inevitably the case and certainly the medical literature gives examples of apparently unexplained fractures.

Clavicular fractures are best treated conservatively and have an excellent prognosis. Mild analgesia may be helpful.

Fractures of long bones may require some form of simple splinting to immobilise the limb and thus reduce pain.

Skull fractures are more serious, and the possibility of underlying haemorrhage must be considered.

The majority of neonatal fractures will heal uneventfully with conservative treatment.

Cephalohaematomas

These result from bleeding between the periosteum and skull bones, and take the shape of the underlying skull bone. As they resolve, they may exacerbate jaundice, and the possibility of associated injury (such as skull fracture or intracranial bleeding) should be ruled out. Most cephalohaematomas are benign and resolve without problems. During resolution, the swelling may increase in size; this is usually due to fluid shift into the haemorrhage by osmosis as the clot breaks down. The carers should be warned of this, as it can cause concern.

Nerve palsies

Erb's palsy and facial palsy are the most common nerve palsies. Erb's palsy is due to damage to the brachial plexus (cervical roots C5, 6 and 7), and is commonly associated with traction on the neck and shoulders during difficult deliveries,³ although cases occurring in infants delivered by CS have been reported. The result is usually a flaccid arm held in a pronated and internally rotated position. Recovery rates vary according to different studies. Between 49 and 94 per cent make a full recovery, with most improving by 12 months of age.⁴ Early physiotherapy can help, and surgical treatment techniques to repair damaged nerves are now available for those cases that do not resolve spontaneously. Such cases should be referred early.

Facial palsies are commonly ascribed to obstetric manoeuvres, such as the use of forceps causing pressure damage; however, facial palsies also occur in infants delivered normally.³ Most are probably the result of external pressure causing a lower motor neuron injury, and the prognosis is excellent. If an upper motor neuron lesion is suspected, the infant should be investigated for possible cerebral injury or congenital disorders. There is no specific treatment required.

Sternomastoid tumours

These are the result of bleeding into the sternomastoid muscle. They are not normally recognised at birth, and do not become obvious until a few weeks of age. Physiotherapy is required to prevent contracture of the muscle. The prognosis is good.

Traumatic cyanosis

This is a petechial rash present over the face and head, and may extend to the upper body, although the rest of the child is usually spared. It is probably the result of venous congestion, resolves spontaneously and is only of importance because it has been mistaken for true cyanosis. Simple reassurance is all that is required.

Lacerations

Occasionally, the infant may suffer skin lacerations during delivery, usually during CS. They are usually superficial and heal without problems. Suturing or use of steri strips may be needed for deeper wounds.

THE NEWBORN EXAMINATION

This is included in this chapter because it plays a major role in the care of the newborn. It entails a clinical examination of the infant, carried out in the first week of life. It is meant as a screening health check, although there has been much controversy concerning its usefulness. At least 80 per cent of mothers find it a useful and reassuring process.⁵

It is probably not worth performing this examination within the first 24 hours of life, as there is a high chance of both false-negative and false-positive findings. Equally, assuming the infant is well, a 24-hour interval provides a chance for the infant to recover from the stresses of birth, and allows bonding to occur.

The newborn examination should be performed in a well-lit, warm room to prevent the exposed infant getting cold.

As with all medical examinations, it helps to have a routine system. By convention, the neonatal check is performed from the head and working down. Auscultation of the heart is opportunistic, as the infant needs to be quiet. A full explanation of the examination process would be lengthy, and the reader is referred to any of the standard textbooks of neonatology for this. A few points to remember include the need for proper hand hygiene when examining infants, and that the infant should not be left exposed for prolonged periods of time. It is often best to leave the nappy area until last. As part of the newborn check, parents should be asked about the passage of urine and stool, as well as any feeding concerns. In addition, a check should be made of the weight and head circumference. Increasingly, early neonatal pulse oximetry is used as part of the examination to screen babies for both undiagnosed cardiac (i.e. congenital heart disease) and non-cardiac (i.e. occult infection) anomalies. This test has very good sensitivity and specificity of diagnosis.⁶

COMMON NEONATAL PROBLEMS PRESENTING ON THE POSTNATAL WARD

Feeding

This is a huge subject and is one of the most common causes of anxiety in mothers.

There are two methods of feeding infants: breastfeeding and the use of formula milk feeds. Breastfeeding is clearly the best choice for a number of reasons, including the following:

- it adapts to the infant's nutritional needs;
- it has anti-infective properties;
- it helps with bonding;
- it helps the mother lose weight;
- it aids contraception;
- it is convenient and free.

However, there are a few problems associated with breastfeeding. Contrary to many mothers' preconceptions, breastfeeding is not always established readily. This can lead to a sense of failure and to the abandonment of breastfeeding if no support is available. Ill and preterm infants do not readily feed. In this situation, facilities should be available to help with the expression of breast milk until such time as the child is ready to suckle. There are often concerns about milk volumes; these are usually helped by support and reassurance. Test weighing has previously been used to try to quantify the amount of milk an infant is getting; however, this is not only unhelpful, but indeed can be positively detrimental to breastfeeding as it often instils a further sense of failure in the mother.

Other problems include concern about inverted nipples, cracked nipples, engorged breasts, overfeeding and weaning. These concerns should be easily addressed with the right support and information. Mastitis can also cause problems, but is not a reason to stop breastfeeding. Antibiotics or non-steroidal anti-inflammatory drugs (NSAIDs) may be indicated. There are very few contraindications to breastfeeding. Probably the most common are chronic ill-health in the mother (such as cystic fibrosis), potential infective risk (e.g. HIV in developed countries), acute ill-health in both the mother and infant, and certain metabolic disorders in the infant (such as phenylketonuria and galactosaemia).

Artificial feeding with formula milk is the alternative. Problems specific to this include:

- poor preparation of feeds;
- inadequate sterilisation;
- cost.

Other problems common to both methods include problems with sucking and swallowing coordination. These may be due to anatomical factors, such as cleft palates or large tongues, as well as physiological factors, such as immaturity of the sucking reflexes.

Vomiting can be a major problem, and is most commonly due to gastro-oesophageal reflux. Assuming that the infant is well and growing, reassurance is usually all that is needed. Examination to exclude other causes of vomiting, such as pyloric stenosis and sepsis, should be performed. Failure to thrive is often due to feeding problems, but usually presents later in life. Bilious vomiting is pathological until proven otherwise, and should always prompt the search for a cause.

Urine/stools

It is not uncommon for neonatologists to be asked to review an infant who has either not passed urine or not opened his/her bowels. Either situation is usually benign. A detailed history, including review of the antenatal progress and birth, is important. The external genitalia and anus should be examined as part of the assessment.

Most infants pass urine within the first 24 hours. This is often missed if it occurs at the time of birth. If there is any doubt but the infant otherwise appears well, it is worth placing cotton wool ball(s) in the nappy. An infant who has not passed urine within the first couple of days or in whom there is any other concern may need further investigation to exclude either obstruction (such as posterior urethral valves in males) or renal disease.

An infant who has not opened his or her bowels within the first 2–3 days should also be reviewed. Obstruction due to anal atresia should be obvious shortly after birth; however, conditions such as anal stenosis and Hirschprung's disease are easily missed if not considered. Investigation in such situations may involve gentle rectal examination, radiological tests and possibly rectal biopsy. Advice should be sought from a neonatologist and/or paediatric surgeon.

Weight loss

It is normal for infants to lose weight in the first week of life. This is predominantly due to water loss. Breastfed infants tend to lose slightly more weight than bottlefed infants. By 1 week of age, infants should start putting weight on. The average weight gain is 20–30 g/day in term infants. Weight loss in excess of 10 per cent is unusual and needs further investigation. There is a long list of causes of excess weight loss, ranging from inadequate intake, through inadequate nutritional content, to feed intolerance and ill-health.

Skin lesions

Skin lesions are a common cause of concern in the otherwise well newborn. They include the following:

- *Birthmarks* such as the flammeus naevus (or 'stork mark') and port wine stains. It should be noted that strawberry birthmarks do not appear until a few weeks of age. Another birthmark is the Mongolian blue spot (very common in Asian and Afro-Caribbean babies), which consists of blue macules found over the back and is caused by melanocytes in the deep dermal layers.
- *Skin defects*, such as the aplasia cutis lesion. This is a congenital absence of the skin over the scalp. It usually has a punched-out appearance, with a healed edge, and it is important to distinguish it from trauma. These lesions usually heal spontaneously, by granulation. Plastic surgery, when the child is older, is required for larger lesions.

- **Rashes.** Common rashes include erythema toxicum neonatorum, a red maculopapular rash, which comes and goes in the first few days and is of no clinical significance. Miliaria may also cause concern; this rash is caused by obstruction of sweat glands. Pustular rashes are common; most are sterile, but possible infection needs to be excluded. Nappy rashes include napkin dermatitis and candidiasis, both of which are very common and cause considerable anxiety.
- **Skin tags.** These can occur anywhere on the body; common sites are around the ears, anus and vagina. Pre-auricular skin tags have classically been associated with renal disorders, although the evidence is tenuous.

Facial problems

- **Clefts of the lip** are usually obvious at birth. With better antenatal screening, many are now diagnosed on antenatal ultrasonography. The possibility of an associated chromosomal disorder should be considered, although most are independent of any other disorder. Although cosmetically they may look very abnormal, the surgical results are excellent. Parents need careful counselling from an early stage, including the use of 'before and after surgery' photographs for reassurance. During the neonatal period, the main concern is one of feeding, and referral for specialist advice at an early stage is paramount.
- Isolated **clefts of the palate** are almost never detected antenatally. They may be detected at a newborn check or can present in the early neonatal period as difficulty in feeding, apnoeas, choking episodes, poor feeding and chest infection. They are often associated with syndromes, and a meticulous neonatal examination should be performed. Referral to a geneticist may be indicated if there are other dysmorphic features. The specialist cleft lip and palate centre should be involved at an early stage.
- **Soft palate defects** can be particularly difficult to diagnose and may not be detected until late in childhood. They can result in feeding problems, as well as speech difficulties, and it is thus important that the palate is visualised to the back of the mouth, as well as palpated as part of the newborn examination.

Orthopaedic

- **Talipes** ('club foot') is a common referral for paediatric assessment. It is important to differentiate between fixed talipes and positional talipes. The former needs referral to orthopaedic surgeons and physiotherapy, whereas the latter is of no consequence and the parents can be reassured.
- Examination of the **hips** is performed to detect dislocation. The hip should be held in a flexed, slightly internally rotated position, between index finger and thumb,

while the knee is stabilised within the palm of the hand. The hip is then downwardly displaced to see if it can be dislocated. It is then externally rotated and upward pressure is exerted on to the outer trochanter of the hip with a view to reducing a dislocated hip. These are essentially the Ortolani and Barlow manoeuvres and are designed to diagnose a dislocatable or dislocated hip (in which case a 'clunk' should be felt). This is to be distinguished from a clicky hip, which is usually either due to poor examination technique or lax ligaments around the joint. Dislocated and dislocatable hips need referral to the orthopaedic team. Ultrasonography is useful to discriminate where there is uncertainty. It is also indicated in babies at greater risk of dislocated hips (breech deliveries, positive family histories). The use of double nappies is no longer recommended.

Accessory digits

It is not uncommon for infants to be born with accessory fingers and toes. Most of these are pre-axial and not associated with any other problems. The infant should be thoroughly examined for other anomalies. Most accessory digits are attached by a thread of skin, and are easily dealt with by tying off with a suture. Those with thicker bases should be referred to a plastic surgeon.

Surgical

- **Hernias.** Common hernial sites include the umbilicus and inguinal canal. Umbilical hernias are easily reducible and usually resolve spontaneously. They are more common in Afro-Caribbean and Asian infants. Inguinal hernias are more serious. They are up to six times more common in males than females and there is an increased incidence of complications in the newborn. Early referral to a paediatric surgeon for operative correction is advised. Premature infants more commonly develop inguinal hernias than term infants.
- **Bilious vomiting** always needs investigating; although it may be innocent, the risk of intestinal obstruction or other serious pathology must be considered.
- **Hydrocoeles** are due to fluid accumulation in the scrotum as a result of incomplete closure of the processus vaginalis. They can be differentiated from inguinal hernias because it is possible to get above them and they transilluminate. Most hydrocoeles resolve spontaneously.
- **Hypospadias** occurs in approximately 1:300 male infants. It is characterised by a congenitally short urethra that opens on to the ventral surface of the penis, an abnormally formed foreskin, and chordee of the penis. Referral to a paediatric urologist is required. The parents should be advised not to have the child circumcised, as the foreskin is vital in any reconstructive surgery. The possibility of

chromosomal abnormalities (especially sex chromosome problems) needs to be considered in severe cases.

- *Undescended testes* are common in the newborn male. Most are unilateral, and reassurance that descent will occur is all that is required. If the testicle has not descended by one year of age, referral to a paediatric surgeon is warranted. Bilaterally undescended testicles are much more unusual and require further investigation to exclude underlying disorders, such as intersex or hormonal disorders of the pituitary–adrenal–testicular axis.

Genetic

Paediatricians are commonly asked to review an infant whose appearance has given cause for concern. Most of the time, simple reassurance is all that is required. However, in all cases the child should be carefully and thoroughly examined. There are many dysmorphic features – too numerous to list here. In cases where doubt exists, further advice should be sought from a clinical geneticist. Chromosomal tests, as well as other investigations (dictated by the presenting condition), may be needed. It is important that the parents are carefully counselled. If doubt exists, this should be explained, to avoid erroneous conclusions being made.

Eyes

- The vast majority of *sticky eyes* are due to blocked tear ducts; simple toileting with lukewarm sterile water and cotton wool or gauze is all that is required. If the discharge persists, or is particularly copious, infections should be considered, and a swab sent for microbiological culture and sensitivity. The eyes should then be treated with topical antibiotics. Staphylococcal infections are the most common and are usually successfully treated with either topical gentamicin or neomycin. Chloramphenicol eye drops are also available and popular, but can mask chlamydial infection. Chlamydial infection should be considered if the discharge is copious or persistent. *Chlamydia* requires special culture mediums to grow, and is treated with chlortetracycline eye ointment plus systemic erythromycin.
- Congenital *cataracts* are rare. The newborn check is designed to detect them by looking for the normal red reflex with an ophthalmoscope. If a cataract is present, the red reflex will be absent, or partially obscured, depending on the size of the cataract. In this situation, urgent referral to an ophthalmologist is required. With early intervention, it is possible to improve subsequent vision.

Cardiac murmurs

Heart murmurs are a common finding in newborn infants; however, most cardiac murmurs in the newborn are innocent flow murmurs – these are especially audible in the first days

of life. As a general rule, identification of a cardiac murmur should lead to a careful clinical examination, an ECG and measurement of limb oxygen saturations in the right arm and lower limbs (i.e. pre-ductal and post-ductal oxygen saturations). The majority of infants will be found to have a soft systolic murmur (i.e. with a grading of 1–2/6), a normal cardio-vascular examination, no significant change in pre-ductal and post-ductal oxygen saturations, and a normal ECG. These infants can be reviewed in 4–6 weeks, as the chance of a significant cardiac lesion is very small. Parents should be warned of the small risk of a cardiac defect; if they have any concerns, such as the child getting breathless, tired, not feeding or going blue, they should seek medical advice urgently.

Infants who do not meet these criteria should be referred to a paediatric cardiologist for further investigation.

Maternal group B streptococcal infection

It is generally accepted that infants of group B *Streptococcus* (GBS) carriers are at greater risk of infection. However, quantifying that risk is difficult. Equally, given the high carriage rate amongst the normal population (estimated between 30 and 50 per cent), it is difficult to ascertain the best treatment approach.

GBS disease is divided into early and late onset.

Early-onset GBS disease is caused by passage of the infant through the genital tract in a carrier mother (many women are carriers and few babies are affected). It may present as:

- a clinical picture which mimics severe perinatal asphyxia;
- severe respiratory failure at birth;
- signs of early neonatal sepsis, such as temperature instability, lethargy, irritability, respiratory signs and tachycardia.

It is a neonatal emergency with potentially life-threatening consequences.

Universal pregnancy screening programmes and the use of prophylactic antibiotics are not recommended in the UK (see Chapter 44).

In an attempt to identify at-risk babies, it is recommended that infants born to mothers who are GBS carriers and have one or more of the following features deserve special attention:

- previous infant born with GBS disease;
- spontaneous onset of premature labour;
- prolonged rupture of membranes;
- evidence of invasive GBS disease in the mother.

If mothers are given sufficient antibiotics early enough in the labour, the infant should be adequately covered [A].⁷

If this does not occur, or the infant is in any way unwell, he or she should be screened and treated with intravenous antibiotics. Subsequent management will depend on the clinical course and the results of cultures.

Late-onset GBS disease is probably related to infection after birth from a carrier mother. It can be present days or weeks later, most commonly with pneumonia or meningitis.

Renal

In addition to determining whether or not a baby has passed urine (see above under Urine/stools), other renal problems usually relate to infants who have been found to have renal anomalies during antenatal ultrasound screening. Assuming the infant is well, repeated scanning can be performed within the first few weeks of life; many anomalies will have resolved. If there are continuing abnormalities, further investigation is required to delineate the nature of the anomaly.

Infants with significant bilateral renal anomalies on antenatal ultrasound (e.g. bilateral dysplastic, cystic kidneys or bilaterally dilated ureters) need more urgent investigation. They should also be monitored for failing renal function.

Metabolic

The Guthrie test is a screening test performed on all newborn infants within the first week of life. It involves the collection of blood drops from a heel prick, and screens for:

- hypothyroidism;
- phenylketonuria;
- cystic fibrosis (in certain parts of the UK, immunoreactive trypsin levels are measured).

In addition, a few parts of the UK are also using the test to screen for sickle cell disease and medium-chain acyl-coenzyme A dehydrogenase deficiency (MCAD). The test should be performed once the infant has been established on feeds for a few days.

Sacral dimples

Sacral dimples are a common finding, usually at the base of the spinal column. It is also important to ask about bowel actions and urine excretion and to check the lower limbs for normal movements and power. Assuming the base is easily seen and there are no other abnormalities, simple reassurance is all that is required. If the base is not visualised, or if the sacral dimples are larger than 0.5 cm diameter or associated with other features, such as tufts of hair, ultrasound investigation and paediatric review are indicated.

The most commonly associated problem is tethering of the spinal cord, which usually presents later in life.

Umbilical cord

The umbilical cord is a common source of concern. The cord stump usually falls off within a few days.

- The most serious problem is one of *infection*. It is common for the cord stump itself to become colonised with commensal organisms, resulting in a 'sticky' or 'smelly' cord stump. Assuming the infant is otherwise well, with no signs of ascending infection, simple toileting with sterile saline or water is all that is needed [A].⁸

- Should there be any signs of spreading infection or systemic illness, the infant must be treated immediately. Ascending infection from the cord stump is usually due to *Escherichia coli*, other Gram-negative organisms or *Staphylococcus aureus*, and is a neonatal emergency requiring intravenous antibiotics.
- Umbilical stump *granulomas* do not present until after the cord stump has separated. Most resolve, although some practitioners treat them with application of a silver nitrate stick. Great care should be exercised so as not to cause chemical burns to the surrounding skin. They must be differentiated from a patent urachus, which is an embryological remnant connecting the bladder to the base of the umbilical cord and can result in passage of urine. It requires surgical correction.

Jaundice

Jaundice is a common and potentially serious problem with numerous causes:

- physiological jaundice, due to overloading of the immature hepatic system as a result of excessive red blood cell breakdown: the infant develops an unconjugated hyperbilirubinaemia between the second and fifth days, settling by a week of age;
- sepsis;
- haemolysis due to rhesus or ABO incompatibility.

Acute haemolytic disease usually presents within the first 24–48 hours of life, thus any baby appearing jaundiced within this time must be investigated.

Treatment may not be necessary. The most important reason for treating jaundice is to prevent kernicterus, which is associated with severe unconjugated hyperbilirubinaemia and may result in death or major neurological sequelae. Most infants can be treated with simple phototherapy, although for more serious cases exchange transfusions are needed.

Prolonged jaundice is also of concern in the neonate. As a general rule, any term infant with evidence of jaundice beyond 10–14 days of age, or a preterm infant after 3 weeks of age, should be considered as having prolonged jaundice. There are numerous causes, of which the most common is 'breast milk jaundice' (a diagnosis of exclusion). All infants with prolonged jaundice should be investigated. It is particularly important to exclude an obstruction (e.g. biliary atresia), which can be treated successfully with surgical intervention if diagnosed early.⁹

PROBLEMS ASSOCIATED WITH PREMATURITY

Respiratory distress syndrome (also known as hyaline membrane disease) is due to a lack of surfactant in the lungs, leading to acute respiratory failure. The severity varies from mild respiratory symptoms, requiring minimal input, to severe

respiratory failure, requiring full intensive care and complex ventilator strategies.

Respiratory distress syndrome can either recover or develop into chronic lung disease (bronchopulmonary dysplasia). Other complications include pulmonary interstitial emphysema and other airleak syndromes.

Effectively, every system in the premature infant is at greater risk of problems. Premature infants are at risk of cardiovascular instability and hypotension requiring treatment. They are susceptible to cerebral insults, especially intraventricular haemorrhage and periventricular leukomalacia (the development of cysts in the periventricular areas at a few weeks of age) due to ischaemic injury. Their immature immune systems put them at higher risk of sepsis. They easily become anaemic, due to marrow immaturity, as well as the need for frequent phlebotomy. Their gastrointestinal system is vulnerable. They often show feed intolerance initially, and there is a high risk of necrotising enterocolitis. (Necrotising enterocolitis is a serious condition which affects the lining of the bowel; it probably results from infection superimposed on bowel that has suffered an ischaemic insult.)

Premature infants also have a higher risk of long-term sequelae, including poor growth, neurodevelopmental disabilities and chronic lung disease.

CONCLUSION

This chapter highlights some of the more common problems facing the newborn infant. It concentrates on acute problems occurring in the delivery suite shortly after birth and on concerns that subsequently present on the postnatal wards. Most of the common problems occurring after the first hours following birth are not life threatening, but do cause significant anxiety and morbidity.

ACKNOWLEDGEMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of Sandie Bohin to the chapter on this topic in the previous edition of the book.

KEY POINTS

- Most common neonatal problems are not life threatening.
- Recognising the sick infant from the well infant is vital to avoid disaster.
- The newborn examination is a clinical screening test, and as such its limitations should be borne in mind.

Chapter 62 Perinatal mortality

James Drife

MRCOG standards

Theoretical skills

- Know the definitions of the perinatal mortality rate and its subdivisions.
- Have knowledge of the way in which perinatal deaths are classified, and the leading causes.
- Know how perinatal mortality rates can be kept low or reduced further.

Practical skills

- Recognise that reducing perinatal mortality requires practical obstetric skills.
- Recognise the need for attention to detail in both antenatal and intrapartum care.
- Recognise that skills in risk management are highly relevant.

INTRODUCTION

Although babies may die at any time during pregnancy, and obstetric complications such as preterm labour may result in death of the infant several weeks after delivery, perinatal mortality is strictly defined as stillbirths and deaths of babies in the first week of life. In all countries the perinatal mortality rate (PMR), even with this relatively limited definition, is much higher than the maternal mortality rate. In the UK in 2009 the PMR (7.6 per 1000 live and stillbirths)¹ was 66 times higher than the maternal mortality rate (11.4 per 100,000 maternities), though exact comparison is difficult because of the different denominators (see Chapter 28).

The PMR is widely used as an indicator of the quality of obstetric care and enables comparisons to be made among nations, regions and indeed individual hospitals. The causes of perinatal mortality, however, include a wide range of conditions, such as antepartum haemorrhage, congenital anomalies

and preterm labour. For useful clinical lessons to be learned, perinatal mortality must be subdivided by the stage at which death occurred and by the causes.

The two components of the PMR, the stillbirth rate and the neonatal death rate, reflect different aspects of care and tend to be reported separately. Indeed, in England and Wales the most recent report from the Office for National Statistics (ONS)² did not include the overall PMR. Instead it reported that the neonatal mortality rate had fallen steadily in the previous decade (from 3.8 per 1000 in 2000 to 2.9 in 2011) while the stillbirth rate had remained virtually unchanged (5.3 per 1000 in 2000 and 5.2 per 1000 in 2011). Interestingly, the static stillbirth rate was not one of the ONS report's 'key findings', although it is the subject of increasing concern and research.³

DEFINITIONS

The following definitions are those used in the UK and published in the annual reports of the Centre for Maternal and Child Enquiries (CMACE) which, with its predecessor the Confidential Enquiry in Maternal and Child Health (CEMACH), conducted perinatal surveillance from 2003 to 2009 and produced UK-wide perinatal statistics for the first time.

- *Stillbirth.* The legal definition in England and Wales is 'A child which has issued forth from its mother after the 24th week of pregnancy and which did not at any time after being completely expelled from its mother breathe or show any other signs of life'.
- *Early neonatal death.* Death of a liveborn infant occurring less than 7 completed days (168 hours) from the time of birth.
- *Perinatal mortality rate.* The number of stillbirths and early neonatal deaths (those occurring in the first week of life) per 1000 live and stillbirths.

CMACE also gathered data on deaths that fall outside the strict definition of perinatal mortality. In some regions, for example, late fetal deaths were notified. Other categories and definitions are as follows:

- *Late fetal loss.* Death occurring between 20 weeks + 0 days and 23 weeks + 6 days. If gestation is not known or not sure, all births of at least 300 g are reported.
- *Neonatal death.* Death before the age of 28 completed days following live birth.
- *Late neonatal death.* Death from age 7 days to 27 completed days of life.
- *Post-neonatal death.* Death at age 28 days and over, but under 1 year.
- *Infant death.* Death in the first year following live birth, on or before the 365th day of life (366th in a leap year). Infant deaths therefore include early and late neonatal deaths and post-neonatal deaths.

When infant and neonatal death rates are calculated, the denominator is 'per 1000 live births'. This is slightly different from the denominator 'per 1000 live and stillbirths' which is used to calculate the late fetal loss rate, the stillbirth rate and the PMR.

Definitions of 'stillbirth'

Miscarriages are not included in the PMR. In the UK miscarriages do not have to be registered but it is legally necessary to register stillbirths – i.e. babies born dead after 24 weeks. The dividing line between miscarriage and stillbirth, however, is arbitrary and may vary from country to country. In the United States, for example, there is no single definition used in all states.

In the UK the dividing line was 28 weeks until 1992. When it was lowered to 24 weeks, the official stillbirth rate rose by nearly 30 per cent. The change was made because, with neonatal care, many fetuses born alive at under 28 weeks can now survive. Indeed, survival is possible even below 24 weeks, but this was retained as the dividing line in the UK partly because, under British law, therapeutic abortion for social reasons is allowed up to 24 weeks' gestation.

Internationally, the definition and terminology are inconsistent and this has contributed to confusion about stillbirths.⁴ The official definition of the World Health Organization (WHO) is:

The death of a fetus weighing at least 500 g (or when birthweight is unavailable, after 22 completed weeks of gestation or with a crown–heel length of 25 cm or more), before the complete expulsion or extraction from its mother.

In many parts of the world it may be difficult to define gestation exactly, which is why the WHO definition includes fetal weight or measurement. For international comparisons, however, a definition which includes 'early fetal stage' (22–28 weeks) losses is unhelpful, and WHO has agreed that when countries are being compared stillbirth should be defined as fetal death in the third trimester (≥ 1000 g birthweight or ≥ 28 completed weeks of gestation).⁵

In all countries, if a baby is born alive and dies soon after delivery, this is classified as a neonatal death irrespective of the

gestation. This may lead to some anomalies. For example, in the UK a baby born at 23 weeks' gestation will be included in the national statistics if death occurs after delivery but not if death occurs before delivery.

CONFIDENTIAL ENQUIRIES INTO PERINATAL DEATHS

History

In England and Wales the Confidential Enquiry into Maternal Deaths (CEMD) has been running continuously since 1952, and this method was extended to the deaths of babies in 1992, when the Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI) was set up. Its aim was to improve understanding of the risks of death from 20 weeks of pregnancy to 1 year after birth, and of how these might be reduced. From 1996, CESDI was managed by a consortium of four Royal Colleges – those of Midwives, Obstetricians and Gynaecologists, Paediatrics and Child Health, and Pathology. In 2002, CEMD and CESDI joined to form the CEMACH, which was part of NICE.

In 2009, CEMACH became CMACE, an independent charity funded mainly by the National Patient Safety Agency (NPSA). In 2011 CMACE was closed down and the only data available for 2010–12 are those collected by ONS. In 2012 the Healthcare Quality Improvement Partnership (HQIP) passed the responsibility for the enquiry to the National Perinatal Epidemiology Unit (NPEU) and from 1 January 2013 data have been collected electronically by MBRRACE-UK (which stands for Mothers and Babies – Reducing Risk through Audits and Confidential Enquiries across the UK).⁶

Although this short history produced a bewildering proliferation of acronyms, the aims of MBRRACE-UK are the same as those of its predecessors. Obstetricians should be pleased that the 'confidential enquiry' method of improving care is now being more widely used, after being pioneered 60 years ago by the RCOG and the (then) Ministry of Health when they set up the CEMD. Enquiries into perinatal deaths, however, require a larger infrastructure than the CEMD. Every year in the UK there are around 6000 perinatal deaths (Table 62.1), compared with about 100 maternal deaths.

Table 62.1 Numbers of perinatal deaths in the UK in 2009¹

Total births	794,906
Stillbirths	4125
Early neonatal deaths	1945
Late neonatal deaths	566
Total number of perinatal deaths	6070
Perinatal mortality rate (per 1000 total births)	7.6
Stillbirth rate (per 1000 total births)	5.2
Neonatal mortality rate (per 1000 live births)	3.2

Methods

Between 2009 and 2011, every maternity unit in England, Wales and Northern Ireland had a CMACE coordinator who notified the regional office of each death using a 'Perinatal Death Notification Form'. That form contained details of the mother's background, previous pregnancies and medical history, the current pregnancy and delivery, and the outcome including the cause of death. Autopsy data were not required. In addition, deaths were reported to CMACE by pathologists, coroners, child health systems and local congenital anomaly registers, leading to a very high level of ascertainment. Collaboration with the equivalent organisation in Scotland (NHS Quality Improvement Scotland) provided UK-wide statistics and the National Perinatal Mortality Surveillance programme published a report every year.¹

In June 2012 MBRRACE-UK started work on a secure, web-based electronic data collection system.⁶ Data are now collected on 'late pregnancy losses' (i.e. from 22 weeks' gestation), stillbirths, early and late neonatal deaths and post-neonatal deaths (up to 1 year from delivery). Details are requested of the woman's demographic information, health and previous pregnancies, as well as about the current pregnancy and its outcome. Lead users from each maternity unit in the UK have been recruited to facilitate the accuracy and completeness of the data, which are cross-checked with registration data from the ONS.⁷ A guideline has been produced to help with data entry, and care is taken to ensure that the system is secure and the anonymity of cases is maintained.

The work programmes of MBRRACE-UK

CESDI, CEMACH and CMACE reported on specific subjects, such as intrapartum-related deaths, sudden unexpected deaths in infancy and deaths around the limits of fetal viability. MBRRACE-UK is undertaking similar focused enquiries. As well as its surveillance of perinatal deaths and the CEMD (see Chapter 28) there are confidential enquiries into a rolling programme of selected maternal morbidity topics and selected stillbirth and infant morbidity and mortality topics. The first maternal morbidity topic was sepsis, and the first perinatal topics were congenital diaphragmatic hernia and, for 2014, unexplained stillbirth at term. Analysis of perinatal cases is done by panels from each English region, Scotland, Northern Ireland and Wales.

Perinatal postmortem examination

Autopsy data are not necessarily required by MBRRACE-UK, but postmortem examination after stillbirth can provide additional information in up to 65 per cent of cases of intrauterine deaths at >20 weeks' gestation. Worldwide, however, rates of perinatal autopsy began to decline in the 1990s, and CMACE reported a reduced uptake of postmortems between 2000 and 2009.¹ These falls were partly due to 'organ retention' controversies in the UK and elsewhere, when it came to light

that organs had been retained after postmortem without the permission of parents having been specifically sought. Several official bodies produced guidelines to ensure that parents are better informed, and that clinicians who discuss postmortems with parents understand the process so that consent is full and informed. Policies to promote the uptake of perinatal postmortem include the availability of specialist perinatal pathologists, education (of both staff and the general public) in the value of postmortem, and senior staff involvement in counselling regarding the procedure. The consent process is crucial and is best carried out by a specialist bereavement midwife or a consultant involved with the care of the woman.⁸

INCIDENCE

Worldwide

Of the 140 million babies born every year, at least 2.65 million are stillborn,⁴ and two estimates for 2000 put the figure at around 3.2 million.⁵ A similar number die in the first 4 weeks of life. Three quarters of all neonatal deaths happen in the first week and the risk is highest on the first day. Low- and middle-income countries account for 98 per cent of the world's stillbirths, with global rates ranging from 2/1000 total births in Finland to 40/1000 total births in Pakistan and Nigeria. Over 40 per cent of all stillbirths (an estimated 1.19 million) are intrapartum, mostly associated with obstetric emergencies, while the others are antepartum stillbirths associated mainly with maternal infection and intrauterine growth retardation (IUGR).⁴

These figures are estimates because accurate data are often lacking. Some years ago the Director-General of WHO summed up the problem in developing countries as follows:

There are between 7 and 8 million perinatal deaths, but we do not know exactly how many are stillbirths and how many are early neonatal deaths. In many cases, births of infants who die soon after birth are neither recorded nor counted ... Although the exact medical causes in countries may differ, the problem is simple: the common denominator for these deaths is the lack of appropriate and quality services, confounded by poverty.

In Europe, PMRs are relatively low but still show marked variations. The Euro-Peristat project began in 1999, coordinated from Paris and supported by the European Commission, and now gathers data from almost all European countries – which is no easy task. In the most recent Peristat report the stillbirth rate after 28 weeks of gestation ranged from 1.5 per 1000 total births in the Czech Republic to 4.3 in France, while the overall stillbirth rate (>22 weeks) ranged from under 4 per 1000 to over 8. Neonatal mortality rates (up to 28 days from delivery) ranged from 1.2 per 1000 live births in Iceland to 5.5 per 1000 in Romania.⁹

These results can be affected by differences between countries in the way that data are collected, which is one reason why data collection is difficult. The Peristat report acknowledges

that under-reporting of maternal deaths is widespread in Europe but does not comment on whether this may also be a problem with perinatal deaths. International comparisons are an incentive to countries to improve care but may also discourage them from developing the systems needed to identify all eligible cases and thus push up their figures.

The UK

In the UK every effort is made to ensure that all maternal and perinatal deaths are identified. Data on perinatal mortality have been collected for the last 60 years, during which time there has been a dramatic reduction in perinatal deaths. In 1963 in England and Wales the stillbirth rate was >17 per 1000 total births and the neonatal death rate was >14 per 1000 live births. By 1999 these rates had fallen to 5.0 and 3.9 respectively. It is hard to know how much of this improvement was due to better health of the population and how much to better healthcare, but it is clear that improvements in neonatal intensive care, for example, played a major role in improving the survival rates of babies after preterm delivery.

In 2009, however, the UK stillbirth rate remained at 5.2 per 1000, although the neonatal mortality rate had fallen to 3.2 (Table 62.1). Indeed the UK stillbirth rate has remained largely unaltered since 1992, when the 24-week definition was introduced. The CEMACH report for 2005 commented that 'This lack of progress in reducing the stillbirth rate is a matter of public concern.' The 2009 CMACE report was less outspoken, simply pointing to a non-significant decrease (from 5.4 to 5.2) over the previous decade, but MBRRACE-UK has announced that stillbirth will be a priority for further investigation.⁷

The UK is far from unique, however, in having a static stillbirth rate. A recent review and meta-analysis pointed out that: 'Stillbirth rates in high-income countries have shown little or no improvement over the past two decades.'¹⁰

AETIOLOGY

General risk factors

The review of high-income countries mentioned above¹⁰ identified several modifiable risk factors, of which the highest-ranking was maternal overweight and obesity (BMI >25 kg/m²). Other risk factors included advanced maternal age, smoking and primiparity. Among disadvantaged populations, maternal smoking may contribute to as many as 20 per cent of stillbirths. Pregnancy disorders are also risk factors, as are pre-existing diabetes and hypertension. Abruptio and small for gestational age (SGA) demonstrate the role of placental pathology in stillbirth.

In the UK, CMACE identified these and other risk factors for perinatal mortality.¹ In 2009, of the women who had a stillbirth or neonatal death, 10 per cent had a BMI of over 35 kg/m² – twice the background UK prevalence rate. Other risk factors include the extremes of maternal age, with the

risk of stillbirth increased by a factor of 1.4 among teenage mothers and 1.7 among women over 40. Social deprivation was associated with a 1.6-fold increase in the risk of both stillbirth and neonatal death. Mothers from ethnic minorities were at increased risk. Those of black ethnic origin were 2.1 times more likely to have a stillbirth and 2.4 times more likely to have a neonatal death, compared to mothers of white ethnic origin. Among mothers of Asian ethnic origin, the risks of both these outcomes were increased 1.6-fold. The effects of ethnicity and social class on perinatal mortality are less marked than their effects on maternal mortality but the same groups are at risk.

Classification of perinatal deaths

For many years analysis of perinatal deaths relied mainly on three systems, the Extended Wigglesworth classification (which was based on pathophysiology), and the Obstetric (Aberdeen) and the Fetal and Neonatal Factor classifications. Deficiencies in these systems became increasingly obvious, however. The main problem was that a majority of stillbirths were classified as 'unexplained'. To address this, other systems were developed, such as the ReCoDe (Relevant Condition at Death) system, which focused on the clinical conditions associated with the death rather than why the death occurred.¹¹ This system reduced 'unexplained' stillbirths from 66 per cent to 15 per cent, and identified 57 per cent of previously 'unexplained' stillbirths as 'growth restricted'.

CMACE developed a new classification of its own, also aimed at providing more insight into why babies die and identifying better intervention strategies. This is the classification that was used in the final CMACE report,¹ and it is discussed in the next section.

Table 62.2 CODAC Level I categories: primary causes of death

0 Infection	Infectious causes of death
1 Neonatal	Conditions, diseases and events specific to neonatal life
2 Intrapartum	Mechanics and events of parturition or its consequences
3 Congenital anomaly	Congenital anomalies, chromosomal anomalies and structural malformations
4 Fetal	Fetal conditions, diseases and events
5 Cord	Cord conditions, diseases and events
6 Placenta	Conditions, diseases and events of the placenta and membranes
7 Maternal	Maternal conditions, diseases and events
8 Unknown	Unknown, unexplained and unclassifiable causes of death
9 Termination	Terminations of pregnancy

EMBRRACE-UK has adopted another classification, the cause of death and associated conditions (CODAC) system,¹² which can record more detail about the influences on any particular death. It has been widely used around the world, in both developed and developing countries, and should allow better international comparisons. The system has ten main categories, as shown in Table 62.2.

The system has three levels. Each of these ten Level I categories is subdivided at Level II (giving a total of 94 subcategories) and again at Level III. The aim is to report not only the main cause of death but also the associated relevant conditions so that scenarios of combined events and conditions are captured. Examples of how to use the system are provided in the EMBRRACE-UK guideline.⁷

Causes of perinatal mortality

Table 62.1 shows that stillbirths account for more than two thirds of all perinatal deaths. This may surprise some professionals. We tend to 'blank' antenatal stillbirths, feeling that little can be done to prevent them. Compared to cot deaths (which are much less common), professional and public awareness of stillbirth is low. Mothers who experience stillbirth say they did not know the problem still existed, and in 2009 a campaign was launched by the Stillbirth and Neonatal Death Society (SANDS) to raise awareness and promote research. The name of the campaign, 'Why17?' drew attention to the fact that on average there are 17 perinatal deaths each day in the UK – ten times the number of cot deaths.

The 2009 CMACE report (the most recent report on perinatal mortality in the UK at the time of writing) classified the causes according to the CMACE system.¹ Table 62.3 shows that the proportion with 'no antecedent factors' was still the largest category but had fallen to 27.5 per cent. This was a major improvement on older reports in which almost 75 per cent of

Table 62.3 Causes of stillbirths in the UK* in 2009¹ (n = 3373)

Cause	Percentage

11. Specific fetal conditions	3.8
12. Unclassified	1.7

● *Excluding Scotland

stillbirths were 'unexplained' according to the Wigglesworth criteria. The second leading cause, 'Specific placental conditions', is a pathological diagnosis – CMACE encouraged examination of the placenta when consent for postmortem was withheld – and the question for clinicians is whether the condition causing the placental pathology can be recognised during pregnancy.

At number 5 in Table 62.3, 'Mechanical' causes of death are mainly cord problems (cord around the neck, prolapsed cord and other entanglements). Much less common in this category are malpresentations and uterine rupture. Number 10, 'Associated obstetric factors', includes spontaneous premature labour, premature rupture of the membranes, and deaths categorised as due to birth asphyxia.

Obstetricians and paediatricians want different information from the analysis of neonatal deaths, and CMACE had a specific classification system for each of the two specialties. Table 62.4 shows the obstetric causes, with the leading category being 'Associated obstetric factors'. Within this category the largest subgroups were spontaneous premature labour

Table 62.4 Causes of neonatal deaths in the UK* in 2009¹ (maternal and fetal classification) (n = 2115)

9. Sudden unexpected deaths	2.0
10. Injury / trauma	0.1

and premature rupture of the membranes, which together accounted for 20 per cent of neonatal deaths. Also included in this category was 'intrapartum anoxia', which accounted for 3.3 per cent.

In the neonatal classification of neonatal deaths (Table 62.5) the leading cause is 'respiratory disorder'. Almost 90 per cent of these deaths were in babies born before 32 weeks' gestation. It is not immediately obvious from this table that the main underlying cause of neonatal death is preterm delivery.

Under the previous classification systems, 'intrapartum anoxia' accounted for 8 per cent of perinatal deaths – a proportion which did not change between 1999 and 2007, despite intensive intrapartum fetal surveillance. This was highlighted by the Chief Medical Officer in 2006 as a major cause for concern. In the 2009 CMACE report 'intrapartum-related' deaths still accounted for 8.6 per cent of all perinatal deaths. It is to be hoped that the new and more detailed analysis of these cases will be the first step in reducing this total.

PREVENTION

Worldwide

At the Millennium Summit in New York in 2000, world heads of state named reducing child mortality and improving maternal health among the global Millennium Development Goals. The targets for 2015 were to reduce the under-5 mortality ratio by two thirds and the maternal mortality ratio by three quarters from their 1990 levels. Neither perinatal mortality nor stillbirth was specifically mentioned but strategies for reducing perinatal mortality overlap with those for reducing maternal mortality. A shared theme is the need for functioning health systems which can provide emergency obstetric care.

In developed countries like the UK, the reduction in intrapartum stillbirths during the last 50 years means that most stillbirths occur in the antepartum period. In low-resource countries, however, there is a preponderance of term and intrapartum stillbirths which could be prevented by known risk assessment methods and by prompt delivery, often by caesarian section (CS). The fact that stillbirth is not formally included in any of the major global disease campaigns underlines current fears that 'inappropriate fatalism regarding stillbirths among care givers and policymakers will virtually guarantee that no progress occurs'.¹³

In 2011 the *Lancet* ran an informative series of articles on stillbirth in both developing and developed countries. The final article of this series, entitled 'The vision for 2020',¹³ discussed research themes, and the highest priority theme for low and middle-income countries was how to 'adapt and scale up the most effective components of intrapartum care, particularly the appropriate use of caesarean section.' Other priorities were the improvement of antenatal care and effective mortality audit.

Efforts to reduce stillbirths will also help to reduce early neonatal mortality. For reduction of late neonatal and infant mortality, promotion of breastfeeding is particularly important in developing countries. Not only does it provide appropriate nourishment for the newborn, but it also reduces the risk of infection from artificial feeding, provides passive immunity through maternal antibodies, and acts as a natural contraceptive to ensure adequate pregnancy spacing.

The UK

Perinatal mortality can be reduced only if there is a will to do so, and for many years this seemed to be lacking, at least as far as stillbirth was concerned. The mood is now changing, with the prospect of more research into the causes of fetal death. In the following paragraphs the potential for further reducing the PMR will be discussed under the main themes which emerged from the 2009 CMACE report.¹

Congenital malformation

Congenital abnormalities accounted for 23 per cent of perinatal deaths in 2009 (Tables 62.4 and 62.5). Current screening for congenital abnormalities includes universal fetal anatomy scanning in mid-pregnancy, and screening for chromosomal abnormalities through ultrasound and/or biochemical tests in the public and private sectors. Down's syndrome, the commonest chromosomal abnormality, does not usually cause neonatal death, and therefore the biochemical screening programme has little effect on perinatal mortality.

Around 18 per cent of lethal congenital anomalies at birth are cardiovascular and these constitute the leading cause of death in this category. The cardiovascular system, however, is difficult to visualise adequately at routine ultrasound screening. Specialist cardiac screening is carried out for fetuses at high risk but is too expensive in terms of personnel and equipment to be offered routinely.

The fetal spine is easier to visualise, and most neural tube defects (NTDs) are identified at a gestation at which the woman can be offered termination of pregnancy. This has resulted in a decrease in perinatal mortality from this condition but an increase in therapeutic termination. Ideally, congenital malformations would be prevented rather than being diagnosed early enough for termination, but this is difficult to achieve. The government has advised that all women should take periconceptual folic acid to reduce the incidence

of NTDs, but only a minority do so. Sixty countries including the USA have introduced mandatory fortification of flour with folic acid, but Britain is not one of them.

Intrauterine growth restriction

The 2009 CMACE report confirmed what previously had been strongly suspected – that IUGR is a factor in many of the stillbirths previously classified simply as ‘anteperinatal fetal death’. In 6.6 per cent of cases IUGR was given as the primary cause but when all cases were counted it was associated with 19 per cent of all stillbirths. Risk factors identified among this group were maternal smoking and obesity, extremes of maternal age, and black ethnicity. Previous studies have found that many of the mothers had noticed a change in fetal movements.

Past recommendations have included better screening for IUGR and better communication with mothers so that those with concerns about reduced fetal movements can be seen promptly for checks on fetal wellbeing. Women at risk need particular attention. A Scandinavian study showed that the increased perinatal mortality among ethnic minority women is due to delay in seeking antenatal care, inadequate management of IUGR, misinterpretation of cardiotocographs (CTGs) and poor communication.¹⁴ A study in New Zealand showed that women who miss antenatal visits are at increased risk, and that SGA fetuses who are not identified as such in the antenatal period are more at risk of being stillborn.¹⁵

For all women, routine antenatal care too often fails to identify IUGR. Current UK guidelines recommend screening by fundal height measurement, despite a Cochrane review showing no evidence of benefit. Its sensitivity may be improved by using customised growth charts. Another approach would be routine ultrasound scanning in the third trimester, which is normal practice in France. More evidence is needed, however, on how best to replace the outdated and inadequate technique of fundal height measurement, and how to identify the malfunctioning placenta at an earlier stage.³

Intrapartum-related deaths

In the UK in 2009 there were 288 intrapartum stillbirths and 232 intrapartum-related neonatal deaths. Together they represent 8.6 per cent of perinatal deaths, and in relation to the total number of births (794,906) a risk of 1 in 1529. This risk is almost exactly the same as it was in 1994–5, when a detailed CESDI study of intrapartum-related deaths found sub-optimal care in over 78 per cent of the cases, in which alternative management ‘might’ (25 per cent) or ‘would reasonably be expected to’ (52 per cent) have made a difference to the outcome. The main findings of that report were failure to recognise risk factors before labour, and inadequate assessment of the fetus during labour by heart rate monitoring and blood sampling. There has been no similar confidential enquiry into intrapartum-related deaths since then. The decision of MBBRACE-UK to investigate unexplained stillbirths is therefore very welcome.

There have, however, been new guidelines on standards of care in labour¹⁶ and national evidence-based guidelines on the use and interpretation of electronic fetal monitoring (EFM). These had a gratifying response at local level and the 2002 CESDI report noted that ‘Intrapartum-related mortality has now decreased significantly from 0.95 (1994) to 0.62 (1999) per 1000 live births and stillbirths.’ Since 1999, unfortunately, the figure has been static, at 0.56 per 1000 in 2007 and 0.66 in 2009.

The emphasis now is on identifying ‘low-risk’ women and promoting normal birth. This requires adequate numbers of midwives but there are persistent concerns about the levels of staffing in UK labour wards. Pressure has come not only from the 17 per cent increase in the number of deliveries between 2000 and 2009 but also from the high proportion of deliveries to women born outside the UK – now almost 25 per cent nationally and over 70 per cent in some parts of London. These women are at higher risk and require extra care.

Immaturity

In the 2009 CMACE report ‘extreme prematurity’ accounted for 8.5 per cent of neonatal deaths but this category included only infants born before 22 weeks’ gestation. The contribution of premature delivery after this stage is harder to discern as it is spread among the other categories of the neonatal classification. For example, infants born before 32 weeks’ gestation accounted for all but one of the deaths from intraventricular haemorrhage, as well as the 90 per cent of neonatal deaths from respiratory disorders mentioned previously.

Advances in neonatal care have improved the survival of premature infants to a remarkable degree in the last three decades. Survival rates for babies born at 27–28 weeks’ gestation are now around 90 per cent, although about 20 per cent of these infants survive with some degree of impairment. It is now well recognised that antenatal steroids given to the mother will reduce the risk of perinatal mortality from respiratory distress syndrome, but they must be given at least 24 hours before delivery and sometimes it is impossible to delay delivery long enough for them to work.

Prevention of preterm birth is now the major challenge for obstetrics. Some reduction can be achieved by measures including smoking cessation, avoidance of multiple embryo transfers, cervical cerclage, progesterone supplementation and avoidance of unnecessary iatrogenic preterm delivery, but these have a relatively small effect on the overall preterm birth rate. More research is needed on disease mechanisms and on biomarkers to predict preterm birth, and there is a need for more engagement with pharmaceutical companies to convert knowledge into available therapies.¹⁷

Clinical risk management

For many years it has been standard practice for maternity hospitals to hold perinatal mortality meetings to review cases of perinatal death. The clinical history and pathological findings are examined and the implications for the

management of similar cases are discussed. Many hospitals have extended this method to include 'near-miss' incidents. It is essential that such discussions take place in a blame-free atmosphere, so that constructive suggestions can be made for improving care.

These meetings have tended to focus on the 'person approach', recognising the importance of individuals, but there is increasing emphasis on the 'systems approach' to risk management. This recognises and indeed expects staff to make errors. It concentrates on improving the system to reduce the chance of errors occurring, to recognise them when they do occur and to prevent adverse consequences. The emphasis is on support for staff rather than blame. This is the most constructive approach to reducing perinatal mortality and morbidity and the associated burden of obstetric litigation.

SUMMARY

Worldwide, there are around 6 million perinatal deaths annually, of which about half are stillbirths. All but 2 per cent of these deaths occur in developing countries, where the main causes are poverty, malnutrition and, importantly, lack of access to healthcare. Improvements could be made by basic hygiene, access to trained healthcare workers and promotion of breastfeeding, but reduction in perinatal mortality requires functioning healthcare systems delivering emergency obstetric care.

In the UK, perinatal mortality is comparatively low but could be reduced still further. Intrapartum management has been improved by training in the interpretation of electronic monitoring and more involvement of senior staff, but regular updating is needed and pressures on midwives need to be recognised. Congenital malformations can be detected during pregnancy, but more can be done to prevent them. Neonatal care continues to improve survival rates after preterm delivery but prevention of preterm labour is a considerable obstetric challenge and needs further research. Recognition of at-risk pregnancies requires meticulous antenatal care, and more research is needed to improve the diagnosis and management of IUGR. In this regard, particular attention must be paid to high-risk groups such as obese women and those from ethnic minorities.

EBM

- Maternal steroid administration before preterm delivery reduces perinatal mortality [1a].
- The evidence does not support the routine use of EFM in low-risk labours.
- Dietary supplementation in chronically malnourished women reduces perinatal mortality [1b].

KEY POINTS

- The perinatal mortality rate is the number of stillbirths and deaths in the first week of life per 1000 live and stillbirths.
- Globally the perinatal mortality rate is around 50–60.
- Worldwide, perinatal mortality is due to poverty, malnutrition and infection and lack of emergency obstetric care. It could be reduced by better access to healthcare.
- In the UK the perinatal mortality rate is currently 7.6.
- More than two thirds of perinatal deaths in the UK are stillbirths. Over the last 15 years the neonatal death rate has fallen but the stillbirth rate has not changed.
- Congenital malformations account for 23 per cent of perinatal deaths.
- Antepartum stillbirths could be reduced by more focused antenatal care, concentrating on the detection of IUGR and on better communication with at-risk women.
- The main underlying cause of neonatal death is preterm delivery. There is a need for more research on prevention of preterm birth.
- Perinatal postmortems require fully informed consent from parents, and sensitive counselling is very important.

Chapter 63 Postpartum collapse

Peter J Thompson

MRCOG standards

Theoretical skills

- Understand the pathophysiological basis of physical signs.
- The unconscious patient, resuscitation and intensive care.
- Understand the different aetiologies and clinical presentations of postpartum collapse and have a sufficient understanding of both the medical and surgical treatments of these patients.

Practical skills

- Demonstrate skills in acute resuscitation.
- Management of acute maternal collapse.
- Recognise the cause of a postpartum collapse and be able to both initiate and coordinate a multidisciplinary-based plan of management, often in conjunction with senior medical staff.

INTRODUCTION

Postpartum collapse is a major cause of maternal mortality and morbidity in both the developed and developing worlds. Although the most common causes of postpartum collapse are not confined to the immediate postpartum period, because of the rapid haemodynamic, hormonal and anatomical changes occurring at this time, there is an increased prevalence of these conditions.

Although many of these conditions require specific management plans, the generic treatment of a shocked patient, i.e. airway protection, administration of oxygen and gaining intravenous access, is common to all.

DEFINITION

Postpartum collapse is the onset of shock in the immediate period following delivery of the fetus.

PREVALENCE

There are no good denominator data available to accurately determine the incidence of this condition, though from recent observational studies of severe maternal morbidity at any stage in pregnancy, not all of which result in collapse, the incidence is thought to be between 0.14 and 6 per 1000 [D].¹

AETIOLOGY

There are many causes of postpartum collapse, with the most common and most important being listed in Table 63.1. Many of these aetiologies have common pathways via hypovolaemia, whether it be absolute hypovolaemia, as in haemorrhage, or relative hypovolaemia secondary to changes in the autonomic nervous system, as in uterine inversion. It is noteworthy that with the exception of psychiatric cases all the main conditions that contribute to both direct and indirect maternal mortality in the UK are represented in this list.

In addition many women who collapse are known to show deterioration in their basic observations, temperature, pulse rate, blood pressure, respiratory rate and urine output. It is for this reason that organisations such as NICE have recommended the introduction of early warning systems, though these have not as yet been shown to improve outcome [E]. In obstetrics a specific early warning system has been developed and implemented in most units in the UK, the Modified Early Obstetric Warning System, MEOWS.

The management of many of these conditions has been described elsewhere in this book, and will therefore not be addressed here. This chapter concentrates on the causes of postpartum collapse marked with an asterisk in Table 63.1.

Table 63.1 Aetiology of postpartum collapse

Pulmonary emboli	Vasovagal attacks*	Uterine inversion*
Septic shock	Epileptic convulsions	Cardiac arrest*
Haemorrhage	Cerebrovascular accidents	Cardiac arrhythmia
Amniotic fluid embolus*	Eclampsia	Iatrogenic*

* See text for explanation.

Vasovagal attacks

Vasovagal attacks are relatively common occurrences and are induced by many external stimuli, which result in extreme emotions, such as fright, anxiety or phobias. They are frequently preceded by a prodromal state consisting of dizziness, nausea, sweating, tinnitus and yawning. The aetiology is one of vasodilatation, leading to a pooling of blood and therefore a relative hypovolaemia. As a result, the heart begins to empty, stimulating mechanoreceptors in the wall of its left ventricle. This, in turn, acts centrally to initiate further vasodilatation and a bradycardia. These attacks usually resolve spontaneously, although it is advisable to position the patient flat and then elevate her legs to encourage central venous return and hence adequate filling of the heart [E]. Similar syncopal episodes may also be present in patients with cardiac disease, specifically those women who have arrhythmias or obstructive heart disease.

Cardiac arrest

Cardiac arrest during the postnatal period is usually associated with hypovolaemia, obstructive heart disease or complex congenital heart disease. However, with increasing maternal age at the time of delivery, ischaemic heart disease is now seen more commonly. Indeed, in the Confidential Enquiry into Maternal Deaths (CEMD) 2006–08,² six women died following myocardial infarction (three of these cases were secondary to ischaemic heart disease) and a further five women died of ischaemic heart disease where no evidence of myocardial infarction was found at autopsy. The rate of myocardial infarction is usually quoted as one in 10,000 births. The interim publications from UK Obstetric Surveillance Service (UKOSS) have only found 2.4 cases per 100,000 maternities, with further efforts being made to ascertain if this is a true incidence or if it represents under-reporting.³ Reversible causes of cardiac arrest are listed in Table 63.2.

Table 63.2 Reversible causes of cardiac arrest

Four Hs	Four Ts
Hypovolaemia	Tension pneumothorax
Hypoxia	Cardiac tamponade
Hyper/hypokalaemia, hypocalcaemia, acidaemia	Thromboembolic or mechanical obstruction
Hypothermia	Toxic or therapeutic substance in overdose

Resuscitation of women who have had a cardiac arrest in pregnancy is usually complicated by the fact that, when supine, a gravid uterus will compress the inferior vena cava, decreasing venous return. Emptying the uterus by delivering the fetus will improve stroke volume by 60 per cent and is therefore mandatory if resuscitation is not rapidly successful

and delivery should occur within 5 minutes [D]. Although this latter problem is not present in the immediate postpartum period, the uterus may still be of sufficient size to cause significant aortocaval compression, and therefore resuscitation should be conducted with the uterus displaced to the left [D]. Previously it was recommended that this be achieved by placing the woman on a tilt, with a reported increased cardiac output of 25 per cent when compared to a supine patient.^{4,5} However recent recommendations suggest that the preferred option is displacing the uterus as described above.

Management consists of diagnosing and treating any reversible cause of the arrest, while simultaneously following the European Resuscitation Council Guidelines 2010 for Adult Advanced Life Support.⁶ These are summarised in Fig. 63.1. Once a cardiac arrest has been diagnosed it is essential that resuscitation begins promptly, as survival is related to early CPR and, if appropriate, defibrillation. It is therefore a prerequisite that staff are trained on a regular basis so that they are able to both provide this level of basic life support and to use an automated electronic defibrillator. The previously recommended precordial thump is thought to have a very low success rate, and then only when administered within the first few seconds of the onset of the cardiac arrest. It is therefore no longer recommended outside a critical care environment as it may delay calling for help [D]. Basic life support should begin once the airway is opened and it is confirmed that the unconscious patient is either not breathing or is performing only occasional gasps. The initial part of the resuscitation is to perform chest compression at a rate of 100 per minute and a compression to ventilation ratio of 30:2. The most recent guidelines suggest that chest compression begins before rescue breaths are given as in these initial moments of a non-asphyxial cardiac arrest oxygenation of the blood is high, but delivery of oxygen to the myocardium and brain is poor. Chest compression is often performed sub-optimally and the person leading the resuscitation needs to rotate the person performing chest compressions regularly, approximately every 2 minutes. There is also significant emphasis in the new guideline regarding performing uninterrupted chest wall compression.

Post-resuscitation care should include transfer of the patient to a critical care unit or coronary care unit [D]. Patients who are hypothermic should not be warmed and those who are pyrexial should receive antipyretics [C].

Amniotic fluid embolus

Amniotic fluid embolism is rare, with estimates of the incidence varying between 1.3 and 12.5 per 100,000.⁷ Good denominator data are at present being collected by UKOSS and these preliminary results show an incidence of 1.9 per 100,000 (CI 1.6–2.3) with a mortality rate of 24 per cent, lower than previously thought.³ Due to its high mortality rate, there were 13 direct maternal deaths attributable to amniotic fluid embolism in the years 2006–08.² The aetiology is still debated, but appears to be an anaphylactic reaction to the passage of amniotic fluid and particulate matter into the

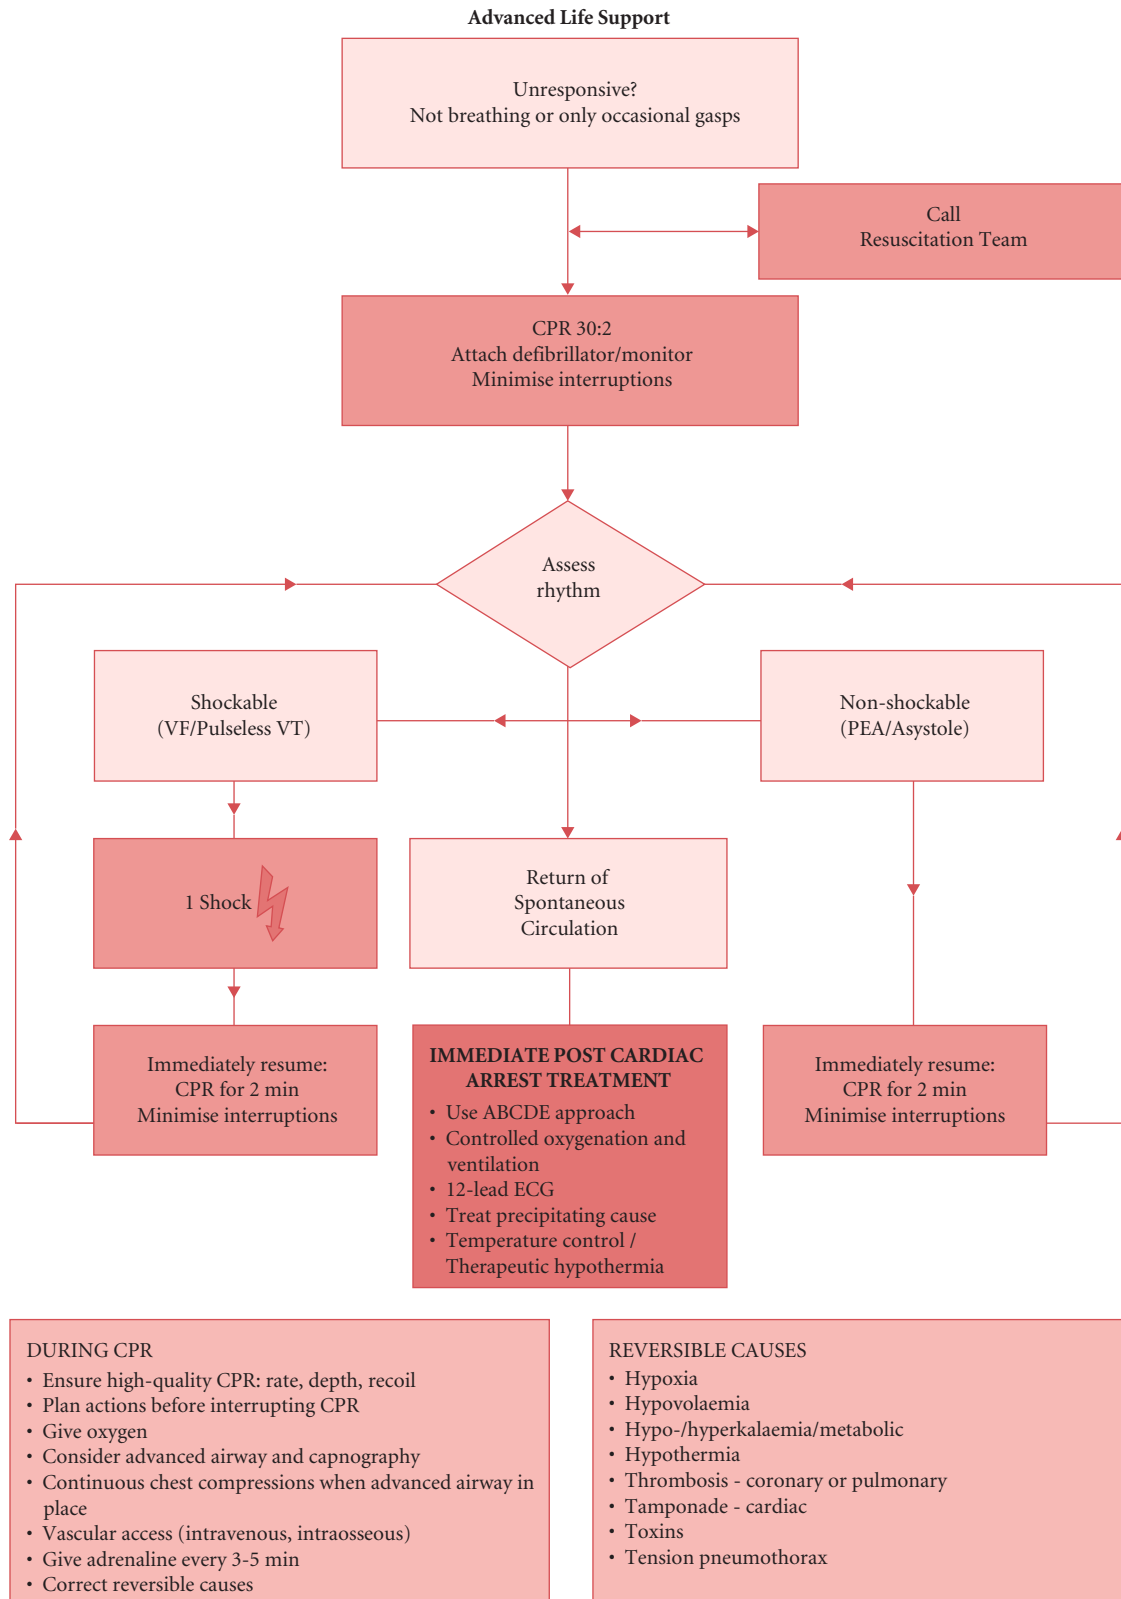

Fig. 63.1 European resuscitation guidelines for advanced life support (copyright European Resuscitation Council – www.erc.edu – 2014/017, reproduced with permission). PEA pulseless electrical activity; VF ventricular fibrillation; VT ventricular tachycardia

lungs. This results in a biphasic model where initially patients develop pulmonary hypertension and hypoxia presenting as respiratory distress, central cyanosis and circulatory collapse, with survivors undergoing a resolution of the pulmonary hypertension and subsequent development of left ventricular failure.⁸ Approximately half of the patients who survive the initial insult develop disseminated intravascular coagulopathy (DIC). Diagnosis of the condition is suspected when patients collapse in labour or shortly after delivery with signs of central cyanosis, although confirmation of the diagnosis can be made on examination of lung tissue at postmortem, or on examination of blood films for the presence of squames or fetal hair. If however the mother dies, diagnosis should be confirmed by immunochemistry. Management of these patients revolves around the generic treatment of shock and coagulopathies, with the former often requiring the information provided by pulmonary artery wedge pressures to guide inotropic interventions [D]. Although high-dose hydrocortisone has been suggested as an appropriate treatment, no studies have examined this.

Uterine inversion

Uterine inversion is a rare condition, occurring with an incidence of one in 10,000 pregnancies. Although maternal death secondary to uterine inversion is well recognised, in the CEMD 2006–08¹ there was only one such case, and in the previous triennial report covering 2003–05, no such deaths were documented. In the recent case uterine replacement was not attempted.

The degree to which the fundus of the uterus inverts is variable, with the mildest form being dimpling of the fundus and the most severe being complete inversion, where the fundus of the uterus passes through the cervix. There is no agreement on the aetiology of this condition, although several factors appear to be associated with its occurrence. These include:

- mismanagement of the third stage of labour, either by inappropriate traction during controlled cord traction or too-rapid removal of the placenta during manual removal;
- maternal age >25 years;
- a sudden rise in intra-abdominal pressure in the presence of a relaxed uterus;
- a fundally placed placenta with a short umbilical cord.

Patients present with a picture of shock in the absence of visible blood loss. This shock appears to be of neurogenic origin secondary to traction on structures adjacent to the uterus. The fundus of the uterus may be visible at the introitus; however, if not, it will be detected on vaginal examination. This latter examination is mandatory in all patients who appear to be shocked in the immediate postpartum period in the absence of visible blood loss [E]. Not only can this lead to the exclusion of a diagnosis of an inverted uterus, but a diagnosis of a supraplevator haematoma will also be excluded.

Treatment is based on the principles of managing a shocked patient and then replacing the uterus as soon as possible. If

the diagnosis is made immediately, the uterus can often be replaced manually prior to the onset of shock. However, once the uterus has been inverted for only a few minutes, the tissues surrounding it constrict, preventing its replacement. In this circumstance, manual replacement may be possible using general anaesthesia [D]. If this fails, O'Sullivan's hydrostatic technique may be attempted: the vagina is filled with warm saline while being blocked at the introitus with the attendant's fist. The hydrostatic pressure resulting from the instillation of 4–5 L of saline may be sufficient to balloon the vagina and reverse the inversion [D].

Should neither of these techniques result in replacement of the uterus, a laparotomy and Haultain's procedure should be performed before the uterus becomes ischaemic from obstruction of its blood supply. At laparotomy, traction is placed on the round ligaments and an incision is made through the muscular ring in the posterior uterine wall. Continued manual pressure on the fundus from the vagina and traction of the round ligaments will allow replacement of the uterus, and the incision is closed [D]. In all these treatment options, it needs to be remembered that if the placenta is still attached it should not be removed until the uterus has been replaced, as the uterus will be unable to contract and constrict the placental bed blood vessels and therefore major haemorrhage may ensue [E].

In all the previously described management options, once the uterus is correctly sited, a Syntocinon infusion should be commenced to encourage contraction of the uterus [E]. It should be noted that a recurrence rate of approximately 30 per cent has been quoted in the literature, although recent figures are unavailable.

Iatrogenic causes

Iatrogenic causes of loss of consciousness in the postnatal period include inappropriate advice on positioning the woman, with a resultant syncopal episode, and reactions to the administration of drugs. Although any drugs may be administered at this time, those that are most frequently used include syntocinon, ergometrine and local anaesthetics.

Syntocinon may cause sudden hypotension and, in women who are supine and have recently haemorrhaged, can be sufficient to result in loss of consciousness. This situation should be managed as for any shocked patient, with the appropriate positioning of the woman, protection of the airway and the administration of oxygen and intravenous fluids. In the previous CEMD, it has been reiterated that syntocinon should be used with care in such situations. Ergometrine, which is usually administered along with syntocinon, is a powerful smooth-muscle constrictor and is contraindicated in women with severe hypertension, as it may precipitate a hypertensive crisis and haemorrhagic cerebrovascular accident.

In women with inadequate analgesia, infiltration of the perineum with a local anaesthetic is mandatory prior to surgical repair of the perineum. Lidocaine, the most widely used local anaesthetic for this purpose, is ideally suited, with an

onset and duration of action after infiltration of 5 minutes and 1 hour, respectively (maximum plasma concentrations occur at 25 minutes). Overdosage usually presents as light-headedness, sedation, paraesthesia, twitching and convulsions. However, if the drug is administered intravenously, it may result in the precipitation of cardiac arrhythmias and cardiac arrest. This is one of the reversible causes of cardiac arrest and should be managed according to the guidelines described by the European Resuscitation Council [E].⁶ In addition, in the event of local anaesthetic-induced cardiac arrest, if there is no rapid response to normal CPR then a lipid emulsion should be administered as per the regimen in the British National Formulary.

It is therefore imperative for all healthcare professionals who infiltrate with lidocaine to ensure that injections are not intravenous and to be aware of the maximum dose of lidocaine that can be administered safely. This will depend, among other

things, upon the patient's size and the degree of vascularity of the area being infiltrated. This latter variable can be altered by the administration of vasoconstrictors to the local anaesthetic. The recommended maximum dose of lidocaine is 200 mg (500 mg if administered with adrenaline). However, this situation is complicated by the fact that most local anaesthetics are labelled in percentage solutions and hence professionals need to understand how much lidocaine there is in a specified percentage solution. This equation is shown below.

One litre of a 100 per cent solution contains 1 kg of the active ingredient. Therefore, 10 mL of 0.5 per cent lidocaine contains:

$$\frac{1000 \text{ g} \times 10 \text{ mL} \times 0.5}{1000 \text{ mL} \times 100} = 0.05 \text{ g} = 50 \text{ mg}$$

EBM

- There are few randomised controlled trials of the management of acute postpartum collapse.
- There are, however, internationally accepted evidence-based guidelines for adult resuscitation.

KEY POINTS

- All healthcare practitioners should be aware of the local guidelines to treat the shocked patient.
- European guidelines are available for resuscitation following cardiac arrest.
- Pregnant women who have had a cardiac arrest need to have their uterus displaced to the left.
- Prompt replacement of an inverted uterus may be life saving.
- Local anaesthetic solutions are labelled in per cent and can easily be converted into milligrams.
- Local and national guidelines are essential for the management of these conditions.
- Good denominator data for many of the conditions that cause postpartum collapse are being collected by UKOSS.

Chapter 64 Postpartum haemorrhage

Peter J Thompson

MRCOG standards

Theoretical skills

- Understand the definitions and differing aetiologies of primary and secondary postpartum haemorrhage.
- The techniques for control of postpartum haemorrhage.
- Retained placenta.
- Appropriate use of blood products.

Practical skills

- Demonstrate skills in acute resuscitation.
- Recognise a postpartum haemorrhage and be able to both initiate and coordinate a multidisciplinary-based plan of management.
- Complete objective structured assessment of technical skill in perineal repair and manual removal of placenta.

INTRODUCTION

Haemorrhage is still one of the leading causes of maternal mortality in the United Kingdom with postpartum haemorrhage (PPH) playing a significant role in the deaths of nine women in the last triennial report.¹ Any discussion of PPH must cover both the primary and secondary conditions, although the majority of this chapter is aimed at the management of primary PPH.

DEFINITIONS

The differentiation between primary and secondary PPH is more than an academic discussion, as the aetiology, clinical presentation, treatment and prognosis of the two conditions are very different.

PPH is subclassified as follows:

- Primary PPH is defined as the loss of 500 mL of blood from the genital tract following, but within the first 24 hours of, the delivery of the baby. A caveat is added in that if the blood loss is <500 mL, but is sufficient to cause hypovolaemic shock in the patient, this is also classified as a primary PPH. A new definition of massive PPH has been introduced, being the loss of greater than 1000, 1500 or 2500 mL of blood. Owing to the relatively low risks of blood loss below these levels, this is thought to be of greater clinical relevance. The incidence of this complication is being used in some units as an indicator of the standard of maternity care and is being promoted by RCOG as one of their clinical indicators on the maternity scorecard.^{2,3}
- Secondary PPH is more of a subjective diagnosis, as its definition is blood loss from the genital tract of a volume greater than expected after the first 24 hours, but within the first 12 weeks of delivery.

INCIDENCE

The incidence of primary PPH in the developed world is approximately 5 per cent of all deliveries.⁴ The incidence of massive PPH in the United Kingdom has been reported as 6.7 per 1000. This figure was obtained by analysis of a cohort of 48,865 women who delivered in a one-year period. Although significant morbidity will be associated with this condition, other data concerning its incidence are limited. However in the last triennial report on maternal mortalities in the UK there were five deaths secondary to PPH, half the number in the previous report. Despite this decrease in prevalence in three of these cases there was a lack of routine observations performed in the postnatal period.¹

AETIOLOGY

The most common aetiology of primary PPH is uterine atony, followed by genital tract trauma.

Uterine atony may have many causes, including retained placental fragments, and is associated with prolonged labour, multiple pregnancies, polyhydramnios, instrumental

deliveries and grand multiparity. Other somewhat rarer causes include coagulopathies, pathological placentation (e.g. placenta accreta) and uterine inversion. These rarer causes retain a significant level of importance because of their relative over-representation among severe cases of haemorrhage.

The major aetiological factors associated with secondary PPH are retained placental fragments and endometritis.

MANAGEMENT

It is important to discuss the options for the prevention of PPH with women antenatally. It has been well established that active management of the third stage of labour, with the administration of syntometrine at the time of delivery of the infant's anterior shoulder followed by controlled cord traction, is associated with a relative risk of PPH of greater than 11 of 0.34 (95% CI 0.14–0.87) [A].⁵ However, there is a substantial increase in the risk of maternal side effects, such as nausea with active management of the third stage of labour when compared to physiological management.⁵ Whilst most episodes of PPH occur in women with no known risk factors, those with recognised risk factors should be encouraged to deliver in a consultant-led unit with consideration given to siting of an intravenous cannula and blood being taken for estimation of the haemoglobin concentration, and serum should be grouped and saved [E]. Such women include those in the risk categories mentioned above, as well as women who have had a previous PPH, who have a risk of recurrence of approximately 25 per cent. Examination of the placenta post-delivery should identify a proportion of women who have retained placental fragments and who will require manual removal of the placenta. Relative risks for the development of PPH that are present in the antenatal and intrapartum period are listed in the RCOG guideline on this topic.⁶

Significant PPH is an obstetric emergency that requires a multidisciplinary team for optimum management [E]. Initial management is dependent upon rapid diagnosis. This is difficult, as it is well recognised that both obstetricians and midwives are poor at accurately estimating blood loss at the time of delivery. This can be further confounded by the ability of fit young women to maintain their blood pressure, either with or without a tachycardia, until they have lost approximately 15 per cent of their blood volume.

Resuscitation

Immediate management needs to revolve around the principles of ABC: airway, breathing and circulation. In this case this is likely to involve resuscitation of the hypovolaemic patient with the application of facial oxygen, siting of two large-bore (14/16 G) intravenous cannulae, fluid administration and examination to determine the aetiology of the haemorrhage, often performing uterine massage [E]. At this time blood should also be taken for diagnostic tests, including full blood count, coagulation screen, urea and electrolytes and cross

match (4 units). Although for many years clinical teaching has been that fluid replacement by colloid is superior to the use of a crystalloid, examination of randomised controlled trials (RCTs) in patients with hypovolaemia has failed to show any benefit with the preferential use of colloids [A].⁷ Although these studies are in the non-pregnant population, it is reasonable to extrapolate this conclusion to fit pregnant women. In this early stage of resuscitation, it is important to obtain blood for a full blood count, clotting studies and group- and cross-matching. If the haemorrhage is thought to be 'massive' then the local massive haemorrhage protocol should be formally initiated at this time.

Disseminated intravascular coagulation

DIC is a life-threatening complication of massive haemorrhage. Regardless of the aetiology, the management should revolve around maintaining an adequate intravascular volume and treating the underlying cause, in this case stopping the haemorrhage. This condition is discussed in more detail in Chapter 46, Antepartum haemorrhage. However, one should aim to follow four basic principles:

- 1 to maintain the intravascular volume;
- 2 to administer fresh frozen plasma (FFP) at a rate to keep the activated partial thromboplastin:control ratio <1.5;
- 3 to administer packed platelets to maintain a platelet count $>75 \times 10^9/L$;
- 4 to administer cryoprecipitate to keep the fibrinogen level $>1 \text{ g/L}$.

Although administration of blood components should be guided by haematological results in conjunction with a senior haematologist, as described above, this should not be delayed until the patient is moribund, as successive Confidential Enquiries into Maternal Deaths (CEMDs) have identified delay in transfusion as a significant contributor to maternal mortality [D]. In addition if blood is required but fully cross-matched units are not available then O rhesus-negative blood can be administered, though in most cases group specific uncross-matched blood can be available within 10–15 minutes.

Specific management strategies

Uterine atony can be managed pharmacologically or by a combination of pharmacological and surgical interventions. If the placenta is thought to be complete, the uterus is clinically atonic and there are no significant signs of genital tract trauma, an examination in theatre may be avoided by the administration of ergometrine followed by a syntocinon infusion. Although the former has significant side effects, including nausea, vomiting and hypertension, its tonic action on the uterine muscle is a valuable adjunct to therapy with syntocinon alone. However, caution is necessary in patients with pre-eclampsia, who may suffer episodes of severe hypertension following the administration of ergometrine.

Should these efforts fail to control the bleeding, examination of the genital tract needs to be performed with adequate lighting and patient analgesia. This usually means examination in an operating theatre with the patient having a regional or general anaesthetic. If the bleeding is significant, this examination should not be delayed in order to obtain blood results; if the anaesthetist is concerned about the risks of siting a regional anaesthetic in the presence of a possible coagulopathy or hypotension, then immediate resuscitation should be followed by the administration of a general anaesthetic [E].

Examination under anaesthesia should include examination of the vagina, cervix and, in the case of continued bleeding, exploration of the uterine cavity digitally to identify and remove any retained fragments of the placenta. If the uterine cavity is explored digitally, this should be covered by the administration of a broad-spectrum antibiotic. At this time, if no other cause for the haemorrhage has been identified, administration of prostaglandin analogues, either intramuscularly (if carboprost is available) or rectally (if only misoprostol or gemeprost is available), is advisable. The success of carboprost administration was as high as 88 per cent in one study. Misoprostol administration has also been thought to be effective in decreasing blood loss in cases of primary PPH, although there are limited data on optimal dosage, route and efficacy.⁸ Suggested dosages of these uterotonics can be seen in Table 64.1. Bimanual compression of the uterus may also need to be performed at this stage; this decreases blood loss partly because of the fact that it puts the uterine arteries under tension. In addition to uterotonics, drugs that promote coagulation can be administered, such as tranexamic acid and recombinant factor VIIa. These drugs are not, however, without risk, with recombinant factor VIIa in particular having a recognised risk of thrombotic cerebrovascular accidents and myocardial infarction.

Table 64.1 Suggested dosages for uterotonics

Uterotonic	Route of administration	Dosage
Syntocinon	IV	Bolus dose of 5 IU, followed if necessary by an infusion of 40 IU in 40 mL of saline run at 10 mL/hour
Syntometrine	IM	1 mL
Ergometrine	IV/IM	250–500 µg
Carboprost	IM	250 µg every 15–90 minutes, to a maximum of 2 mg (eight doses)
Misoprostol	PR	800 µg
Gemeprost	Intrauterine	1–2 mg

If these pharmacological and basic surgical steps have not achieved haemostasis, the uterus can be packed by either a traditional technique using gauze⁹ or, as has more recently been described, balloon insufflation.^{10,11} This technique can be employed regardless of whether the abdomen is open or closed, and may therefore avoid the need for open laparotomy [D]. Indeed, the provisional data on the use of balloon insufflation using a Rusch urological balloon appear very encouraging, although there are problems related to when and by how much the balloon should be deflated.

Should these steps fail, the patient will require a laparotomy. At that time, either unilateral or bilateral uterine artery ligation can be performed, with success rates reported of more than 90 per cent [D].¹²

This technique involves placement of a suture through the broad ligament to include 2–3 cm of myometrium. The suture should be placed approximately 2 cm above the point where an incision for a lower-segment caesarean section (CS) would be, thus ligating the ascending branch of the uterine artery and avoiding inclusion of the ureter in the suture.

Arterial ligation has been modified into a series of step-wise procedures producing uterine devascularisation. This technique, described in Egypt, involves five steps: unilateral ligation of the uterine artery at the level of the lower segment; bilateral ligation of the uterine artery at the level of the lower segment; low ligation of the uterine artery after mobilisation of the bladder; unilateral ovarian vessel ligation; and bilateral ovarian vessel ligation [D].¹³ The first two of these steps resulted in haemostasis in more than 80 per cent of cases in the original report. Although ligation of the internal iliac arteries has been well described in the literature, it requires a high level of surgical skill and is reported as avoiding hysterectomy in only 50 per cent of cases.¹⁴ The surgical time and complication rate in this series were also higher than when a hysterectomy was performed. After all these levels of uterine devascularisation, subsequent menstruation and successful pregnancies have been reported.

The use of compression sutures of the uterus has been reported from Switzerland and the UK,^{15,16} although their exact role in the treatment of PPH has yet to be established. Compression sutures are only of possible benefit if bimanual compression of the uterus results in significant decrease in blood loss. Initially, the operation described by B-Lynch involves inserting a compression suture through a lower uterine segment incision, either the CS incision or making a new incision. The suture is placed 3 cm below the incision and 3 cm in from its lateral border, through the uterine wall and cavity, exiting through a similar position on the superior aspect of the incision 3 cm above and 4 cm in from the lateral border. It then passes over the uterine fundus 3–4 cm from the right cornu and passes posteriorly down the uterus to enter the posterior uterine wall at the same level as the upper anterior entry point. The suture is then placed under moderate tension, while an assistant compresses the uterus. It is then placed back through the posterior wall on the left at a similar point as on the right. The suture is passed back over the fundus and then

inserted through the upper and lower incisions on the left in a similar fashion as on the right. It is then tied. Initially, this technique was described using a 2-catgut suture on a 70 mm round-bodied hand needle. However, since the withdrawal of catgut, an alternative suture would be 1-monocryl.

A modification of the technique without opening a previously intact uterus has also been described.

Other options, such as arterial embolisation and the use of recombinant factor VIIa, have been successfully described; however, good denominator data on the success rates of these are not available at this time.^{17,18}

The importance of good denominator data is demonstrated by the UK Obstetric Surveillance System (UKOSS), where rare conditions are identified and registered with a central coordinating body. One such study into the prevalence of peripartum hysterectomy showed that 50 women who subsequently went on to have a hysterectomy had had a B-Lynch suture inserted, which compares to the nine cases in the world literature where this procedure failed.

Data on all three of these procedures are now being collected by UKOSS.

Hysterectomy with ovarian conservation may be required as a life-saving procedure. In the UK, it has a reported incidence of approximately 4.1 per 10,000 deliveries.¹⁹ Experienced obstetricians need to be involved in the decision-making process during this cascade of events and, where possible, the patient and her relatives should be kept fully informed.

Selective arterial embolisation has been described both prior to hysterectomy and for persistent bleeding following hysterectomy. However, as mentioned above, its efficacy is still unknown and at the present time its use is limited by its availability.

The post-operative management of these patients may include the use of critical care units, with careful monitoring of central venous pressure being a recommendation from consecutive maternal mortality reports [D]. In the long term, these patients may also need professional counselling, especially if they have undergone a hysterectomy, and a debriefing with the lead clinician in charge of the patient's care is likely to improve patient understanding and satisfaction [E].

The management of secondary PPH may, if severe, follow similar lines to the above. However, if milder, the management will depend upon the aetiology of the condition, with patients with suspected endometritis being treated with broad-spectrum antibiotics and those with suspected retained fragments of the placenta by uterine exploration. Because of the high incidence of infection, it is important that any uterine instrumentation is covered by administration of a broad-spectrum antibiotic [E]. In this situation, the role of ultrasound in the detection of retained products of conception is limited, because of the difficulty in distinguishing between placental tissue and an organised blood clot on ultrasonographic examination [E].

EBM

- A systematic review of RCTs shows that active management of the third stage of labour decreases the incidence of PPH.
- A systematic review of the optimal choice of fluid for resuscitation shows no advantage in choosing a colloid before a crystalloid.
- No high-order avoidance exists to support one form of surgical management of PPH over any other.
- There are few RCTs of the management of PPH.
- A series of retrospective and prospective studies has shown that even with severe haemorrhage, a combination of medical and surgical treatment should avoid the need for hysterectomy in the vast majority of cases.
- The efficacy of different therapies for peripartum haemorrhage is being assessed by UKOSS.

KEY POINTS

- PPH is still a cause of maternal mortality in the United Kingdom.
- Active management of the third stage of labour decreases the risk of PPH.
- Early identification of PPH with accurate estimation of blood loss is essential.
- Acute management requires a multidisciplinary approach with the involvement of senior clinicians.
- It is important to monitor central venous pressure in severe cases.
- Early transfusion and correction of coagulopathy is fundamental.
- All units need their own detailed protocols for the management of massive PPH.

Chapter 65 Postpartum pyrexia

Peter J Thompson

MRCOG standards

Theoretical skills

- Genital tract sepsis is the leading cause of direct maternal death
- Prevention of complications of surgery including infection, wound, urinary tract, respiratory, intra-abdominal and pelvic.
- Primary and secondary infection.
- Know the characteristics, recognition, prevention, eradication and pathological effects of all commonly encountered bacteria, viruses, *Rickettsia*, fungi, protozoa, parasites and toxins, including an understanding of the principles of infection control.

Practical skills

- Be able to perform an examination under anaesthetic and remove retained placental fragments.
- Manage postpartum sepsis.
- Demonstrate skills in acute resuscitation.

INTRODUCTION

Historically, postpartum sepsis was most commonly secondary to infection with group A *Streptococcus*, and the prognosis was poor. Although the advent of antimicrobial therapy has significantly improved the prognosis, the last triennial Confidential Enquiry into Maternal Deaths (CEMD) report demonstrates that puerperal sepsis is not a disease of the past as although this report noted a fall in maternal mortality, the opposite was true for deaths secondary to sepsis. Indeed, one of the 10 recommendations from the report concerns the management of genital tract sepsis as this was identified as the leading cause of direct maternal death. The increase from previous reports shows that in 26 cases a woman's maternal death was due to sepsis, with 13 of these deaths being due to group A streptococcal infection.¹

DEFINITIONS

Normal core body temperature is 37–37.5°C, with a diurnal variation of body temperature resulting in evening temperatures being 0.5–1°C higher than those in the morning. Oral and axillary temperatures are usually 0.4 and 1°C lower than core temperature, respectively. Persistent elevation of body temperature above those normal levels is termed 'pyrexia' or fever. The standard definition for puerperal fever used for reporting rates of puerperal morbidity is an oral temperature of 38.0°C or more on any two of the first 10 days postpartum, or 38.7°C or higher during the first 24 hours postpartum. For definitions of sepsis and severe sepsis see the relevant chapter, though it is worth reiterating here that septic shock is defined as the persistence of hypoperfusion of organs causing organ dysfunction that is not corrected by adequate fluid replacement.

PREVALENCE

Following delivery, pyrexia is common, with fever secondary to disorders of the breast occurring in approximately 18 per cent of healthy mothers.^{2,3} Benign fever with resolution in the first 24 hours occurs with an incidence of 3 per cent.⁴ Fever associated with infection is also common, with urinary tract infection (UTI) occurring in 2–4 per cent of women following delivery and endometritis in 1.6 per cent. Infections of the lower genital tract are uncommon and account for only approximately 1 per cent of cases of puerperal infection.⁵

AETIOLOGY

The aetiology of pyrexia following delivery can be separated into four broad categories:

- 1 benign fever;
- 2 breast engorgement;
- 3 infections of the urogenital tract;
- 4 distant infections.

The most common infections of the urogenital tract are endometritis, UTIs and infections of perineal repairs. Although not all pyrexias are of an infective origin, infection is the most important diagnosis and a detailed history should be taken and thorough examination performed to identify possible sites of infection. Rare causes of infection should be borne in mind in those patients who have recently been in tropical countries. Specific infections in the puerperium are caused by the same organisms that cause these infections at other times; however in addition one should consider the possibility of Lancefield group A streptococcal infection and the possibility of influenza, both of which are known to carry a significant mortality risk in pregnancy and the puerperium. In 2009 the risks of community-acquired group A streptococcal infection were circulated by the Inspector of Microbiology and Infection Control, where he quoted a 20–50 per cent mortality rate.

The development of endometritis is secondary to contamination of the uterine cavity with vaginal organisms during labour and delivery, with subsequent invasion of the myometrium. Endometritis is usually a polymicrobial infection associated with mixed aerobic and anaerobic flora. Bacteraemia may be present in 10–20 per cent of cases. The organisms that contribute to this condition include groups A and B beta-haemolytic streptococci, aerobic Gram-negative rods, *Neisseria gonorrhoeae* and certain anaerobic bacteria.

Regardless of the aetiology of the pyrexia, the common pathway appears to be the production of endogenous pyrogens released by leukocytes in response to an antigenic stimulus. These then act on the hypothalamus, which in turn acts on the vasomotor centre, resulting in an increased production of heat and a decrease in heat loss.

MANAGEMENT

Prophylaxis

Prophylaxis against infections in the puerperium is particularly important in the case of delivery by caesarean section [A],⁶ although there is no good evidence supporting the use of antibiotics at the time of instrumental delivery [A]⁷ and recent publications from NICE suggest that women with congenital heart disease do not require antibiotic prophylaxis against infectious endocarditis.⁸ If, however, women with congenital heart disease develop pyrexia, then this must be excluded and close liaison with local cardiologists should be maintained [E], as in previous triennial reports into maternal mortality there were indirect deaths attributable to infectious endocarditis. In the most recent report there were three such deaths: two late coincidental deaths in drug users and one from secondary acute endocarditis.¹

In cases where puerperal women have been exposed to H1N1 infection or been in contact with people with invasive group A streptococcal infection prophylaxis may be indicated and liaison with infectious disease units is indicated [E].

In addition all postnatal women should have their observations taken and recorded on a modified obstetric early warning system chart, MEOWS. Most importantly, abnormal observations need to be documented and acted upon.

General management

Management will depend upon the origin of the pyrexia; however a general philosophy of following a sepsis care bundle will both help to identify patients and then lead to the initiation of a general treatment package. One such example of a treatment package is the Sepsis Six (Box 65.1). Instigation of such sepsis care bundles have seen the rates of mortality from septic shock decrease from 46.5 per cent in 2001 to 18 per cent in the recently published PROCESS trial; this was the mortality rate in the usual care arm of the trial where 70 per cent of hospitals were using protocolised management of septic shock [B].

Because of the diverse nature of aetiologies mentioned above, a thorough history and examination need to be per-

Box 65.1 Sepsis Six

1. Administer high-flow oxygen
2. Take blood cultures
3. Give broad-spectrum intravenous antibiotics
4. Give intravenous fluids
5. Measure serum lactate and haemoglobin
6. Accurately measure the urine output

formed, paying particular attention to examination of the breasts, chest and any wound sites. This includes an abdominal examination of the uterus for tenderness, a sign of endometritis. The endometrial cavity should be thought of as a wound site in this situation [E]. Features that are more typical of a benign fever are the presence of early low-grade pyrexia in the absence of any other symptomatology.

Appropriate cultures should be taken and, depending on the clinical features present, these may include wound and vaginal swabs, midstream specimens of urine, sputum samples and blood cultures. Management should consist of supportive therapy to ensure hydration and, where necessary, the administration of regular paracetamol, which acts as an antipyretic and will improve patient comfort, while not altering the course of the disease process [B].⁹ In cases of severe septicaemia, transfer to a critical care unit may be required so that inotropic support can be initiated; however it is essential that administration of broad-spectrum antibiotics occurs within one hour of diagnosing a septic state. This is known to improve survival rates.

Specific management

This should be aimed at the administration of an appropriate antibiotic, which may need to be given intravenously in the first instance. In line with controls assurance standards, all hospitals

should have an antibiotic policy determined by examination of the antibiotic sensitivities of organisms that have been detected within that unit. These policies need to be regularly reviewed, easily accessible and well promoted throughout the hospital. Once the relevant culture results are available, it is essential that any empirical antibiotic therapy commenced is reviewed in light of the known antibiotic sensitivities.

The management of proven endometritis has been shown to be optimal if antibiotics that cover *Bacteroides fragilis* and other penicillin-resistant anaerobic bacteria are used. When uncomplicated endometritis is clinically improving on intravenous therapy, there appears to be no advantage in continuing oral therapy [A].¹⁰ As no single antibiotic regimen has yet been shown to be superior to others in the treatment of UTIs, therapy should be determined by policies based on the antibiotic sensitivities of bacteria isolated locally [A].¹¹

As already mentioned, the Health Protection Agency in England has noted an estimated 62 per cent increase in the incidence of invasive group A streptococcal infections, with a reported increased mortality rate of 25 per cent. While not all these cases were in postpartum women, some fatalities were. A high index of suspicion should be maintained when patients present with symptoms suggestive of invasive group A streptococcal sepsis, such as general malaise, high fever, severe muscle aches, dizziness, hypotension, confusion, unexplained diarrhoea and vomiting, localised muscle tenderness, pain out of proportion to external signs and a flat red rash over large areas of the body.

Red-flag signs that are suggestive of influenza or group A streptococcal infection can be seen in Table 65.1. Where either of these conditions is suspected appropriate cultures including throat swabs should be taken and antibiotics or antiviral therapy commenced without awaiting the results of these cultures as in the sepsis bundle above.

Where group A streptococcal sepsis is suspected, immediate liaison with a consultant microbiologist is required, the Health Protection Unit must be informed and any contacts who show signs or symptoms of non-invasive group A

streptococcal infection should be treated with penicillin V or, if allergic, azithromycin, and their appropriate contacts traced and treated.¹²

Women thought to have H1N1 infection should be treated with oseltamivir and infection control regimens put in place, including wearing personal protective equipment; in addition in the case of aerosol-generating procedures such as intubation, FFP3 masks should be worn. Although a recent Cochrane review has questioned whether the use of oseltamivir results in a clinically significant benefit in healthy young adults, this review did not consider the benefits in a pregnant population, believing them to already be proven.¹³

Wound infections and endometritis may both be complicated by abscess formation. In these circumstances, antibiotic therapy alone is insufficient, and surgical drainage will be required [E]. The long-term complications of endometritis include subfertility [D].

The management of fever associated with breast problems is detailed elsewhere (see Chapter 67, Problems with breastfeeding).

EBM

- Systematic reviews of randomised controlled trials (RCTs) show:
 - a decrease in infective morbidity following caesarean section if prophylactic antibiotics are used;
 - in cases of endometritis, antibiotics that cover *Bacteroides fragilis* and other penicillin-resistant anaerobic bacteria should be used;
 - if the endometritis is uncomplicated, oral therapy following intravenous therapy is unnecessary.
- RCTs show that the administration of paracetamol to pyrexial patients increases their comfort and does not affect the progress of the disease.
- Expert opinion regarding controls assurance suggests that all hospitals should have their own antibiotic policy.
- In cases of proven sepsis expert opinion is that broad-spectrum intravenous antibiotics should be administered within 1 hour of diagnosis and a sepsis bundle be initiated.

Table 65.1 Red-flag symptoms for H1N1 infection and invasive group A streptococcal infection

H1N1 infection	Invasive group A <i>Streptococcus</i>
Temperature of 38°C	Temperature of 38°C
Cough	Hypotension
Rhinorrhoea or other upper respiratory symptoms	General malaise
Headache	Severe myalgia
Chills	Localised muscle tenderness
Myalgia, which can be severe	Pain out of proportion to the external signs
Vomiting and/or diarrhoea	Flat red rash over parts of the body
	Vomiting and/or diarrhoea

KEY POINTS

- Puerperal sepsis is still a significant and increasing cause of maternal mortality.
- A thorough examination and acquisition of appropriate cultures are mandatory.
- The NHS Executive has produced guidelines regarding controls assurance which suggest that all hospitals should have their own antibiotic policy.
- Paracetamol administration is safe and improves patient comfort.
- Implementation of sepsis bundles has decreased the mortality from sepsis in the general population.

Chapter 66 Disturbed mood

Peter J Thompson

MRCOG standards

Theoretical skills

Understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of:

- manic depression, psychoneurosis, puerperal disorders (baby blues, depression), mood disorders, schizophrenia, reaction to pregnancy loss.

Practical skills

- Observation of the above.

INTRODUCTION

There is significant morbidity and mortality associated with mood disorders in pregnancy, with the morbidity being in both social and physical terms. In the past, it was felt that pregnancy had a protective affect with fewer women committing suicide than would be expected;¹ however, this has been contradicted by reports into maternal mortality in the UK and evidence suggests that the prevalence of psychiatric disorders at conception is the same as in the female non-pregnant population. In the last Confidential Enquiry into Maternal Deaths (CEMD) triennial report there were 13 indirect deaths caused by suicide, with another 16 late maternal deaths. Of the 13 indirect deaths four were during the antenatal period. When all 29 women are considered, most of these deaths were violent (87 per cent) with over half secondary to hanging or multiple injuries from jumping from a height. Of these women, 19 had a past history of psychiatric illness, but in the nine cases where this was identified it was considered to have been appropriately managed in only four cases.²

Antenatal disorders of mood tend to involve the management of pre-existing psychiatric conditions. However, while any psychiatric condition can arise in the postnatal period, either as a recurrence or *de novo*, there are specific postnatal disorders of mood. These fall into three broad categories: 'baby blues', postnatal depression and puerperal psychosis. This section aims to cover all four of the areas above.

DEFINITIONS

'Baby blues' (or postpartum blues) is the term used to describe the transient experience of tearfulness, anxiety and irritability that frequently occurs in the first few days following delivery.

In comparison, postpartum psychosis is defined as a severe mental disorder usually occurring in the first 4 weeks after delivery, characterised by the presence of irrational ideas and unusual reactions to the baby. In addition, these patients also suffer fewer specific symptoms, such as restlessness, irritability, insomnia and lability of mood.

The symptoms of postnatal depression do not differ from the symptoms of depression at other times of life, but a temporal association with childbirth distinguishes it from other forms of depression. There does, however, seem to be little agreement on what the limits of this temporal relationship are, which makes assessment of the literature more difficult. Most studies are limited to depression with onset within 3 months of delivery, although some studies extend this limit to 6 months.

INCIDENCE

As antenatal disorders of mood disturbance are usually due to pre-existing psychiatric conditions, the incidence is approximately the same as amongst non-gravid women of a similar age.

More than 50 per cent of women suffer from postpartum blues, usually commencing on the fourth or fifth postnatal day.³ The incidence of postnatal depression is approximately 10–15 per cent,⁴ whereas postnatal psychosis is rare, occurring in 0.1 per cent of cases.⁵

AETIOLOGY

Antenatal conditions

As already mentioned, although antenatal mood disorders are usually secondary to pre-existing conditions, they can be precipitated for the first time by a significant life event – the

pregnancy. Pregnancy can place an additional strain on many relationships, not to mention the worries of future financial burdens, which may be sufficient to destabilise a susceptible individual. Therefore, these conditions may be secondary to the social implications of pregnancy rather than the pregnancy itself.

Baby blues

As the immediate postnatal period is a time of significant physiological and social change, it is not surprising that a significant number of mothers suffer from disorders of mood. Baby blues is a self-limiting condition that has not been associated with any specific metabolic or endocrinological disturbance. It is more common in women following their first delivery, and some authors believe that sufferers are not more likely to have a past psychiatric history than non-sufferers. Other factors such as lack of sleep, hospitalisation and pain have been implicated in the aetiology of this condition.

Postnatal depression

The social and physiological changes seen at this time are also relevant to postnatal depression and puerperal psychosis. Although it is still true that no specific endocrinological change has been associated with the onset of postnatal depression, it has previously been hypothesised that the fall in both progesterone and oestrogen concentrations is implicated, as these hormones are known to have psychoactive properties. Unlike baby blues, postnatal depression is associated with a past history of psychiatric illness. One of the problems with determining the aetiology of this condition is that not all experts even recognise it as a separate disease entity.

Puerperal psychosis

Whether puerperal psychosis is a discrete disease entity or a rapidly evolving affective psychosis is a matter of much debate. The aetiology of puerperal psychosis is poorly understood; however, it does appear to be more common following the first delivery and in patients with previous bipolar disorders, and is recognised as having a 25 per cent risk of recurrence in subsequent pregnancies. Many patients also suffer from recurrent relapsing affective disorders for the remainder of their lives.⁶

MANAGEMENT

Antenatal conditions

Management of psychiatric illnesses during pregnancy is similar to that outside pregnancy and should include both pharmacological and non-pharmacological therapies. The main concerns for both women and their physicians are the effects that psychotropic drugs may have on the fetus, due to

their high transplacental transfer rates. Indeed, although these drugs are not licensed for use in pregnancy, it is well established that if medication is withdrawn for mood disorders, anxiety disorders and schizophrenia, there are high rates of relapse during pregnancy. In view of this, several reviews have been published examining the possible teratogenic effects of these drugs (see Chapter 27, Medication in pregnancy). However, as new data are established daily on the adverse effect of drugs, readers are encouraged to search for the latest systematic reviews and teratology databases for themselves, e.g. <http://toxbase.u5e.com/>.

Overall, antidepressants as a group have not been associated with an increase in major malformations, although in the case of paroxetine, and more recently fluoxetine, both the relevant drug company and the FDA in the US issued a warning regarding cardiac malformations following paroxetine usage in the first trimester [D].⁷

Following treatment in the first trimester of pregnancy, benzodiazepines, antipsychotic medications and lithium have all been associated with small but significantly increased risks of teratogenicity in the offspring. Therefore, women with a psychiatric disorder who are pregnant or who are trying to conceive should be counselled regarding the relative risks of disease relapse and fetal exposure to medication, and where appropriate an alternative, safer drug may be prescribed [C].

Women with a past history of psychiatric problems are at an increased risk of developing postnatal depression, and should therefore be identified and offered increased professional support following delivery [E]. Screening for mood disorders is a routine part of antenatal care in the UK, and should occur both antenatally and postnatally. Early diagnosis and treatment can help reduce the negative impact of mental illness on the whole family unit.

In addition to the above it is usually recommended that women with significant disorders of mood will require a written care plan, which is formulated by a multidisciplinary team, and may include liaison with the social service sector to implement a safeguarding plan for the unborn child.

Baby blues

Research into the management of this condition is limited, with the only significant research being focused on an attempt to identify women who are at increased risk of developing either postnatal depression or puerperal psychosis. Management consists of providing a supportive environment for the new mother, with both professionals (particularly midwives) and the family working together [E]. Drug therapy is not indicated, as the condition is usually self-limiting. Those women in whom the condition persists beyond 10–14 days⁹ and those who have marital difficulties appear to have an increased risk of developing puerperal psychosis.

NICE has recommended in its guideline on postnatal care of women that resolution of these symptoms should be confirmed between 10 and 14 days post-delivery, and if they have

not resolved, assessment for postnatal depression performed and where appropriate further referral instigated [E].¹⁰

Postnatal depression

Whether or not postnatal depression is a separate disease entity from depression, there is no doubt that it can have significant long-term effects on the mother–infant relationship and the development of the infant. Therefore, early detection and appropriate treatment are essential. The Edinburgh Postnatal Depression Score is a self-report scale that has ten items relating to symptoms of depression. The detection rates of postnatal depression in the community can be improved by implementation of the Edinburgh Postnatal Depression Score at a 6-weeks postnatal check [C].¹¹

The treatment of postnatal depression in the past has mainly revolved around social support and supportive therapy, the administration of sex hormones (oestrogen and progesterone) and the prescription of antidepressants. In the case of sex hormone therapy, a systematic review of studies that used oestrogen or progesterone to treat women with postnatal depression showed discouraging results. Treatment with high doses of oestrogen did appear to reduce the depression scores of women with severe postnatal depression, but the potential side effects of thromboembolic disease, endometrial hyperplasia and inhibition of lactation make this an unattractive therapy for women to take. Progesterone therapy was associated with a higher incidence of postnatal depression than placebo. This could be because the mood elevation seen with natural progesterone is not an effect of synthetic progestogens.¹² Therefore, these medications cannot be recommended for women with postnatal depression [A]. Modern therapy, therefore, revolves around supportive therapy and pharmacological treatments.

Early involvement of a psychiatrist with experience in this condition is essential [E] and if the patient requires hospitalisation, it is preferable to avoid separation from the baby, which will necessitate admission to a specialised mother-and-baby unit [D]. Ten trials have been included in a systematic review of the treatment of postnatal depression with psychosocial and psychological interventions as compared with the usual postpartum care.¹³ This review showed a risk ratio of 0.44 (CI 0.24–0.88) for the evidence of depression at 1 year in favour of the interventions [A].

There are sparse data where the role of antidepressants for the treatment of this condition has been investigated in the context of a randomised controlled trial (RCT), though a recent review in the Cochrane database has shown an increased response and remission rate when comparing selective serotonin re-uptake inhibitors (SSRIs) to treatment with placebo. This analysis does however point out the limitations of the review, including the small numbers of patients involved [A].¹⁴ NICE has recommended that for women with a new onset of mild to moderate depression in the postnatal period, self-help strategies, non-directive counselling and brief courses of cognitive–behavioural therapy or interpersonal psychotherapy should be offered first, with antidepressant medication

reserved for those who are resistant to the above, those with a history of severe depression and those who decline psychological treatment. For those with moderate depression with a history of a depressive episode or those with severe depression during the postnatal period, treatment should be with structured psychological treatment or, if the patient has a preference for them, with antidepressants. If antidepressants are to be used then NICE recommends that the drugs of first choice are SSRIs (with the exclusion of paroxetine). If these treatments fail separately, a combination of the two treatments should be considered [E].⁸

Puerperal psychosis

This is a psychiatric emergency and its treatment requires hospitalisation. As it is preferable to avoid separation of the mother from her infant, admission to a specialised mother and baby unit should be arranged, where antidepressant and neuroleptic medication can be initiated and supervised by psychiatrists [C]. Failure to treat the condition aggressively is associated with rates of infanticide as high as 4 per cent [C].¹⁵ This aggressive treatment may include electro-convulsive therapy [D].

EBM

- Systematic review of two RCTs shows progesterone therapy to be of no benefit, although oestrogen therapy may decrease the severity of depression when used as adjunctive therapy.
- An RCT has shown that fluoxetine is as effective as cognitive–behavioural therapy for the treatment of postnatal depression.
- Cohort studies show that the Edinburgh Postnatal Depression Score is effective in detecting women at risk of postnatal mood disorders.
- Retrospective cohort studies show that most drugs used to treat psychiatric conditions are relatively safe to use in pregnancy.

KEY POINTS

- Most drugs used to treat psychiatric disorders are relatively safe to use in pregnancy.
- Postnatal screening for postnatal depression using the Edinburgh Postnatal Depression Score is effective.
- The best treatment for postnatal depression appears to be cognitive–behavioural therapy, with the administration of antidepressants where necessary. The antidepressants of choice are SSRIs.
- Puerperal psychosis is a psychiatric emergency.
- Most women who commit suicide following or during pregnancy have a significant history of mental health disorders.

Chapter 67 Problems with breastfeeding

Peter J Thompson

MRCOG standards

Theoretical skills

- Infant feeding; understand the advantages of breastfeeding for both the mother and neonate.
- Be aware of interventions that improve breast engorgement.

Practical skills

- Perform a reliable and appropriate examination, including breast examination.
- Detect breast problems.

INTRODUCTION

Although a physiological process, breastfeeding is an action that women perform for only a small part of their lives. For it to be successful, not only do the correct physiological processes have to occur, but both the mother and neonate need to adapt to this situation, and whereas some mothers and babies seem to be able to establish it without any problems, others do not. Increasingly, the proportion of women breastfeeding has been identified as a high priority for the government in their White Paper 'Our Healthier Nation'.¹ Indeed, the WHO recommends exclusive breastfeeding until the age of 6 months.² For these targets to be reached, interventions of proven benefit need to be employed throughout the health service. To this aim, UNICEF has developed a programme whereby maternity services that employ their Ten Steps to Successful Breastfeeding and seven-point plan for sustaining breastfeeding can apply for Baby Friendly status. These are evidence-based standards designed to promote, protect and support breastfeeding, with new standards produced in 2012. They cover topics including the establishment of local policies, training of staff, antenatal and postnatal education of women and the establishment of support groups. As an incentive to maternity services, many clinical commissioning groups in England are insisting on their acute trusts achieving Baby Friendly status. Other initiatives to encourage breastfeeding have included trials concerning supplying breastfeeding mothers with monetary incentives.

DEFINITIONS

There are extensive data in the literature supporting the concept that the optimum food for babies is breast milk. The benefits bestowed upon the infant are pertinent in both the short and long term. Included in these benefits is reduced morbidity from respiratory, gastrointestinal, urinary tract and middle ear infections, as well as a decreased tendency towards atopy and obesity. For the mother, there are both health benefits, such as a decrease in the incidence of epithelial ovarian cancer and premenopausal breast cancer, as well as financial benefits. Therefore, conditions that interfere with breastfeeding constitute important epidemiological health issues.

INCIDENCE

The last national audit in 2010 showed that following delivery approximately 81 per cent of women in the UK commence breastfeeding, a 5 per cent rise from the survey performed in 2005. Breastfeeding is much more common among women from least-deprived areas, those educated over the age of 18, those in ethnic minorities, those aged over 30 and women in England rather than other parts of the United Kingdom.³ However, in the UK, these rates fall to approximately 69 per cent after 1 week, 55 per cent at 6 weeks and 34 per cent at 6 months. All of these are significant rises on the figures found in the 2005 survey. Despite these increases the number of women exclusively breastfeeding at 6 months of age is still less than 1 per cent.

AETIOLOGY

The establishment of lactation is dependent upon a variety of influences, including the production of prolactin from the anterior pituitary gland and oxytocin from the posterior pituitary gland. These hormones stimulate milk production and ejection, respectively. However, problems with lactation are rarely due to pituitary–hypothalamic-axis dysfunction. Indeed, the main reasons why women neither initiate breastfeeding nor continue it as long as in other European countries appear to relate to social and cultural issues. This section

does not attempt to discuss these, but concentrates on the management of mastitis, breast abscess formation, enforced separation of mother and baby, and poor infant feeding. Many of these problems are interrelated and it has been suggested that the majority can be avoided by using a technique of feeding on demand and attaching the baby to the nipple in the correct position from the first feed onwards.⁴

MANAGEMENT

Mastitis

Mastalgia is defined as painful breasts. The prevalence of this condition varies with the duration of breastfeeding, though of women who fed for 6 months 46 per cent complained of breast engorgement, blocked milk ducts or mastitis.³ The aetiology of this condition revolves around the imbalance between the production of milk and infant consumption that occurs in a small proportion of women. When milk production exceeds the infant's requirements, the alveolar spaces within the breasts become distended, with the breast feeling hot, swollen and tender. This swelling leads to compression of the capillaries, which in turn increases the arterial pressure to the breasts, causing compression of the connective tissues and a decrease in lymphatic drainage. This results in the formation of oedema and engorgement of the breast (obstructive mastitis), which may develop into infective mastitis.

Five factors have been associated with the development of breast engorgement: delayed initiation of feeds, infrequent feeds, time-limited feeds, a late shift from colostrum to milk production, and the habit of administering supplementary feeds.⁵ Therefore, avoidance of these will significantly decrease the incidence of this problem.

Many interventions have been proposed for the treatment of breast engorgement, some of which have been the subject of systematic reviews, which have examined both traditional and modern treatments. The most effective treatments tested involved the use of anti-inflammatory agents [B]. The agents tested are not available in the UK, and it is uncertain whether these results are applicable to similar agents. Interventions, such as the topical application of cabbage leaves, the use of gel packs and ultrasound treatment, all showed an improvement in symptoms, though not to a greater extent than placebo. It has been postulated that these improvements are secondary to warming and physically massaging the breast [A].⁶

As previously mentioned, breast engorgement may become complicated by infection, leading to infective mastitis. The most common causative organism is *Staphylococcus aureus*, with others occasionally being implicated, including *Staphylococcus epidermidis*, groups A, B and F beta-haemolytic *Streptococcus*, *Haemophilus influenzae* and *Escherichia coli*. Management consists of the administration of an antibiotic that is effective against beta-lactamase-producing bacteria and encouraging the mother to continue breastfeeding or manually expressing milk [B].

Breast abscess formation

Although uncommon, the exact prevalence of this condition is not well reported, with the better estimates being in the region of 0.4 per cent.⁷ It does, however, appear to be more common in women over 30 years of age, primiparous women and particularly following mastitis, with a reported incidence of 5–11 per cent most commonly following inadequate treatment of the mastitis.⁸ Not surprisingly, therefore, the prevention of abscess formation is achieved by the avoidance of milk stasis.^{9,10} However, unlike for infective mastitis, most authors would recommend that feeding from the affected breast ceases when pus is draining from the nipple [C]. The commonest causative organism is, as with mastitis, *Staphylococcus aureus*. Once formed, abscesses require either surgical drainage, under general anaesthesia,¹¹ or preferably needle aspiration with or without ultrasound control,^{12,13} with concomitant administration of broad-spectrum antibiotics [C]. Ultrasound-guided aspiration is most successful when the abscess is 3 cm or less in diameter, with failure being associated with abscesses greater than 5 cm in diameter [B].¹⁴ Repeat needle aspiration may be required and should continue until the abscess is less than 4 mm in diameter. When surgical drainage is performed, choice of incision for the drainage is controversial; circumferential incisions give optimum cosmetic results, but radial incisions carry a smaller risk of damage to other lactiferous ducts. Therefore, it would seem sensible to perform circumferential incisions to drain superficial abscesses, whereas deep abscesses should be drained via a radial incision [E].

Enforced separation of mother and baby

Separation of mother and baby, usually secondary to the ill-health of one or both parties, may have a significant impact on the establishment of breastfeeding. The successful long-term establishment of breastfeeding is dependent upon frequent feeding,⁶ and this is obviously complicated when the parties are physically separated or when one or other party is too ill to feed. Indeed, ensuring that mothers and babies are together 24 hours a day is one of the 'Ten Steps to Successful Breastfeeding' promoted by UNICEF. However, systematic reviews have failed to show improved prevalence of long-term breastfeeding in groups of women who commence feeding early (within 30 minutes) when compared to those who commence feeding their infants between 4 and 8 hours post-delivery, though early skin-to-skin contact does appear to prolong duration of breastfeeding [A].^{15,16}

If breastfeeding is to be established in these circumstances, the expression of breast milk, in place of frequent feeds, is essential [D]. This can be done by hand or mechanically, with collection of the milk in a container to feed the infant at a later date.

This problem is seen commonly in babies admitted to a neonatal unit and, because of the previously noted advantages of breastfeeding such children, many units have established milk banks to store this milk. There are occasions when breastfeeding may be contraindicated, for example maternal HIV

infection, or relatively contraindicated, for example severe maternal ill-health. In such conditions, it may be appropriate to prescribe a dopamine antagonist, such as cabergoline, which will cause the production of milk to stop.

Poor infant feeding

Poor infant feeding secondary to ill-health has already been considered above. Poor technique of breastfeeding is another cause of poor feeding. A systematic review of increased support for mothers by healthcare professionals has shown a significantly decreased risk of discontinuation of breastfeeding. This effect was larger when there was both professional and lay support and the effect increased further when these supporters were UNICEF trained [A].¹⁷

EBM

Systematic reviews of randomised controlled trials (RCTs) show that:

- prolonged breastfeeding is not more prevalent in women who perform the first feed within 30 minutes of birth;
- support from a professional person increases the likelihood of a woman exclusively breastfeeding;
- the treatment of choice for breast engorgement is an anti-inflammatory agent.

There are few RCTs on the management of the other breast pathologies mentioned above, with most evidence coming from cohort or retrospective studies.

KEY POINTS

- Breastfeeding is beneficial to both mother and infant.
- A high proportion of women never commence breastfeeding and, of those who do, fewer than half will still be breastfeeding at 6 months.
- Women with obstructive and infective mastitis should continue to breastfeed.
- Women with breast abscesses should discontinue breastfeeding and will require needle aspiration or surgical drainage.

Chapter 68 Normal and abnormal development of the genitalia

Rebecca Deans and Sarah M Creighton

MRCOG standards

Theoretical skills

- Revise your knowledge of the embryological development of the male and female urogenital system.
- Understand the situations in which a disruption in these pathways can lead to disorders of sex development, Müllerian anomalies and Wolffian duct remnants.
- Understand the classification of Müllerian anomalies.
- Know about first-line investigations for disorders of sex development and Müllerian anomalies and treatments available in tertiary referral centres.

Practical skills

- Be able to take an appropriate history.
- Be able to initiate appropriate investigations to enable a diagnosis and/or tertiary referral

INTRODUCTION

Fetal development of the gonads, external genitalia, Müllerian ducts and Wolffian ducts can be disrupted at a variety of points, leading to a wide range of conditions with a large spectrum of clinical presentations. Disorders of sex development (DSD) occur when there is a disruption of either gonadal differentiation or fetal sex steroid production or action. Müllerian anomalies and Wolffian duct remnants occur when there is disruption of the embryological development of these systems. An understanding of embryology, as well as molecular genetics, helps us determine the biological basis of these conditions. Many of these cases present in infancy, with initial investigations and treatment performed by paediatric endocrinologists. Some will present for the first time to the gynaecologist and fertility subspecialist with primary amenorrhoea or infertility. Paediatric and urological surgeons

may have initially treated others. Patients with DSDs may have coexisting medical problems and require thorough evaluation. As well as anatomical and fertility concerns for these patients, there are often many psychological issues; therefore management in a multidisciplinary team (MDT) is essential for the management of more complex cases. In some conditions, the optimal operative management is still uncertain, and there is currently debate regarding the optimal timing or need for genital surgery in patients with DSD conditions who present in childhood.

NORMAL EMBRYOLOGICAL DEVELOPMENT OF THE INTERNAL AND EXTERNAL GENITALIA

Genetic sex is determined at the moment of conception by the presence or absence of the Y chromosome, and after week 6 should guide the subsequent development of the fetus down one of two standard pathways – male or female. Until this time, development is the same in all fetuses. Primordial germ cells (the precursors of gametes) can be seen at 3 weeks in the endoderm of the yolk sac wall. During weeks 5 and 6, they migrate by amoeboid movement to the genital ridge (future gonad), an area of mesenchyme medial to the developing mesonephros and Wolffian (or mesonephric) duct. During week 6, primitive sex cords form around the germ cells in the indifferent gonad. The two Müllerian (or paramesonephric) ducts also appear lateral to the Wolffian ducts. At the same time, at the caudal end of the fetus, the cloacal membrane folds and is separated into the anterior urogenital and posterior anal parts. The urogenital section with the genital tubercle will become the future external genitalia, and by week 7 consists of a genital tubercle, urogenital membrane, urogenital folds and, more laterally, labioscrotal swellings. At the end of week 7, the urogenital membrane has degenerated and the urogenital sinus freely communicates with the amniotic fluid.

The first noticeable divergence in male and female fetuses is the differentiation of gonadal structure. The indifferent gonad has the potential for testicular or ovarian development.

The presence of intact germ cells seems necessary for the ovary to develop, but this is not required for testicular development. The gonad remains undifferentiated until around 42 days. After gonadal differentiation has occurred, the presence or absence of gonadal hormone production and other fetal factors then guides the development of the Müllerian ducts, Wolffian ducts and external genitalia. Sertoli cells in the fetal testis secrete anti-Müllerian hormone (AMH – also called Müllerian inhibiting substance, MIS), leading to active regression of the Müllerian ducts. Early Leydig cells commence production of testosterone which acts through the androgen receptor on the Wolffian ducts, leading to the development of the vas deferens, seminal vesicle and epididymis. Testosterone is converted to its active metabolite dihydrotestosterone (DHT). The fetal ovaries do not secrete androgen or AMH, and therefore there is female external genital development, growth of the Müllerian ducts and spontaneous regression of the Wolffian ducts.

STANDARD MALE PATHWAY

In an XY fetus, activation of the *SRY* (sex-determining region of the Y chromosome) gene at the end of week 6 guides the indifferent gonad to commence development into a testis.¹ Other autosomal genes (e.g. *WT1*, *SOX9*, *SFI*) are also involved in this genetic cascade.² The medullary sex cord cells become Sertoli cells, surrounding the primitive germ cells. At puberty, these will become the seminiferous tubules surrounding the spermatozoa. Sertoli cells produce AMH, which acts locally to cause apoptotic regression of the adjacent Müllerian ducts from 7 weeks. The appendix testis and prostatic utricle are usually all that remain of the Müllerian ducts in the male.

At around weeks 8–10, Leydig cells appear in the testis and start to secrete testosterone. The control of testosterone production may be independent initially, then under the control of placental human chorionic gonadotrophin (hCG) through the shared leutinizing hormone/hCG receptor (LHCGR), and subsequently by 20 weeks the hypothalamic pituitary (gonadotrope) axis becomes active and fetal leutinizing hormone (LH) production controls steroidogenesis. Testosterone acts through the androgen receptor and causes development of the Wolffian ducts into the vasa deferentia, and later the seminal vesicles and epididymides. Testosterone is also released into the circulation and undergoes peripheral conversion to its more active metabolite DHT by the enzyme 5 α -reductase type 2, and acts on the target tissues of the perineum resulting in development and growth of the genital tubercle, urogenital sinus, urogenital folds and labioscrotal swellings into the glans penis, penile shaft, urethral tube and scrotum, respectively. The penis is similar in size to the clitoris at 14 weeks and, under the influence of DHT, continues growing until birth. Testicular descent is mediated by the Leydig cells under the influence of the hypothalamic pituitary (gonadotrope) axis, commences at 12 weeks, and is usually complete by week 34.

STANDARD FEMALE PATHWAY

Traditionally, ovarian development in an XX fetus has been considered a ‘default pathway’; however, emerging research indicates that a distinct set of genes are expressed in the developing ovary and required for maintaining ovarian integrity and actively opposing testicular development (*DAX1*, *WNT4/RSPO1*), termed ‘anti-testis’ genes.^{3–5} These genes, in combination with the absence of the *SRY* gene, cause the indifferent gonad to commence ovarian differentiation at around week 7. The sex cord cells degenerate and secondary sex cords form and surround the primordial germ cells. Between 5 and 24 weeks, rapid mitotic expansion of primordial oogonia occurs, followed by first meiotic division (8–36 weeks), and subsequently meiotic arrest as primordial follicles. The presence of ovaries is not required for regression of the Wolffian ducts, and it is the absence of local testosterone that causes their regression at 10 weeks. The paroophoron, epoophoron and Gartner’s cysts are all that may remain of the Wolffian ducts in the female. The absence of circulating testosterone also leads to an absence of peripheral DHT and directs the genital tubercle, urogenital sinus, urogenital folds and labioscrotal swellings to develop into the clitoris, lower vagina, labia minora and labia majora, respectively.

As AMH is not produced by the fetal ovary, the Müllerian ducts continue to develop. These paired mesodermal ducts originate in week 5, lateral to the Wolffian ducts at the third to fifth thoracic segment. They are thought to be associated with the basement membrane of the Wolffian ducts and grow caudally guided by them. The cranial ends of the Müllerian ducts are independent of the Wolffian ducts and remain separate as the Fallopian tubes. At the pelvis, the Müllerian ducts cross the Wolffian ducts anteriorly to lie medially next to each other. At weeks 8–10, the pelvic Müllerian ducts have fused and subsequent breakdown of their medial walls leads to a single tube, which will become the upper vagina, cervix and the uterine epithelium and glands. Surrounding mesenchymal tissue will become the myometrium and stroma. At their caudal end, the fused Müllerian ducts form the Müllerian tubercle, which connects with a thickened area of the urogenital sinus that develops into the paired sinovaginal bulbs. This connection of the endodermal urogenital sinus and mesodermal Müllerian ducts forms the vaginal plate – a column of squamous tissue. It remains unknown how much of each tissue (and possibly some of the Wolffian duct) contributes to this developing vagina. In weeks 10–16, the vaginal plate enlarges and develops a cavity, which is separated from the urogenital sinus by an endodermal membrane.

Gradual change of the lower Müllerian duct epithelium from columnar to stratified squamous epithelium occurs, ending at the future external cervical os. By month 5, the urethra and vagina are separated by a septum, and the endodermal membrane between the vagina and urogenital sinus breaks down to form the hymen. The urogenital sinus forms the vaginal vestibule.

HUMAN SEX DEVELOPMENT

Human sex development can be divided into three main parts:

- 1 chromosomal sex (presence of X and/or Y chromosome);
- 2 gonadal sex (development of the gonad into either testis or ovary);
- 3 phenotypic or anatomic sex (appearance of the internal and external genitalia).

This differs from the concept of gender or 'brain sex', which encompasses gender identity (which is one's self-representation), gender role behaviour and sexual orientation. Occasionally, there is discordance between sex and gender, as well as the elements of gender. It is important to note that no single category dictates someone's sex, and it is important to consider all components of sex when managing the patient with DSD.

KEY POINTS

- The *SRY* gene directs the gonad to become a testis.
- The absence of the *SRY* gene in combination with 'anti-testis' genes differentiates the gonad to the ovary.
- The presence or absence of androgens acting via androgen receptors determines external genital development.
- The presence of gonadal testosterone production leads to Wolffian duct differentiation into vas deferens, epididymis and seminal vesicle.
- The presence of gonadal AMH production leads to Müllerian duct regression.
- The absence of gonadal AMH production allows Müllerian duct differentiation into the upper vagina, cervix, uterine glands and epithelium and Fallopian tubes.
- The absence of gonadal testosterone production allows Wolffian duct regression.
- The genital and urinary systems are closely associated and therefore abnormalities that occur in the Müllerian system commonly affect the renal system.
- Definition of sex encompasses chromosomal sex, gonadal sex, and phenotypic sex. Gender relates to psychosexual development.

ABNORMAL EMBRYOLOGICAL DEVELOPMENT: DISORDERS OF SEX DEVELOPMENT

Definition and classification

Over the last 20 years, there has been a significant increase in the understanding of the underlying aetiology of many forms of abnormal embryological development. Clinicians were becoming increasingly aware that traditional terms,

such as intersex, true hermaphroditism, female pseudohermaphroditism and male pseudohermaphroditism, were confusing, inaccurate and often considered negative by the patients involved. Therefore, a new consensus meeting was held in 2005, and one of the main elements to emerge was a new nomenclature system for this group of disorders, which is more generic, diagnostically accurate and less derogatory.⁶⁻⁸

The term 'disorders of sex development' or DSD was established to describe congenital conditions with atypical development of chromosomal, gonadal or anatomical sex. This encompasses a blend of the physically defining features associated with males or females, i.e. karyotype, gonadal structure, internal genitalia and external genitalia, and covers a diverse range of conditions including individuals with standard male or female genitalia who may have a variety of internal genital organs and karyotype, and also those with ambiguous external genitalia. In addition, an updated classification system was proposed (Table 68.1) which divides conditions into:

- sex chromosome DSD;
- 46XY DSD;
- 46XX DSD.

This new classification system also embodies a wider range of disorders, for instance sex chromosome DSD includes Turner's syndrome (45X) and Klinefelter's syndrome (47XXY), which were not previously considered 'intersex' conditions. Similarly, female patients with congenital adrenal hyperplasia (CAH), who were traditionally considered to have an adrenal disease, are now included as 46XX DSD due to the surgical and reproductive consequences associated with this disorder. Although there are a large number of DSD conditions, only the more common conditions have been considered in this chapter (Table 68.2).

With new knowledge concerning fetal sexual differentiation and development, greater awareness and understanding

Table 68.1 Updated nomenclature for disorders of sex development: adapted from Ref. 6, with permission

Terminology used previously	Proposed new terminology
Intersex	Disorders of sex development (DSD)
Male pseudohermaphrodite	
Undervirilisation XY male	
Undermasculinisation XY male	46XY DSD
Female pseudohermaphrodite	
Overvirilisation of an XX female	
Virilisation of an XX female	46XX DSD
True hermaphrodite	Ovotesticular DSD
XX male or XX sex reversal	46XX testicular DSD
XY sex reversal	46XY complete gonadal dysgenesis

Table 68.2 Key features of DSD conditions

DSD condition	Karyotype	External genitalia	Internal genitalia	Special features
Congenital adrenal hyperplasia (CAH)	XX	Virilised/masculinised	Uterus and ovaries	Coexisting glucocorticoid (and sometimes also mineralocorticoid) deficiency requiring steroid replacement therapy
Complete androgen insensitivity syndrome (CAIS)	XY	Female	Testes	Absent pubic and axillary hair; at risk of osteoporosis; gonadal malignancy risk small until after 50 years of age
Swyer's syndrome	XY	Female	Streak gonads and uterus	High risk of gonadal malignancy; poor breast development; normal axillary and pubic hair
5 α -reductase deficiency	XY	Female or ambiguous at birth, virilising/masculinising at puberty	Testes	In those with testes <i>in situ</i> , 60–80% undergo change of gender from female to male at some point from late childhood onwards
17 β -hydroxysteroid dehydrogenase – type 3 deficiency	XY	Variable; often female or ambiguous at birth, virilising/masculinising at puberty	Testes	In those with testes <i>in situ</i> , 60–80% undergo change of gender from female to male at some point from late childhood onwards
46XX/XY ovotesticular DSD	71% XX 20% XX/XY 7% XY 2% other	Often ambiguous	Mix of ovary and/or testis and/or ovotestes; uterus or male ducts	Fertility described as both males fathering a child and females carrying a pregnancy

of female sexual function and a more patient-centred emphasis on condition management, it is hoped that patient care will be improved in this group of individuals. Although there are no RCTs or even adequate long-term data to inform the management of DSD, currently expert opinion and a few small cohort studies and retrospective, uncontrolled trials form the basis of management.⁹ Disclosure of important aspects of the patient's condition (karyotype, gonadal status, fertility potential) is essential.¹⁰

Incidence

The incidence of DSD conditions in the UK is unknown. An estimate for the prevalence is one in 2000.¹¹ Conditions with autosomal recessive inheritance are more prevalent in communities in which consanguinity is common.

Aetiology

Most DSD conditions occur due to a genetic or environmental disruption to the pathway of fetal sexual development. This disruption can be of gonadal differentiation or development, sex steroid production, sex steroid conversion or tissue utilisation of sex steroids.

Presentation and investigation

Every DSD condition has a spectrum of severity and therefore may present in a variety of ways:

- ambiguous genitalia at birth;
- mismatch of fetal chromosomal results, such as amniocentesis or chorionic villus sample with phenotype at birth;

- salt-losing crisis in neonatal life (CAH);
- sibling history of intersex;
- ambiguity of the genitalia developing in childhood or puberty;
- inguinal hernia with unexpected gonad;
- pelvic mass with gonadal tumour;
- primary amenorrhoea or pubertal delay;
- infertility;
- sexual dysfunction;
- part of a syndrome with other anomalies (e.g. renal anomalies in Denys–Drash syndrome).

Initial investigation will depend on presentation, but should include karyotype, testosterone, LH, follicle-stimulating hormone (FSH), 17-hydroxyprogesterone and pelvic ultrasound scan. Further investigation will depend on initial findings, external genital appearance and clinical presentation, and may include androstenedione, DHT, oestradiol, 24-hour urinary collection for steroid metabolites, hCG stimulation test, synacthen test, renal ultrasound scan, MRI and DNA for genetic testing.

Management

The areas to consider in intersex management are:

- accurate diagnosis;
- need for hormone replacement therapy;
- screening for associated medical conditions;
- providing information on the condition;
- psychological treatments;
- disclosure of diagnosis;
- genetic counselling for other family members;
- sex assignment for children;
- gonadal malignancy risk;
- fertility options;
- genital surgery options for ambiguous genitalia;
- vaginal enlargement options;
- access to peer support.

Accurate diagnosis at presentation is essential, and referral to an appropriate paediatric or adult multidisciplinary DSD service (endocrinology, gynaecology, surgery and psychology expertise), where available, is ideal. Individuals with different DSD conditions may require specific medical and surgical treatments; however, all should have access to experienced clinical psychologists and peer support via the relevant national support organisations. Over the past decade, a major shift in management has been the recognition that all patients have a right to information concerning the details of their condition, and the provision of this information and the options available need sensitive communication in a supported environment. Ideally, this should be with the expertise of a trained clinical psychologist. It is no longer considered good practice to withhold condition details from the patient.^{8,10} There is no evidence other than clinical experience and ethical evaluation on which to base this management, as

there have been no studies evaluating long-term psychological outcomes with concealed or revealed diagnosis information; however, it is considered that disclosure should be planned with the opportunity for ongoing dialogue,¹² and in general disclosure is associated with enhanced psychosocial adaptation.¹⁰ Gonadal malignancy and fertility options vary with the different DSD conditions.⁸

Cases presenting at birth or in childhood may be seen by a paediatric gynaecologist as part of a DSD team, but more often will be under the care of a paediatric endocrinologist, paediatric surgeon or paediatric urologist. The majority of these cases will have presented due to ambiguous genitalia. After thorough evaluation and diagnosis, sex of rearing is assigned and cosmetic genital surgery is considered where relevant. Currently, many neonates with ambiguous genitalia are assigned as females. The rationale for early feminising genital surgery for the more severely virilised cases includes relative technical ease of surgery, negating the need to disclose the disorder to the patient, and an assumed ‘one stage’ procedure, with the theoretical aim of initially aiding parental acceptance of the child’s assigned gender, and later improving the psychological outcomes for the child.^{13,14} All of the indications for genital surgery are now being re-evaluated, and current management based upon clinical audits and vocal adult patient support groups has led to recommendations to delay unnecessary genital surgery till an age of informed consent, and to individualise care.

At present, it remains unknown whether infant genital surgery has an effect on parental acceptance of assigned gender or on later psychological outcomes for the child. Small cohort studies suggest that the majority of infants undergoing genital surgery will require repeat genital treatment (surgery or vaginal dilatation therapy) at or after puberty, mainly for vaginal introital stenosis but also for cosmesis. Sexual function in subjects with DSD has been noted to be impaired compared to population controls.^{15,16} Sexual function following feminising genital surgery also contributes to loss of sensation and subsequent reduced sexual function.¹⁹ Small observational studies of adults who had undergone clitoral reduction surgery in childhood have suggested that orgasm is reduced^{14,20,21} and that genital surgery may contribute to adult sexual dysfunction.^{22–24} Whether sexual impairment is due to genital surgery or simply the DSD condition is still debated.¹⁶ Certainly the role of vaginoplasty in the child is less clear and therefore deferring this procedure until adolescence where informed consent may be ascertained is generally the recommendation.^{16,17}

Gynaecologists are more often involved in the care of the older child developing ambiguous genitalia at puberty, or in follow-up of adults who underwent feminising genital surgery as children. In many subjects born with ambiguous genitalia, there will be vaginal hypoplasia or agenesis, and the gynaecologist will need to discuss the treatment options at the appropriate time. Where childhood surgery has been performed, there is a strong possibility that repeat surgery

may be required for vaginal stenosis, hypoplasia or genital cosmesis. This treatment is indicated to improve psychological and sexual outcomes; however, there have been no studies to provide evidence that improvements in these outcomes are achieved.

Enlargement procedures for vaginal hypoplasia include self-dilatation therapy or surgical vaginoplasty. These interventions are offered to improve psychological and sexual outcomes. There is disagreement about both the optimal timing and the choice of intervention; however, it is recommended that these should be performed during or after adolescence.²⁵ There is a consensus now that vaginal dilatation therapy is the treatment of choice for vaginal hypoplasia due to the absence of surgical risk, including the later risk of malignancy in vaginal graft material. In a retrospective study, the success of dilators was as high as 86 per cent for achieving normal vaginal length, and 81 per cent of patients were able to have intercourse free of pain,²⁶ but success depends on the motivation of the patient, and the appropriate time to start treatment must be individualised. Concomitant psychological support may improve outcomes. The surgical vaginoplasty method depends on the genital configuration and surgeon's expertise. In some cases, the aim of vaginoplasty is to open up the lower vagina, with the upper vagina being normally developed. A pull-through vaginoplasty with complete separation of the vagina from the urethra may be required where the vagina does not reach the perineum but instead has joined the urethra near to the bladder, forming a single urogenital perineal opening (the high-confluence vagina). In conditions in which the entire vagina is hypoplastic or absent, there are many vaginoplasty techniques: laparoscopic tension via an external traction device, peritoneal grafting, amnion grafting, skin grafting, bowel grafting, muscle flaps, labial expansion flaps, etc. Each method has different risks and benefits. The surgical risks include malignancy (in graft material), contracture leading to introital stenosis or loss of vaginal length, vaginal prolapse, dry vagina or excessive vaginal discharge.

EBM: Genital surgery for ambiguous genitalia

- There is only minimal evidence to inform management.
- There have been few studies of psychological outcomes after childhood clitoral and genital surgery.
- Cohort studies include beneficial effects of surgery and minimising families' concerns and distress.^{14,17}
- Cohort studies suggest the cosmetic and anatomical outcomes of vaginal and clitoral childhood surgery may be poor.¹⁵
- Control-matched cohort studies of adult female sexual function suggest that childhood cosmetic clitoral surgery impairs sexual function but does not prevent orgasm.^{14,20,21}

EBM: Vaginal enlargement procedures for vaginal agenesis or hypoplasia

- The treatment of choice is dilator therapy and should be the first line in the absence of previous surgery.
- Vaginal dilator therapy should be reserved for adolescent and adult patients and avoided in children.
- Studies suggest that vaginal enlargement self-dilatation therapy is successful in up to 86 per cent of cases.^{26,27}
- Studies show that childhood vaginal enlargement surgery may require revision in up to 90 per cent of cases.^{17,18}
- There are no RCTs of the outcomes of different vaginoplasty techniques.
- Retrospective uncontrolled studies have not shown one method of vaginoplasty surgery to have superior results to another method.

46XX DSD – ABNORMAL EMBRYOLOGICAL DEVELOPMENT OF MÜLLERIAN DUCTS AND PERSISTENCE OF WOLFFIAN STRUCTURES

Abnormal development of the Müllerian ducts can lead to a wide range of conditions. Many are subtle variations of normal Müllerian anatomy, and often remain asymptomatic or require no treatment. Others are transverse or longitudinal structural abnormalities or agenesis of parts of the Müllerian ducts, and may present to the gynaecologist in a variety of ways. An understanding of the timing and sequence of embryological development of the entire urogenital system helps in understanding the range of conditions that occur. Occasionally, Müllerian anomalies may be associated with other conditions such as renal or spinal abnormalities or, more rarely, developmental defects of the cloaca such as bladder exstrophy, cloacal anomalies or anorectal anomalies. Ovarian development is independent of Müllerian duct development. Also considered in this section are lower transverse vaginal septae and the imperforate hymen (which derive from the urogenital sinus endoderm) and persistence of Wolffian duct remnants.

Müllerian anomalies

Definitions

There have been many attempts to classify Müllerian abnormalities, and the American Fertility Society classification is historically the most widely used (Fig. 68.1). Congenital Müllerian abnormalities generally fall into one of three groups: normally fused single Müllerian system with agenesis of one or more parts; unicornuate systems (unilateral hypoplasia or agenesis of one Müllerian duct); or lateral fusion failures (including didelphic and bicornuate anomalies).

I. Hypoplasia/ agenesis (a) vaginal (b) cervical (c) fundal (d) tubal (e) combined	II. Unicornuate (a) communicating (b) non-communicating	III. Didelphus
	(c) no cavity (d) no horn	IV. Bicornuate (a) complete (b) partial
V. Septate (a) complete (b) partial	V. Arcuate	VII. DES drug related

Fig. 68.1 American Fertility Society classification of Müllerian anomalies. (From The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, Müllerian anomalies and intrauterine adhesions: *Fertil Steril* 1988; 49: 944–55.) Reproduced with permission of the American Society for Reproductive Medicine: DES, diethylstilbestrol.

Rokitansky syndrome (agenesis of the uterus and vagina) is considered separately later in this section. More recently a new classification system has been developed by ESHRE/ESGE²⁸ which classifies abnormalities of uterus (U0–6), with two subclasses incorporated, the cervix (C0–4) and vagina (V0–4). This system is complex and as yet is not in widespread clinical use.

Incidence

The prevalence is thought to be 0.5 per cent in the female population.²⁹ The incidence in women with infertility is substantially higher. The most common are septate and bicornuate anomalies.

Aetiology

The cause of Müllerian anomalies is unknown; they may be due to genetic errors, teratogenic events or a combination of these. Only a minority of cases appear to have a family history. It is assumed that there has been failure of fusion of the two Müllerian ducts, failure of one or both ducts to develop, or failure of resorption of the areas of Müllerian duct fusion. The causes of transverse vaginal septae are unknown.

Presentation and investigation

The spectrum of anomalies is wide and around 75 per cent of these women will remain asymptomatic. The remaining 25 per cent will present in a variety of ways. Secondary sexual development is normal as ovarian development and function are independent of Müllerian duct and urogenital sinus growth.

Presentation of Müllerian anomalies

- primary amenorrhoea;
- cyclical abdominal pain (obstruction to menstruation);

- severe dysmenorrhoea (obstruction to menstrual drainage from one Müllerian duct, e.g. the non-communicating rudimentary horn associated with a unicornuate uterus);
- pelvic mass – haematocolpos (vagina distended with menstrual blood) or haematometra (uterus distended with menstrual blood);
- menorrhagia;
- dyspareunia (transverse or longitudinal vaginal septae);
- infertility and recurrent miscarriage;
- ectopic pregnancy;
- obstetric complications, e.g. preterm birth, abnormal lie and uterine rupture.

Investigation of Müllerian anomalies

This includes an assessment of the internal and external uterine contours. Ultrasound, MRI and a hysterosalpingogram are often used, sometimes in association with laparoscopy or hysteroscopy. Imaging of the renal tract is also indicated.

Management

Management of these anomalies depends on the type of anomaly and the presenting features. Symptomatic uterine and longitudinal vaginal septae can be resected hysteroscopically. The horns of a bicornuate uterus can be joined together into one cavity by an abdominal metroplasty. Any form of obstruction to menstrual flow requires surgery to relieve the obstruction and prevent pain and endometriosis. The didelphic uterus is often associated with vaginal septae that can lead to unilateral obstruction and requires careful vaginal surgery to remove the septum. Transverse vaginal septa can be of varying thicknesses, and complete removal is essential to try to prevent a stenotic ring at the site of surgery. For thick transverse vaginal septa, a combined abdomino-perineal procedure is often required.

The hymen usually opens after the fifth month of fetal life. An imperforate hymen presents either in neonatal life with a mucocolpos or at puberty with haematocolpos. A purple-blue bulge at the introitus associated with primary amenorrhoea is diagnostic. Surgery to create an adequate window for vaginal drainage cures the problem.

Rokitansky syndrome (also called Mayer–Rokitansky–Kuster–Hauser (MRKH) syndrome)

Definition and incidence

This condition is agenesis or hypoplasia of the vagina and uterus. The uterus is either absent or consists of a small central rudimentary uterine bud or bilateral uterine buds on the pelvic side walls. The incidence in the UK is estimated as between one in 4000 and one in 6000 females.

The aetiology remains unknown. The control mechanisms leading to Müllerian duct regression in males and Müllerian duct survival and growth in females are not well defined.

Presentation and management

The usual presentation is primary amenorrhoea with normal secondary sex characteristics. Occasionally, the condition is identified in childhood. Investigation is as standard for primary amenorrhoea, and should exclude intersex conditions and include renal tract imaging due to the 30–40 per cent incidence of associated renal anomalies.

Management needs to encompass both psychological interventions, to help with aspects such as accepting the diagnosis, living with the condition, forming relationships and improving sexual function and quality of life outcomes, and interventions that can be used to enlarge or create the vagina. The aim of vaginal enlargement techniques (both surgical vaginoplasty and self-applied vaginal dilatation therapy) is to improve sexual function; however, there have been no studies to assess the effectiveness of these interventions on this outcome. Vaginoplasty surgery and dilators should not be used in childhood. Uterine transplant is not an option for the foreseeable future, although tissue engineering techniques may eventually provide new treatment options. As ovarian function is normal, fertility is possible via surrogacy.

Incomplete regression of the Wolffian system

Parts of the Wolffian duct may fail to regress completely in females, presenting as cysts lateral to the Müllerian duct. Usually these are incidental findings and most are asymptomatic, although they can grow to be large. The epoophoron and paraoophoron can be found beside the ovary in the mesosalpinx. Gartner's duct (the lower part of the Wolffian duct) cysts can occur anywhere from the broad ligament down to the vagina, and may present as vulval or vaginal masses. Wolffian remnants are also seen in the cervix. Very rarely, the Wolffian system may persist as the primitive mesonephric system draining functioning glomeruli, and an extra ureter can be found emptying into the vagina.

KEY POINTS

- Abnormalities of the Müllerian system are asymptomatic in 75 per cent of women.
- Imaging of the renal tract should be performed whenever abnormalities of the Müllerian system are found.
- This condition should be considered high on the list of differential diagnosis in patients presenting with painless amenorrhoea, and normal secondary sexual development.

46XX DSD – Congenital adrenal hyperplasia

This condition occurs in an XX fetus due to an enzyme deficiency (usually 21-hydroxylase) in the adrenal gland. The XX fetus proceeds down the female development pathway, with

ovarian formation and development of the Müllerian ducts into uterus, cervix and upper vagina. Owing to the adrenal enzyme deficiency, cortisone production is deficient, and so the adrenal gland undergoes hyperplasia to try to produce sufficient cortisol. A by-product of this survival mechanism is the production of large quantities of androgens. These high circulating androgen levels lead to masculinising effects at the external genitalia, and ambiguous genitalia or normal-looking male genitalia at birth.

This is one of the most common DSD conditions, with a UK population prevalence estimated at one in 10,000, of whom half are female. It is the only DSD condition that can be life threatening, as unrecognised cortisol deficiency can lead to a salt-wasting crisis in the neonate. Management aims to correct the cortisol deficiency and excess androgen production. Gender assignment at birth is usually female due to the presence of ovaries and uterus with fertility potential. Genital surgery to cosmetically feminise the appearance has been standard practice in the past, although there is now controversy concerning the benefits and risks of this procedure.⁸ Adolescents and adults considering surgery to reduce the size of the clitoris, for cosmetic concerns or due to pain during sexual intercourse, are counselled that the actual risk of damage to clitoral orgasm is unknown, but is estimated at 20–25 per cent. At puberty, a review of the vagina is necessary to identify obstruction, stenosis or hypoplasia.

Other causes of XX fetal virilisation

In a manner similar to that of CAH, other exogenous causes of androgens (e.g. maternal androgen-secreting tumours or the use of virilising drugs such as danazol in pregnancy) may rarely lead to masculinising of the external genitalia in an XX fetus.

46XY DSD – Androgen receptor defects: CAIS

Androgen insensitivity syndrome occurs due to the complete inability of the body to respond to androgens. The cause is a disruption of the androgen receptor gene on the long arm of the X chromosome. Previously the condition was called testicular feminisation, due to the erroneous assumption that the testes must be producing a feminising factor. In this condition, an XY fetus proceeds initially down the pathway of male fetal sexual determination. The SRY gene leads to normal testicular development, and both AMH and testosterone are normally produced. The AMH ensures regression of the Müllerian duct; however, due to the lack of ability of all body cells to respond to androgen, female external genitalia develop and female CNS organisation occurs. The result is an XY female with absent Müllerian structures, normal female genitalia, variable vaginal hypoplasia, absent or sparse pubic and axillary hair, normal breast development, normal female behaviour and gender identity and intra-abdominal testes that produce high levels of circulating testosterone.

Androgen insensitivity syndrome can also occur as a partial form (partial androgen insensitivity syndrome, PAIS) in which some response to androgens occurs. The aetiology of this condition is less well understood, although some cases have a disruption in the androgen receptor gene allowing some function. Presentation is a spectrum from ambiguous genitalia to a normal male phenotype with infertility. For those cases identified in early infancy, assignment of sex of rearing is difficult, with no data concerning outcome. Future sexual function as male or female is unknown, with physical growth of the genitalia being unpredictable and a lack of scientific knowledge about how sexual orientation and gender identity develop. It is likely that both male- and female-type behaviours and gender identity are at least partly pre-programmed by the fetal sex steroid environment, and in PAIS the fetal sex steroid environment is unknown.

46XY DSD – Gonadal dysgenesis

In this condition (also known as Swyer's syndrome), disruption at the very start of the male sex determination pathway causes an XY fetus to divert to the female development pathway. In 15–30 per cent of cases, the fault lies with the *SRY* gene, and gonadal testicular differentiation does not occur. In the remaining cases, disruption of other testis-determining genes is assumed to be the cause. In the absence of *SRY* activation, ovarian determination probably occurs, but cannot be sustained due to the lack of a second X chromosome. The result is a dysgenetic (abnormally formed) streak gonad. As this gonad produces neither AMH nor testosterone, the external genital development is female and the Müllerian ducts develop into the vagina, uterus and cervix.

The streak gonad again fails to produce hormones at puberty, leading to the usual clinical presentation of primary amenorrhoea with poor breast development. In contrast to CAIS, these women have normal pubic and axillary hair and the presence of a normal uterus. Investigation will show raised gonadotrophins and low testosterone and oestradiol levels. Menstruation usually commences with hormone replacement therapy (oestrogen and progesterone are necessary), and pregnancy is possible with donor oocytes. Gonadectomy is recommended due to the high malignancy risk of dysgenetic gonads.

Other forms of XY gonadal dysgenesis that can lead to DSD conditions are less well understood. Partial gonadal dysgenesis with some testicular function, and mixed gonadal dysgenesis (a unilateral testis and a contralateral streak gonad) are conditions that usually present with variable degrees of genital masculinisation or ambiguity. Regression of each Müllerian duct depends on the local concentration of AMH produced by the fetal gonad on each side, and unilateral uterine development can occur if one gonad is more dysgenetic and hence produces less AMH than the contralateral gonad (see Chapter 69, Karyotypic abnormalities).

46XY DSD – Androgen biosynthetic defects (5- α -reductase type 2 deficiency and 17- β -hydroxysteroid dehydrogenase type 3 deficiency)

These conditions may present in a similar fashion with genital ambiguity at birth. In the past, most cases were assigned to a female sex of rearing; however, this management is currently under review and now each case is individually considered.⁸ Both are autosomal recessive conditions in which an XY fetus initially starts down the male development pathway with normal testis development. However, there is a deficiency of enzymes involved in androgen synthesis, leading to mainly female external genital development. If left untreated in childhood, both conditions will result in increasing masculinisation at puberty, and possibly a change in gender identity from female to male for some individuals. 5- α -Reductase-type 2 is the enzyme responsible for the peripheral conversion of testosterone to the more potent androgen DHT required for fetal genital masculinisation. 17- β -Hydroxysteroid dehydrogenase type 3 is the gonadal enzyme needed for the final step in testosterone production in the fetal testis, i.e. conversion of androstenedione to testosterone. Each of these enzymes has more than one isoenzyme, and it is likely that activation of other isoenzymes is responsible for the virilisation seen at puberty.

Clinical presentation of both these conditions is usually mild ambiguity of the genitalia (clitoromegaly) at birth or in early childhood in an XY female. However, the presentation can be variable, and a number of these patients will present to a gynaecologist with virilisation at puberty. Müllerian structures are absent and Wolffian structures are present. The testes are intra-abdominal in childhood, and often descend to the inguinal canal or labioscrotal folds after puberty. Without childhood intervention, secondary sexual development is usually masculine, with poor breast development and normal pubic and axillary hair. The incidence of these conditions is unknown, but with the new scientific knowledge of these enzymes over the past decade, 17- β -hydroxysteroid dehydrogenase type 3 deficiency is now being diagnosed in some cases previously labelled as CAIS. In cases diagnosed in childhood, the management and assignment of gender are difficult. There have been insufficient cohorts raised as either males or females from childhood to evaluate the outcomes of adult gender identity, sexual function, psychological outcomes and quality of life. Fertility may be possible as a male, although infertility is common. Diagnosis is by DNA serum samples, and urinary steroid profile (either 24 hour or spot sample).

46XX/46XY DSD

This condition is defined by the presence of both ovarian tissue with Graafian follicles and testicular tissue containing distinct tubules in one person. It is said to be the rarest

DSD condition, but has a higher prevalence in some areas, such as Africa. The gonads can be any mix of ovary, testes and ovotestes. The aetiology is unknown.

Most cases present with ambiguous genitalia, although clinical presentation is very variable. The degree of genital masculinisation is thought to be a reflection of the amount of functional testicular tissue. The spectrum of internal genital development is influenced by the composition of the adjacent gonad, with up to 80 per cent having internal female organs and therefore being potentially fertile. The karyotype is 46XX in the majority, with a smaller proportion having a mosaic XX/XY karyotype, and only a minority having a 46XY karyotype. At present, there are insufficient data from cohort studies to advise on optimal management in terms of gender assignment in childhood.

Chapter 69 Karyotypic abnormalities

Diana Fothergill

MRCOG standards

Theoretical skills

- Know the abnormalities that may occur with a female phenotype, and associated implications for health.

Practical skills

- Be able to investigate, diagnose, initially manage and refer where appropriate.

INTRODUCTION

There are a number of karyotypic abnormalities that may present to the gynaecologist with an initial complaint of primary amenorrhoea. Others will have been diagnosed in childhood but are referred on for further management by paediatricians and endocrinologists. Some karyotypic abnormalities have little impact on gynaecological problems, but those affecting the sex chromosomes are covered briefly in this chapter. This is a rapidly changing field of medicine, and more sophisticated tests can lead to refinements in original diagnoses, so it may be appropriate to repeat genetic investigations or to test other cell lines.

TURNER'S SYNDROME (45X AND MOSAICS)

This is probably the commonest abnormality in females involving the sex chromosomes. Although 1 in 2500 live-born girls are affected, most pregnancies with this abnormality miscarry, probably secondary to major cardiac defects. It is estimated that 10 per cent of all miscarriages have a 45X karyotype.¹ The incidence does not rise with increasing maternal age, but screening early pregnancies for increased nuchal thickness has led to more cases being diagnosed antenatally, as cystic hygroma and non-immune hydrops are frequently features of Turner's syndrome. Over half of these girls will have some form of mosaicism. The rate of detection is partly

dependent on how hard it is looked for, as the cell lines may vary in different tissues. If Turner's syndrome is clinically suspected but the blood karyotype is normal, it is advisable to check a second tissue such as a skin biopsy.²

Over two-thirds of Turner's syndrome cases result from loss of a paternal sex chromosome; in some there are fragments of a sex chromosome still present. If this is a Y chromosome, there is a 12 per cent risk of gonadoblastoma development, and gonadectomy is usually advised.²

Physical abnormalities associated with Turner's syndrome

- Growth failure: low birthweight and short stature;
- ovarian failure: no secondary sexual development in most cases, occasionally secondary amenorrhoea in mosaicism;
- inverted, widely spaced nipples, and shield chest;
- webbed neck;
- puffy hands and feet in babies due to lymphoedema;
- low hairline;
- cubitus valgus;
- short fourth metacarpal;
- high, arched palate, micrognathia and defective dental development;
- renal dysgenesis;
- left-sided cardiac malformations, coarctation of the aorta;
- distortion of the Eustachian tube leading to otitis media;
- nail dysplasia;
- eye deformities.

Intelligence is usually normal, but there is an increased risk of impairment of non-verbal skills, e.g. maths and visuospatial.³ The phenotypic abnormalities result in most cases being diagnosed in infancy and childhood. The girls are then usually referred to a gynaecologist after optimal growth potential has been achieved using growth hormone, for advice about long-term hormone replacement therapy (HRT). However, spontaneous pubertal development can occur, particularly in girls with mosaicism. In most girls, ovarian failure will have occurred early in life; although they have a uterus and vagina, they will not develop any secondary sexual characteristics without hormonal supplements. A low dose of oestrogen is given initially to encourage steady growth of the breasts; this is usually started after the age of 12 years, as

the administration of oestrogen promotes epiphyseal fusion, which stops further growth.⁴ The dose of oestrogen is gradually increased over 2 years. The transdermal route is preferred as it has better effects on bone density; it can be started at 6.25 µg/24hrs, by cutting patches into quarters, increasing to 12.5 mcg after a year. If the girl presents initially at an older age, the starting dose can be 12.5 µg as these girls are usually very keen to commence their pubertal development and be like their peer group. The uterus will respond to oestrogen therapy, so after 2 years it is necessary to add progestogens cyclically to produce regular endometrial shedding, or in a continuous combined regime to suppress endometrial development. HRT should be continued until at least the age of 50 years. Cryopreservation of ovarian tissue may be an option for future fertility, particularly for girls with mosaicism.⁵ Mothers have also preserved their oocytes for their daughters' future use.

There are a number of long-term health issues which affect women with Turner's syndrome:

- hypertension;
- coarctation of the aorta – 11%; bicuspid aortic valve – 16%; dissecting aortic aneurysm;
- diabetes – 25%;
- hypothyroidism – 25–30%;
- coeliac disease – 4–6%;
- sensorineural hearing loss – 50%;
- renal disease;
- eye problems – red–green colour blindness in 8%, and increased risk of amblyopia;
- osteoporosis.

Premature mortality in women with Turner's syndrome is three times higher than in the general population.⁶ The gynaecologist may be the only point of regular medical contact and needs to be aware of these issues, particularly when pregnancy is desired. A full cardiological assessment is advisable before referral to an assisted conception unit for counselling about treatment with donor oocytes.⁷ Clinical pregnancy rates are reported to be comparable to those of other women with primary ovarian failure but there is an increased risk of complications including diabetes and hypertension in the pregnancy, and delivery by caesarian section (CS) may be required because of the woman's short stature.⁸

Ideally women with Turner's syndrome should have annual checks of blood pressure, thyroid function and liver function tests, lipids and glucose. Every 3–5 years they should have an echocardiogram, bone densitometry and audiogram.⁹

EBM

- There is little published evidence on the effects of long-term HRT in women with Turner's syndrome and on the optimal preparation to be used.
- Oestrogen therapy has been shown to increase bone mineral density.

Patients with Noonan's syndrome have a similar phenotypic appearance to Turner's syndrome. Noonan's syndrome has an autosomal dominant trait with no abnormality of the sex chromosomes and there is no effect on ovarian function.¹⁰

47XXX

These girls are not often referred to gynaecologists, although 47XXX is the most common female chromosomal abnormality, occurring in about 1 in 1000 live-born females. They may have genitourinary abnormalities but are of normal or tall height, and sexual development occurs normally. Academic performance is usually below average; there may be motor and speech delay, and attention deficit. The ovaries often fail prematurely and women may present with secondary amenorrhoea and require HRT. Somewhat surprisingly, most women give birth to chromosomally normal children, but prenatal diagnosis should be considered.

48XXXX, 49XXXXX

These are very rare disorders. Almost all girls with these karyotypes have developmental delay and learning difficulties. Craniofacial anomalies such as hypertelorism, upslanting palpebral fissures and a flat nasal bridge are commonly found, as is ovarian dysfunction.

46XY

Characteristically, this diagnosis is made when a phenotypically normal girl presents with primary amenorrhoea or delayed puberty. There are a variety of conditions that are associated with this karyotype.

In androgen insensitivity syndrome, the problem lies with the end-organ response to testosterone. It is an X-linked recessive disease due to mutations in the *AR* gene. The testes are functional and Müllerian inhibition factor is produced, so the uterus and vagina do not develop. Dilator therapy is usually indicated to allow intercourse. Breast development usually takes place, as circulating testosterone is peripherally converted to oestrogen, but there is absent pubic hair due to the abnormal androgen receptors.¹¹

In Swyer's syndrome, or pure gonadal dysgenesis, there is a lack of functional gonadal tissue and, as a consequence, Müllerian structures persist and a normal uterus and vagina are found. Breast development does not normally occur and typically girls present above average height with delayed puberty. Pubic and axillary hair may be present due to the effect of peripherally produced androgens. Treatment is similar to that for Turner's syndrome, with oestrogen to develop the breasts and the addition of progestogens to cause withdrawal bleeds. Donor egg and embryo pregnancies have been reported.¹²

Streak gonads may be present; as there is a 30 per cent risk of malignant change, gonadectomy is advised.³

STRUCTURAL ABNORMALITIES OF THE X CHROMOSOME

There are many abnormalities that can occur in the X chromosome. The commonest is an isochromosome for the long arm, most often found in mosaic form with 45X. Deletions of part of the long or short arm have variable effects depending on the level at which the deletion has occurred. If the short arm is missing, most girls will be of short stature; if the long arm is missing, there is usually gonadal dysgenesis. It is of interest to note that although one X chromosome is inactivated, it is necessary to have two normal X chromosomes to maintain fertility.

KEY POINTS

- Karyotypic abnormalities are a common cause of primary amenorrhoea.
- HRT is required in all patients with ovarian failure.
- Ovum donation may be an option for fertility.
- Turner's syndrome has long-term health implications.

Chapter 70 Menarche and adolescent gynaecology

Diana Fothergill

MRCOG standards

Theoretical skills

- Know the normal sequence of events in puberty to be able to recognise when investigation is appropriate.
- Know the causes of delayed puberty and how to establish the diagnosis.
- Know how the management of excessive menstruation differs in adulthood.

Practical skills

- Be able to assess the stage of development of secondary sexual characteristics.
- Have observed consultations with the girl and parent, and be able to obtain the history and counsel about management.

INTRODUCTION

Puberty marks the change from childhood to adolescence, with the development of breasts and secondary sexual hair and the onset of menstruation. At the same time there is a period of accelerated growth. The age at which the changes

take place is variable, but it is abnormal for there to be no sign of secondary sexual development at the age of 13 years.

The trigger for the changes to start is an increasing frequency and amplitude of pulses of gonadotrophin release. The ovaries are then stimulated to begin to produce oestrogen, which acts on the breast tissue to promote growth. This usually begins at around the age of 9 and takes about 5 years to be completed. There is evidence to suggest that this is occurring at a younger age, particularly in African-American girls, prompting a reassessment of the age at which precocious puberty should be investigated.¹

Causes of precocious puberty

- Idiopathic;
- McCune–Albright syndrome (a genetic disorder of the bone with *café au lait* spots, polyostotic fibrous dysplasia and hormone excess);
- tumours of the adrenal or ovary-producing steroids;
- cerebral tumours;
- ingestion of exogenous oestrogens.

Pubic hair growth is stimulated by androgens released by the ovary and the adrenal gland. Breast and pubic hair development is described in five stages following the classification by Marshall and Tanner (Table 70.1).² Growth charts indicate the range of normal ages at which these stages are attained.

Table 70.1 Marshall and Tanner staging

Stage	Breast	Pubic hair
I	Pre-adolescent, elevation of papilla only	No pubic hair
II	Breast bud – elevation of breast and papilla as small mound; enlargement of areolar diameter	Sparse growth of long downy hair along the labia
III	Further enlargement but no separation of the contours	Hair coarser, darker and more curled; over mons
IV	Projection of the areola and papilla to form a secondary mound above the level of the breast	Adult-type hair but no spread to thighs
V	Mature; areola recessed to general contour of breast	Adult, with horizontal upper border and spread to thighs

In most girls, breast development starts before the growth of pubic hair.

Even before these changes are obvious, there is acceleration of growth, which is frequently accompanied by a rapid increase in shoe size. The peak height velocity, of approximately 8 cm/year, occurs just before the onset of menses – on average around the age of 12 years. Oestrogen promotes closure of the epiphyses, so final height is usually attained about 2 years after menarche.

Menarche occurs 2.3 ± 1 years after the onset of breast development. The average age of menarche has declined and is now 12.52 years in white girls and 12.06 years in African-Americans.³ The factors involved include improved nutrition and genetic influences: daughters often undergo menarche at a similar age to their mothers. Initial menstrual cycles are usually anovulatory and often irregular for several years.

DELAYED PUBERTY

Most referrals to gynaecologists are because of concern about delay in the onset of menstruation. In order to determine the likely cause for this it is first important to establish whether puberty itself is delayed. A detailed history should be taken, asking about general health, the age at which breast and pubic hair development started, and if the girl has had a growth spurt or still appears to be growing. Any chronic illness may lead to constitutional delay in puberty. The family history should include the age when mother and siblings went through puberty.⁴ Teenage girls may be reluctant to answer questions and the mother frequently gives much of the history, but it is important to address the girl rather than talking directly to the mother. Examination should include accurate measurement of height, together with assessment of the stage of breast and pubic hair development, and these should be plotted on growth charts. The examination should be sensitively performed – ask the girl if she wishes her mother to be present, as some feel more embarrassed with the mother there – and only expose one part of the body at a time. An internal examination should not be performed; inspection of the external genitalia is all that is necessary, as further assessment of the internal organs will be achieved by ultrasound scanning of the pelvis.

Investigations usually include:

- measurement of gonadotrophins – follicle stimulating hormone (FSH) and luteinising hormone (LH) – and oestrogen;
- karyotyping;
- ultrasound scan of the pelvis to confirm the presence of the uterus and ovaries;
- possibly X-ray to determine bone age.

Additional biochemical tests to assess thyroid function, prolactin and 17- α -hydroxyprogesterone may be appropriate.

ABSENT BREAST AND PUBIC HAIR DEVELOPMENT

Hypogonadotropic hypogonadism

The majority of girls with low gonadotrophins have constitutional delay in puberty; there will often be a family history of delayed puberty. Another possibility is that it may be secondary to chronic illness, for example cystic fibrosis.

Girls with anorexia nervosa have low levels of gonadotrophins and, if the problem starts at a young age, will have absent or poorly developed secondary sexual characteristics. A similar situation is found in many athletic girls, the classic example being gymnasts, who have a low bodyweight and very low body fat. This can lead to the 'female athletic triad', with disordered eating, amenorrhoea and osteopenia, and an increased risk of stress fractures.⁵

Congenital deficiency of gonadotrophins is more rarely encountered; it may be associated with anosmia due to hypoplasia of the olfactory lobes, when it is known as Kallman's syndrome. Brain imaging will be necessary to establish this diagnosis.

Acquired deficiency may follow damage to the hypothalamus or pituitary as a result of trauma, tumour such as a craniopharyngioma, irradiation or infection – frequently secondary to hydrocephalus. Infiltration of these organs can also occur in haemochromatosis, which may be secondary to transfusions for sickle cell disease or thalassaemia and to Wilson's disease.

In all these conditions, ultrasound will confirm the presence of an immature uterus and small, inactive ovaries. The bone age will help to differentiate cases of constitutional delay, as it will be behind chronological and height age.

Treatment may be required if there are no signs of spontaneous onset of puberty, although most girls with constitutional delay will proceed to normal development if left untreated. A study conducted on untreated girls indicated that they experienced considerable distress, which affected their success at school, work or socially; 50 per cent would have preferred to receive treatment.⁶ Pulsatile gonadotrophins have been used but are very difficult to sustain, as they require a subcutaneous injection attached to a portable pump for several months. The more widely used approach is to give low doses of ethinyl oestradiol 1–2 mg/day for 3–6 months, or a 25 μ g transdermal patch cut into eighths or quarters. Frequently, spontaneous sexual maturation then occurs, but if not, the dose is gradually increased over several years.

Hypergonadotrophic hypogonadism

This occurs when there is failure of gonadal development. The normal release of gonadotrophins occurs, but as there is no response from the gonad, there is no negative feedback to control gonadotrophin levels. The commonest cause is Turner's syndrome (45X), or other genetic problems (see Chapter 69). Other causes include damage to the ovaries by irradiation, surgery, chemotherapy or infection. Galactosaemia is also associated with ovarian failure and its management presents a challenge, as oral preparations of oestrogen and progesterone contain lactose. Autoimmune ovarian failure may be associated with other autoimmune disorders such as Addison's disease, vitiligo and hypothyroidism.

One of the less common causes of congenital adrenal hyperplasia is the deficiency of 17- α -hydroxylase. This enzyme is required to produce both oestrogen and testosterone, so virilisation does not occur at birth, but there is also a failure of development of secondary sexual characteristics.

The treatment consists of gradually increasing levels of oestrogen replacement, combined with progesterone to induce withdrawal bleed once endometrial development has been stimulated.

NORMAL BREAST AND PUBIC HAIR DEVELOPMENT

Anatomical causes

If puberty has progressed normally but the girl has failed to menstruate, the commonest cause is an anatomical abnormality, such as Müllerian agenesis, which is described in detail in Chapter 69. Girls with an imperforate hymen or transverse vaginal septum usually present as an emergency with cyclical abdominal pain, possibly with a palpable abdominal mass. The blockage prevents the flow of menstrual blood and there is usually a tense blue bulge seen at the introitus. Ultrasound scanning may show a distended vagina containing blood, and normal ovaries. Where there is a thin imperforate hymen, treatment is straightforward, as incision will allow the blood to drain and the mass will resolve. Treatment of a thicker and possibly higher septum is more complex and is best dealt with in a tertiary referral centre, as injudicious excision can result in stricture formation which is difficult to treat and will lead to considerable problems with intercourse.

Hyperprolactinaemia

This is more often a cause of secondary amenorrhoea, but can present as primary amenorrhoea and there may not be any galactorrhoea. A high prolactin level should

prompt investigation for a pituitary adenoma. Treatment is the same as in the older female, with dopamine agonists such as cabergoline, which will result in the onset of menstruation.

Congenital adrenal hyperplasia

Menarche is often delayed in this condition, and when menstruation starts it may be erratic. Poor control of the condition, often due to poor compliance with treatment, may be the cause. The ovaries also often have a polycystic appearance on scan. Fertility rates in these women are poor for a number of reasons: infrequent ovulation, difficulties in achieving penetrative sex, and failure to form relationships.⁷

NORMAL BREAST BUT SCANTY OR ABSENT PUBIC HAIR DEVELOPMENT

This is the classical presentation of androgen insensitivity syndrome. The karyotype will be XY. Pubic hair fails to grow because of end-organ insensitivity to androgens, but breast development occurs due to peripheral conversion of androgens to oestrogen. No hormonal treatment is required.

MENORRHAGIA AND DYSMENORRHOEA

As initial menstrual cycles are usually anovular, they are normally painless, but bleeding may be prolonged.

Girls are often referred to gynaecologists because of concern about missing school, particularly when studying for state examinations, due to heavy and painful periods. Almost invariably they are accompanied by a mother who will tell you about the problems she had with her periods. It is very important to speak to the girl herself to try to establish if there is a genuine problem, and to make some effort to quantify the loss by the degree of soakage of the pads used. The number of pads used per day may be quite misleading, and as most women do not know what amount of loss is normal, it can be very difficult for a girl to know whether she is actually experiencing an abnormal amount of bleeding.

Excessive menstrual loss will usually result in a fall in the haemoglobin level, and occasionally the loss can be so great that emergency admission and transfusion are required. Many of these girls will have an underlying medical disorder. It is most important to exclude a coagulation disorder, such as von Willebrand's disease, or a platelet dysfunction, which may be present in a third of these cases.^{8,9} There may be no previous personal or family history of bleeding symptoms. If such a disorder is found, it may be possible to treat the girl with desmopressin on a cyclical basis.¹⁰

The oral contraceptive pill is usually prescribed and, where blood loss is recurrently excessive, it can be helpful to prescribe this continuously for three or more cycles to reduce the frequency of withdrawal bleeds. However several studies have reported that the number of days of bleeding is not statistically different from conventional cyclic dosing.¹¹ The levonorgestrel intrauterine system (Mirena) has also been used successfully. The uterine cavity has to be at least 5–6 cm to enable insertion, and a general anaesthetic is likely to be required.¹²

Occasionally girls present with life-threatening haemorrhage. The options for treatment include medroxyprogesterone acetate 5 mg orally every 1–2 hours for 24 hours and then 20 mg daily for 10 days, or a 50 µg oral contraceptive pill taken 6-hourly for 48 hours, then reduced to once daily over the next 3 days.¹³ Intravenous oestrogen has also been used (40 mg 4-hourly for 24 hours) combined with a highly progestational oral contraceptive pill, but is not readily available in many pharmacies. It is rarely necessary to perform a diagnostic curettage.

Dysmenorrhoea usually responds to simple analgesia or oral contraceptives. However, where these measures fail, it is important to bear in mind the possibility of partial obstruction of menstrual flow. There are a number of reported cases of obstructed hemivagina and uterine horn associated with ipsilateral renal agenesis.¹⁴ The usual presentation is severe cyclical pain with an abdominal mass due to a hemihaematometra and haematocolpos. Removal of the occluded vaginal septum allows drainage and relief of symptoms. Endometriosis occurs in many of these patients, presumably secondary to the enforced retrograde menstrual flow.

There are many causes of chronic pelvic pain in young women, including psychosomatic factors. It is important to realise that endometriosis should be excluded in chronic pelvic pain that has not responded to simple measures. Laparoscopy may be indicated. The symptoms are often not those typically encountered in older women.¹⁵

EBM

All girls with menorrhagia who are found to be anaemic should be investigated for a bleeding disorder, including testing for von Willebrand's disease and platelet function defects.

KEY POINTS

- Secondary sexual characteristics start to develop in most girls by the age of 14 years.
- Menarche normally occurs 2 years after breast development has commenced.
- Ovarian failure is the commonest cause of delayed puberty – karyotyping and gonadotrophins are essential investigations.
- Tests for bleeding disorders should be performed for any girl with moderate to severe menorrhagia.
- Endometriosis can occur in teenagers.

Chapter 71 Ovarian and menstrual cycles

Mohammed Khairy and Rima Dhillon

MRCOG standards

Theoretical skills

- Have a thorough understanding of the physiology of the menstrual cycle.
- Be able to explain dysfunction in the cycle (e.g. anovulation) with reference to ovarian and uterine physiology.
- Understand the mechanism of action of drugs that affect the cycle.

Practical skills

- Be able to interpret the menstrual and gynaecological history.
- Be able to initiate appropriate investigations to enable a diagnosis.

INTRODUCTION

Successful human reproduction depends on optimal spermatogenesis and ejaculatory function in males, and an exquisitely regulated hypothalamic–pituitary–ovarian (HPO) axis and endometrial preparation in females. The HPO axis orchestrates steroidogenesis and folliculogenesis (oogenesis) in the ovary, culminating in monthly ovulation. This is mirrored in cyclic endometrial preparation in the uterus for implantation of a pregnancy or cyclic menstruation in the absence of implantation.

Understanding the regulation of ovarian and menstrual function is therefore crucial to the rational management of many gynaecological disorders. These include delayed puberty, amenorrhoea, anovulatory infertility, abnormal uterine bleeding and also ovarian stimulation in assisted reproduction treatment.

In this chapter we will address the basic facts about the different compartments of the HPO axis controlling the ovarian and menstrual cycles.

THE HPO AXIS

The hypothalamus

The hypothalamus contains neurons secreting gonadotrophin-releasing hormones (GnRH) in the ventromedial nucleus. These neurones would have migrated in fetal life from the olfactory placode. Failure of migration of these neurons results in congenital absence of GnRH or hypogonadotropic hypogonadism, usually associated with anosmia (Kallmann's syndrome). The hypothalamic GnRH centre receives afferent neurons from the limbic system, olfactory centre, occipital cortex and other nuclei in the hypothalamus controlling energy metabolism and the stress response.¹

During intrauterine life and shortly after birth these neurons secrete GnRH in a pulsatile manner into the hypothalamic hypophyseal portal circulation. Here the neurons stimulate the GnRH receptor-bearing gonadotrophs in the anterior pituitary resulting in the synthesis and pulsatile secretion of gonadotrophins (FSH and LH).²

The amount of GnRH reaching the systemic circulation is very low and its half-life is very short (2 minutes); therefore GnRH pulses cannot be easily measured. Instead the LH pulses (half-life of 20 minutes) can be measured in the circulation and so are used as indirect measure of GnRH pulses. The pulsatile secretion of GnRH is essential for maintaining gonadotrophin secretion and ovarian activity. Sustained exposure to GnRH (as seen in the use of GnRH analogues) leads to an initial increase of gonadotrophins (flare response) which is followed after 10–14 days by down-regulation and desensitisation of GnRH receptors with subsequent very low levels of gonadotrophins and ovarian steroid hormones.²

Shortly after birth the GnRH pulse generator becomes completely suppressed and remains so till puberty. It is believed that attainment of a critical level of fat content leads to leptin hormone signalling from adipose tissue that releases the GnRH pulse generator from the prepubertal inhibition, with initiation of puberty.

During the reproductive years the hypothalamic GnRH pulse centre is under the influence of various endocrine

and paracrine regulators. Some of these exert a stimulatory effect, for example leptin, insulin, activin and high levels of oestrogens at ovulation. Others exert an inhibitory effect, for example ghrelin, inhibin, corticotrophin-releasing hormone (CRH), thyrotrophin-releasing hormone (TRH), prolactin, oestrogens, progestins, androgens, opioids and melatonin.

These regulators mediate their actions primarily by neuropeptide and amine transmitters namely kisspeptin (stimulatory), pro-opiomelanocortin (stimulatory), neuropeptide Y (inhibitory), dopamine (inhibitory), GABA, serotonin and norepinephrine.

It follows that reproductive function (as initiated by GnRH pulses) is under the influence of energy levels (leptin, insulin, ghrelin), stress (CRH, TRH, opioids), gonadal signals (oestrogens, progestins, androgens, inhibins, activin) and light/dark signals (melatonin). Various pharmacological agents which affect the neurotransmitters' levels can also affect reproductive function.² The GnRH pulse frequency and amplitude is dependent on the balance of these signals as well as on the timing, duration and amplitude. For example, the rapid rise of oestrogens at the time of ovulation triggers the LH surge, and the sustained level of GnRH inhibits gonadotrophins. Other pituitary hormones also have an inhibitory effect on GnRH and gonadotrophin secretions as in hyperprolactinaemia. Pathological lesions disconnecting or damaging the

hypothalamic hypophyseal portal circulation lead to disruptions of the GnRH pulses and a state of hypogonadotrophic hypogonadism (as part of hypopituitarism).^{1,2}

The pituitary gland

The pituitary gonadotrophins FSH and LH are both glycoprotein hormones. These hormones share a common alpha unit with other glycoprotein hormones, such as thyroid stimulating hormone (TSH) and human chorionic gonadotrophin (hCG), but each has a unique beta subunit. All these hormones act on transmembrane G-protein receptors that cause an increase in cyclic adenosine monophosphate (cAMP). There is cross-responsiveness of these receptors to the various glycoprotein hormones.³

The gonadotrophins are secreted from the pituitary gland mainly in response to GnRH pulses from puberty onwards. The GnRH receptors are membrane receptors which are down-regulated by sustained exposure of gonadotrophs to GnRH.³

The FSH hormone has a half-life of 4 hours and is under the influence of both GnRH and gonadal hormones; therefore its pulses are not accurately reflective of GnRH pulses. LH pulses, with a short half-life, are a more accurate reflection of GnRH pulses. These LH pulses are of higher frequency (every 60–90 minutes) and lower amplitude in the follicular phase of ovarian cycles, compared with the lower frequency (120–160 min) and higher amplitude signals in the luteal phase.³

CLINICAL POINTS

- The down-regulated GnRH receptors, following prolonged administration of a GnRH analogue, are responsible for the pituitary suppression and prevention of natural ovulation in cycles of in-vitro fertilisation (IVF). A similar effect has been achieved, although for a shorter period, using GnRH antagonists, which act by competitive blockade of GnRH receptors rather than down-regulating the GnRH receptors. In GnRH antagonist cycles, the GnRH agonist can be used to initiate a surge of LH, similar to natural cycles, with less risk of inducing ovarian hyperstimulation syndrome.
- An exaggerated positive feedback of leptin in obese women and patients with polycystic ovarian syndrome leads to an increase in GnRH/LH pulse frequency, with an increase in ovarian androgen production leading to chronic anovulation. On the other hand, there is a subset of morbidly obese women in whom there is a congenital leptin deficiency with increased caloric intake and low FSH/LH levels.
- Stress- and/or weight-related amenorrhoea are due to combined inhibitory signals by the neuropeptide Y and stress hormones, leading to suppressed GnRH secretion and functional hypothalamic amenorrhoea.

CLINICAL POINTS

- The similar structural activity of hCG and TSH explains the transient hyperthyroidism seen in states of increased hCG, such as molar pregnancies and hyperemesis gravidarum.
- Spontaneous activating mutations of G-protein linked to receptors of glycoprotein pituitary hormones lead to a condition of precocious puberty called McCune–Albright syndrome (MAS). The classic triad of features in MAS (polyostotic fibrous dysplasia, autonomous endocrine hyperfunction and *café au lait* skin pigmentation) can be explained by activation of the G-protein's alpha subunit and increased intracellular cAMP levels.

The ovary

Embryologically ovarian tissue is formed from three main types of cells:

- 1 Primordial germ cells derived from endodermal cells of the yolk sac which migrate at 6 weeks of intrauterine life

to the genital ridge. During the 6th to 8th week of development, the primordial germ cells grow and begin to differentiate into oogonia.

- 2 Coelomic (sex cord) cells which develop into granulosa cells that surround the oogonia to form the primordial follicles.
- 3 Mesenchymal (sex stromal) cells which later form the theca cells and other ovarian stromal cells.

Until 10 weeks of gestation the germ cells and surrounding sex cord and sex stromal cells are not differentiated, and the gonadal ridges are bi-potential gonads. These gonads develop into ovaries by lack of paracrine factors transcribed by the genes in the sex determining region on the Y chromosome (*SRY*).^{3,4}

THE OVARIAN CYCLE

Gonadotrophin-independent phase

By 12 weeks of gestation some germ cells (oogonia) start to enter into meiosis and become primary oocytes surrounded by flattened granulosa cells to form primordial follicles. The primary oocytes are arrested in the prophase stage of the first meiotic division (diploid cell). The remaining oogonia have ongoing cycles of mitosis and reach a peak number of 5–6 million at 20 weeks' gestation.

The few primary oocytes that survive are those that are surrounded by flat, spindle-shaped follicular or pregranulosa cells. This oocyte–pregranulosa cell complex is enclosed by a basement lamina. At this stage of development, the primary oocyte with its surrounding single layer of pregranulosa cells is called a primordial follicle. Primordial follicles are 30–60 μm in diameter. The first primordial follicle usually appears around 6 weeks into intrauterine life, and the generation of primordial follicles is complete by about 6 months after birth.^{3,4}

The first step in follicular growth is that a primordial follicle becomes a primary follicle. The primary follicle forms as the spindle cells of the primordial follicle become cuboidal cells. In addition, the oocyte enlarges. Thus, the primary follicle contains a larger primary oocyte that is surrounded by a single layer of cuboidal granulosa cells.

The secondary follicle contains a primary oocyte surrounded by several layers of cuboidal granulosa cells. The granulosa cells of a primary follicle proliferate and give rise to several layers of cells. In addition, stromal cells differentiate, surround the follicle and become the theca cells. These theca cells are on the outside of the follicle's basement membrane. The oocyte increases in size to a diameter of about 120 μm . As the developing follicle increases in size, the number of granulosa cells increases to about 600, and the theca cells show increasing differentiation. The progression to secondary

follicles also entails the formation of capillaries and an increase in the vascular supply to developing follicular units.

The increasingly abundant granulosa cells secrete fluid into the centre of the follicle creating a fluid-filled space called the antrum. At this stage, the follicle is now called a tertiary follicle. In tertiary follicles, gap junctions are formed between theca and granulosa cells. In addition, tight junctions and desmosomes exist between adjacent cells. Gap junctions may also exist between the oocyte and the granulosa cells closest to the oocyte and may function as channels to transport nutrients and paracrine signals from the granulosa cells to the oocyte and vice versa. The granulosa cells closest to the oocyte also secrete a layer of mucopolysaccharides (the zona pellucida).

These stages occur independent of gonadotrophin stimulation and under the effect of local autocrine and paracrine factors such as growth differentiation factor (GDF) and anti-Müllerian hormone (AMH). The latter is produced from the granulosa cells and reaches the systemic circulation in levels proportional to the secondary follicle pool. In the absence of further gonadotrophin stimulation the secondary follicles undergo apoptosis and atresia.

This process of gonadotrophin-independent recruitment to secondary follicles and apoptosis in absence of gonadotrophins is continuous during intrauterine, pre-pubertal and reproductive life till depletion of the follicular pool at the age of menopause. Unlike spermatogenesis, the atretic follicles cannot be replenished; therefore the ovarian reserve of follicles is a finite pool. On average the number of primordial follicles is about 1–2 million at birth and decreases to about 400,000 at initiation of puberty and is less than 1000 by the age of menopause, with only about 500 oocytes destined to ovulate during a woman's reproductive lifespan. The rate of loss of the primordial follicle pool is variable among individual females, with variable age of loss of fertility and menopause (40–55 years). It is believed that natural fertility is lost around 10 years earlier than the age of menopause (fixed-interval hypothesis). The duration of the gonadotrophin-independent phase is around 74–80 days.^{3,4}

Gonadotrophin-dependent phase

In the absence of pituitary gonadotrophins, the growing follicles in the ovary will be destined to atresia (apoptosis). The rise of pituitary gonadotrophins during the reproductive years, as a result of release of hypothalamic GnRH pulse centre from pre-pubertal inhibitory signals, leads to rescue of the preantral/antral follicles.

The number of rescued and recruited follicles depends on the pool of secondary follicles available at the time of the rise of FSH, which is indirectly related to the total pool of primordial follicles in the ovary (ovarian reserve). It also depends on the level of FSH and duration of rise (**selection window**).

A critical step of this rescue process is the induction of aromatase enzyme activity in the granulosa cells which converts the androgens synthesised in the theca cells into oestrogen under the effect of LH.

Therefore the two gonadotrophins, FSH and LH, act preferentially on the two main steroid-producing cells (granulosa and theca cells) in the ovary. The main effect of FSH is the rescue of granulosa cells (and oocytes) from atresia and induction of aromatase activity. The main role of LH is the stimulation of steroidogenesis by acting on theca cells to synthesise androgenic substrates that are converted into oestrogens in the granulosa cells. This is called **the two cell, two gonadotrophins theory**. The effect of this synchronised action of FSH and LH is conversion of the microenvironment of the secondary pre-antral follicles from one dominated by androgens into one dominated by oestrogens.

The effect of the latter is further proliferation of the granulosa and theca cells with accelerated production of oestrogen and peptide hormones (inhibins, activin, follistatin) and formation of a cavity (antrum) in which the oocyte is surrounded by a few layers of granulosa cells projecting into the cavity.

The follicular cavity fluid contains a myriad of growth factors and signalling molecules involved in bidirectional communication between the oocyte and surrounding granulosa.^{3,4}

Inhibins/activin/follistatin and insulin-like growth factors

The granulosa cells of the growing follicles secrete a group of proteins which are important for regulating the HPO axis. In the early follicular phase FSH induces granulosa cells to secrete activin and inhibin A. Activin augments FSH action by increasing its receptors and up-regulates granulosa cell proliferation and aromatase enzyme production. Activin also inhibits the theca cells, androgen production.

Inhibin A exerts a negative feedback effect on the pituitary synthesis and secretion of FSH and stimulates theca cell LH receptors and androgen production. The granulosa cells also secrete follistatin, which combines activin and inhibits its action; it also directly suppresses FSH synthesis and secretion by the pituitary.^{5,6}

As the follicular phase progresses (Fig. 71.1) inhibin A activity predominates over activin. This facilitates the selection of the dominant follicle which is able to maintain steroidogenesis in the face of declining FSH levels. Concurrent with these effects the insulin-like growth factor-2 (IGF-2) and its binding protein (IGF2 BP) modulate intra-ovarian activity of FSH and LH so that in androgen-dominant follicles there is a higher concentration of IGF2 BP and lower concentration of bioavailable IGF-2. This leads to decreased FSH action on the granulosa and less steroidogenic activity with less oestradiol

production and follicular atresia.^{5,6} This could be one of the mechanisms for arrest of follicles and anovulation in polycystic ovary syndrome in the presence of hyperinsulinaemia and hyper-androgenaemia.

In the luteo-follicular transition and early follicular phase, inhibin B is secreted by the granulosa cells, recruited from the secondary follicles pool, to enter the gonadotrophin-dependent phase.^{5,6}

The dominant follicle

In the mid-follicular phase (usually on day 7–8 of a 28-day cycle) selection of a dominant follicle (which is usually over 10 mm in diameter at that stage) occurs by the effect of rising oestrogen and inhibin A levels produced by actively growing follicles. This results in a negative feedback effect on the pituitary gonadotrophin (FSH/LH) secretion, and starvation of most of the follicles of the necessary FSH to support granulosa cell proliferation and aromatase activity. The dominant follicle expands in size with an exponential rise of oestradiol levels. This further accentuates the decline in FSH levels and leads to atresia of the rest of the follicles. In natural cycles selection of a single dominant follicle and monofollicular ovulation is the rule, whilst in ovarian stimulation cycles the prolonged exogenous FSH stimulation leads to support and survival of more than one follicle.^{3,4}

The dominant follicle (Fig. 71.1) accumulates more fluid in the follicular cavity and its granulosa cells become organised into three compartments: mural granulosa cells surrounding the antrum; cumulus oophorus (which is a stalk of granulosa cells connecting the oocyte to the mural granulosa); and corona radiata (which is a layer of granulosa cells in direct contact with the oocyte). The oocyte with its surrounding corona radiata and cumulus oophorus are bathed within follicular cavity fluid. The latter separates it from the mural granulosa and outer theca cells. The follicle is now known as the pre-ovulatory or Graafian follicle.^{3,4} The Graafian follicle continues to produce oestrogen, independent of FSH stimulation, and has the highest number of granulosa cells and oestradiol levels with the lowest androgen-to-oestrogen ratio. This follicle also develops LH receptors in the granulosa cells, which helps with maturation of the oocyte and prepares the follicle for the ovulatory stimulus of the LH surge. The LH receptors also ensure adequate progesterone production by the luteinised granulosa cells from the corpus luteum after ovulation.^{3,4}

Ovulation

When the estradiol (E2) levels peak to 300–400 pg/ml (500–900 pmol/L) (which usually coincides with a follicle size of 18–20 mm), the pituitary gland responds by a surge of LH levels to about 15–30 IU/L. This leads to a cascade of changes

in the Graafian follicle and leads to ovulation within 36 hours (34–39 hours) of the onset of the LH surge.

The LH surge initiates the following changes in the Graafian follicle and ovary:

- 1 Resumption of meiosis in the oocyte with extrusion of the first polar body (the oocyte becomes haploid), and the oocyte becomes arrested into the metaphase of the second meiotic division which is completed at fertilisation with extrusion of second polar body.
- 2 Induction of angiogenesis and increased vascularity and capillary permeability in the theca cell layers with increased production of follicular fluid and increase in intrafollicular pressure.
- 3 Synthesis and secretion of various prostaglandins that help increase blood flow in the follicular wall and stimulate smooth muscle cells within the ovarian stroma that help expel the oocyte.
- 4 Activation of matrix metalloproteinases and other proteolytic enzymes that digest the follicular wall and ovarian capsule at the site of the follicle to facilitate follicular rupture and oocyte release the i.e. ovulation.
- 5 LH stimulates progesterone synthesis by the granulosa and theca cells shortly before ovulation. This further accentuates the LH surge and ensures adequate luteinisation of the theca and granulosa cells and adequate corpus luteum function later.

The resulting effect of these changes is follicular wall rupture with release of follicular fluid and the oocyte and its surrounding cumulus cells. This is usually picked up by the fimbrial end of the tube, and is transported to the ampullary part of the fallopian tube where fertilisation may occur.

In a regular 28-day cycle the gonadotrophin-dependent phase (follicular phase of the ovarian cycle) lasts about 14 days. However, this is variable amongst individuals and leads to variable lengths of the follicular phase and subsequent variable menstrual cycle lengths as the corpus luteum lifespan is nearly fixed at about 14 days. The timing of ovulation is therefore difficult to predict prospectively; however a fertile period when ovulation is likely to occur can be predicted using the woman's menstrual history and cycle lengths.^{3,4}

The luteal phase

After the release of the oocyte–cumulus complex the follicular antrum is filled with blood and new blood vessels form. The theca–lutein cells become full of cholesterol (luteinised) and the resulting structure is called a corpus luteum. The corpus luteum produces oestrogen, progesterone (P4) and inhibin A in response to LH pulses. These in turn suppress FSH and LH secretion by the pituitary. In the face of declining FSH and LH levels the corpus luteum functions for only about 10 days, with peak activity at about 7 days after ovulation (mid-luteal

peak of progesterone on day 21 of a 28-day cycle). It then enters into an apoptosis and regression phase of about 4 days if pregnancy does not occur. In the absence of pregnancy, the corpus luteum has a fairly predictable life span of 14 days. The falling oestradiol and progesterone levels lead to apoptosis and shedding of the endometrium. The falling ovarian steroid levels release the hypothalamus and pituitary from the negative feedback effect, with a subsequent increase in FSH levels and ensuring a new cycle of recruitment of secondary follicles. The luteo-follicular transition phase is characterised by increasing FSH levels, low oestradiol and progesterone levels and high inhibin B secreted by the granulosa cells of recruited follicles.^{3,4}

If pregnancy occurs the hCG produced by the trophoblast of the implanting embryo rescues the corpus luteum from apoptosis and atresia, enabling the corpus luteum to function and produce progesterone till 10–12 weeks' gestation when the placenta takes over this function.^{3,4}

THE MENSTRUAL CYCLE

The endometrium undergoes cyclic changes which mirror the effect of the hormones produced by the growing follicles and corpus luteum in the ovary.

In the early follicular phase the endometrium is rebuilt from the basalis layer after its superficial layer has been shed in the menses of the previous cycle. The prevailing oestradiol secreted from the ovary leads to active mitosis and proliferation of the endometrial glands and stroma. This leads to an increase in the thickness of the endometrium from 2–3 mm to about 6–8 mm by the end of this **proliferative phase**.

Following ovulation the prevailing progesterone hormone leads to more functional maturation of the endometrial glands and decidualisation of the endometrial stroma. Histologically these changes are reflected in enlarged tortuous endometrial glands that are full of secretions; hence this phase is called the **secretory phase**. The stroma appears oedematous with an increased number and coiling of the spiral arteries and pericapillary leukocytic and cellular infiltrates, a process called decidualisation. The effect of the epithelial changes is secretion of adhesion molecules, such as integrins and glycodefins, which mediate the attachment of the blastocyst (in the case of successful fertilisation) that initiates the implantation process. The effect of stromal decidualisation is recruitment of immunological cells (natural killer cells, dendritic cells) that help regulate the trophoblastic invasion and effect changes in the spiral arteries that lead to the development of the early placenta. The peak of secretory changes in the endometrium is 7–9 days after ovulation when the endometrium is most receptive to implantation of the blastocyst, the so called **implantation window**.

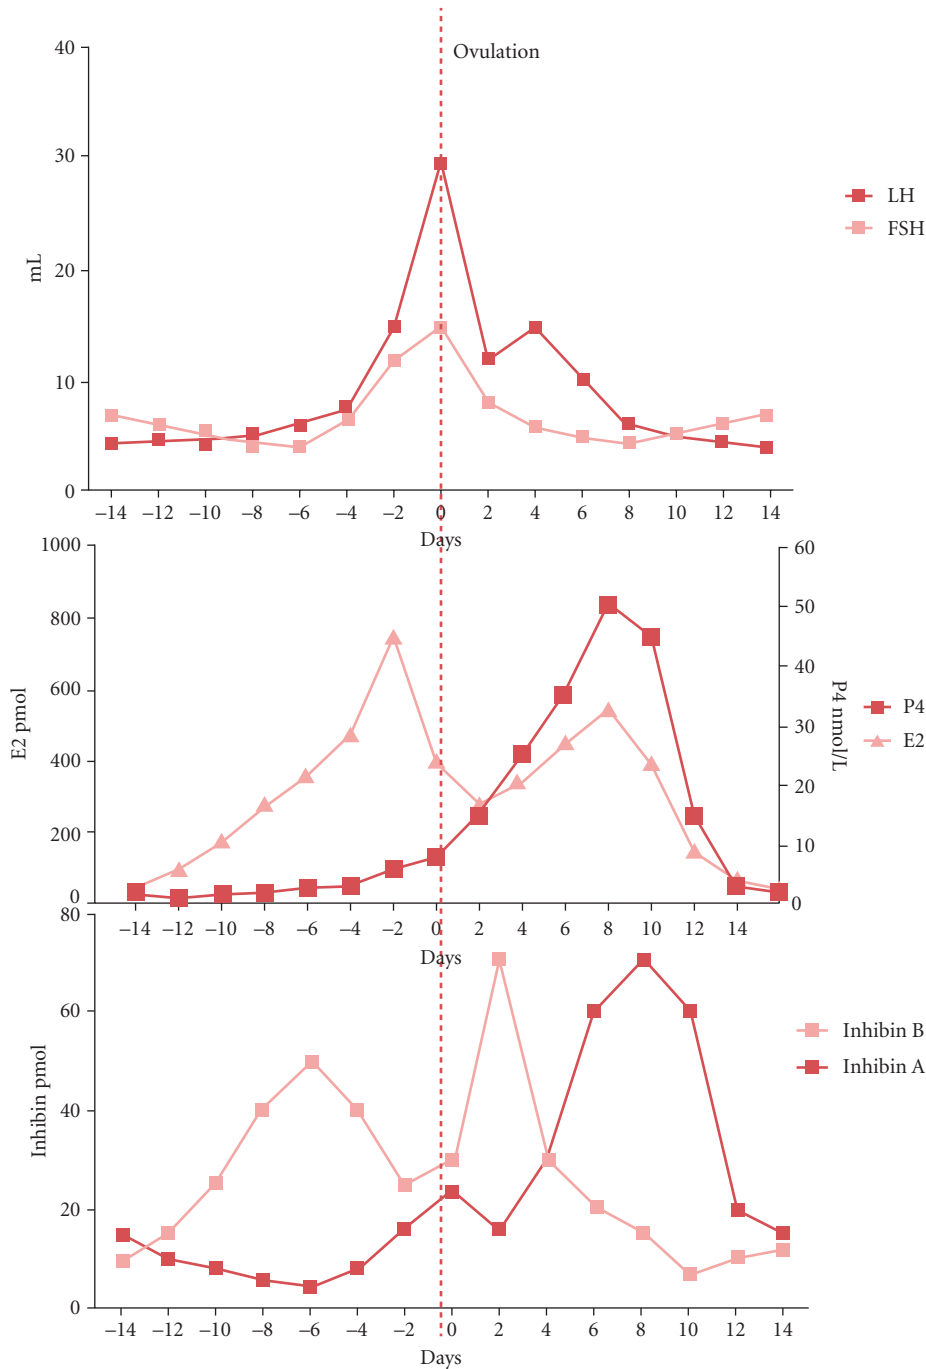

Fig. 71.1 Depiction of the changes of pituitary hormones (FSH/LH), ovarian steroids (E2, P4) and ovarian peptide hormones in a normal ovarian and menstrual cycle

If fertilisation occurs and a blastocyst successfully implants in the endometrium the trophoblast of the implanting embryo secretes hCG which rescues the corpus luteum. This prolongs the lifespan of the corpus luteum and maintains progesterone secretion till about 10 weeks' gestation when the developing placenta takes over the hormonal production (luteo-placental shift). As a result of maintenance of oestrogen and progesterone production and stability of the decidua,

pregnant women will experience the physiological amenorrhoea of pregnancy.

If there was no fertilisation or a blastocyst could not successfully implant then the declining corpus luteum function (starting around day 10–12 after ovulation and almost complete by day 14) is associated with falling oestrogen and progesterone levels. This in turn initiates apoptosis in the endometrium with release of prostaglandins and lysosomal

enzymes from the cells, setting waves of vasoconstriction leading to ischaemia. There is further breakdown of blood vessels and cells followed by vasodilatation, with escape of blood cells (erythrocytes, leukocytes, platelets) as well as various proteolytic enzymes (metalloproteinases, enkephalinases, fibrinolysins) into the endometrial stroma. The effect of these waves of vasoconstriction and vasodilatation with apoptosis and proteolysis culminates into endometrial sloughing at the junction of superficial and basal layers forming the menstrual bleeding. In concert with these changes the released prostaglandins from the endometrium, as well as the myometrial cells under the effect of falling progesterone levels, lead to myometrial contractions. This leads to expulsion of the menstrual blood from the uterus.^{3,4}

A normal menstrual phase is expected to last 2–6 days and the amount of bleeding is generally 20–80 ml. The rising oestradiol level caused by the recruited follicles leads to rapid repair and rebuilding of the endometrium and the end of the menstrual phase.

Menstrual bleeding in ovulatory cycles (oestrogen/progesterone withdrawal bleeding) is characterised by being synchronised and less prolonged and associated with menstrual cramps due to higher levels of prostaglandins, while in anovulatory dysfunctional menses are usually prolonged, erratic, heavy and painless. Cases of dysfunctional menorrhagia (prolonged and/or heavy menses due to mainly anovulation and/or dysfunctional molecular changes in the endometrium in the absence of significant pathological changes) may benefit from progestins only or sequential oestrogens/progestin treatment to mimic the oestrogen/progesterone withdrawal bleeding in normal cycles. The prostaglandin synthetase inhibitors (such as non-steroidal anti-inflammatory agent mefenamic acid) are also used as a treatment of dysfunctional menorrhagia.

CLINICAL POINTS

- Luteal phase defect is a condition characterised by either a short luteal phase or a subnormal secretion of progesterone in the luteal (secretory) phase leading to defective implantation, with either infertility or miscarriage. In IVF cycles due to prolonged pituitary suppression and lack of hormonal support of the corpus luteum, luteal phase support is given by administering progesterone either vaginally or by intramuscular injection to help implantation and improve pregnancy rate.
- In a healthy pregnancy the hCG level usually shows a long linear rise every 48 hours until it reaches a peak of around 100,000 IU/L around 10 weeks' gestation. The minimum rise of hCG level in viable intrauterine pregnancies is generally around 53–66 per cent of baseline. This level of rise, however, is not observed in most ectopic pregnancies. This serves as the basis of monitoring of early pregnancy complications with serial hCG levels. There is, however, a considerable overlap between viable and non-viable pregnancies and ectopic

gestations in hCG levels, and the interpretations of findings should be in conjunction with transvaginal ultrasound scans and in the context of clinical presentation and risk factors.^{8,9}

KEY POINTS

- The ovarian and menstrual cycles are tightly coordinated in order to ensure a receptive endometrium at the time at which the embryo is ready to implant.
- The pituitary hormones LH and FSH are regulated by feedback from the ovarian sex steroids (oestrogens and progesterone) and peptides (inhibin).
- Advancements in IVF are underpinned by an understanding of the interplay between the pituitary gonadotrophins and ovarian steroids and glycoproteins. This has allowed for the development of drugs to influence the menstrual cycle, including injectable gonadotrophins to stimulate multiple follicular development for IVF.
- Anovulation should be investigated by using timed measurements of FSH, LH and progesterone, sometimes with additional measurement of prolactin and thyroid function.
- Underlying cause for anovulation needs to be established before considering treatment options.

Chapter 72 Contraception and termination of pregnancy

Kulsum Jaffer

MRCOG standards

Learning outcomes

- To understand and demonstrate appropriate knowledge, skills and attitudes in relation to fertility control – contraception, sterilisation and termination of pregnancy

Theoretical skills

- Thorough understanding of all methods of contraception – reversible, irreversible and emergency contraception.
- Methods, risks and laws relating to termination of pregnancy.

Practical skills

- Candidates should be able to take an appropriate history and counsel patients requesting contraceptive advice, sterilisation and termination of pregnancy.
- DFSRH, LoC IUT and LoC SDI are highly recommended.

INTRODUCTION

Many factors determine the method of contraception a person chooses. To be effective, contraception must be used correctly and consistently. Contraceptive effectiveness is usually presented in terms of failure rates rather than success rates and is expressed as failure rates per 100 Woman Years (WY). One WY is equal to 13 cycles. Most contraceptive users are medically fit and can use any contraceptive method safely. However, some medical conditions are associated with increased health risks when certain contraceptives are used, either because the method adversely affects the condition or because the condition, or its treatment, affects the contraceptive. The World Health Organization (WHO) published the WHO Medical Eligibility Criteria (WHOME C)¹ for contraceptive use which

Table 72.1 Definition of UKMEC categories (from reference 2, with permission)

UKMEC	Definition of category
1	A condition with no restriction for the use of the contraceptive method.
2	A condition where the advantages of the contraceptive method generally outweigh the theoretical or proven risks.
3	A condition where the theoretical or proven risks of the contraceptive method outweigh the advantages. Expert clinical judgement and/or referral to a specialist contraceptive provider is recommended.
4	A condition which represents an unacceptable health risk if the contraceptive method is used.

relates to the safety (in terms of direct health risk) of using a contraceptive method by women with certain medical conditions or using certain drugs. The UK Medical Eligibility Criteria (UKMEC)² were adapted from WHOME C for use by UK clinicians in line with national health policies, needs, priorities and resources (Table 72.1).

FERTILITY AWARENESS METHODS

These are more commonly known as natural family planning (NFP). They have been defined by the WHO as ‘the voluntary avoidance of intercourse by a couple during the fertile phase of the menstrual cycle in order to avoid a pregnancy.’³ Fertility awareness (FA) methods are associated with higher failure rates than other available methods of contraception. They are often perceived as being better for women’s health than hormonal and intrauterine methods. Some choose natural methods on moral or religious grounds, others because they have experienced, or have concerns about, the side effects of artificial methods or because they have medical conditions which limit their contraceptive choice.⁴ FA methods rely on the fact that there are only certain days during the menstrual cycle when conception can occur. Following ovulation, the

ovum is viable within the reproductive tract for a maximum of 24 hours. However, the life span of the sperm is considerably longer, in the region of 3–7 days. These methods require long periods of sexual abstinence. They provide low and varying levels of efficacy and do not provide any protection against sexually transmitted infections (STIs).

Cycle or rhythm method

Cycle length is recorded for a minimum of six cycles. Likely fertile days are then calculated allowing for the survival time of sperm and ova, using the following formula:

First fertile day = shortest cycle minus 20

Last fertile day = longest cycle minus 10

This method requires a significant period of sexual abstinence, e.g. in cases of a regular 28-day cycle, 10 days of sexual abstinence are required during each cycle.

Temperature method

Following ovulation there is a rise in the progesterone levels which produces a rise in the basal body temperature of 0.2–0.4°C that is maintained until the onset of menstruation. The fertile phase ends after 3 consecutive high temperatures are recorded (>0.2°C above the 6 preceding recordings). This is known as the '3 over 6' rule. Intercourse is avoided from the onset of menstruation until the day on which the third higher-level temperature has been recorded. Intercourse is then allowed until the onset of the next menstruation. In case of a 28-day cycle abstinence is required for about 18 days per cycle. Infection, illness and medication can affect the body temperature and interfere with the method. A failure rate of 1.20 per 100 WY has been reported.⁵

Cervical mucus method (Billings method)

During the follicular phase of the cycle the cervical mucus appears like raw egg white (i.e. it is clear, slippery and stretchy: spinnbarkeit phenomenon). The final day of the 'fertile mucus' is considered to be the day when ovulation is most likely to occur. Abstinence must be maintained from the day when fertile mucus is first identified until 3 days after the peak day. The end of the fertile period is characterised by the appearance of 'infertile mucus' which is scanty and viscous. Semen, sexual excitement, spermicides, lubricants, bleeding and vaginal infections can confuse mucus assessment. The actual failure rate for typical use has been reported as 22 per 100 WY.⁶

Cervical palpation method

Daily self-palpation of the cervix helps to detect the changes occurring in the size of the external os and its position relative to the introitus. The cervix rises during the follicular phase of the cycle. At ovulation it reaches peak height from

the introitus with maximum softness and the os admits a fingertip. The cervix then descends, becomes closed and firm and is closer to the vulva towards the end of the luteal phase.

Minor clinical indicators of fertility

Ovulation pain (mittelschmerz), mid-cycle show of blood, onset of breast symptoms, skin and mood changes can occur in some women. When present they can be helpful in confirming the major signs.

Various combinations of FA methods can be used to increase the accuracy of identification of the fertile and infertile periods.

Personal fertility monitors

Persona is a small hand-held device that is able to detect urine concentrations of estrone-3-glucuronide (E3G) and luteinising hormone (LH) and thus signifies the start and end of the fertile period. On potentially fertile days, a red light indicates the need for abstinence from intercourse. Safe days are indicated by a green light and a yellow light implies that a urine sample is required. Following the urine test, a red or green light will be displayed depending on the LH and E3G ratio. Persona can be used for cycle lengths between 23 and 35 days. It cannot be used if a woman is experiencing menopausal symptoms, is breastfeeding, has recently given birth, is taking hormones or is on tetracyclines. The failure rate is around 6 per 100 WY.

Lactational amenorrhoea method (LAM)

A woman who is fully breastfeeding and is amenorrhoeic during the first 6 months after childbirth has a 2 per cent chance of getting pregnant [B]. Hence LAM is categorised as one of the NFP methods.⁷

BARRIER METHODS

These provide a physical barrier which stops the sperm from getting into the vagina or upper genital tract. There are many types available including male and female condoms, caps, diaphragms, sponges and spermicides. They provide varying degrees of protection from STIs, including HIV and premalignant and malignant disease of the cervix.

Male condom

The majority of these are made from fine latex rubber. Those who suffer from latex sensitivity can use polyurethane condoms [C]. Oil-based lubricants and vaginal preparations drastically reduce the strength of the condom [C]. Failure rates for condoms range from 2 to 18 per 100 WY.

Female condom (femidom)

This is a polyurethane sheath, 15 cm long and 7.5 cm in diameter with rings at both ends. It is stronger than the male latex condom with less risk of splitting and is not weakened by oil-based lubricants and vaginal preparations. Failure rates are in the region of 5–21 per 100 WY.

Occlusive caps

These comprise the diaphragms, cervical and vault caps and the Vimule. They should be used in combination with spermicides to provide maximum protection [C]. Occlusive devices are available in a range of sizes and initially need to be fitted by trained personnel. They require a high degree of motivation for successful use which is reflected in the varying rates of efficacy.

Diaphragm

A diaphragm is a thin latex rubber or silicone hemisphere, the rim of which is reinforced by a flexible flat or coiled metal spring. The flat spring diaphragm is for the normal vagina, whereas the coil and arcing spring ones are for the tight and lax vaginae respectively. Their external diameters range from 55 to 95 mm, with 5 mm increments. The diaphragm should lie across the cervix extending from the posterior vaginal fornix to behind the symphysis pubis. Urinary tract infections are more common in diaphragm users. Inflammatory reactions, abrasions or even frank ulcers can also be caused by local pressure.

Cervical caps

These are the Dumas, Vimule and Prentif caps made from latex. The FemCap is made from silicone. It snugly fits onto the cervix by suction.

Vaginal sponge

This is made of polyurethane foam and impregnated with spermicide. It is inserted in the vagina to cover the cervix. It acts as a carrier for the spermicide and absorbs the semen. The 'Today' and 'Protectaid' contraceptive sponges have currently been withdrawn from the UK market.

Spermicides

These are chemicals that bring about sperm death by causing osmotic changes in the sperm. The most common spermicide is Nonoxino-9. It can cause vaginal irritation and ulceration and may increase the risk of HIV transmission. The use of condoms lubricated with Nonoxinol-9 is not recommended [B]. Spermicides are used in conjunction with barrier methods.

Coitus interruptus

This is the withdrawal of the penis from the vagina before ejaculation takes place and therefore requires considerable control on the part of the man. Failure rates of about 10 per 100 WY have been quoted.⁸

COMBINED HORMONAL CONTRACEPTION (CHC) (BOXES 72.1, 72.2)

This includes the combined oral contraceptive (COC) pill, the transdermal patch and the vaginal ring. The patch and the

Box 72.1 CHC: UKMEC Category 3 – Risks generally outweigh benefits

CHC: UKMEC Category 3 – Risks generally outweigh benefits

Breastfeeding – between 6 weeks and 6 months postpartum and fully or almost fully breastfeeding

Postpartum – <21 days postpartum

Smoking – aged ≥ 35 years and smoking <15 cigarettes per day, or stopped smoking <1 year ago

Obesity – BMI >35 kg/m²

Cardiovascular disease – multiple risk factors for arterial cardiovascular disease

Hypertension – elevated blood pressure >140 – 159 mmHg systolic or >90 – 94 mmHg diastolic; also adequately controlled hypertension

Family history of venous thromboembolism (VTE) in a first-degree relative aged <45 years

Immobility (unrelated to surgery) – e.g. wheelchair use, debilitating illness

Known hyperlipidaemias – e.g. familial hypercholesterolaemia

Migraine without aura, at any age – continuation of the method

Past history (>5 years ago) of migraine with aura at any age

Undiagnosed breast mass – initiation of the method

Past history of breast cancer and no evidence of recurrence for 5 years; carriers of known gene mutations associated with breast cancer (e.g. *BRCA1*)

Diabetes – with nephropathy/retinopathy/neuropathy; or other vascular disease

Gallbladder disease – symptomatic medically treated or current

History of cholestasis – past COC-related

Viral hepatitis – acute or flare

HIV – on antiretroviral therapy (drug interactions)

Drugs which induce liver enzymes – e.g. rifampicin, rifabutin, ritonavir, St John's Wort and certain anticonvulsants (i.e. phenytoin, carbamazepine, barbiturates, primidone, topiramate, oxcarbazepine) and lamotrigine

Box 72.2 CHC: UKMEC Category 4 – Unacceptable health risk and should not be used

CHC: UKMEC Category 4 – Unacceptable health risk and should not be used

Breastfeeding – <6 weeks postpartum
 Smoking – aged ≥ 35 years and smoking ≥ 15 cigarettes per day
 Cardiovascular disease – multiple risk factors for arterial cardiovascular disease
 Hypertension – blood pressure ≥ 160 mmHg systolic and/or ≥ 95 mmHg diastolic; or vascular disease
 VTE – current (on anticoagulants) or past history
 Major surgery with prolonged immobilisation
 Known thrombogenic mutations
 Current and history of ischaemic heart disease
 Stroke
 Valvular and congenital heart disease – complicated by pulmonary hypertension, atrial fibrillation, history of subacute bacterial endocarditis
 Migraine headaches – with aura at any age
 Breast disease – current breast cancer
 Diabetes – with nephropathy, retinopathy, neuropathy or other vascular disease
 Viral hepatitis – active or flare
 Cirrhosis – severe decompensated disease
 Liver tumours – benign hepatocellular adenoma and malignant hepatoma
 Systemic lupus erythematosus (SLE) – positive or unknown antiphospholipid antibodies

ring are no different from the pill in terms of mechanism of action, safety and efficacy. However, there is no data regarding the major side effects of the ring and the patch therefore at present it is advisable that the data for COCs also applies to the NuvaRing and the Evra patch.

Mode of action

All CHCs inhibit ovulation. The vaginal and cervical mucus becomes scanty and viscous and inhibits sperm transport. The endometrium becomes atrophic and is unreceptive for implantation.

Non-contraceptive benefits

CHCs decrease menstrual pain and blood loss. There is a decrease in the incidence of functional ovarian cysts, benign ovarian tumours, benign breast disease, pelvic inflammatory disease (PID) and acne. There is also a 50 per cent reduction in ovarian and endometrial cancers which continues for 15 years after stopping the CHC. There is a possible protective effect against rheumatoid arthritis, thyroid disease and duodenal ulceration.

Major side effects

Venous thromboembolism

The most common serious risk of CHC is VTE. This risk is the most during the first year of CHC use. If a woman is not on any CHC, the risk of VTE is 4–5 per 10,000 WY. The risk of VTE with COCs is double that of the non-users (9–10/10,000 WY). The Danish retrospective study⁹ and the MEGA case-controlled study¹⁰ have not only found an increased relative risk (RR) for VTE with desogestrel and gestodene but also with cyproterone acetate and drospirone compared to levonorgestrel (LNG). Pill users who have a factor V Leiden mutation have up to 20 times the risk of VTE compared to non-pill users.

Myocardial infarction

A meta-analysis of 23 studies showed that there is an overall increased risk of 2.5 of myocardial infarction with current COC use compared with never users.¹¹ This risk increases with smoking and hypertension.

Stroke

The risk of ischaemic stroke is increased among current users of COCs (RR 2.7) [B]. This risk is further increased with smoking and hypertension and in migraine sufferers.

Migraine

The risk of ischaemic stroke is increased in migraine sufferers and the use of CHC further increases this risk. Migraine with aura at any age is a UKMEC 4 category for CHC use.

Cancer

Breast cancer

A large meta-analysis showed that there is an increased risk of breast cancer with COC use (RR 1.24), which is an increase of 24 per cent above the background risk. This increased risk occurs soon after starting COC and is not duration dependent but disappears after 10 years of discontinuation of the COC.¹²

Cervical cancer

There is a slight increased risk of cervical intra-epithelial neoplasia, cervical cancer and also the morbidity from it with the duration of COC use [B].

COC pill

This is almost 99 per cent effective. COC formulations are either fixed dose or phasic, when the dose of the estrogen and progestogen changes during the cycle. Phasic preparations are designed to mimic the body's cyclical variation in hormone levels. Additional precautions are not needed when using CHCs with antibiotics (non-enzyme-inducing). Zoely and Qlaira are the relatively newer COCs.

Zoely

This contains 1.5 mg of estradiol and 2.5 mg of nomegestrol acetate (NOMAC). It has a 24/4 regimen with no pill-free interval. The 17 β -estradiol is identical to the endogenous human 17 β -estradiol whereas NOMAC is a progestogen with strong antigonadotrophic and mild antiandrogenic properties. Randomised studies have shown that its efficacy is comparable to other COCs.

The withdrawal bleeding is shorter and lighter and there is a higher incidence of absent withdrawal bleeds. There have been some withdrawals from trials due to weight gain, acne and lack of withdrawal bleeding. The effect on haemostatic and metabolic parameters is less than other COCs but this clinical relevance is yet to be established.

Missed-pill guidelines for Zoely are as follows:

- **Day 1–7:** The missed pill should be taken as soon as possible and extra precautions should be used for the next 7 days.
- **Day 8–17:** The last missed pill should be taken as soon as possible. The rest of the pack is taken in the usual manner.
- **Day 18–24:** Omit the inactive pills and start the next pack straight away or discard the active pills and take the inactive ones before starting the new pack.

Qlaira

Qlaira is a COC containing estradiol valerate (E2V) and dienogest (D) in the doses shown in Table 72.2.

Reducing the pill-free interval has been shown to decrease mood changes, headaches, menstrual loss and pelvic pain. Therefore, it may be suitable for women who complain of estrogen withdrawal symptoms (as above). In situations when extra precautions are needed, 9 days of extra precautions are needed for Qlaira instead of the 7 days for conventional COCs. It delivers 17 β estradiol (E2) which is a body identical estrogen. Studies have shown that it has less effect on the haemostatic parameters and lipid profile than Microgynon 30 and Logynon. It may therefore prove useful for women over 35 and those with uncomplicated diabetes.¹³ It contains 26 active and two placebo tablets. Hence the pill-free interval is reduced to 2 days. Reducing the pill-free interval has been shown to decrease mood changes, headaches, menstrual loss and pelvic pain. Therefore, it may be suitable for women who complain of estrogen withdrawal symptoms (as above). Pearl index (failure rate) is 0.4 per 100 WY which is similar to those reported for other COCs.

Qlaira has different missed-pill guidelines to the other COCs. The following guidelines should be followed if one pill is missed for more than 12 hours:

Table 72.2 Dosage of E2V and D in Qlaira

Days	2	5	17	2	2
E2V	3 mg	2 mg	2 mg	1 mg	0
D	0	2 mg	3 mg	0	0

- **Days 1–17:** Take the missed pill immediately and the next tablet at the usual time (even if it means taking two on the same day). Continue with the tablet taking in the normal way. Abstain or use an additional contraceptive method for 9 days.
- **Days 18–24:** Discard the rest of the packet. Start taking the day 1 pill from a new packet immediately and continue taking these pills at the correct time. Abstain or use an additional contraceptive method for 9 days.
- **Days 25–26:** Take the missed tablet immediately and the next tablet at the usual time (even if it means taking two tablets on the same day). Additional contraception is not necessary.
- **Days 27–28:** Discard the forgotten tablet and continue tablet taking in the normal way. Additional contraception is not necessary.

Dianette

This contains 35 μ g of ethinyl estradiol and 2 mg of cyproterone acetate. It is not licensed as an oral contraceptive but is used as one. It is used for treating moderate to severe acne and hirsutism. There is an increased incidence of VTE in Dianette users more than the second generation COCs. A few cases of severe depression have been reported with Dianette. Therefore it has been advised by the Committee on Safety of Medicines (CSM) that it should be withdrawn 3–4 cycles after the condition for which it was prescribed initially has resolved.

Evra patch

With this patch 20 μ g of ethinyl estradiol and 150 μ g of norelgestromin are released every 24 hours. It is the first transdermal contraceptive applied once weekly for 3 weeks followed by a patch-free week (3 weeks on, 1 week off). The Pearl index is 1.24 per 100 WY. It has been reported that contraceptive efficacy is reduced in women weighing over 90 kg. It provides a new delivery system and another contraceptive choice for women. Efficacy, cycle control and safety profile are similar to COCs.

NuvaRing

This is a flexible, latex-free ring made of plastic and ethylene vinyl acetate which releases 120 μ g of etonogestrel (ENG) and 15 μ g of ethinyl estradiol daily. It is 54 mm in diameter and 4 mm thick. It is placed vaginally once every 3 weeks and following a 1-week ring-free interval a new ring is inserted. Efficacy and cycle control are comparable to the COCs. Side-effect profile is also similar to that of COCs. However, women have reported more vaginal symptoms of vaginitis, leukorrhoea, foreign body sensation, coital problems and expulsion.¹⁴ It provides another useful contraceptive for women.

Missed-pill guidelines for COC

See Figure 72.1

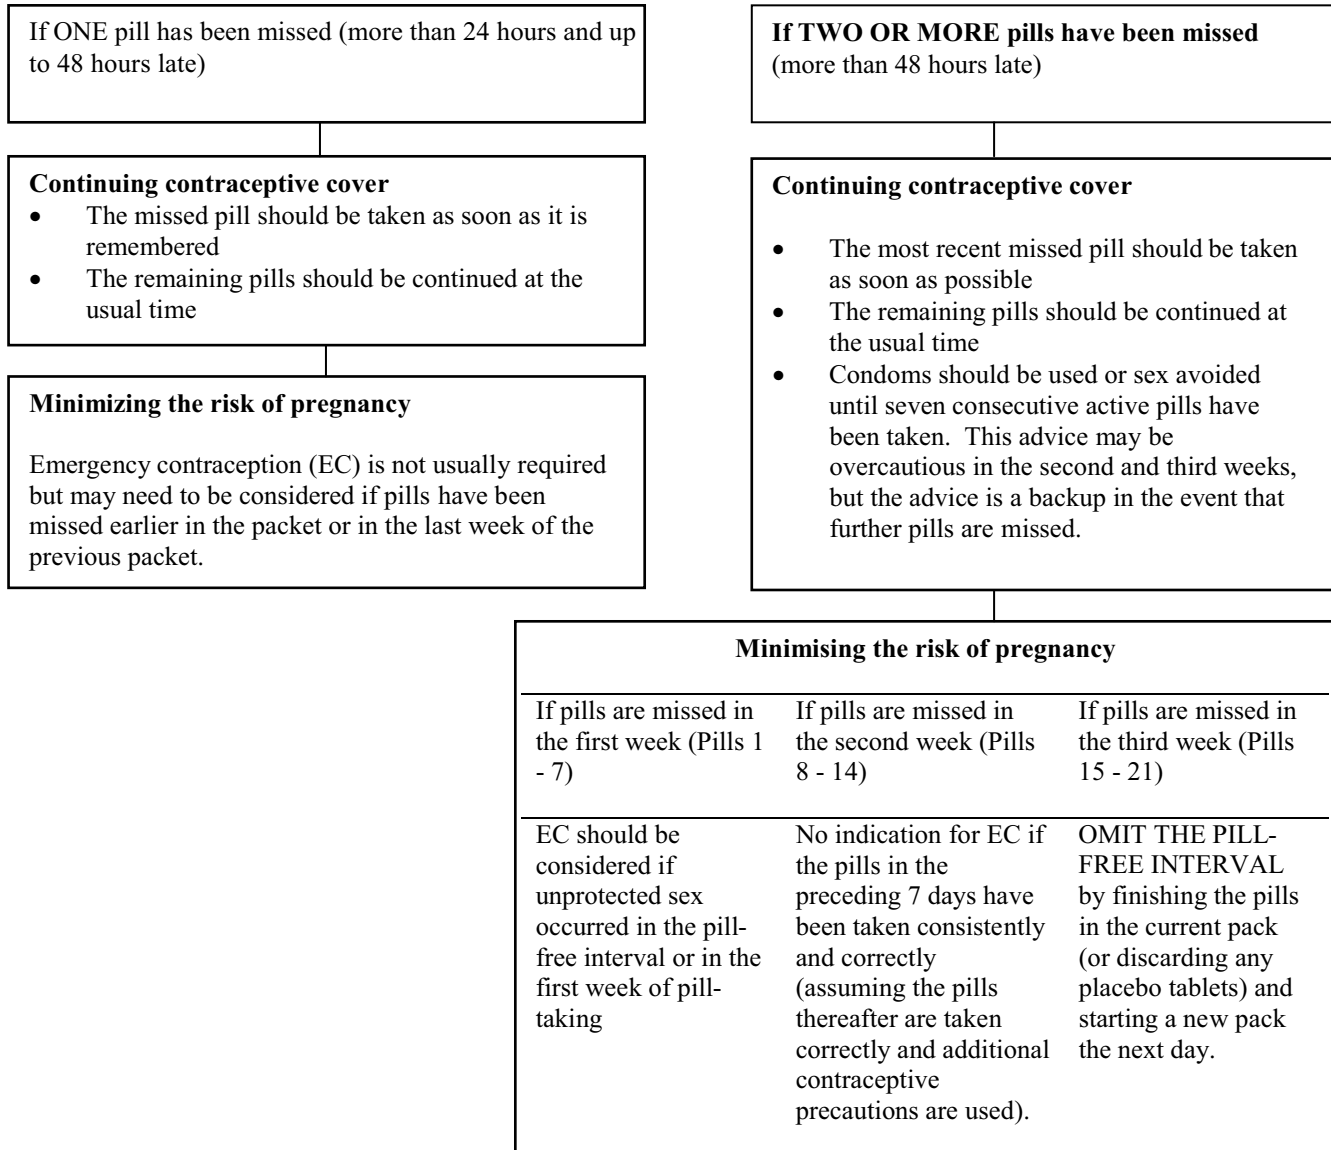

Fig. 72.1 Advice for women missing combined oral contraceptive pills (except Qlaira and Zoely). (Reproduced from FFRHC/FSRH guidance - combined oral contraception - missed pills recommendations, CEU Guidance May 2011, with permission.)

Table 72.3 Tailored regimens for use of combined hormonal contraception (CHC). (From FSRH – CHC Guidance October 2011, updated August 2012, with permission)

Type of regimen	Suggested regimen	CHC-free period
Extended use	Tricycling (3 cycles taken continuously back to back i.e. 3 pill packets or 3 rings, or 9 patches)	7 days taken after finishing the 3 rd packet, 3 rd ring or 9 th patch
Shortened pill-free interval	3 weeks of CHC use	4 days taken after each packet of pills, each ring or 3 rd patch
Extended use with shortened pill-free interval	Method used continuously (≥ 21 days; pill-, patch- and ring-free weeks omitted) until breakthrough bleeding occurs for 3-4 days	4-day interval
Extended use with standard pill-free interval	Method used continuously (≥ 21 days; pill-, patch- and ring-free weeks omitted) until breakthrough bleeding occurs for 3-4 days	7-day interval

Extended prescribing regime for CHCs

Continuous or extended regimens of CHC use are advocated by the Faculty of Sexual and Reproductive Healthcare (FSRH). These are safe but are out of product licence. These regimens are only applicable for monophasic pills (Table 72.3).

PROGESTOGEN-ONLY PILLS (POPs) (BOXES 72.3, 72.4)

Mode of action

POPs alter cervical mucus and prevent sperm penetration. The endometrium is altered so that it is not conducive for implantation. In addition, traditional POPs can inhibit ovulation but this can be variable – up to 60 per cent, whereas in the case of the desogestrel-only pill, Cerazette, 97 per cent of the cycles are anovulatory. Therefore, inhibition of ovulation is the main mode of action of Cerazette [C].

Effectiveness

Failure rates for traditional POPs vary from 0.3 to 8.0 per 100 WY, but are lower for women aged over 40 years (0.3 per 100 WY) compared to younger women. The failure rates of the traditional pills and Cerazette are similar [B]. There is no evidence to suggest that the efficacy of any POP is

Box 72.3 POP: UKMEC Category 3 – Risks generally outweigh benefits

POP: UKMEC Category 3 – Risks generally outweigh benefits

Current and history of ischaemic heart disease and stroke – continuation of the method
Past history of breast cancer and no evidence of recurrence for 5 years
HIV – on antiretroviral therapy (drug interactions)
Cirrhosis – severe (decompensated)
Liver tumours – hepatocellular adenoma and malignant hepatoma
SLE – positive or unknown antiphospholipid antibodies

Box 72.4 POP: UKMEC Category 4 – Unacceptable health risk and should not be used

POP: UKMEC Category 4 – Unacceptable health risk and should not be used

Breast disease – current breast cancer

reduced in women weighing >70 kg and therefore one pill per day is advised as per licence [B].

Side effects

Changes in the bleeding pattern are common. Two in 10 women are amenorrhoeic, whereas 4 in 10 have regular bleeding and another 4 in 10 have irregular bleeding. Mood changes can occur with POP use.

Risks

There is no causal association between POP use and cardiovascular disease (VTE, myocardial infarction and stroke) or breast cancer. Women of any age with a history of migraine (with or without aura) can safely use POPs.

Missed-pill guidelines for POPs

See Figure 72.2.

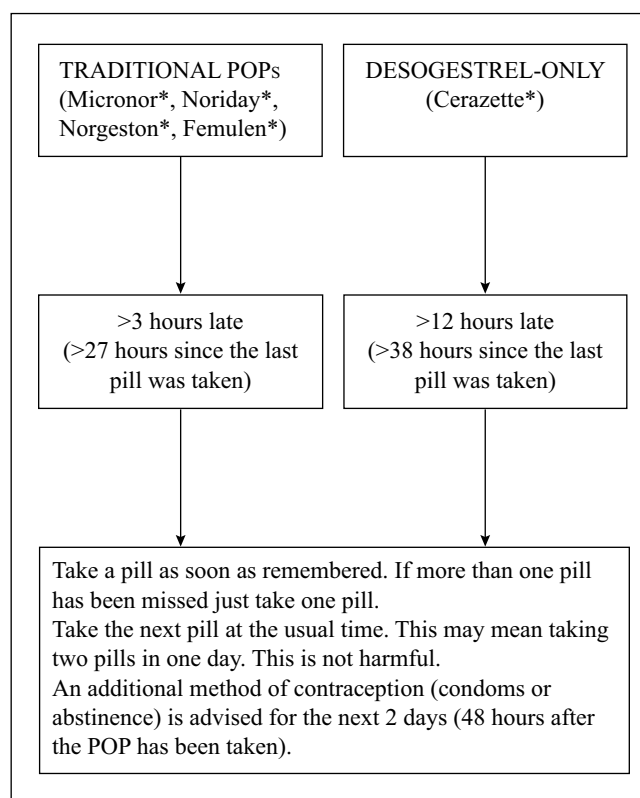

Fig. 72.2 Missed-pill guidelines for POP. (Reproduced from FFPRHC/FSRH – Clinical guidance Progestogen-only Pill, November 2008 with permission.)

LONG-ACTING REVERSIBLE CONTRACEPTION (LARCs) (BOXES 72.5, 72.6, 72.7, 72.8)

- LARC methods require administering less than once per cycle or month.
- They are more cost effective than COCs even at 1 year of use.
- Intrauterine devices, systems and implants are more cost effective than injectables.
- Increased uptake will reduce unintended pregnancies.

The LARC methods are:

- Non-hormonal: Intrauterine device (IUD or Cu-IUD);
- Hormonal: – Intrauterine system (IUS);
 - Progestogen-only injectable contraception (POIC);
 - Progestogen-only implant (POI);

Box 72.5 IUD: UKMEC Category 3 – Risks generally outweigh benefits

IUD: UKMEC Category 3 – Risks generally outweigh benefits

Postpartum – between 48 hours and <4 weeks
 VTE – current (on anticoagulants)
 Ovarian cancer – initiation of the method
 Pelvic tuberculosis – continuation of the method
 AIDS – initiation of the method
 SLE – initiation of the method in women with severe thrombocytopenia

Box 72.6 IUD: UKMEC Category 4 – Unacceptable health risk and should not be used

IUD: UKMEC Category 4 – Unacceptable health risk and should not be used

Pregnancy, puerperal sepsis and immediate post-septic abortion
 Unexplained vaginal bleeding – initiation of the method
 Gestational trophoblastic disease (GTD) – persistently elevated beta-human chorionic gonadotrophin (hCG) levels or malignant disease
 Cervical cancer – initiation of the method in women awaiting treatment
 Endometrial cancer – initiation of the method
 Ovarian cancer – initiation of the method
 Current PID, symptomatic and asymptomatic chlamydial infection or purulent cervicitis or gonorrhoea – initiation of the method
 Pelvic tuberculosis – initiation of the method

Box 72.7 LNG-IUS: UKMEC Category 3 – Risks generally outweigh benefits

LNG-IUS: UKMEC Category 3 – Risks generally outweigh benefits

Postpartum – between 48 hours and <4 weeks
 Current and past history of ischaemic heart disease – continuation of the method
 Stroke – continuation of the method
 Pelvic tuberculosis – continuation of the method
 AIDS – initiation of the method
 Cirrhosis – severe, decompensated
 Liver tumours – hepatocellular adenoma and malignant hepatoma
 SLE – positive or unknown antiphospholipid antibodies

Box 72.8 LNG-IUS: UKMEC Category 4 – Unacceptable health risk and should not be used

LNG-IUS: UKMEC Category 4 – Unacceptable health risk and should not be used

Puerperal sepsis
 Post-septic abortion
 Unexplained vaginal bleeding – initiation of the method
 GTD – persistently elevated beta-hCG levels or malignant disease
 Cervical cancer – initiation of the method in women awaiting treatment
 Endometrial cancer – initiation of the method
 Ovarian cancer – initiation of the method
 Breast cancer – current
 Current PID, symptomatic and asymptomatic chlamydial infection or purulent cervicitis or gonorrhoea – initiation of the method
 Pelvic tuberculosis – initiation of the method

Intrauterine contraception – IUD and LNG-IUS

The gold standard IUDs are the T-shaped IUDs with banded copper on the arms and containing at least 380 mm² copper. They last for 10 years whereas other Cu-IUDs and LNG-IUSs are for 3–5 years [C].

Jaydess, a new LNG-IUS Jaydess is licensed for 3 years. It contains 13.5 mgs of LNG which is released at a rate of 6–10 mcg/day. It is slightly smaller than the Mirena and has a silver ring for identification from the Mirena on ultrasound.

It is not recommended for the treatment of heavy menstrual bleeding ((HMB) nor offers protection from endometrial hyperplasia.

Levosert contains 52 mgs of LNG and is licensed for 3 years for contraception and treatment of HMB. It is not licensed for endometrial protection.

A Cu-IUD inserted in a woman at the age of 40 years or over can be retained for 1 year after the last menstrual period if aged over 50 years or 2 years if under 50 years or until contraception is no longer required [C]. The LARC guideline recommends that women who have the LNG-IUS inserted at or after the age of 45 years and are amenorrhoeic may retain the LNG-IUS until the menopause [E].

Effectiveness

Failure rates are less than 2 per cent with TCU380A and TCU380S coils and less than 1 per cent for LNG-IUS [C].

Mode of action

IUDs work by inhibiting fertilisation by direct toxicity [B]. An inflammatory reaction within the endometrium can also have an anti-implantation effect. Copper is toxic to the ovum and the sperm and the copper content of the cervical mucus inhibits sperm penetration as well. LNG-IUS works primarily by its effect on the endometrium, preventing implantation. In addition, its effect on cervical mucus reduces sperm penetration [B].

Insertion and removal prerequisites

A sexual history should be taken from all women attending for IUD/IUS insertions to assess the risk of STIs. Prior to IUD/IUS insertion, women at higher risk of STIs (age <25 years, change in sexual partner, or more than one partner in the last year) should be offered testing for *Chlamydia trachomatis*, as a minimum [C]. For women assessed as being at higher risk of STIs, and whose test results are not available at the time of the insertion, then the use of prophylactic antibiotics to cover chlamydia should be considered (Good Practice).

Additional protection is never needed at IUD insertion, as the mode of action is by inhibition of fertilisation and implantation and these effects are immediate after insertion. It is however required before IUD removal, as viable ova or sperm may be present in the female genital tract before removal. The woman is therefore advised to abstain, use condoms or start a CHC 7 days before removal [C].

Antibiotic prophylaxis for the prevention of infective endocarditis is NOT recommended in women undergoing intrauterine insertion or removal even in women with conditions where the risk of endocarditis is increased.¹⁵

Discontinuation

The most common reasons for discontinuation of intrauterine contraception are unacceptable vaginal bleeding and pain.

Another reason is PID/infection. Discontinuation rates for all reasons are similar for different IUDs – framed or frameless – and for LNG-IUS [A].

Risks

Expulsion

Expulsion of intrauterine contraception occurs in approximately 1 in 20 women and is most common in the first 3 months after insertion and often during menstruation [B]. A Cochrane review found a small excess in expulsions with Multiload Cu375 compared to TCU380A in the fourth and subsequent years. The expulsion rate for a frameless Cu-IUD was higher than the TCU380A at 1 year. Early expulsions with a frameless device (GyneFix) are common.¹⁶

In general there is no difference in the rates of expulsion of the various IUDs and between IUD and IUS [A].

PID

Although there is a six-fold increase in the risk of PID in the 20 days after the insertion of intrauterine contraception the overall risk is low unless there is exposure to STIs [B].

Management

In a woman with an intrauterine contraceptive *in situ* and with signs and symptoms suggestive of pelvic infection then appropriate antibiotics should be commenced. Where possible triple swabs should be taken prior to commencing antibiotic therapy. There is no need to remove the device at this stage. The intrauterine method can be removed if symptoms fail to improve 72 hours after commencement of antibiotics.

The removal should be carried out at an appropriate time (see above in prerequisites for insertion and removal). There may even be a need to give emergency hormonal contraception following the removal. The woman should be followed up to ensure resolution of symptoms, counselling for safer sex and partner notification. The partner also needs to be treated with appropriate antibiotics.

Presence of Actinomyces-like organisms (ALOs)

ALOs can be detected on smears in women who have intrauterine contraception *in situ*.

Management

If there are no signs or symptoms suggestive of pelvic infection then there is no need to remove the device. Neither there is any need for subsequent screening.

If symptoms of infection develop then the woman should be advised to seek medical advice. Other causes of infection, e.g. STIs, should be considered at this stage.

Perforation

The risk of uterine perforation associated with intrauterine contraception is up to 2 per 1000 insertions [B]. It is more

common at the time of insertion. Women should be informed about signs and symptoms of uterine perforation and infection. There should be a 6-week interval after an asymptomatic, suspected perforation before an IUD/IUS insertion is attempted again.

Management

If perforation is suspected at the time of insertion the procedure should be stopped and vital signs (blood pressure and pulse rate) and level of discomfort monitored until they are stable. An ultrasound scan and/or plain abdominal X-ray should be organised to locate the device if it has been left *in situ*.

Ectopic pregnancy

The ectopic pregnancy rate for Cu-IUD users is 0.02 per 100 WY (0.3–0.5 per 100 WY for those not using contraception) [A].

Bleeding patterns and pain

Spotting, light bleeding, heavier or longer periods are common in the first 3–6 months following Cu-IUD insertion (C). These bleeding patterns usually decrease with time.

Irregular bleeding and spotting is common during the first 6–8 months of LNG-IUS insertion. By 1 year amenorrhoea or light bleeding ensues [B].

Management

Women who experience problematic bleeding while using an intrauterine contraceptive should have a sexual history taken to establish STI risk and/or be investigated for gynaecological pathology if clinically indicated. When these have been excluded, bleeding problems in cases of LNG-IUS can be treated with mefenamic acid or ethinylestradiol (alone or as an oral contraceptive) provided there are no contraindications to estrogen therapy. Non-steroidal anti-inflammatory drugs or antifibrinolytics, e.g. tranexamic acid, can be used to treat abnormal bleeding with Cu-IUDs.

Vasovagal syncope

The incidence of vasovagal syncope at intrauterine contraception insertions is 0.2–2.1 per cent. The signs of syncope are sweating, pallor and bradycardia: a pulse of <60 bpm.

Management

- Abandon procedure, lower head or raise legs;
- Remove instruments and + coil;
- Monitor blood pressure and pulse;
- Administer oxygen (FSRH – essential for intrauterine-contraception-inserting clinics).

Medication

- Atropine IV (0.6 mg/mL) (bradycardia: heart rate <40 bpm or systolic blood pressure <90 mmHg);
- Repeat every few minutes up to a dose of 3 mg.

Lost threads

Management

Women should be advised to use another method until it is confirmed that the device is *in situ*. The cervical canal can be explored with a thread retriever or a Spencer Wells forceps to bring the threads down if they are in the canal. If this is not successful then an ultrasound scan of the pelvis should be organised. If the intrauterine method is not located on ultrasound then a plain X-ray of the abdomen should be arranged to identify an extrauterine location. It is presumed that the intrauterine method has been extruded, if there is failure to visualise the device on X-ray.

Pregnancy

Management

An ectopic pregnancy should be excluded. If the threads of the device are visible then the intrauterine method should be removed up to 12 weeks' gestation. Women who become pregnant with an intrauterine contraception *in situ* should be informed of the increased risks of second-trimester miscarriage, preterm delivery and infection if the intrauterine method is left *in situ*. Removal would reduce adverse outcomes but is associated with a small risk of miscarriage.

Hormonal side effects

Due to the systemic absorption of LNG (though in very small amounts) progestogenic side effects such as headaches, mood changes, acne, breast tenderness or change in libido can occur with LNG-IUS [C].

Ovarian cysts

There has been a slightly increased incidence of functional ovarian cysts in LNG-IUS users compared to IUD users [B].¹⁷

Non-contraceptive benefits

LNG-IUS reduces menstrual blood loss and decreases pain and is therefore used as first-line therapy for heavy menstrual bleeding. It provides endometrial protection from the stimulatory effects of oestrogens and is used with oestrogen therapy in the management of menopausal symptoms [B]. It can also be used in the management of endometriosis.

PROGESTOGEN-ONLY INJECTABLE CONTRACEPTION (BOXES 72.9, 72.10)

Three POICs are available in the UK. They are:

- Depot medroxyprogesterone acetate (DMPA) 150 mg given as deep intramuscular (IM) every 12 weeks. It is the most commonly used POIC in the UK.

Box 72.9 POIC: UKMEC Category 3 – Risks generally outweigh benefits

UKMEC Category 3 – Risks generally outweigh benefits

Cardiovascular disease – multiple risk factors for arterial cardiovascular disease
 Hypertension – vascular disease
 Current and history of ischaemic heart disease and stroke
 Unexplained vaginal bleeding
 Breast cancer – past and no evidence of disease for 5 years
 Diabetes – nephropathy, retinopathy, neuropathy and other vascular disease
 Cirrhosis – severe (decompensated)
 Liver tumours – hepatocellular adenoma and malignant hepatoma
 SLE – positive or unknown antiphospholipid antibodies

Box 72.10 POIC: UKMEC Category 4 – Unacceptable health risk and should not be used

POIC: UKMEC Category 4 – Unacceptable health risk and should not be used

Breast cancer - current

- Subcutaneous DMPA (Sayana Press) 104 mg given subcutaneously every 13 weeks. It has been available in the UK since June 2013. It is bioequivalent to IM DMPA. It is administered via Unijet which is a new delivery system and is in a pre-filled injector which needs to be shaken vigorously to ensure a uniform suspension. It can be injected into the upper anterior thigh or anterior abdomen. Rates of bone loss, amenorrhoea, weight gain and return to fertility are the same as for IM DMPA. It will be beneficial for women who are on anticoagulants as there is less likelihood of haematoma formation. Also it may be more advantageous for very obese women when there is concern that the injection may not reach the muscle.
- Norethisterone enanthate (NET-EN) 200 mg, licensed for short-term use. It is also given deep IM but 8-weekly.

Mode of action

The main mode of action is inhibition of ovulation [C]. Thickening of the cervical mucus prevents sperm penetration into the upper reproductive tract. It also brings about changes in the endometrium making the environment unfavourable for implantation.

Effectiveness

The failure rate of DMPA is <4 in 1000 over 2 years [A].

Return of fertility

There is a delay in the return of fertility of up to 1 year with POIC [C]. However there is no evidence to suggest that fertility is reduced in the long term.

Discontinuation

Fifty per cent of POIC users will discontinue the method within 1 year. The main reasons for discontinuation are bleeding problems and weight gain [B].

Side effects

Bleeding problems

Amenorrhoea, spotting, infrequent bleeding or prolonged bleeding can occur with POICs. Amenorrhoea is more likely as duration of use increases. A third of women are amenorrhoeic at 3 months and 70 per cent by 12 months of use [B].¹⁸

Women who experience problematic bleeding while using a POIC should have a sexual history taken to establish STI risk and/or be investigated for gynaecological pathology if clinically indicated. When these have been excluded bleeding problems can be treated with mefenamic acid or ethinylestradiol (alone or as an oral contraceptive) provided there are no contraindications to estrogen therapy [C]. Sometimes giving the injection 2 weeks earlier helps with the bleeding but this is not evidence based.

Weight gain

The average weight gain among women using DMPA is between 2 and 6 kg. It tends to be more in women with a BMI >30 than in those with a BMI of <25.

Health concerns

Cardiovascular disease

POICs do not appear to be associated with an increased risk of stroke, VTE or myocardial infarction [C]. They are medically safe for women when estrogens are contraindicated.

Bone mineral density (BMD)

Concerns have been raised about the potential detrimental effects of DMPA on BMD. There has been particular concern about use of DMPA in women aged <18 years (who have not yet attained their peak bone mass) and among older women (who are approaching the menopause, when bone loss will occur). DMPA is associated with a small loss of BMD which mostly recovers when DMPA is discontinued [B]. There is no evidence that DMPA increases fracture risk in present or past users [E].

The Department of Health MHRA¹⁹ issued guidance that was endorsed by the FSRH on the use of DMPA as follows:

- In women aged under 18 years DMPA may be used as first-line contraception after all options have been discussed and considered unsuitable or unacceptable [C].
- A re-evaluation of the risks and benefits of treatment for all women should be carried out every 2 years in those who wish to continue use [E].
- For women with significant lifestyle and/or medical risk factors for osteoporosis other methods of contraception should be considered.

Drug interactions

Enzyme-inducing drugs do not reduce the contraceptive efficacy of DMPA. Therefore the injection intervals do not have to be reduced [C].

Non-contraceptive benefits

This improves dysmenorrhoea and the symptoms of endometriosis.

PROGESTOGEN-ONLY IMPLANT (BOXES 72.11, 72.12)

Nexplanon is the only POI available in the UK. It has replaced Implanon. Nexplanon is bioequivalent to Implanon. It is a single rod which contains 68 mg of ENG in a membrane of ethylene vinyl acetate. It is licensed for 3 years [C] just like Implanon. Nexplanon is radio-opaque and has a different introducer and insertion technique to the Implanon.

Other POIs are Norplant, a six-rod LNG implant, and Jadelle, a two-rod LNG implant. These implants are licensed for 5 years' use. They are not available in the UK but UK healthcare professionals may see women who have had them inserted in other countries.

Box 72.11 POI: UKMEC Category 3 – Risks generally outweigh benefits

UKMEC Category 3 – Risks generally outweigh benefits

Current and history of ischaemic heart disease and stroke – continuation of the method

Unexplained vaginal bleeding

Breast cancer – past and no evidence of disease for 5 years

Cirrhosis – severe (decompensated)

Liver tumours – hepatocellular adenoma and malignant hepatoma

SLE – positive or unknown antiphospholipid antibodies

Box 72.12 POI: UKMEC Category 4 – Unacceptable health risk and should not be used

POI: UKMEC Category 4 – Unacceptable health risk and should not be used

Breast cancer - current

Mode of action

The main mode of action is inhibition of ovulation [B]. Thickening of the cervical mucus prevents sperm penetration into the upper reproductive tract. It also brings about changes in the endometrium making the environment unfavourable for implantation.

Effectiveness

The overall pregnancy rate is <1 in 1000 over 3 years' use [B]. The interaction of any enzyme-inducing medication, e.g. certain anticonvulsants, antiretroviral therapy, rifampicin or rifabutin, is not harmful to women but it is likely to reduce the effectiveness of the implant.

Therefore CONSISTENT USE OF CONDOMS IS RECOMMENDED.

Use of other contraceptives should be encouraged for women who are long-term users of any of these drugs.

Side effects

Bleeding problems

Bleeding irregularities are common with POIs. They include prolonged bleeding, irregular bleeding and oligomenorrhoea/amenorrhoea. Up to 20 per cent of women using implants will be amenorrhoeic [C].

Women who experience problematic bleeding while using a POI should have a sexual history taken to establish STI risk and/or be investigated for gynaecological pathology if clinically indicated. When these have been excluded, bleeding problems can be treated with mefenamic acid or ethinylestradiol (alone or as an oral contraceptive) provided there are no contraindications to estrogen therapy [C].

Weight gain

This has been reported in various studies ranging from 3–12 per cent.

Other changes

Mood changes and loss of libido can occur. Acne can improve, occur or worsen whilst using the implant. There is no evidence of a causal association between the use of an implant and headache [C].

Discontinuation

Rates of up to 43 per cent within 3 years have been reported [C]. A third of the women discontinue because of bleeding irregularities. Less than 10 per cent discontinue the method because of other side effects.

Complications with removal

Complications (only in the region of 1 per cent of removals) include deeply sited, non-palpable, broken or migrated implants. As Nexplanon contains barium sulphate it is radio-opaque. Hence it can be identified on X-rays. Ultrasound and MRI can also be used to locate the implants.

Complicated implants should be referred to specialised centres for removal.

Health concerns

VTE

There is little or no increase in the risk of VTE with the use of POIs [C].

BMD

There is no evidence to suggest that POIs have any clinically significant effect on BMD [C].

Endocarditis

Prophylactic antibiotics to prevent endocarditis are not needed for insertion and removal of implants [E].

EMERGENCY CONTRACEPTION

Emergency contraception (EC) prevents a pregnancy following any unprotected sexual intercourse (UPSI). In 2002, a Judicial Review ruled that pregnancy begins at implantation and *not* at fertilisation: thus EC is not considered an abortifacient. Three methods of EC are available in the UK:

Intrauterine device

A copper IUD can be inserted up to 5 days after the first episode of UPSI. If the timing of ovulation can be estimated, insertion can be beyond 5 days of UPSI, as long as it does not occur beyond 5 days after ovulation [C]. It is effective immediately after insertion. IUDs with banded copper on the arms and containing at least 380 mm² of copper have the lowest failure rates and should be the first-line choice, particularly if the woman intends to continue the IUD as long-term contraception [A]. The failure rate is 1 per cent.

Prerequisites

Prior to emergency IUD insertion, women at higher risk of STIs (age <25 years, change in sexual partner, or more than

one partner in the last year) should be offered testing for *Chlamydia trachomatis* (as a minimum) [C]. For women assessed as being at higher risk of STIs, if results of testing are not available at the time of emergency IUD insertion, the use of prophylactic antibiotics, at least to cover chlamydia, should be considered (Good Practice).

Mode of action

This is the same as for routine IUDs.

Contraindications

The same contraindications apply as for routine IUD insertions.

Hormonal methods

Progestogen-only emergency contraception (POEC)

LNG – Levonelle1500, Levonelle One Step

Mode of action

Its exact mode of action is not known but it is thought that it works mainly by inhibiting ovulation. It prevents follicular rupture. LNG is given in a single dose of 1.5 mg as soon as possible after UPSI and within 72 hours [A]. However it can also be given up to 96 hours outside product licence, but there is limited evidence of efficacy [E]. It can be used more than once in a cycle. The WHOMEC for contraceptive use advises that there are no medical contraindications to the use of hormonal EC. Women who are on liver enzyme-inducing drugs should be advised to take double the dose, i.e. 3 mg of LNG [C]. This use is outside the product licence.

Ulipristal acetate (UPA)

ellaOne

This is a selective progesterone receptor modulator (SRPM).

Mode of action

Its primary mode of action is thought to be inhibition or delay of ovulation. It can prevent ovulation after the LH surge has started.

How should it be used?

One tablet should be taken orally as soon as possible, but no later than 120 hours after UPSI or contraceptive failure. If vomiting occurs within 3 hours, another tablet should be taken. Ulipristal is not recommended to be used more than once per cycle as the safety of efficacy of repeated exposure has not been assessed. If hormonal contraception is continued after administering UPA, barrier contraception should be used until the next period or withdrawal bleed.

Effectiveness

Individual studies suggest that UPA is as effective as LNG for EC. There have been no studies comparing the efficacy of UPA to the IUD for the purpose of EC. A meta-analysis suggests

that regardless of the type of EC drug used, the risk of pregnancy is significantly increased with increasing BMI.²¹

Contraindications

UPA is contraindicated when there is a hypersensitivity to any of its excipients. It is not recommended in those with severe hepatic impairment, or in women with severe asthma. Breastfeeding women are advised not to breastfeed for 1 week after treatment as it is found in breast milk up to 5 days after intake.

Side effects

The most commonly reported side effects are abdominal pain and menstrual disorders, e.g. irregular vaginal bleeding, premenstrual syndrome and uterine cramps.

Does UPA interact with other drugs?

Liver enzyme inducers, e.g. rifampicin, phenytoin, carbamazepine, ritonavir and St John's Wort, may reduce plasma concentrations of UPA and may reduce efficacy. Use of UPA with antacids, proton pump inhibitors and H₂ receptor antagonists, or any other drugs that increase gastric pH, may reduce absorption of UPA and decrease efficacy. Therefore it is not advisable to use UPA with liver enzyme-inducing drugs and drugs that increase gastric pH.

UPA binds to progesterone receptors and so may reduce the efficacy of progestogen-containing contraceptives. The CEU (Clinical Effectiveness Unit) therefore advises 14 days of extra precautions if commencing CHC, 16 days with Qlaira and 9 days with POP following UPA administration.

QUICK-STARTING CONTRACEPTION

Quick-starting contraception is contraception, when a woman requests it rather than waiting for the next period.

The clinician has to be reasonably certain that the woman is not pregnant or at risk of pregnancy. If the woman's preferred method is not available then a bridging method, e.g. CHC or POP, can be used till the preferred method is available.

Quick starting can also be initiated immediately after EC administration, but extra precautions need to be observed (Table 72.4). A pregnancy test should be advised 3 weeks after the last episode of UPSI.

STERILISATION

Sterilisation is a permanent and usually an irreversible method of contraception. In the UK about 50 per cent of couples over the age of 40 use this method.

Counselling and written information regarding the procedure, its risks, benefits and failure rates should be provided to the client. Discussion and information should also be given regarding other methods, especially the long-acting reversible methods of contraception.

Both men and women should be informed that reversal operations are rarely provided by the NHS.

Female sterilisation: tubal occlusion

Methods

Female sterilisation usually involves blocking both Fallopian tubes during laparotomy, mini-laparotomy, laparoscopy or via hysteroscopy.

The Pomeroy technique is the most widely used ligation technique. It involves using absorbable sutures to tie the base of a loop of the Fallopian tube near the mid-portion and cutting off the top of the loop. This procedure destroys 3–4 cm of the tube, making reversal more difficult.

Table 72.4 Summary of additional contraceptive requirements when quick-starting contraception. (Adapted from FSRH Quick Starting Contraception, CEU September 2010)

Method	Method of EC	Requirements for additional contraception (condoms/avoidance of sex)
Combined oral contraceptive pills (except Qlaira)	Quick starting after POEC	7 days
	Quick starting after UPA EC	14 days
Qlaira combined oral contraceptive pill	Quick starting after POEC	9 days
	Quick starting after UPA EC	16 days
Combined vaginal ring/transdermal patch	Quick starting after POEC	7 days
	Quick starting after UPA EC	14 days
Progestogen-only pill (traditional/desogestrel)	Quick starting after POEC	2 days
	Quick starting after UPA EC	9 days
Progestogen-only implant	Quick starting after POEC	7 days
	Quick starting after UPA EC	14 days
Progestogen-only injectable	Quick starting after POEC	7 days
	Quick starting after UPA EC	14 days

A modified Pomeroy procedure rather than Filshie clip application may be preferable for postpartum sterilisation performed by mini-laparotomy or at the time of caesarian section (CS), as this leads to lower failure rates [B]. Mechanical occlusion of the tubes by either Filshie clips or rings should be the method of choice for laparoscopic tubal occlusion [A]. Diathermy should not be used as the primary method of tubal occlusion because it increases the risk of subsequent ectopic pregnancy and is less easy to reverse than mechanical occlusive methods [C].

Hysteroscopic sterilisation by tubal cannulation and placement of intrafallopian implants

Micro-inserts made from nickel–titanium and stainless steel are inserted hysteroscopically through the cornual ends of both tubes. This can be performed under local anaesthesia and/or intravenous sedation. These generate fibrosis around the devices and the tubes are occluded by 3 months after the procedure. Additional contraception needs to be used until a hysterosalpingogram is performed at 3 months to confirm full occlusion of the tubes. It is an irreversible procedure and the failure rates quoted are the same as for the other methods of tubal occlusion.

Risks

Efficacy

The failure rate for female sterilisation is 1 in 200. Women should be informed that with tubal occlusion pregnancy can occur several years after the procedure.

Safety

There is no evidence to suggest that there is an increased incidence of bleeding problems and consequently an increased hysterectomy rate after tubal occlusion.

Adverse events for placement of intrafallopian implants include uterine or tubal perforation, infection, device migration or expulsion, pelvic pain and vasovagal reaction.

Male sterilisation: vasectomy

Methods

The technique of vasectomy involves division of the vas with fascial interposition or diathermy. RCOG advises that a no-scalpel technique should be used to identify the vas as there is a lower rate of early complications [A]. The procedure can be carried out under a local anaesthetic and is safer than female sterilisation. Following the procedure, men should be advised to use effective contraception until two consecutive semen samples 4 weeks apart confirm azoospermia. (The first sample should be taken at least 8 weeks after surgery.)

Risks

Failure rate

The failure rate for vasectomy is 1 in 2000. Both early and late failures can occur. Therefore men should be informed that pregnancies can occur several years after vasectomy. Early failures can occur because the wrong structure has been occluded (leaving one or both vasa intact) or because the vas is partially occluded (if ligatures or clips are applied too loosely). There could be congenital duplication of one or both vasa. Although the vasa may have been occluded bilaterally, if there are any more vasa, spermatozoa can still be released. Recanalisation of the vas can occur at an early or late stage. Early recanalisation is recognised by post-vasectomy sperm counts which may at first be azoospermic or reduced but then rapidly increase again. Late recanalisation presents with a pregnancy several months or years after two consecutive azoospermic samples.

Chronic testicular pain

This is probably due to distension and granuloma formation in the epididymis and vas deferens following the operation [B]. Men should be informed of this and reassured that there is no sinister association.

Cancer

There is no increase in testicular or prostatic cancers following the vasectomy operation [B].

Heart disease

There is no increased incidence of heart disease associated with vasectomy.

INDUCED ABORTION

The 1967 Abortion Act came into effect on 27 April 1968. The Human Fertilisation and Embryology Authority (HFEA) made changes to the Abortion Act in 1990 which came into effect on 1 April 1991. Section 4 of the Abortion Act 1967 states that no person is under any obligation to participate in any treatment authorised by the act. This does not apply in an emergency, where the woman's life is in immediate danger or there is immediate risk of grave or permanent injury.

The Abortion Act 1967 states that:

- the abortion must be performed within an NHS hospital or approved clinic;
- the Chief Medical Officer must be informed of the abortion that has taken place;
- two registered medical practitioners must certify in good faith that the operation is being performed for grounds specified within the act.

The 1967 Abortion Act amended by the HFEA in 1990 has five categories. They are:

- A The continuance of the pregnancy would involve risk to the life of the pregnant woman.
- B The termination is necessary to prevent grave permanent injury to the physical or mental health of the pregnant woman.
- C The pregnancy has not exceeded its 24th week and the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, or injury to the physical or mental health of the pregnant woman.
- D The pregnancy has not exceeded its 24th week and the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, or injury to the physical or mental health of any existing child(ren) of the family of the pregnant woman.
- E There is substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be seriously handicapped.

Ninety-eight per cent of abortions are carried out under the terms of 'C' of the Abortion Act.

Abortion under clause 'E' of the abortion act is legal beyond 24 weeks. Common reasons are chromosomal abnormalities and congenital malformations. Down's syndrome is the most commonly reported chromosomal abnormality.

Pre-abortion management

Pre-abortion management should include non-directive counselling to address alternatives to abortion, i.e. continuing with the pregnancy, adoption or fostering.

The majority of women will come to a decision quickly but there will be others who will require additional support. Care pathways for additional support, including access to social services, should be available.

A full medical history is taken. An ultrasound scan is usually carried out prior to the procedure to confirm an intrauterine pregnancy and its gestation. Blood tests include haemoglobin measurement, a full blood count and ABO and rhesus grouping [C]. Other tests are carried out if indicated depending on clinical grounds. Chlamydia screening should be offered to all. Details of the abortion methods, the procedures and their risks should be discussed with the woman. In order to prevent repeat terminations, discussion of future contraception is vital at this stage. Antibiotic prophylaxis at the time of surgical abortion reduces infective complications, whereas there is limited evidence of decreasing infections in case of medical abortions.

The following regimens are suitable for periabortion prophylaxis [C]:

- Metronidazole 1 g rectally or 800 mg orally prior to or at the time of abortion
plus
- Doxycycline 100 mg orally twice daily for 7 days, commencing on the day of abortion
OR

- Metronidazole 1 g rectally or 800 mg orally prior to or at the time of abortion
plus
- Azithromycin 1 g orally on the day of abortion.

All chlamydia-positive women should have a full STI screening and contact tracing and treatment of partners.

Methods (Table 72.5, Fig 72.3)

Surgical procedures

Vacuum aspiration should be avoided at gestations below 7 weeks as the failure rate is higher. Conventional vacuum aspiration is an appropriate method at gestations of 7–15 weeks and can be carried out either under local or general anaesthesia [B]. For first-trimester suction termination, either electric or manual aspiration devices may be used, as both are effective and acceptable to women and clinicians. For gestations above 14 weeks, surgical abortion by D&E, preceded by cervical preparation, is safe and effective and should be undertaken by specialist practitioners who have a reasonable caseload to maintain their skills. Cervical preparation should be considered in all cases. The various regimens are:

- Up to 14 weeks: misoprostol 400 mg vaginally or sublingually 3 hours before surgery;
- 14–18 weeks: osmotic dilators.

Medical abortion

Medical abortion using mifepristone plus prostaglandin is the most effective method of abortion at gestations of less than 9 weeks [A].

The following regimen is safe and effective:

- Mifepristone* 200 mg orally followed 36–48 hours later by misoprostol 800 µg vaginally or sublingually. A second dose of 400 mg of misoprostol may have to be given for

* This regimen is unlicensed.

Table 72.5 Abortion methods at different gestational ages

Gestation	Method
Up to 9 weeks	Early medical termination
Up to 10 to 11 weeks	Manual vacuum aspiration (MVA)
6 to 16 weeks	Vacuum aspiration under local or general anaesthesia
Above 14 weeks	Dilatation and evacuation (D&E) (cervical preparation)
9+ to 24 weeks	Medical method

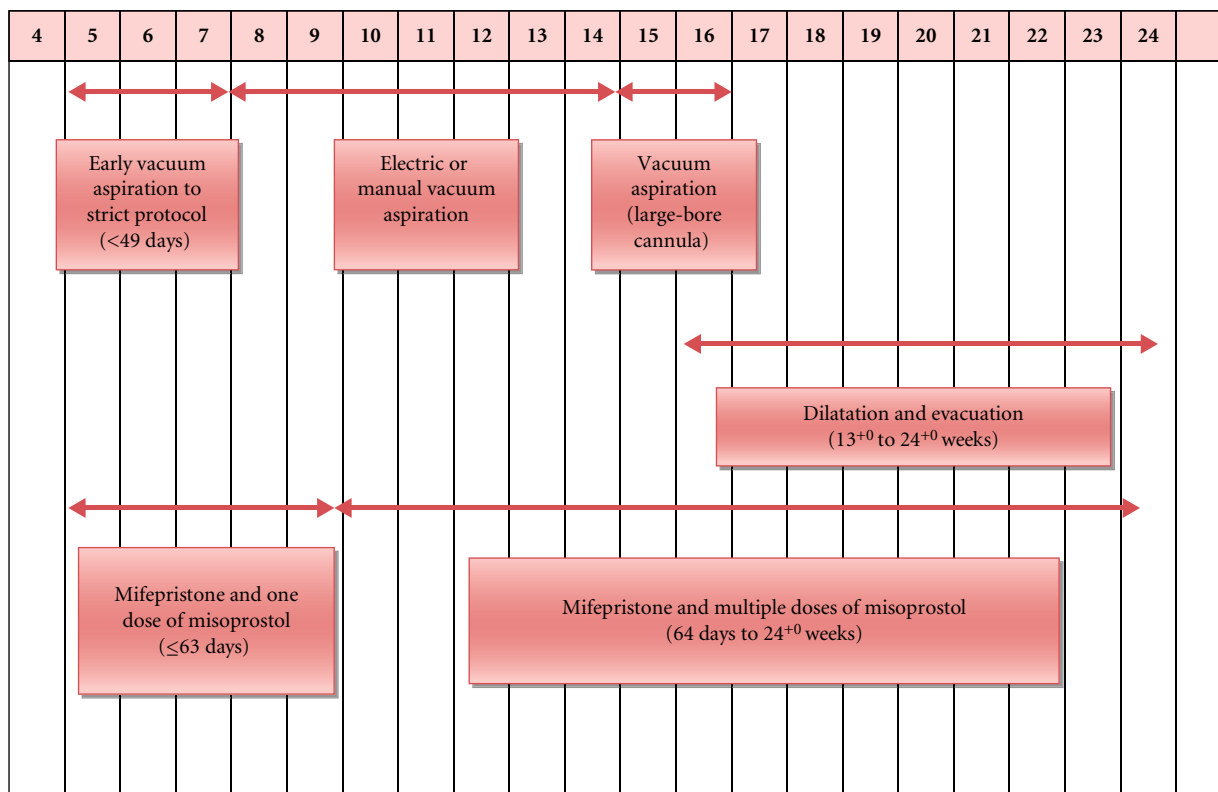

Fig. 72.3 Summary of abortion methods appropriate for use in abortion services in Great Britain by gestational age in weeks. (Reproduced from: FSRH Clinical Effectiveness Unit reports and reviews, 2008–2009, London: RCOG; with the permission of RCOG.)

gestations between 7 and 9 weeks if abortion has not occurred 4 hours after administration of misoprostol.

For gestations between 9 and 24 weeks the regimen is as follows:

- Mifepristone* 200 mg orally followed 36–48 hours later by misoprostol 800 µg vaginally. A maximum of 4 further doses of misoprostol 400 µg may be administered at 3-hourly intervals, vaginally or orally (depending on the amount of bleeding).

* This regimen is unlicensed.

Complications

Retained products of conception

This is the commonest complication following abortion, more so following a medical abortion. An ultrasound scan is helpful in diagnosing retained products but the decision to intervene and perform a surgical evacuation should be made on clinical grounds.

Haemorrhage

The risk of haemorrhage is 1 in 1000 abortions. The risk is lower for early abortions (occurring in less than 1 in 1000 and rising to 4 in 1000 at more than 20 weeks) [B].

Uterine perforation

The incidence is 1–4 in 1000. The risk is lower for abortions performed early in pregnancy and those performed by experienced clinicians [B].

Uterine rupture

This has been reported in association with mid-trimester medical abortion. However, the risk is under 1 in 1000 [B].

Cervical trauma

The risk of damage to the external cervical os at the time of surgical abortion is moderate (no greater than 1 in 100) [B]. The risk is lower when abortion is performed early in pregnancy and when it is performed by an experienced clinician. Cervical preparation prior to the procedure decreases the risk of cervical trauma.

Failed abortion and continuing pregnancy

All methods of first-trimester abortion carry a small risk of failure to terminate the pregnancy (less than 1 in 100) necessitating another procedure.

Post-abortion infection

Genital tract infection, including PID of varying degrees of severity, can occur. The risk is reduced when prophylactic

antibiotics are given or when lower genital tract infection has been excluded by bacteriological screening [B].

Future reproductive outcome

There is no evidence to suggest that induced abortion has any effect on subsequent ectopic pregnancy, placenta praevia or fertility. However, it may be associated with a small increase in the risk of subsequent miscarriage or preterm delivery [B].

Psychological sequelae

There is no evidence to suggest that these are increased following an induced abortion.

Aftercare

Rhesus prophylaxis

Anti-D immunoglobulin G (250 IU before 20 weeks of gestation and 500 IU thereafter) should be given to all non-sensitised Rhesus-negative women within 72 hours following abortion, whether by surgical or medical methods [B].

Contraception

This should have been discussed at the pre-abortion assessment. The chosen method of contraception can be initiated immediately following the abortion. Oral contraceptives can be commenced on the following day of the procedure. Injectables can be administered on the same day, whilst the subdermal implant and intrauterine contraception can be inserted immediately following a first- or second-trimester termination of pregnancy. Sterilisation can also be safely performed at the time of induced abortion. However, this is associated with higher rates of failure and regret on the part of the woman [B].

Follow-up

Women should be given written information about the symptoms they may experience following the abortion. They should be given a 24-hour telephone helpline number to contact in case of any problems. Routine follow-up following a successful abortion is not necessary.

Chapter 73 Endometrial function

Hilary OD Critchley and Christine P West

MRCOG standards

- Understand the physiology of normal menstruation.

INTRODUCTION

The main function of the endometrium is to receive a fertilised ovum (blastocyst) during implantation. As this occurs relatively infrequently, cyclical breakdown and regeneration of the endometrium during the menstrual cycle are pivotal reproductive events. These changes are under the control of the hypothalamic–pituitary–ovarian axis, with ovarian steroids acting directly within the endometrium via local intracellular receptors. Many other local mediators are involved in the complex and dynamic processes that take place within this metabolically highly active organ.

ENDOCRINE REGULATION OF ENDOMETRIAL FUNCTION

The uterine endometrium is a target organ for sex steroids and is exposed to an orchestrated sequence of circulating oestrogen, progesterone and progesterone withdrawal (result of regression of the corpus luteum in absence of pregnancy). Sequential exposure to oestrogen and progesterone, as a consequence of cyclical ovarian activity, results in repeated episodes of cellular proliferation and differentiation with regular menstrual bleeding.^{1,2} The proliferative phase of the endometrial cycle corresponds to the ovarian follicular phase. The secretory phase of endometrial differentiation is under progesterone domination and corresponds to the ovarian luteal phase. In the follicular phase, oestrogen secreted from the dominant follicle promotes regeneration and proliferation of the endometrium with up-regulation of both oestrogen (ERs) and progesterone receptors (PRs). The mid-secretory phase is a period of peak exposure to circulating progesterone and is often referred to as the ‘implantation window’.

Endometrial expression of sex steroid receptors permits the endometrium to respond to ovarian oestradiol and progesterone. Exposure of the endometrium to these sex steroids, acting via their cognate receptors (ERs and PRs) results in a cascade of gene expression that is essential for preparation of the endometrium in anticipation of successful implantation. In the absence of a pregnancy, the corpus luteum regresses, progesterone levels fall and progesterone withdrawal is the trigger for the cascade of events that culminate in shedding of the upper zone of the endometrium.

Menstruation is a fundamental reproductive process in women and displays all the hallmarks of an inflammatory event. Equal in importance to the shedding of the endometrium is its regeneration (repair), which commences 36 hours after the onset of bleeding and is normally completed by day 5–6 of the cycle. The processes involved in endometrial repair remain to be defined; however they are likely to share common features with wound-healing processes. Thus endometrial repair will involve overlapping phases of inflammation, its resolution, tissue formation, remodelling and angiogenesis.^{3,4} The capacity of the human endometrium to efficiently regenerate each month also supports the presence of adult progenitor cells within the local endometrial environment (for a detailed review of this aspect of endometrial biology see Gargett *et al.* 2012⁴).

MORPHOLOGICAL CHANGES

The three classic phases of the menstrual cycle are the oestrogen-dominated proliferative phase, the post-ovulatory and progesterone-dominated secretory phase, and the menstrual phase.⁵

The endometrium is composed of two layers. The upper functional layer is shed during menstruation. During the follicular phase of the cycle the endometrium proliferates from the basal layer in response to oestradiol. The developing glands are initially straight and tubular within a compact stroma but later become more convoluted. Following ovulation, exposure to rising levels of progesterone from the corpus luteum induces secretory changes in the endometrial glands. Sub-nuclear vacuoles appear initially, followed by evidence of glandular secretory activity. This is accompanied in the late

luteal phase by oedema and predecidual changes in the stroma and increased coiling of the spiral arterioles, which supply the endometrium.

Failure of conception results in regression of the corpus luteum and an abrupt decline in circulating levels of oestrogen and progesterone. In the endometrium there is loss of tissue fluid, stromal infiltration of leukocytes and intense vasoconstriction of the spiral arterioles. Distal ischaemia and vasodilatation lead to tissue breakdown and bleeding from the damaged vessels. Thirty-six hours after the onset of bleeding, the process of endometrial regeneration commences in the basal layer.⁶

CELLULAR AND MOLECULAR EVENTS

Progesterone is the endocrine signal that is responsible for the establishment and maintenance of pregnancy. Progesterone withdrawal is the primary initiating event for the cascade of molecular and cellular events that lead to menstruation. Following shedding of the upper functional layer, the endometrium displays remarkable and immediate regenerative capacity.³

The precise local mechanisms involved in the control of the highly coordinated cyclical tissue 'injury' and 'repair' that occur in the absence of a pregnancy have still to be fully elucidated. Modern molecular technologies have permitted an expansion of knowledge of gene profiles across the menstrual cycle, including during the 'putative window' of implantation and at the time of progesterone withdrawal.

Valuable insight about progesterone action and endometrial function has come from the observations of pharmacological withdrawal of progesterone from the endometrium. Studies with PR ligands have identified local mechanisms that may be targeted in order to modulate both endometrial receptivity and endometrial bleeding.⁷

The molecular and cellular mechanisms within the uterine endometrium regulating the key reproductive events – implantation and menstruation – involve complex interactions between the endocrine, vascular and immune systems.^{3,8} Oestrogen and progesterone, via cognate receptors, regulate the expression of a cascade of local factors within the endometrium that act in a paracrine, autocrine and intracrine manner.

The receptors for sex steroids are members of a large family of nuclear transcription factors that regulate the expression of numerous genes. Members of the nuclear receptor super-family expressed by endometrial cells include progesterone (PR), oestrogen (ER α and ER β), androgen (AR) and glucocorticoid receptors (GR). The role for these latter two receptors in regulation of endometrial function has thus far received limited attention.⁹ The endometrial expression of the PR, ER α and ER β varies temporally and spatially across the menstrual cycle. Both endometrial ER α and PRs are up-regulated during the proliferative phase by ovarian oestradiol and subsequently down-regulated in the secretory phase by progesterone. The administration of a PR antagonist,

mifepristone (RU486) in the early secretory phase will block the progesterone-induced down-regulation of PR (and ER α) in non-pregnant human endometrium.

The localisation of the PRs in the human endometrium is well documented, with maximal expression in glandular and stromal cells during the mid-late proliferative phase and decreased expression in epithelial cells (maintenance of stromal expression) in the secretory phase.¹⁰ There are two main isoforms, PRA and PRB. Both are nuclear receptors that shuttle between the cytoplasm and nucleus. PRA and PRB are reduced in the glandular epithelium during the secretory phase; however PRA is maintained in the stroma.^{11–13} PRs are not present in endometrial endothelial cells or immune cells, indicating that actions of progesterone on these cell types are indirect or paracrine in nature. It is this differential expression of PRs that may explain the early reversibility of induction of menstruation. Early P-withdrawal events occur in PR-positive cells enabling cessation of the inflammatory response with the replacement of progesterone. Subsequent events probably involve PR-negative cells, e.g. immune cells, thereby rendering the cascade of events leading to endometrial breakdown (menses) inevitable.

Oestrogen action is mediated by the two subtypes of oestrogen receptor referred to as ER α and ER β . These two structurally related subtypes of ER are derived from separate genes. In the upper functional layer, ER α expression increases in both glandular and stromal cells in the proliferative phase and declines in the secretory phase due to suppression by progesterone. In the basal layer, ER α is expressed in glandular and stromal cells throughout the menstrual cycle. In the endometrium, the only sex steroid receptor present in the endothelium and smooth muscle walls of endometrial vessels is ER β . Thus any direct effects of oestrogen on endometrial vessels, including angiogenesis and permeability, will be mediated by ER β , and the actions of progestins will be mediated indirectly by perivascular stromal cells. The function of ER β in the uterus is still to be determined. The physiological role of endometrial AR has also not been established. During the normal cycle stromal cells are the predominant cell type expressing the ARs and thus androgen effects in the endometrium are likely to be mediated by the stroma. A more detailed discussion of the mechanisms of steroid receptor function in the endometrium is outwith the scope of this brief review.

The availability of molecular technologies, including microarray studies and detailed bioinformatics analysis, has contributed to the expanding literature on gene profiles during the progesterone-dominant 'receptive phase' of human endometrium.¹⁴ This knowledge is important for understanding the requirements for a receptive endometrium and successful implantation and how disturbances of endometrial structure and function may play a role in subfertility. Equally important is the insight such knowledge has provided for fertility control (contraception). Valuable insight about progesterone action, progesterone withdrawal and endometrial function has come from the observations of pharmacological withdrawal of progesterone from the endometrium. Studies with ligands for the PR have advanced

our understanding of local mechanisms that may be targeted to modulate both endometrial receptivity and endometrial bleeding.

Disturbances of the tightly controlled sequence of injury and repair events within the endometrium contribute to menstrual disorders, such as heavy menstrual bleeding (HMB). A new classification of causes of abnormal uterine bleeding (see Chapter 75) should facilitate future research into endometrial disorders which contribute to such problems.^{15,16} Early studies of menstruation identified a role for prostaglandins (PGs). Progesterone withdrawal results in increases in endometrial PG synthesis and decreases in PG metabolism. More recent research has shed light upon the complex molecular and cellular events within the endometrium following withdrawal of progesterone.^{1,3,8} Local mediators within the endometrium that have been implicated in the regulation of the menstrual process include: cyclooxygenase-2 (COX-2), the inducible enzyme responsible for synthesis of PGs; chemokines (e.g. CXCL8, neutrophil chemotactic factor, interleukin-8 (IL-8); and CCL-2, monocyte chemotactic peptide-1, MCP-1); and a role for hypoxia.³ PG synthesis via COX-2 is relevant since non-steroidal anti-inflammatory drugs (NSAIDs) are widely used in the treatment of menstrual complaints including heavy and painful periods. Changes in the structure and viability of the endometrium are due to the release of mediators that degrade the extracellular matrix including matrix metalloproteinases (MMPs).¹⁷ A phenomenon of blood vessel function at menstruation is modest platelet aggregation and fibrin deposition compared to that following vessel damage elsewhere in the body. It is notable that menstrual bleeding extends over 3–5 days and is not accompanied by scarring. The uterus is a rich source of PGs and uterine fluid contains high fibrinolytic activity and fibrin degradation products, suggesting active fibrinolysis occurs. Indeed agents targeting the fibrinolytic system are a first-line management for complaints of HMB. Given limitations with current treatments, novel therapeutic interventions are being explored, including the role(s) for selective progesterone modulators (SPRMs) in the pre-surgical and medical management of uterine fibroids.¹⁸

Following menstruation the endometrium rapidly repairs with regeneration of all cell types (epithelial, vascular and stromal). The exposed surface is rapidly covered with fibronectin, leukocytes are removed and the epithelium regenerates. Full repair is usually complete by day 6 of the menstrual cycle. A host of local mediators are involved in endometrial repair, including IL-8 endothelins and vascular endothelial growth factor (VEGF). These factors also play a key role in

the angiogenic processes necessary for reconstitution of the endometrial vasculature.³

ACKNOWLEDGEMENT

We thank Sheila Milne for assistance with manuscript preparation.

Chapter 74 Uterine fibroids

Christine P West

MRCOG standards

Theoretical skills

- Understand the epidemiology, pathophysiology and clinical features of uterine fibroids.
- Understand the principles of investigation by imaging and hysteroscopy.
- Understand the nature, complications and adverse effects of medical, surgical and radiological management of fibroids.

Practical skills

- Be familiar with hysteroscopic assessment of submucosal fibroids.
- Understand the surgical techniques of hysterectomy and myomectomy and be able to recognise and manage their complications.

INTRODUCTION

Uterine fibroids, also known as myomas or leiomyomas, are benign tumours arising from the myometrium. They are composed of round whorls of smooth muscle and connective tissue and may be single or multiple. Their site may be intramural, submucosal or subserosal and their presentation and symptoms vary according to their size and situation within the uterus. While they may present with heavy menstrual bleeding (HMB) or pressure symptoms, they are commonly asymptomatic, found incidentally by ultrasound examination.

Uterine fibroids are a frequent indication for gynaecological intervention, most commonly hysterectomy. In the past many hysterectomies were carried out for asymptomatic fibroids because of concerns about the nature and consequences of a pelvic mass. Advances in imaging have facilitated the diagnosis of fibroids and enabled more women to be managed conservatively. Fibroids may be implicated in the causation of miscarriage and subfertility, but this chapter primarily addresses the evidence base for the management of abnormal uterine bleeding associated with the fibroids.

PREVALENCE

The prevalence of uterine fibroids in women of reproductive age has been estimated at around 25 per cent, based on clinical presentation. With the widespread use of imaging techniques it is now apparent that the actual prevalence may be much higher¹ with the majority of women reporting no symptoms. One community study of 1364 women in the USA² reported cumulative incidences of up to 70 per cent by the age of 50 in white women and over 80 per cent in black women, although the corresponding number considered clinically relevant was 35 and 50 per cent respectively. However, another large multistate study of 5023 women screened in early pregnancy reported a prevalence of only 11 per cent.³

Increased prevalence of fibroids is reported in women presenting with HMB. In studies in which heavy blood loss has been objectively confirmed by direct measurement,⁴ 40 per cent of women with losses above 200 mL were found to have fibroids, compared with only 10 per cent whose losses were below 100 mL. Although a causal relationship with HMB has not been firmly established, it is likely that fibroids contribute to heavy bleeding if present submucosally or where intramural fibroids cause distortion of the endometrial cavity. There is little evidence that subserosal or pedunculated fibroids contribute to heavy blood loss.⁴ Similarly the only direct association between uterine fibroids and nulliparity or infertility was found in women with submucosal fibroids.⁵

EPIDEMIOLOGY

It is evident that the incidence of fibroids increases with age and that fibroids subsequently regress in size and undergo degeneration after the menopause.¹ Rates among black women are two to three times greater than among white women and fibroids occur at a younger age.⁵ Other risk factors include a younger age at menarche, reduced parity and a family history of fibroids.⁵ Child-bearing has a protective effect which increases with the number of live births but decreases as the length of time from the last birth increases.⁵ Smoking and the long-term use of the oral contraceptive pill and

Depo-Provera are associated with a reduced risk⁶ and users of the levonorgestrel-releasing intrauterine system (LNG-IUS) for contraception have a lower rate of development of fibroids compared with users of copper-containing devices.⁶ Other possible risk factors, less consistently reported, include increased BMI, reduced physical exercise and high consumption of red meat, with a protective effect from exercise and consumption of green vegetables.⁵

The majority of fibroids do not increase in size during pregnancy¹ although degenerative changes may occur secondary to altered vascularity, with around 5 per cent of women developing clinical and ultrasound features of red degeneration.

PATHOPHYSIOLOGY

The development of fibroids involves the transformation of normal smooth muscle cells (myocytes) into abnormal myocytes followed by stimulation of growth into clinically apparent tumours. Fibroids contain increased levels of receptors for both oestrogen and progesterone compared with normal myometrium.⁷ Within the uterus angiogenesis or new blood vessel formation occurs in response to cyclical fluctuations in steroid hormones. Fibroids are relatively avascular but there is abnormal proliferation of surrounding blood vessels, leading to a hypothesis that abnormal angiogenesis plays a key role in the development of fibroids. Within fibroids there is altered expression of various angiogenic growth factors, including epidermal growth factor (EGF), vascular endothelial growth factor (VEGF) and transforming growth factor beta. Abnormal responses of these various growth factors to physiological fluctuations of ovarian steroid hormones appear to play a key role in the development of fibroids.⁷ It is likely that genetic factors are also involved¹ but currently it remains unclear how fibroids begin to grow and there is no explanation for their heterogeneity in terms of numbers, size, site and behaviour within and between individuals.

Transformation of a benign fibroid to highly malignant leiomyosarcoma was thought to occur in a small minority of cases but genetic studies¹ now indicate that sarcomas have a distinct origin.

MANAGEMENT

This chapter will review the evidence underlying the treatment of women with fibroids who present with symptoms, in particular HMB. In common with all gynaecological disorders, the age and reproductive intentions of the individual woman and her preferences in relation to the various treatments will play a key role in management. Options for women desiring future fertility or those actively seeking a pregnancy will differ from those who have completed child-bearing. Psychosocial and cultural factors also influence decision making.

Investigation

Suspicion of fibroids is usually based on a history of HMB together with the presence of a pelvic mass or a palpably enlarged uterus on pelvic or abdominal examination. Pressure symptoms may be present. History, followed by abdominal and pelvic examination, should be supplemented by a full blood count if heavy bleeding is a presenting feature.⁸ If the uterine enlargement is no greater than a 10–12 week gestation size, medical management can be initiated within primary care without further investigation, after exclusion of pregnancy.⁸ Failure to respond to medical therapy or a uterus that is palpable abdominally is an indication for further assessment [E].⁸

Investigation of abnormal bleeding is covered elsewhere (Chapter 75) but these recommendations also apply to investigation of women with suspected fibroids. Transvaginal ultrasound should be the preliminary investigation [A],^{1,6,8} combined with abdominal ultrasound where the uterine enlargement is in excess of 12-week size. It is important to visualise the ovaries and endometrium and, where possible, to document the size, number and position of individual fibroids as well as the overall uterine dimensions [E]. MRI has no advantage over ultrasound for the detection and routine imaging of fibroids^{1,8} and is considerably more costly. However it has greater precision and is associated with less inter-observer variation than other techniques, particularly with larger uteri [B]. Where submucosal fibroids are suspected (Table 74.1), MRI, hysteroscopy or transvaginal saline infusion sonography improves diagnostic accuracy [A].^{1,8}

The presence of a large pelvic mass will give rise to concerns regarding its nature. A recent large literature review⁹ concluded that uterine leiomyosarcoma (LMS) is very rare with an overall incidence of 0.64/100,000 per year. Its estimated prevalence in a presumed fibroid is 0.14% [C]. Risk is positively correlated with age and is extremely low below the age of 40 [C]. Rapid fibroid enlargement is a feature of LMS but in the absence of factors such as pain or abnormal bleeding it is poorly predictive.^{1,9} Fibroid growth during ovarian suppressive treatment with a GnRH agonist or after menopause should raise suspicion about its nature. There are no features which can predict an LMS on any imaging technique with certainty [C]. Characteristics which should lead to a suspicion of sarcoma include solitary lesion, oval shape, size >8cm, high vascularity with central necrosis and absence of calcification⁹ [D]. Gadolinium-enhanced MRI scanning can be a helpful assessment tool^{1,9} [C]. Elevation of serum LDH and LDH isoenzyme 3 has been reported in leiomyosarcoma although its role in diagnosis is currently unclear.

Table 74.1 Classification of submucosal fibroids

Type	Description
0	Pedunculated
1	Less than 50% intramural
2	Greater than 50% intramural

Endometrial biopsy should be carried out if there is prolonged irregular bleeding in women over 45 or those with other risk factors for endometrial cancer or uterine sarcoma [D].⁸

Conservative management

Asymptomatic fibroids do not require active management and there is no consensus regarding the need for on-going surveillance. First-line management of HMB in women with uterine fibroids should follow national guidelines.⁸ Iron deficiency anaemia should be treated with oral iron. Some women will wish to avoid further treatment, either medical or surgical, and this preference should be respected [E]. The evidence supporting the use of medical therapies for HMB in women with fibroids is reviewed below.

Medical management

Non-hormonal therapy

Non-steroidal anti-inflammatory drugs (NSAIDs) are not effective in the reduction of heavy bleeding secondary to the presence of fibroids⁶ but may be beneficial for management of pain associated with degeneration¹⁰ as well as menstrual pain (see Chapter 76) [C]. There have been no randomised controlled trials (RCTs) evaluating antifibrinolytics in the management of HMB associated with fibroids, but results of a non-random comparative study¹¹ reported a blood loss reduction of around 50 per cent in women with clinically diagnosed fibroids. On the basis of this information, tranexamic acid should be used in preference to NSAIDs in the first-line management of fibroid-associated HMB [C].

Combined oral contraceptives

There is no evidence that the oral contraceptive pill causes enlargement of fibroids;⁶ indeed, long-term use may be protective [C].^{5,12} Good-quality data on the use of the combined oral contraceptive pill (COCP) in the treatment of fibroid-associated HMB is lacking. An early comparative study demonstrated a 50 per cent reduction in measured blood loss with a high-dose COCP in women with clinically diagnosed fibroids.¹¹ A small RCT comparing a COCP (30 µg ethinyl-estradiol plus 150 µg levonorgestrel) with the LNG-IUS¹³ reported a reduction in measured blood loss of only 13 per cent after 12 months of treatment with the COCP, although there was a reduction of 53.5 per cent using pictorial assessment charts [B]. Mean haemoglobin at 12 months was 10.2 g/dL in the group treated with the COCP. There are no data on continuous COCP use in women with fibroid-related HMB or on use of tranexamic acid in conjunction with a COCP although these options may be used in clinical practice [E]. While the use of the combined pill is not contraindicated in women with fibroids who desire contraception [B], available data suggest that it has limited effectiveness in the control of HMB, particularly when this is associated with anaemia [B].

Levonorgestrel-releasing intrauterine system

The role of the LNG-IUS has not been fully evaluated in women with fibroids. The presence of fibroids greater than 3 cm and significant cavity distortion are regarded as contraindications to inclusion in large-scale clinical trials of its use for HMB,⁸ thus limiting availability of high-quality information. In the only prospective RCT to date, in which the LNG-IUS was compared with a low-dose COCP in women with fibroids and HMB,¹³ blood loss measured by the alkaline haematin method reduced by 91 per cent after 12 months with the LNG-IUS [B]. Recruitment was restricted to fibroids less than 5 cm in diameter and with no cavity distortion. Treatment failure was reported in 6 out of 29 participants (23 per cent) in this group.

A systematic review of 10 small prospective studies of the LNG-IUS in 269 women with HMB and fibroids reported consistent reduction of menstrual loss and improvement in haematological parameters [C].¹⁴ Where stated, uterine size greater than 12 weeks' gestation or significant cavity distortion were exclusion criteria. Rates of amenorrhoea varied between 5 and 50 per cent at 12 months. A prospective cohort study comparing LNG-IUS use in women with and without fibroid-related HMB¹⁵ reported a 27 per cent prevalence of breakthrough bleeding in the fibroid group after 3 years of use compared with 9 per cent in the women without fibroids. The incidence of expulsion may be increased in the presence of fibroids. Using data from the studies cited above,^{14,15} the rate of expulsion of the LNG-IUS was 8 per cent among 248 women with fibroids, compared with only 1 per cent of 86 without fibroids.^{14,15} Another study reported a greater rate of expulsion with fibroids greater than 3 cm¹³ but numbers were small. There is no evidence that use of the LNG-IUS has any significant effect on the growth of fibroids.¹⁴

On the basis of this information, the use of the LNG-IUS can be beneficial in women with HMB associated with fibroids, including those with anaemia [B] but data is limited to those with uteri below 12 weeks' gestation size and without significant cavity distortion [C]. Even within these limitations, women should be warned of the increased risk of prolonged breakthrough bleeding and of expulsion [C].

Progestogens and androgens

Progestogens, even in high doses, do not shrink fibroids;⁶ thus use of oral progestogens in women with fibroids should be purely symptomatic and in a regimen that is effective for HMB (Chapter 75) i.e. for 21 days out of 28.⁸ The long-term use of depot medroxyprogesterone acetate (DMPA) may protect against the development of fibroids [C]¹⁶ but there is no evidence to support its use for fibroid-related symptoms.

Both the androgen danazol⁶ and the androgenic anti-progesterone gestrinone⁶ (see Chapter 77) reduce fibroid size and blood loss during treatment [B] and may be helpful in the short-term control of fibroid-associated bleeding but their role in relation to other therapies is unclear. Androgenic side effects are fewer with gestrinone compared with danazol.

Antiprogesterones and selective progesterone receptor modulators (SPRMs)

A systematic review of three RCTs of the antiprogesterone mifepristone¹⁷ has highlighted the potential role of antiprogesterones for the treatment of fibroids. At a dose of either 5 mg or 10 mg daily for 3 to 6 months, mifepristone significantly reduced menstrual blood loss, assessed pictorially, compared with placebo. However there was no significant effect on fibroid or uterine volume. In a controlled trial of the SPRM ulipristal acetate, women with fibroid-related excessive menstruation were randomised between 5 mg or 10 mg of the active drug and placebo for a treatment period of 13 weeks.¹⁸ Over 70 per cent of the women in both active treatment groups developed amenorrhoea with a corresponding improvement in haemoglobin and haematocrit. Fibroid volume was reduced by 25 per cent in the women treated with 10 mg and by 12 per cent with 5 mg of ulipristal acetate. A further study by the same group compared both doses of ulipristal acetate with the gonadotrophin-releasing hormone (GnRH) analogue leuprolide acetate 3.75 mg/month, given for 13 weeks.¹⁹ Reduction of menstrual blood loss and rates of amenorrhoea were similar in all three groups but median onset of amenorrhoea was 7 days in the women treated with ulipristal acetate, compared with 21 days for leuprolide acetate. Moderate to severe vasomotor side effects were reported by 10 and 40 per cent of the women respectively, with serum oestradiol remaining in the mid-follicular range in the women treated with ulipristal acetate, compared with postmenopausal levels with the GnRH analogue. However overall uterine volume reduction was significantly greater with the GnRH analogue (47 per cent compared with 20–22 per cent).

Both these studies were carried out in women due to undergo surgery for their fibroids. However approximately half the women in both studies opted not to undergo surgery at the end of the 13-week treatment period. Follow-up of these women showed a slower regrowth of the fibroids after ulipristal acetate, indicating its potential role in the medical management of fibroids.

There have been concerns about antiprogestogenic effects on the endometrium. Endometrial biopsies from the women in the above trials of ulipristal acetate have shown non-physiological changes, including extensive cystic glandular dilatation but with inactive epithelium and no evidence of hyperplasia.²⁰ These changes are collectively referred to as progesterone receptor modulator-associated endometrial changes and had regressed in the majority of the samples taken 6 months after treatment.

Current evidence is that ulipristal acetate is effective for rapid control of HMB secondary to fibroids [B]. It is licenced in the UK for short-term use at a daily dose of 5 mg for 3 months prior to hysterectomy. This would have particular application for women presenting with severe anaemia. Treatment should be started in the first week of the menstrual cycle. The licence has recently been extended so that 3 month courses of treatment can be repeated intermittently after treatment free intervals of at least one full menstrual cycle. Currently there is limited data on its effect on surgical outcomes or on longer

term use beyond four courses of treatment for medical management of fibroid associated symptoms.

GnRH analogues

Treatment with GnRH agonists induces amenorrhoea and shrinkage of fibroids [A].^{6,10} However, after cessation, regrowth is rapid. These changes are secondary to temporary ovarian suppression, and long-term treatment with GnRH agonists carries a risk of bone loss. Currently the role of these agents is largely limited to preoperative shrinkage of fibroids, although there is scope for their longer-term use with the addition of hormonal add-back.

Shrinkage of fibroids with a GnRH agonist prior to hysteroscopic or conventional surgery has been advocated on the basis of reduced fibroid size and vascularity. Their use prior to hysterectomy or myomectomy has been the subject of a systematic review²¹ that was based on 26 RCTs. When used together with iron therapy for 3 to 4 months prior to surgery, they are effective in the treatment of preoperative anaemia [A]. They significantly reduce intra-operative blood loss, particularly in women with very large uteri, and significantly increase the likelihood of a transverse rather than a midline abdominal incision or a vaginal rather than an abdominal hysterectomy [A]. However, their cost effectiveness for routine use for women who do not fall into these specific categories has been challenged.²²

There have been no randomised trials of GnRH agonists prior to hysteroscopic myomectomy, although they are widely used in this situation. One non-randomised controlled study²³ reported a significant reduction in operating time, blood loss, volume of distending medium and treatment failure following pre-treatment with a GnRH agonist [C].

In women who have contraindications to surgery or decline surgery and in whom other medical measures have failed, long-term relief of HMB may be achieved with GnRH agonists in combination with low-dose hormone replacement therapy (HRT).^{6,10} It has been suggested that the GnRH agonist should be administered alone for 3 months to obtain fibroid shrinkage⁶ before addition of the HRT [E]. Add-back therapy with tibolone maintains fibroid shrinkage and symptom relief while reducing vasomotor symptoms and preventing bone loss [B].²⁴ Low-dose oral oestrogen–progestogen combinations also relieve hypo-oestrogenic side effects and protect bone^{6,10} and are less costly than tibolone. Currently there is a lack of evidence relating to the optimum choice of add-back therapy.

HRT in menopausal women with fibroids

Conservative management is often offered to women with symptomatic fibroids who are perimenopausal on the basis that their symptoms will resolve spontaneously when they reach the menopause. It is therefore relevant to consider the effect of HRT on fibroids. Limited information from RCTs suggest that oral combined HRT or tibolone does not promote the growth of fibroids [B]¹⁰ although enlargement of fibroids has been reported with transdermal use [C].⁶ However HRT may

increase the risk of heavy bleeding in women with submucosal fibroids.¹⁰ On the basis of this information, oral continuous combined HRT preparations or tibolone can be used for the relief of vasomotor symptoms in postmenopausal women with fibroids [B] although they may increase bleeding problems related to fibroids or delay their resolution.

SURGICAL TREATMENT

Hysteroscopic surgery

Small submucous fibroids are implicated in heavy and abnormal menstrual bleeding and can be removed hysteroscopically. However, assessment of the effectiveness of hysteroscopic resection has been based on case series from single centres.^{6,8} The procedure is normally restricted to Type 0 and Type 1 fibroids (Table 74.1) that are less than 3–5 cm in diameter, although removal of Type 2 fibroids has also been described using a staged approach and pre-treatment with a GnRH analogue [D].^{6,10} The complications of hysteroscopic surgery include fluid overload, uterine perforation, haemorrhage and infection (see Chapter 75). Case review and cohort studies^{6,8,25} have reported relief of menstrual symptoms in 69–85 per cent of women after up to 15 years of follow-up [C]. Effectiveness can be increased by concurrent endometrial resection in women not desiring future pregnancies.^{8,25} For women with asymptomatic submucous fibroids who are trying to conceive naturally or with the aid of IVF, removal by resection is recommended¹⁰ on the basis that it improves the chance of conception²⁶ [C] but the quality of the evidence is poor²⁷ and there are no data to support an improvement in pregnancy outcome. For relief of HMB associated with small submucous fibroids, hysteroscopic removal is likely to be cost effective [C].²⁸

Abdominal myomectomy

Myomectomy is a well-established alternative to hysterectomy for symptomatic women wishing to preserve their fertility.^{6,10,26,28} Reduction of menstrual bleeding in more than 80 per cent of women has been reported in retrospective case series⁶ [D] but there is no relevant data from randomised trials. Recurrence of fibroids is common, with a 5-year cumulative recurrence rate of 62 per cent in one case series.²⁸ Haemorrhage is a potential problem at myomectomy and several interventions to reduce operative blood loss have been tested in small randomised trials.²⁹ Significant reduction was seen with vasopressin, misoprostol, tranexamic acid, gelatine–thrombin matrix, chemical dissection with mesna and pericervical tourniquet although there is no clear consensus as to which is most effective.²⁹ Uterine artery embolisation (UAE) can be used prior to myomectomy in selected cases¹⁰ but experience of this is limited. GnRH agonists have been shown to reduce operative blood loss when used for the pre-treatment of large uteri [A].²¹ Women consenting to myomectomy need to be specifically counselled regarding the potential risk of emergency hysterectomy (less than 1 per cent) in the event of severe operative haemorrhage [E].

Subserosal and intramural fibroids may be removed successfully by laparoscopy in specialist centres but the laparoscopic approach is usually restricted to cases with no more than three fibroids and diameters smaller than 8 cm [C].¹⁰ Larger fibroids require morcellation or removal by opening the upper vagina in order to maintain the benefits of a laparoscopic approach. Larger fibroids require morcellation or removal by opening the upper vagina to maintain the benefit of a laparoscopic approach. Women must be thoroughly counselled about the risks of morcellation⁹ (see section below on hysterectomy) and laparoscopic techniques avoided if there are any clinical or imaging features which raise suspicion of a possible uterine sarcoma.

A meta-analysis of six randomised trials comparing laparoscopy with laparotomy for abdominal myomectomy³⁰ concluded that laparoscopy takes longer but is associated with reduced blood loss, faster recovery and fewer overall complications [A]. Data on menstrual bleeding outcome were not included. However there was no difference in other outcomes, including pregnancy rate or fibroid recurrence. In contrast to earlier studies, the incidence of scar rupture in pregnancy was not increased with the laparoscopic approach, presumably as a consequence of improved suturing techniques. Procedural costs are not significantly different.²⁸ There is no evidence that removal of subserosal or intramural fibroids enhances fertility^{26,27} or improves pregnancy outcome and there remains a lack of evidence relating to the effectiveness of removing fibroids which are not causing endometrial cavity distortion for reduction of HMB.

Uterine artery embolisation

This technique was initially performed for the control of postpartum haemorrhage (PPH) but is now widely used for the treatment of symptomatic fibroids and is approved in the UK by NICE,⁸ by RCOG and by the Royal College of Radiologists (RCR).³¹ It is performed under radiological screening after selective catheterisation of the uterine arteries via one or both femoral arteries. Particles, most commonly polyvinyl alcohol, are injected to embolise the uterine vascular bed.^{31,32} It is carried out under local anaesthesia but usually requires overnight hospitalisation for opiate analgesia because of severe but short-lived post-procedural ischaemic uterine pain. Fibroid shrinkage is gradual and progressive, reaching a mean of around 60 per cent at 6 months¹⁰ with further reduction thereafter. Improvement in pain and pressure symptoms is reported by 80–90 per cent of women^{28,31} in prospective cohort studies [C]. Median measured menstrual blood loss reduction following UAE has been reported as 50 per cent after 6–9 months and 80 per cent after 36–48 months [C].³³

Early side effects of treatment include puncture site bruising, pain and mild febrile reactions (post-embolisation syndrome).³¹ The latter is treated with rest and NSAIDs and usually resolves within 10–14 days. Later complications (Table 74.2) include vaginal discharge, delayed passage of infarcted submucosal fibroids and ovarian failure, the latter mainly in women over 45. The most important major

Table 74.2 Complications of uterine artery embolisation^{31,34}

Complication	Incidence
Procedure related:	
Groin haematoma	<1%
Arterial complications	<1%
Non-target embolisation	<1%
Early (within 30 days):	
Post-embolisation syndrome	16-18%
Late (usually after 30 days):	
Septicaemia requiring emergency hysterectomy	<1%
Spontaneous fibroid expulsion	7-10%
Fibroid impaction requiring surgical intervention	3-5%
Prolonged vaginal discharge	12-16%
Endometritis	0.5%
Ovarian failure - all ages	1.5-7%
Ovarian failure under age 45	<1%

complication is severe sepsis, which may necessitate emergency hysterectomy.

A systematic review of four RCTs³² comparing UAE with hysterectomy concluded that UAE is associated with a shorter procedure and duration of hospital stay, reduced risk of blood transfusion and faster return to normal activities compared with surgery [A]. Satisfaction and quality-of-life scores were similarly high in both groups at 2 and 5 years of follow-up although further intervention rates were higher following UAE (see below). The rate of major complications was lower after UAE although the difference was not significant, but minor complications were more frequent and more likely to occur following discharge from hospital (see Table 74.2). The incidence of ovarian failure, measured by serum follicle stimulating hormone (FSH), showed no difference after 5 years of follow-up when compared with hysterectomy and ovarian conservation. Only one RCT compared UAE with myomectomy and again satisfaction rates were high and not significantly different after 2 years of follow-up.³²

UAE is contraindicated in women with asymptomatic fibroids [E], those with current or recent pelvic infection [A] and in cases where there is serious doubt about the nature of a pelvic mass. In the latter situation, MRI is superior to ultrasound in confirming the diagnosis of fibroids⁹ and therefore is recommended for routine use prior to UAE.³¹ Bleeding irregularities should be investigated prior to UAE [E]. Although the size or number of fibroids is not known to influence outcome, fibroids in certain sites require special consideration.³¹ Pedunculated subserous fibroids may infarct and become detached into the peritoneal cavity, and large submucosal fibroids may detach and cause cervical obstruction following embolisation, requiring surgical intervention. Women consenting to UAE should be warned of the remote risk of emergency hysterectomy (less than 1 per cent) in the event of severe post-procedural sepsis [E].

Long-term outcome of UAE

Up to one third of women in the randomised trials had required a further procedure for fibroids 5 years following UAE,³² compared with only 4–10 per cent after surgery. These included hysterectomy, repeat embolisation and hysteroscopic or other vaginal procedures. Reinterventions were lower, at 23 per cent after 7 years in a large cohort study,³⁴ possibly reflecting the influence of patient self-selection. The need for further treatment is age related with only 10 per cent of those over 40 at the time of treatment requiring a further procedure.³¹

In women who have not completed child-bearing, the choice between myomectomy and UAE will be influenced by prospects for future pregnancy. A systemic review of observational studies reported an ongoing pregnancy rate of 63.7 per cent after UAE compared with 77.9 per cent after myomectomy with live-birth rates of 57.8 per cent and 77.4 per cent respectively [C].³⁵ Further information from randomised trials is awaited.

Information on new fibroid growth after UAE is lacking. One study reported a prevalence of new fibroid growth in only 7 per cent of women 5 years after UAE compared with 60 per cent after myomectomy.³⁶ Although numbers in the myomectomy group were very small, this figure is consistent with data from a large case series.²⁸ Further information from longer-term follow-up will be important in counselling women.

Results to date strongly support the use of UAE for symptomatic fibroids [A]. Although the initial costs of UAE are significantly less than those of hysterectomy, this advantage appears to lessen with time so that by 5 years overall costs are similar. A cost–utility analysis comparing UAE, hysterectomy and myomectomy³⁷ showed that quality-adjusted life years (QALYs) gained over 5 years were high after all three interventions but marginally higher after hysterectomy at a lower total cost because of the avoidance of reinterventions. Myomectomy was more costly than UAE but overall differences were marginal. Further information on predictors of long-term outcome of UAE would enable clinicians to target treatment more effectively. There is also a clear need for more randomised studies and longer-term follow-up of UAE in women actively seeking future pregnancy.

MRI-guided focused ultrasound (MRg-FUS)

This technique uses a high-frequency, high-energy ultrasound beam to destroy fibroid tissue by coagulative necrosis, in conjunction with an MRI thermal mapping system to visualise the anatomy and monitor the temperature of the tissue.^{28,38} It is performed as an outpatient procedure under light sedation. The technique remains under development and data is mainly limited to results of small-scale prospective or retrospective cohort studies of women not seeking future fertility.^{10,28,38} These studies report significant improvement in fibroid-related symptoms in 50–80 per cent of women and reduction in fibroid volume of 10–25 per cent after 6–12 months [C]. Treatment failed in up to 30 per cent of women by 12 months.

However recovery is rapid and morbidity is low. There is potential for tissue injury such as burns to skin and nerves.

The treatment has limitations as it is time consuming, taking 2–4 hours to treat a single fibroid and due to safety concerns only a small proportion of the fibroid volume may be treated.^{10,38} The latter restriction may be relaxed with greater experience of the technique. Most studies have excluded uteri with greater than four fibroids and diameters greater than 10 cm although prior shrinkage with GnRH analogues has been described.³⁸ The procedure is not suitable for fibroids close to the bowel, bladder or sacrum or for non-enhancing or pedunculated fibroids and the presence of surgical scars may be a contraindication. Due to these factors, up to 40 per cent of women may be technically ineligible for the treatment. This is in contrast to UAE where over 90 per cent are technically eligible.³⁹

MRg-FUS has been approved by the FDA in the USA for treatment of women not desiring future fertility [C]. Limited recent experience with women seeking fertility has been reassuring. However, randomised comparisons of its outcome compared with surgery and UAE are required to assess whether it has clear advantages over available alternatives. Theoretically it would seem to be of potential use in women desiring future fertility for treatment of single fibroids encroaching on the endometrium. Until further data are available its role remains unclear.

Other conservative options

Endometrial ablation is not specifically contraindicated for women with fibroids although the presence of fibroids greater than 3 cm or significant cavity distortion have been exclusion criteria for large-scale clinical trials. Most second-generation techniques are not suitable for women with large or distorted cavities although first-generation methods can be used in conjunction with resection of submucosal fibroids in women with HMB not desirous of future pregnancy.¹⁰ The presence of uterine fibroids was found to significantly increase the risk of further surgery following endometrial ablation in an English cohort study of over 100,000 women.⁴⁰

Myolysis or heat destruction of fibroids using various energy sources has been investigated in small-scale trials^{10,28} but only focussed ultrasound, described above, has developed to a clinically useful degree. Laparoscopic uterine artery occlusion has been described but evidence is limited^{10,28} and it has no obvious advantage over radiological embolisation.

Hysterectomy

Hysterectomy offers a definitive cure for women with heavy bleeding associated with fibroids who have completed child-bearing [A]³¹ and is still the most commonly performed procedure for this indication. Although expensive in the short term and not without risk^{6,8,10,28} (see Chapter 75), it may provide a cost-effective option for women who are less likely to benefit from more conservative approaches. Further information based on larger comparative studies is needed to enable clinicians and patients to make an informed choice. The abdominal route has been most commonly used for large

uteri although the vaginal route can be used by experienced operators,⁸ usually after GnRH pre-treatment. Laparoscopic techniques are increasingly available in large centres. These involve the use of morcellation which can lead to rare complications such as direct injuries to intestine or blood vessels and seeding of tissue fragments within the peritoneal cavity leading to growth of parasitic fibroids.⁹ There has been particular concern about reports of intraperitoneal seeding of unsuspected uterine sarcoma, leading to advice from the FDA discouraging the use of power morcellators.⁹ Although the low prevalence and lack of specific diagnostic features makes preoperative diagnosis of LMS difficult, it has been suggested that laparoscopic morcellation should be avoided in women over the age of 40 with clinical or imaging features which raise concerns about the nature of a presumed fibroid.⁹ However as yet there are no agreed guidelines, apart from the need for detailed patient information and informed consent [E].

EBM

These recommendations are based on three evidence-based clinical guidelines (two specific to the management of fibroids) and ten systematic reviews or meta-analyses. Some of the recommendations regarding management are based on information from non-randomised trials, case series or prospective cohort studies.

KEY POINTS

- Management of uterine fibroids should be based on the nature of the symptoms and the reproductive wishes of the individual woman [E]. Asymptomatic fibroids, even if very large, do not routinely require active management [E].
- Transvaginal ultrasound, combined with abdominal ultrasound for uteri larger than 12 weeks' gestation size, is the primary investigation for suspected fibroids [A].
- Both hysteroscopy and transvaginal sonohysterography (saline infusion sonography) are of value in the further investigation of suspected submucosal fibroids [A].
- MRI scanning should not be used as a primary investigation but has greater diagnostic accuracy than ultrasound and is indicated if there is doubt about the nature of a uterine mass or for assessment of suitability for UAE [B].
- LMS is very rare with an estimated prevalence of 0.14% in a presumed fibroid and is extremely rare below the age of 40. MRI with contrast enhancement may prove helpful in distinguishing between LMS and fibroid [C].
- Tranexamic acid should be used in preference to NSAIDs in the symptomatic management of HMB associated with fibroids [C].
- COCPs are not contraindicated in the presence of fibroids and may protect against fibroid growth [B] but have limited effectiveness in reduction of HMB, especially when this is associated with anaemia [B].
- Progestogens do not shrink fibroids but may relieve HMB at high doses if used continuously or for 21 days out of 28 [D].

- Progestogen-releasing IUDs are beneficial for fibroid-associated HMB [B] but evidence is based on cases without significant cavity distortion and patients should be warned of an increased risk of expulsion [C].
- Gestrinone or danazol can be used for the short-term management of fibroid-associated HMB [B].
- Selective progesterone receptor modulators have potential as a medical alternative to surgery for management of symptomatic fibroids but current evidence is limited to short and medium term use.
- GnRH agonists shrink fibroids and relieve HMB [A] and may be used in conjunction with add-back low-dose continuous combined HRT or tibolone for longer-term treatment [B].
- Treatment with low-dose oral combined HRT or tibolone is not contraindicated for relief of menopausal symptoms in women with fibroids but may cause a recurrence of bleeding problems related to fibroids or delay their resolution [C].
- GnRH agonists are useful adjuncts to surgery in cases of anaemia, very large fibroids and where uterine shrinkage may result in a transverse abdominal incision or a vaginal rather than an abdominal hysterectomy [A].
- Heavy bleeding associated with the presence of Type 1 or 2 submucous fibroids may be relieved by hysteroscopic resection [C].
- Myomectomy is an alternative surgical treatment for women with HMB and other fibroid-associated symptoms who wish to retain their fertility [C].
- Haemorrhage is a potential problem at myomectomy and interventions are available to reduce operative blood loss [B].
- Laparoscopic myomectomy is associated with shorter hospital stay and faster recovery than laparotomy in selected cases [B] but there is no evidence relating to its role in women with fibroid-associated HMB.
- UAE is an effective alternative to hysterectomy for symptomatic fibroids in women who have completed childbearing [A] but up to one third of women require further intervention because of lack of symptom control.
- UAE is not contraindicated for women wishing to conserve fertility but the pregnancy outcome is less favourable compared with myomectomy [C].
- MRI-guided focussed ultrasound is of potential use as a uterus-conserving option for selected women with symptomatic fibroids [C] but further information based on larger RCTs is required.
- Hysterectomy is an effective treatment for symptomatic fibroids in women who have completed childbearing [A]. The optimum technique and safety of the laparoscopic approach for removal of large fibroids have yet to be determined.

Chapter 75 Abnormal uterine bleeding

Christine P West

MRCOG standards

Theoretical skills

- Understand the epidemiology, causes and methods of investigation of abnormal uterine bleeding.
- Be familiar with the nature, complications and adverse effects of medical and surgical treatment of heavy menstrual bleeding.

Practical skills

- Be familiar with the practical skills of endometrial sampling, hysteroscopy, polypectomy and insertion of the levonorgestrel intrauterine system.
- Be aware of techniques of endometrial ablation.
- Understand the surgical techniques of abdominal, vaginal and laparoscopic hysterectomy and be able to recognise and manage postoperative complications.

INTRODUCTION

Menstruation is an issue of concern to many women in contemporary society. In the past, large family sizes, prolonged breastfeeding and reduced life expectancy limited the number of menstrual cycles experienced, but currently women may experience more than 400 menstrual periods during reproductive life, and problems related to menstruation are a common cause of referral, both to GPs and to gynaecologists. Abnormal bleeding can be a consequence of pelvic pathology, including malignant disease, but the majority of women who present with menstrual problems have no underlying abnormality. Indeed, a significant proportion of women with symptoms of heavy bleeding are found to have normal menstrual blood loss if the volume is measured objectively. Concern about the widespread use of hysterectomy in this situation has led to a well-developed evidence base for medical management. This evidence base, together with less invasive surgical methods, has increased the range of available options.

DEFINITIONS

The 2007 evidence-based guideline, commissioned by NICE,¹ rejected use of the term menorrhagia in favour of heavy menstrual bleeding (HMB). HMB is defined as 'excessive menstrual blood loss which interferes with the woman's physical, emotional, social and material quality of life, and which can occur alone or in combination with other symptoms'. The former definition of heavy blood loss, based on measured loss of more than 60 to 80 mL per period,² is used only as a research tool. Problems that may be associated with heavy bleeding include pain and mood swings (see Chapters 76 and 79). Other menstrual symptoms which may or may not be associated with heavy blood loss involve changes in cycle pattern that may be hormonal or secondary to structural pathology. These changes include cycle irregularity, prolonged bleeding, intermenstrual bleeding (IMB) and postcoital bleeding (PCB). The term abnormal uterine bleeding (AUB),³ favoured by the International Federation of Gynaecology and Obstetrics (FIGO), is defined as 'bleeding from the uterine corpus that is abnormal in volume, regularity and/or timing that has been present for the majority of the last 6 months'. Acute AUB, requiring immediate intervention, may occur in the context of ongoing chronic AUB or as an isolated episode.

EPIDEMIOLOGY

The reported prevalence of HMB varies between 4 per cent and 50 per cent, depending upon the population under study and the methods used.¹ In studies based on subjective self-assessment, the prevalence is around 20–25 per cent. In those using objective measurements, between 9 and 13 per cent of women have blood loss above 80 mL.¹ In an English community-based study of 1513 menstruating women⁴ aged 18 to 54, the twelve-month cumulative incidence of self-reported menstrual disorders was 25 per cent for HMB, 29 per cent for changes in cycle pattern, 17 per cent for IMB, 6 per cent for PCB and 9 per cent for the occurrence of at least one prolonged period lasting 10 days or longer.

Menstrual cycle patterns change significantly with age,¹ with an overall decrease in cycle length and increase in regularity until the perimenopause, when cycle variations become more common. The incidence of HMB rises with age, as do changes in cyclical pattern, including both long and short cycles and episodes of prolonged menstruation.⁴ However, the incidence of both intermenstrual and PCB declines progressively with age.⁴ There is a significant association between objectively confirmed HMB and uterine fibroids, with a greater prevalence of the latter in Afro-Caribbean women (see Chapter 74). Apart from this correlation and some inherited blood disorders (see below), there are no obvious racial or genetic associations with heavy menstrual blood loss. Mental and emotional health are known to influence HMB reporting rates¹ although the relationship is not well understood.

CAUSES

A recent FIGO working party has proposed the PALM-COEIN system of classification of causes of AUB in the reproductive years (Table 75.1).³ It is envisaged that this approach may facilitate future research into the epidemiology and treatment of menstrual disorders.

However, it is recognised that some of the conditions listed may be present in asymptomatic women, and the classification may be oversimplistic in relation to clinical management of the presenting complaint(s). Studies involving objective measurements of blood loss have shown that in a high proportion of women reporting heavy periods, the quantity of blood loss is not abnormal.² A study of women referred to gynaecological clinics because of excessive menstrual loss showed that more than half did not perceive this issue as severe or as their main problem.⁵ There was considerable overlap between problems related to bleeding and other menstrual problems such as pain and cyclical symptoms. Psychosocial factors may also influence presentation.

Structural causes

Fibroids (leiomyomata), particularly those situated submucosally, are the most common structural cause of HMB, prevalent in around 30 per cent of women with this complaint (see Chapter 74). Heavy bleeding associated with fibroids is often painless; painful heavy periods may be secondary to

Table 75.1 FIGO classification system for causes of abnormal uterine bleeding in non-pregnant women³

Structural causes	Non-structural causes
Polyp	Coagulopathy
Adenomyosis	Ovulatory dysfunction
Leiomyomata – submucosal	Endometrial
Leiomyomata – other	Iatrogenic
Malignancy or hyperplasia	Not yet classified

adenomyosis (see Chapter 78). Endometrial **polyps** may cause heavy bleeding but are more often asymptomatic or associated with IMB. A retrospective review of 2500 outpatient hysteroscopies⁶ reported a 17 per cent incidence of endometrial polyps in women presenting with IMB or PCB, compared with 10 per cent of those with HMB. Submucous fibroids were reported in 30 per cent of women with HMB and 20 per cent with IMB or PCB. The incidence of both polyps and fibroids rises with increasing age^{1,6,10} although age alone is poorly predictive of the presence of these lesions. **Histological abnormalities** of the endometrium are usually confined to the perimenopause. They range from simple or complex hyperplasia to severe atypia and malignancy. The incidence of **malignancy** rises with age and is rare in premenopausal women. It has been estimated that the rate of endometrial cancer in women presenting with HMB in primary care is less than 1 per 10,000 below the age of 40, 3 per 10,000 between 40 and 44, and 8 per 10,000 in women of 45 to 49,¹ although these data do not relate to bleeding patterns or to those referred to secondary care. The incidence of endometrial cancer among premenstrual women undergoing endometrial investigation in secondary care is between 0.2 and 1 per cent.¹ Similarly, the probability of a woman in the community with PCB having cervical cancer is 1 in 44,000 at age 20 to 24, rising to 1 in 2800 between 35 and 44 years and 1 in 2400 at 45 to 54 years.⁷

Non-structural causes

Coagulation disorders, in particular von Willebrand's disease (vWD), have been reported in between 5 and 20 per cent of women with HMB.¹ These conditions are most prevalent among young women in whom there is likely to be a history of other bleeding problems (particularly at previous surgical or dental procedures).

Ovulatory dysfunction is common following menarche and in the lead-up to menopause. The condition is painless and in teenagers usually limited to a few cycles. During the perimenopause it may lead to any of the histological abnormalities mentioned above. Abnormal bleeding secondary to ovulatory dysfunction is also a well-recognised consequence of polycystic ovary syndrome. Irregular bleeding may be associated with other endocrine disorders, particularly thyroid disease, although the underlying mechanism is unclear. Bleeding which occurs at mid-cycle in association with the oestradiol surge is regarded as physiological.

Endometrial causes involve disorders in the local control of menstruation (see Chapter 73). A review of 20 observational and diagnostic studies¹ showed that the majority of women investigated for menstrual bleeding disorders have no histological or structural abnormality and no evidence of any abnormality of ovulation. In such cases the most likely cause of both heavy and/or irregular menstrual bleeding is endometrial dysfunction.

Iatrogenic causes include the use of hormonal contraceptive preparations, intrauterine devices and anticoagulants. Breakthrough bleeding associated with hormonal

contraception is discussed in Chapter XXX). **Not yet classified** might include conditions currently poorly defined, such as bleeding from arterio-venous malformations or chronic endometritis.³

MANAGEMENT

Decisions regarding investigations and treatments of AUB are influenced by a number of factors, which include the age and reproductive wishes of the individual woman, the pattern and severity of her symptoms and the degree of social disruption that she experiences. Many women may simply seek reassurance. A detailed and accurate history is essential in eliciting any relevant medical problems and assessing the impact of the problem in each individual case. While simple menstrual calendars may be helpful in clarifying the pattern of bleeding, objective blood loss measurements and/or pictorial charts⁸ are regarded as research tools and not recommended in routine clinical practice [E].

Investigation

History, examination and basic investigation

This is covered in the national evidence-based guideline¹ and falls within the scope of primary care. History taking should define the presenting problem, determine the impact on the wellbeing of the patient and detect abnormal bleeding patterns and/or symptoms that may require further investigation [E]. Abdominal and bimanual pelvic examinations should be performed [E]. In the absence of abnormal features no additional investigations are required prior to the initiation of medical therapy [E]. If the uterus is enlarged, an ultrasound scan is the first-line investigation for delineating fibroids or excluding other causes of a pelvic mass [A]. A full blood count should be carried out in all women with HMB [C]. Additional blood tests such as ferritin, female hormone levels and/or thyroid function are not required in the absence of specific indications [C]. Testing for coagulation disorders, in particular vWD, should be considered in young women with a personal or family history suggestive of such conditions [C].¹

Further investigation

Endometrial biopsy should be taken to exclude endometrial cancer or atypical hyperplasia in cases of prolonged, irregular or persistent IIMB in the presence of specific risk factors (age over 45, obesity, tamoxifen therapy) [E]. It is also recommended in women over 45 if previous treatments have failed [E].¹ Various endometrial sampling devices are available for use in outpatients. The most common is the Pipelle sampler, which has been shown to have high sensitivity in the detection of both endometrial cancer and atypical hyperplasia.¹

Endometrial biopsy does not detect polyps or fibroids^{9,10} and if these are suspected on the basis of history or

clinical examination then current guidance is that transvaginal ultrasound scanning (TVS) should be performed [A].^{1,11} Abdominal ultrasound is required if the uterus is palpable abdominally. Hysteroscopy provides accurate visualisation of the uterine cavity and greater accuracy than TVS in distinguishing between polyps and submucosal fibroids^{9,10,11} although it is more invasive and potentially more costly.⁹ In centres where provision for outpatient hysteroscopy is limited, the ultrasound based technique of saline infusion sonography¹¹ is useful in delineating the uterine cavity, but this method is not regarded as a first line investigation [A]. Dilatation and curettage has been replaced by the clinic-based techniques described above for routine investigation and should not be used alone as a diagnostic tool [B].¹ Current guidelines^{1,12} recommend that TVS should be used, together with endometrial biopsy if indicated, for the initial investigation of AUB, with hysteroscopy as a back up technique [A]. However a recent economic evaluation¹⁰ has suggested that initial investigation by hysteroscopy may be more cost effective in secondary care if contemporary 'one-stop' testing and treatment modalities are available during a single visit.

Intermenstrual and postcoital bleeding

Careful examination of the cervix is essential, and suspicious findings are indications for colposcopy. In sexually active women, chlamydial infection should be excluded [B]. If IMB occurs only mid-cycle, then further investigation is not required. Although the incidence of structural and histological abnormalities rises with increasing age,^{6,9} fibroids and polyps can cause symptoms in younger women. As discussed above, TVS is currently regarded as the primary investigation for the detection of endometrial polyps or submucosal fibroids [A], backed up by biopsy and/or hysteroscopy if additional investigations are required. In the majority of cases, no abnormality is found and spontaneous resolution of both IMB and PCB commonly occurs.¹³

MEDICAL MANAGEMENT

Non-hormonal therapy

For women with HMB who prefer to avoid hormonal treatment or who wish to conceive, antifibrinolytics (tranexamic acid)¹⁴ or non-steroidal anti-inflammatory drugs (NSAIDs) e.g. mefenamic acid¹⁵ are first-line drugs [A]. Both are used only during menstruation and are generally well tolerated, apart from gastrointestinal side effects which are more common with NSAIDs. Blood loss may be reduced by up to 58 per cent with tranexamic acid [A]¹⁴ but associated menstrual pain is more effectively treated with NSAIDs (see Chapter 76). Blood loss is reduced by around 29 per cent with mefenamic acid, 26 per cent with naproxen but only 16 per cent with ibuprofen.¹⁵ There is no evidence that the long-term use of antifibrinolytics increases the incidence of thrombosis.¹⁴ Since

antifibrinolytics and NSAIDs have different mechanisms of action, they may be used in combination [E]. Ethamsylate (a drug that reduces capillary fragility) was used in the past but recent trials have shown it to be less effective than NSAIDs or tranexamic acid [A].¹ If effective, the use of tranexamic acid and/or NSAIDs can be continued in the long term, but they should be stopped if they do not improve symptoms within three menstrual cycles [E].

Combined oral contraceptive pill (COCP)

For women requiring contraception or for whom hormonal agents are acceptable, COCP preparations are effective in reducing menstrual bleeding, controlling cycle irregularities and relieving menstrual pain, although reports of efficacy have largely been based on indirect evidence from contraceptive studies and one small randomised controlled trial (RCT)¹⁶ which reported a 43 per cent reduction in menstrual blood loss. There is some reluctance on the part of both professionals and consumers to use the COCP for the management of menstrual disorders in older women. For non-smokers with no risk factors for vascular disease, there is no upper age limit for the use of the COCP, and current guidelines recommend it as a first-line therapy for HMB [B].¹

Progestogens

Cyclical progestogens were commonly used in the past, but the current evidence does not support the use of these treatments for HMB when given only during the luteal phase of the cycle [A].¹⁷ They are effective when given at high doses between days 5 and 26 (e.g. norethisterone 5 mg tid) [A].¹⁷ Cyclical progestogens are traditionally chosen for the control of bleeding secondary to ovulatory dysfunction, through their action in opposing the proliferative effects of oestrogen. Both norethisterone and medroxyprogesterone acetate, given cyclically, are generally well tolerated [C].¹ Overall reduction in blood loss is greater with the levonorgestrel-releasing intrauterine system (LNG-IUS) than with high-dose cyclical progestogen, although there is a higher incidence of breakthrough bleeding with the IUS.¹⁷

Progestogens at doses high enough to suppress ovulation can be given continuously by the oral route or as long-acting depot injections (e.g. Depo-Provera) to induce amenorrhoea [A].¹ However, their usefulness is limited by side effects, including bloating, fluid retention, breast tenderness and breakthrough bleeding. There is a small risk of bone mineral loss during prolonged treatment with depot preparations but this effect is reversed after treatment is stopped.

Levonorgestrel-releasing intrauterine system

The LNG-IUS is a well-established treatment for HMB. The continuous exposure of the endometrium to progestogen

induces progressive atrophy, with reduction of menstrual bleeding by around 80 per cent after 3–6 months and more than 90 per cent at 12 months.^{18,19} Spontaneous expulsion occurs in 3–10 per cent of women and the incidence of breakthrough bleeding is around 22–35 per cent in the initial 6–12 months.¹⁸ There is a small (less than 1 per cent) risk of uterine perforation during insertion of the device. Progestogenic side effects of bloating, breast tenderness, headache and acne may occur although they tend to be transient. The predominant side effect which adversely affects compliance is prolonged breakthrough bleeding in up to 10 per cent of women beyond 12 months of use. Discontinuation rates of 17–20 per cent at 12 months, rising to around 28 per cent at 2 years, have been reported.^{18,20} Careful counselling is therefore essential prior to insertion [E].

The LNG-IUS has been compared in three systematic reviews and a meta-analysis^{18–20} with both medical and surgical treatments. The reduction of menstrual blood loss was significantly greater with the IUS than with tranexamic acid or NSAIDs.^{18,19} The side effects of breakthrough bleeding and breast tenderness were more common in women with the LNG-IUS compared with high-dose cyclical norethisterone,^{17,19} but overall satisfaction was greater with the LNG-IUS.

The LNG-IUS has been compared with first- and second-generation methods of endometrial ablation.^{18–20} Although reduction of blood loss was greater following ablation and side effects were more common with the LNG-IUS, all studies reported that overall satisfaction rates were similar at around 83 per cent at 12 months.²⁰ In a study of women awaiting hysterectomy,^{19,20} 64 per cent of those randomised to insertion of the LNG-IUS cancelled their operation after 6 months, compared with 14 per cent in a control group. In a direct comparison with hysterectomy,^{19,20} quality-of-life assessment at 12 months was not significantly different in the two groups, although pain scores were lower after hysterectomy and 20 per cent of the group assigned to the LNG-IUS had opted for hysterectomy in the first year. Costs were three times higher in the hysterectomy group. These results indicate that the LNG-IUS is a highly effective treatment for HMB [A] that has advantages over existing medical treatments and is a potential alternative to surgery.

Other medical therapies

Second-line drugs are available for the control of severe bleeding when simpler measures have failed and, because they more reliably induce amenorrhoea, are useful in the management of severe anaemia. Androgens such as danazol and gestrinone induce amenorrhoea by a combination of negative feedback and direct effects on the endometrium, while gonadotrophin-releasing hormone (GnRH) agonists induce a hypogonadal state via their central action (see Chapter 77). While effective, these approaches are usually limited to short-term use because of their side effects [A].¹ Both danazol and GnRH analogues are of value as

endometrial-thinning agents prior to first-generation methods of hysteroscopic surgery, by reducing operating times and improving ease of surgery [A].²¹ GnRH analogues used prior to hysteroscopic surgery are also associated with a higher rate of postoperative amenorrhoea and improved dysmenorrhoea at 12 months,²¹ although the benefits reduce with time. In cases of severe bleeding due to benign causes in which standard measures have failed, long-term therapy with a GnRH agonist plus hormonal add-back [B] (see Chapters 74 and 77) can be considered if there are contraindications to surgery.

SURGICAL MANAGEMENT

While medical treatment should normally be used as first-line therapy for HMB [E], limitations in efficacy and side effects¹ will result in many women seeking a surgical solution for their problem. The use of the diagnostic techniques described above identifies some women with benign lesions (small sub-mucosal fibroids or endometrial polyps) that are suitable for removal by hysteroscopic surgery^{1,6,12} [D] although the role of such surgery in the management of menstrual disorders has not been subjected to critical evaluation. Various methods of endometrial ablation are now well established as day-case or outpatient procedures and recent developments include second-generation techniques that are simpler and safer than older methods.

Endometrial ablation

The objective of endometrial ablation is the complete destruction of the endometrium down to the basal regenerative layer, resulting in fibrosis of the uterine cavity and amenorrhoea. In practice this is very difficult to achieve and rates of amenorrhoea are around 30 to 40 per cent.²² However, patient satisfaction is over 80 per cent in the short term [A]. A desire for future fertility is an absolute contraindication to endometrial

ablation and women must be counselled regarding the appropriate use of contraception [E].

Initially ablation techniques were carried out under direct hysteroscopic vision and involved the use of fluid for distension and irrigation. They comprised laser ablation, endometrial loop resection using electrodiathermy and rollerball electrodiathermy ablation. Of these, laser ablation was limited by its costs to a very few centres. All are operator dependent, time consuming and carry risks of systemic fluid absorption, haemorrhage and uterine perforation with heat damage to adjacent structures. The MISTLETOE Study,²³ a prospective national survey of more than 10,000 procedures in the UK, reported an immediate complication rate of 4.4 per cent which was related to the experience of the operator [C]. Increasingly these so-called first-generation methods have been replaced by the techniques described below. However, they may be carried out, if appropriate, in conjunction with hysteroscopic resection of fibroids [D] (see Chapter 74).

Second-generation endometrial ablation

Newer techniques have been developed with the goal of reducing operator dependency and minimising risk. Several are currently available, including fluid-filled thermal balloon ablation (TBA), microwave endometrial ablation (MEA) and impedance-controlled bipolar radiofrequency ablation.^{1,22,24} Second-generation methods have been compared with each other,^{22,24} with first-generation methods,^{20,22} with abdominal and vaginal hysterectomy²⁵ and with the LNG-IUS,^{19,20,22} in randomised trials and systematic reviews. Satisfaction rates are similar when compared with first-generation methods^{20,22} but they have shorter operating times (on average 15 minutes) and fewer serious complications (Table 75.2), making them safer and more cost effective [A]. They are also more suitable for use with local rather than general anaesthesia (61 per cent compared to 21 per cent). However, they are associated with a higher incidence of technical equipment failure. Direct comparisons of different second-generation methods have shown no significant disparities in menstrual blood loss

Table 75.2 Complications of endometrial ablation. Data from systematic review of trials (n = 11) comparing 1st and 2nd generation techniques.²²

Complication	2nd generation (%)	1st generation (%)	RR (95% CI)
Equipment failure	9.1	1.6	4.3 (1.5-12.4)
Nausea and vomiting	19.4	7.6	2.0 (1.3-3.0)
Uterine cramps	38.4	33.2	1.2 (1.0-1.4)
Fluid overload	0	3.0	0.2 (0.04-0.8)
Uterine perforation	0.3	1.3	0.3 (0.1-1.0)
Cervical lacerations	0.2	2.2	0.2 (0.08-0.6)
Haematometra	0.7	2.4	0.3 (0.1-0.9)
Haemorrhage	1.2	3.0	NS
Fever	0.1	0.1	NS
Endometritis	2.0	1.4	NS

scores, rates of amenorrhoea or patient satisfaction [B].^{22,24} Second-generation methods are not suitable for women with submucosal fibroids greater than 3 cm and most are restricted to cavity lengths between 4 and 12 cm. Repeat ablation is contraindicated for most second-generation techniques. In contrast to first-generation methods, endometrial-thinning agents are not usually required [A].²¹ Prophylactic antibiotics are commonly used prior to endometrial ablation procedures, although the evidence to support their use is lacking.

Despite the reduced risk of serious complications with second-generation devices, there have been reports of uterine perforation with thermal damage to nearby structures [D].²⁶ It is recommended that the procedures are carried out in conjunction with hysteroscopy or TVS to ensure correct placement [E]. In addition, myometrial thickness should be pre-assessed by ultrasound, particularly in women with previous uterine surgery, including caesarian section (CS), or with a small thin-walled uterus [E].²⁶ The presence of a fixed retroverted uterus or history of conditions which may result in adherence of the bowel to the posterior wall of the uterus, such as severe endometriosis or pelvic infection, are relative contraindications to endometrial ablation.²⁶

Longer term outcome of endometrial ablation

An early life-table analysis of follow-up after endometrial resection²⁷ reported a cumulative hysterectomy rate of 27.4 per cent after 4 years. Data from a recent large English cohort study²⁸ of 114,910 women who had undergone various methods of endometrial ablation indicated that 16.7 per cent had a further procedure within 3 years and 13.5 per cent had a hysterectomy. Risk factors for further intervention in this

study were younger age, lower socio-economic class and the presence of uterine fibroids [C].²⁸

There is some evidence that the long-term risk of further surgery, including hysterectomy, is lower with second-generation methods.^{22,28} Compared with first-generation methods, women who had radiofrequency ablation were significantly less likely to have had further surgery,²⁸ although outcomes after other second-generation methods were not significantly different from first-generation methods.

All methods of endometrial ablation are less effective than hysterectomy in reducing blood loss and pain.²⁵ However, adverse events including sepsis, pyrexia and blood transfusion are less common with endometrial ablation, and recovery time is much faster. Patient satisfaction is high with both procedures. The overall evidence is that endometrial ablation is an appropriate first-line surgical approach where medical methods have failed or are deemed inappropriate [A].

Hysterectomy

Hysterectomy provides a definitive cure for women who have completed child-bearing, but the initial costs and morbidity rates are higher than with other treatments.¹ A large cohort study of 37,298 hysterectomies performed in the UK for benign indications reported an operative complication rate of 3.5 per cent, a postoperative complication rate of 9 per cent and an overall mortality rate of 0.38 per 1000.²⁹ Mortality was 0.25 per 1000 in women undergoing hysterectomy for menstrual problems. The majority of hysterectomies in the latter study were performed abdominally (67 per cent) or vaginally (30 per cent), but the increasing use of laparoscopic methods

Table 75.3 Morbidity of hysterectomy

75.3A Serious morbidity related to the surgical procedure. Data from a systematic review of 34 RCTs (4495 procedures)³⁰

Complication	Abdominal (%)	Vaginal (%)	Laparoscopic (%)*
Bowel injury	0.63	0	0.22
Urinary tract injury	0.94	1.21	3.24
Vascular injury	0.77	0.94	1.54
All injuries	2.34	2.15	5.00
Unintended laparotomy	-	3.02	4.30
Pelvic haematoma	5.23	4.40	3.75
Blood transfusion	4.35	3.22	3.54

75.3B Infective complications. Adapted from Table 12.2, Heavy Menstrual Bleeding Guideline: data from 27 RCTs (3643 procedures)¹

Site	Abdominal (%)	Vaginal (%)	Laparoscopic (%)*
Abdominal wound	7.38	0	1.92
Urinary tract	4.87	1.27	4.77
Chest	4.55	6.67	0.56
Other febrile morbidity	13.15	7.73	10.01

* Any method of laparoscopic hysterectomy

has resulted in investigation of the optimal method of carrying out hysterectomy. A recent systematic review³⁰ of 34 RCTs which included 4495 women has concluded that laparoscopic hysterectomy is associated with a shorter hospital stay and recovery time compared with abdominal hysterectomy [A]. Blood loss and febrile morbidity were lower but the duration of operations and incidences of vascular and urinary tract injuries were significantly greater. Where significant differences were seen, all outcomes were more favourable with vaginal hysterectomy compared with both abdominal and laparoscopic hysterectomy [A] (Table 75.3). All the studies included in the systematic review used prophylactic antibiotics during surgery.

The role of subtotal hysterectomy (whether performed abdominally or laparoscopically) remains unclear. Evidence from nine RCTs³¹ has failed to identify any differences in sexual, bladder or bowel functions following surgery, although the duration of operations, blood loss, febrile morbidity and urinary retention are reduced with the subtotal approach [A]. Women undergoing subtotal hysterectomy should be warned about a 7 per cent risk of occurrence of ongoing menstrual bleeding [A].¹

Despite this evidence supporting the use of vaginal and laparoscopic routes over the abdominal route, individual assessment is essential when deciding the method of hysterectomy.¹ Factors to be considered include the size and mobility of the uterus, vaginal access, history of previous surgery and presence of other gynaecological disease(s) such as endometriosis as well as the skill and experience of the individual surgeon [E]. Patients with more complex clinical presentations may be excluded from randomised trials and/or treated by more experienced surgeons, accounting for the apparently higher morbidity seen in cohort studies compared with randomised trials.^{1,29} Special training in laparoscopic surgical techniques is recommended.³² All decisions regarding hysterectomy must be accompanied by a detailed discussion with the individual woman of the benefits, risks and future implications of the procedure [E].

Hysterectomy may have long-term implications for bladder function; a systematic review³³ estimated a 60 per cent long-term increase in the odds of developing urinary incontinence following hysterectomy. Cohort studies comparing hysterectomy with endometrial resection¹ or ablation³⁴ have reported a higher risk of developing urinary symptoms following hysterectomy. A recent Scottish study found an increased risk of pelvic floor or urinary incontinence surgery following hysterectomy for HMB compared with endometrial ablation.³⁴ This increased risk was observed to be greater in cases of vaginal compared to abdominal surgery. The results of the Scottish study are at variance with those of the large systematic review,³⁰ which applied a shorter period of follow-up and in which many of the studies excluded participants with prolapse and/or urinary dysfunction. The risks of subsequent adnexal surgery and genital fistula repair were also higher following hysterectomy than following endometrial ablation in the Scottish study.

Removal of healthy ovaries at the time of hysterectomy for HMB should not be undertaken without detailed discussion of the potential impact on the woman's subsequent health and

wellbeing, and consideration of relevant issues including her personal and family history of breast and ovarian cancer and her attitude to the use of hormone replacement therapy [E].¹

Economic considerations

National guidelines¹ recommend that medical treatment, in particular the LNG-IUS, should be initially offered for management of HMB, followed by endometrial ablation if medical therapy fails or is unacceptable. Hysterectomy should be considered only if these other options fail or are contraindicated. A model-based economic evaluation comparing the costs of different clinical pathways of treatment for a 42-year-old woman presenting with HMB³⁵ concluded that initial treatment with hysterectomy might be more cost effective than pathways starting with the LNG-IUS or with first- or second-generation endometrial ablation. This model did not take into consideration the use of the IUS in primary care. A recent literature review³⁶ concluded that the LNG-IUS was cost effective in various countries and settings. Factors that influence the success of endometrial ablation also need to be taken into consideration. A large English cohort study²⁸ found that the risk of further surgery was significantly related to patient age, with 27 per cent of women aged 35 or younger at the time of the initial ablation having further surgery, compared with only 10 per cent of those aged over 45. It is also important to consider patient choice. A survey of patient preferences¹ found that 85 per cent of women are willing to accept a 50:50 chance of treatment failure to avoid hysterectomy. Further information from long-term studies may help clinicians to target management in the most cost-effective way.

EBM

These recommendations for the management of heavy and irregular menstruation are based on a national evidence-based guideline, a systematic review of diagnostic procedures, seven systematic reviews of medical therapy and eight systematic reviews or meta-analyses relating to surgical management.

KEY POINTS

- HMB may occur alone or in combination with other symptoms and should be recognised as having a major impact on a woman's quality of life [E].
- The initial management of AUB should take place within a primary care setting following abdominal and pelvic examination and measurement of full blood count [E].
- Sexually active women presenting with intermenstrual or PCB should be tested for chlamydia [B].

- If the history or clinical findings are suggestive of a structural abnormality, ultrasound should be the primary investigation [A], backed up by hysteroscopy or saline infusion sonography if the nature of an intracavity lesion is uncertain [A].
- Endometrial biopsy is indicated in cases of prolonged or irregular bleeding or treatment failure in women over 45 and those with additional risk factors for endometrial cancer, in particular obesity [E].
- NSAIDs and antifibrinolytics are effective in the management of HMB [A], but ethamsylate is ineffective [A].
- The COCP is effective for control of heavy and irregular menstrual bleeding provided there are no contraindications [B].
- Cyclical progestogens are effective for HMB when given for 21 days out of 28 and for control of bleeding associated with ovulatory dysfunction [B].
- Continuous high-dose progestogens (e.g. depot preparations) may be useful if they induce amenorrhoea [B].
- The LNG-IUS device is highly effective in reducing HMB, but adequate counselling is needed prior to insertion [A].
- Drugs that induce amenorrhoea such as GnRH analogues or danazol are useful for the short-term management of heavy bleeding associated with anaemia or for endometrial thinning prior to first-generation methods of endometrial ablation [A].
- Symptomatic endometrial polyps and small submucous fibroids should be removed hysteroscopically [D].
- Endometrial ablation is effective for the relief of HMB [A] and second-generation methods are safer and more cost effective than first-generation methods, as well as simpler and quicker to perform [A].
- Endometrial ablation is cheaper than hysterectomy in the short term but differences narrow with time [A]. Its use in women over 45 is associated with a reduced risk of further surgical intervention [C].
- Long-term satisfaction is high with hysterectomy but it is associated with significant morbidity and mortality [A] and should be offered only if simpler alternatives have failed [E].
- Healthy ovaries should not be removed at hysterectomy without detailed consideration of the risks and benefits [E].
- Vaginal hysterectomy is more cost effective than the abdominal route and should be considered as preferable to abdominal hysterectomy where possible [A].
- Laparoscopic hysterectomy is an alternative to abdominal hysterectomy but carries a greater risk of serious complications and additional specialist training is required [A].
- Subtotal hysterectomy offers no long-term advantages over abdominal hysterectomy and may be associated with continued menstrual bleeding although short-term morbidity is reduced [A].
- The route selected for hysterectomy should be determined by appropriate assessment of the individual patient as well as by the skill and experience of the gynaecologist carrying out the operation [E].

Chapter 76 Dysmenorrhoea and pelvic pain

Christine P West

MRCOG standards

There are no established standards for this topic but the following are suggested:

Theoretical skills

- Understand the epidemiology, causes and management of dysmenorrhoea.
- Understand the epidemiology and causes of chronic cyclical and non-cyclical pelvic pain.
- Understand the principles of management of patients with chronic cyclical and non-cyclical pelvic pain, including alternative and non-hormonal therapies.

INTRODUCTION

Pain during menstruation is an almost universal experience among women and, when severe, it has a significant economic impact through loss of time from work or education. Recognition of the consequences of this problem has led to several large-scale reviews of treatments for dysmenorrhoea, including alternative therapies. There is thus a well-founded evidence base for its management. Pain related to or exacerbated during menstruation or sexual intercourse may be a consequence of underlying pelvic pathology, although not all women with pelvic pain have a gynaecological disorder. This chapter is mainly concerned with gynaecological causes of cyclical pelvic pain but some reference is made to the multifactorial nature of the problem and to management of symptoms of chronic pelvic pain.

DEFINITIONS

Dysmenorrhoea is a descriptive term for pain that occurs during menstruation. Primary dysmenorrhoea, also known as primary spasmodic dysmenorrhoea, is a condition of colicky, cramping, suprapubic pain that may radiate to the lower back and thighs, often associated with gastrointestinal and systemic symptoms. It typically lasts for between 8 and 72 hours,

although milder manifestations are almost universally experienced by young women. Although it can cause significant morbidity, it is not associated with any pelvic abnormality.

Secondary dysmenorrhoea is menstrual pain which is secondary to identifiable pelvic pathology (e.g. endometriosis). It is often associated with deep dyspareunia. Pain which is exacerbated by menstruation and continues throughout the cycle is known as chronic cyclical pelvic pain, a subset of the condition of chronic pelvic pain in which pain of at least 6 months' duration is present continuously or intermittently, not associated exclusively with menstruation or sexual intercourse¹.

PREVALENCE

The reported prevalence of dysmenorrhoea varies widely depending on the population studied and the method of reporting. A systematic review of older studies¹ reported a prevalence of between 45 and 97 per cent. In a review of more recent community-based studies and systematic reviews,² the prevalence ranged between 16 and 91 per cent, with 2–29 per cent reporting severe pain. Studies of teenage or younger women generally reported a higher prevalence and a higher proportion with severe symptoms, compared with those including a wider reproductive age group. The studies did not generally distinguish between primary and secondary dysmenorrhoea. Prevalence was similar in studies from developed and developing countries.

The annual prevalence of chronic pelvic pain has been estimated at 38.3 per 1000 using consultation episodes from a large UK general practice database of women aged 12 to 70 years.³ The 3-month prevalence among women aged 18 to 50 was 23.6 per 1000. This result is considerably lower than the 3-month prevalence of 15 per cent in a community-based US sample of women aged 15 to 50,⁴ but the latter study was based on self-reported pelvic pain and only 25 per cent of the women sought medical advice for help with their symptoms.

EPIDEMIOLOGY

The general consensus in the literature² is that age and parity are inversely related to the incidence of dysmenorrhoea. There is generally an association with family history although it is

not clear whether this is due to genetic factors or conditioning. Users of the oral contraceptive pill have a reduced prevalence, while stress is associated with increased risk. Other factors less consistently reported are low body mass index (BMI), smoking, early menarche and heavy menstrual bleeding.⁵ Exercise and a high intake of fruit and vegetables have been reported as protective in some studies.

A systemic review of studies of risk factors for chronic pelvic pain⁵ concluded that drug or alcohol abuse, psychological co-morbidity and a history of physical or sexual abuse are all associated with an increased risk. It also reported an association between non-cyclical pelvic pain and many gynaecological and obstetric factors including miscarriage, caesarian section (CS), heavy menstrual flow and pelvic inflammatory disease (PID). Factors such as personality traits, coping strategies, health beliefs and influences of family members may predispose an individual to the development of chronic pain.^{5,6}

CAUSES

Primary dysmenorrhoea

Uterine myometrial hyperactivity has been demonstrated in women with primary dysmenorrhoea.⁷ This condition is most commonly attributed to excess prostaglandin production during menstruation, resulting in increased myometrial contractions and enhancement of the normal reduction of uterine blood flow which occurs during menstruation, leading to increased ischaemia. Primary dysmenorrhoea is regarded as a physiological variant of the normal response to ovarian hormonal withdrawal and onset of menstrual bleeding and is not regarded as a pathological condition. However, in common with all painful conditions, there may be psychological, social or emotional factors that influence its impact on the individual affected.

Pain occurring at mid-cycle, known as mittelschmerz, is secondary to follicle rupture and also regarded as physiological. It may be associated with vaginal bleeding.

Secondary dysmenorrhoea

The most common cause of secondary dysmenorrhoea and chronic cyclical pelvic pain (Table 76.1) is endometriosis (see Chapter 77), which occurs in around one third of laparoscopies carried out for pelvic pain.⁸ Adenomyosis is a cause of secondary dysmenorrhoea that is most commonly diagnosed in older multiparous women (Chapter 78). Unlike adenomyosis, uterine fibroids are not typically associated with pelvic pain, although dysmenorrhoea can occur with passage of clots and acute pain may be secondary to fibroid degeneration or expulsion of a submucosal fibroid through the cervix. Cervical stenosis or intrauterine adhesions secondary to surgical procedures cause dysmenorrhoea secondary to retained menstrual fluid (haematometra). Pain from trapped or residual ovaries is usually cyclical, while adhesions can cause non-cyclical

Table 76.1 Causes of dysmenorrhoea and cyclical and non-cyclical chronic pelvic pain

Physiological	Primary dysmenorrhoea Mittelschmerz
Gynaecological	Endometriosis Adenomyosis Uterine fibroids Cervical stenosis and other obstructive causes Pelvic venous congestion Residual/trapped ovary syndrome Pelvic adhesions Pelvic inflammatory disease
Gastro-intestinal	Irritable bowel syndrome Chronic constipation
Urinary tract	Bladder pain syndrome (interstitial cystitis)
Musculoskeletal	Pelvic floor myalgia Myofascial pain
Neurological	Nerve entrapment

pain due to organ distension. Secondary dysmenorrhoea is unusual in young women although both endometriosis and adenomyosis may occur. Another rare cause of the condition is pain secondary to congenital Müllerian abnormalities that are associated with obstructions to menstrual flow⁷ (e.g. cryptomenorrhoea in an accessory uterine horn).

Non-gynaecological causes of pelvic pain

Around one third of laparoscopies carried out for the investigation of pelvic pain are negative.⁸ Non-gynaecological conditions can be exacerbated or enhanced during menstruation and/or intercourse. In particular, irritable bowel syndrome (IBS) is commonly diagnosed following negative investigations for pelvic pain.^{6,7,9} Symptoms suggestive of IBS are abdominal pain or discomfort relieved by defaecation, possibly associated with altered bowel frequency or stool form.¹⁰ The condition is also commonly associated with abdominal bloating and other features such as lethargy, nausea, backache, dyspareunia and bladder symptoms. In a sample of 5051 UK women on a GP database with a recorded diagnosis of chronic pelvic pain,⁹ 21 per cent had gastrointestinal symptoms and 29 per cent were eventually diagnosed with IBS, this diagnosis being more common in the older age group. Milder forms of inflammatory bowel disease may be confused with IBS, but in the former inflammatory markers will be raised. Bowel cancer is uncommon in the reproductive age group but symptoms such as rectal bleeding and unexplained weight loss should prompt urgent referral to a gastroenterologist.¹⁰

Bladder pain syndrome (BPS; formerly known as interstitial cystitis) is also commonly diagnosed in women with chronic pelvic pain.^{6,7,11} Key symptoms are pain, pressure or

discomfort, situated suprapubically, increasing as the bladder fills and relieved by voiding. Pain may radiate to the groin, vagina or rectum, and dyspareunia is frequently located over the bladder base. Two main subtypes of BPS are recognised,¹¹ distinguished mainly by different appearances at cystoscopy. The cause of BPS is unknown.

Chronic cyclical and non-cyclical pelvic pain

The causes of chronic pelvic pain may be less clearly defined than those of primary or secondary dysmenorrhoea, and the condition may result from more than one contributory factor. Changes in peripheral nerve function may occur following acute events such as surgery, trauma, inflammation, fibrosis or infection, resulting in altered visceral sensation and function leading to pain which persists long after the original acute episode.⁶ An example of this would be pain persisting in areas affected by endometriosis after such lesions have apparently regressed or been removed. Similar changes may occur even in the absence of any such acute event. Changes in the CNS itself (central sensitisation) may modify or enhance the original signal leading to enhancement of visceral sensation, known as visceral hyperalgesia.¹¹ This effect causes an increased perception of pain and has been described in association with endometriosis, IBS and BPS. Viscero-visceral hyperalgesia, whereby pain from one organ can induce pain and dysfunction in others with visceral afferent nerves sharing the same distribution, may be a contributing factor.¹² This may explain why women with endometriosis-associated pain may also complain of symptoms of IBS or BPS.

As mentioned above, chronic pain has been shown to be related to CNS amplification of pain processing, which often occurs in the absence of acute injury or inflammation of peripheral structures. Reductions in the grey matter volume of brain regions involved in pain perception have been described in women with unexplained or endometriosis-associated chronic pain, but not in control groups or in women with endometriosis-associated dysmenorrhoea without chronic pain.¹³ The reason for this difference is not clear but suggests that chronic pelvic pain represents some form of central maladaptation of the pain system¹³ which is likely to be multifactorial in nature. Pain arising from disturbance of the central or peripheral nervous system is classified as neuropathic pain.

Pelvic venous congestion is a condition described in multiparous women of reproductive age.¹⁴ Chronic dull, aching pain is characteristically exacerbated perimenstrually, by activity and by sexual intercourse, and relieved by lying down. It is attributed to the presence of dilated veins in the broad ligament and ovarian plexus. Typical appearances have been described at venography and reported with both ultrasound¹⁵ and MRI, although studies reporting accuracy, sensitivity and specificity have not been undertaken and the existence of the condition as an entity distinct from unexplained chronic cyclical pelvic pain is disputed.

Musculoskeletal factors

Pain arising from the muscles or joints within the pelvis or from the muscles of the abdominal wall or pelvic floor may be a component of chronic pelvic pain, resulting from postural changes secondary to the pain^{6,7} or a primary source of it. Nerve entrapment in a surgical scar and pudendal neuralgia¹¹ which may follow childbirth are direct causes of neuropathic pain. Spasm of the pelvic floor muscles is proposed as a secondary cause of chronic pelvic pain and dyspareunia.⁶ Muscle pain and spasm may be derived from myofascial trigger points^{16,17} which are specific areas of tenderness within a taut band of skeletal muscle. Hyperactivity in the nerve endings at such trigger points produces enhanced sensitivity, muscle contraction and referred pain described as deep, aching and poorly localised within the area affected. It is usually exacerbated by activity but may be relieved by pressure or stretching. Pain can be reproduced by sustained compression over the point of tenderness. The development of myofascial trigger point pain is usually secondary to physical causes such as injury, ischaemia or nerve compression, but muscle pain may also arise as a result of visceral disease¹⁶ whereby myofascial trigger points in the zone of pain referral can become activated with the production of superimposed neuropathic pain. This could be one of the mechanisms underlying conditions such as vulvodynia as well as pelvic floor muscle spasm (myalgia).¹¹ Myofascial trigger points may also be detectable in muscles of the anterior abdominal wall in patients with chronic pelvic pain.

Psychological and social factors

Epidemiological studies (see above) have indicated that there is an association between chronic pelvic pain and physical and sexual abuse. There are also potential associations with drug and alcohol abuse, depression, anxiety and sleep disorders, although sleep disorders could be secondary to the pain.⁶ Whilst unexplained symptoms must not be regarded as psychogenic in origin, there may be aspects of personality or past experience which render certain individuals more vulnerable to the development of chronic pain syndromes or impair their abilities to develop coping strategies.⁷ The majority of women with chronic pelvic pain experience sexual dysfunction, most commonly dyspareunia, vaginismus and sexual avoidance, leading to relationship problems which contribute to psychological and social morbidity. Addressing these various issues is likely to be important in resolving the symptoms.

MANAGEMENT

Investigation

The diagnosis of primary dysmenorrhoea is based on the history of typical spasmodic, cramping, suprapubic pain, confined to menstruation and with no features suggestive

of other gynaecological conditions. It should be backed up by clinical examination if appropriate and does not require investigation [E]. It is normally managed by the GP or primary care physician. Referral to a gynaecologist is required if there is a lack of response to standard therapies or if symptoms are atypical, giving rise to a suspicion of endometriosis or other pathology. Pelvic examination is not indicated in a teenager who is not sexually active [E]. A transabdominal ultrasound scan will exclude congenital uterine abnormalities or significant ovarian pathology and should provide reassurance if negative.

Gynaecological symptoms of dyspareunia, abnormal bleeding or a history of previous surgery or infection are suggestive of an underlying cause for the pain. Abdominal and pelvic examinations should be performed to assess tenderness, uterine size and the presence of any masses. Reduced uterine mobility together with tenderness and thickening or nodularity in the pouch of Douglas is suggestive of endometriosis (see Chapter 77). Tender uterine enlargement is suggestive of adenomyosis (see Chapter 78). Localised tender trigger points may be identified in the muscles of the abdominal wall or pelvic floor.

In cases of suspected PID, samples should be taken to screen for sexually transmitted infections (STIs). Ultrasound should be performed if the findings of an examination are abnormal, as it is sensitive in the detection of uterine fibroids and adenomyosis as well as ovarian cysts and endometrioma [A].¹⁸ It has the advantage of being cheap and non-invasive. MRI scanning is useful as an additional tool if ultrasound findings are equivocal. Laparoscopy has an established role in the diagnosis and treatment of endometriosis (see Chapter 77) but is not without risk,¹⁹ nor routinely required prior to a therapeutic trial of medical therapy [E].^{6,7}

For women presenting with chronic pelvic pain, there is evidence that the quality of the initial consultation influences later progress.⁶ Detailed history taking and pelvic examination (not necessarily at the same visit) are essential. The initial history should include questions about the pattern of pain and its association with other problems such as bladder and bowel symptoms and the effect of movement and posture on the pain. Psychosocial factors must be explored in detail and the woman given time to express her ideas, concerns and expectations [E]. Laparoscopy is commonly performed, but in the absence of abnormal clinical or ultrasound findings the likelihood of abnormal findings at laparoscopy is also very low.^{18,20} A randomised trial comparing two therapeutic approaches to chronic pelvic pain concluded that laparoscopy played no important role in management [B].²¹ Although in some cases negative findings may provide reassurance, a study assessing the value of photographic reinforcement after a negative laparoscopy showed no additional benefit.²² However, another study showed that when pelvic ultrasound examination is accompanied by education, counselling and reassurance there is subsequent improvement in measures of pain, compared with ultrasound alone.²²

Management of primary dysmenorrhoea

NSAIDs

These drugs inhibit prostaglandin synthesis via inhibition of the enzyme cyclooxygenase. A systematic review of 73 clinical trials²³ evaluated 21 different non-steroidal anti-inflammatory drugs (NSAIDs) including aspirin, naproxen, ibuprofen, mefenamic acid and diclofenac. All with the exception of aspirin were significantly more effective than placebo in producing moderate or excellent pain relief [A]. The NSAIDs were also more effective than paracetamol [A], but side effects included nausea, indigestion, headache, dizziness, drowsiness and dry mouth. There were not any significant disparities in the efficacy or side effects of different NSAIDs. The review included two small studies of the newer, more selective cyclooxygenase-2 (COX-2) NSAIDs, but there was no evidence favouring these over the older preparations. NSAIDs are an effective treatment for dysmenorrhoea [A] and choice will depend on clinician and patient preferences and costs [E]. NSAIDs may be used in combination with other analgesics such as paracetamol or codeine [E].

Combined oral contraceptive pill

These preparations have been widely used for the relief of primary dysmenorrhoea since before the introduction of large randomised controlled trials (RCTs). The theoretical basis for efficacy is inhibition of ovulation. A systematic review²⁴ concluded that combined oral contraceptive pills (COCPs) are significantly more effective than placebo for pain relief [A] although only one of the five trials included in the review was based on the low-dose formulations in current use. A small RCT comparing continuous with cyclical administration of a low-dose third-generation COCP (ethinyl estradiol 20 mcg plus gestodene 0.075 mg)²⁵ reported that initial pain relief was better with continuous administration, but by 6 months the methods were equally effective [B]. There are no data comparing second- and third-generation formulations but the latter are more expensive and carry a marginally higher risk of thrombotic complications. Transdermal or vaginal administration is also available. Despite the lack of high-quality evidence, combined oral contraceptive preparations should be regarded as a safe and effective therapy for the relief of primary dysmenorrhoea [A].

Other hormonal therapies

Other ovulation suppressive therapies for the treatment of menstrual pain secondary to endometriosis (see Chapter 77), such as continuous high-dose progestogens, androgens and gonadotrophin-releasing hormone (GnRH) analogues, are highly effective [A] but there is limited evidence for their long-term use. Low-dose progestogens can also be used. A prospective non-comparative multicentre study²⁶ of 406 women treated with the low-dose ovulation-suppressive progestogen-only contraceptive desogestrel (75 mcg per day) reported a marked reduction of moderate or severe dysmenorrhoea in

93 per cent of the women [C]. Irregular or non-cyclic bleeding was the most prevalent side effect, experienced by 24 per cent, with 3 per cent reporting prolonged bleeding. The levonorgestrel-releasing intrauterine system (LNG-IUS) is effective in the treatment of menstrual pain secondary to both endometriosis and adenomyosis (see Chapters 77 and 78), and should be regarded as another treatment option for women with primary dysmenorrhoea who are seeking contraception, and for those with contraindications to the combined pill [B]. For women whose symptoms are incompletely relieved with NSAIDs or the contraceptive preparations mentioned above, and for those who develop unacceptable side effects, GnRH analogues plus add-back hormone replacement therapy (HRT) are often well tolerated and long-term safety data is reassuring (see Chapter 77).

Alternative therapies for primary and secondary dysmenorrhoea

These are popular with the public and are widely used. A recent review concluded that assessments of efficacy are limited by the poor quality of available information.²⁷ Interventions that have been assessed in RCTs and systematic reviews are summarised in Table 76.2. These trials were not based exclusively on women with primary dysmenorrhoea. Behavioural therapies aimed at improving coping strategies included three trials of relaxation with or without other treatment, one of pain management training and two of biofeedback.²⁸ All showed some evidence of benefit. Physical therapies such as TENS, exercise,²⁹ acupuncture³⁰ and topical heat appear to be of potential value. Of the herbal and dietary therapies subjected to review, only thiamine and magnesium were more effective than placebo,³¹ with moderate-quality evidence for thiamine. A systematic review of 39 trials of Chinese herbal medicine³² found promising evidence of

benefit for primary dysmenorrhoea when compared to acupuncture, heat compression and conventional medication, but (again) conclusions were limited by poor methodological quality.

Although women with chronic non-cyclical pelvic pain were not included in the studies cited above and other robust evidence is also lacking, physical, dietary and behavioural therapies are likely to be applicable as part of a multidisciplinary approach.

Secondary dysmenorrhoea and chronic pelvic pain

Causes of secondary dysmenorrhoea and cyclical and non-cyclical chronic pelvic pain are listed in Table 76.1. Management of endometriosis and adenomyosis are reviewed in detail in Chapters 77 and 78. Interventions for the management of chronic pelvic pain have been the subject of an RCOG Green-top guideline,⁶ a guideline published by the European Society of Urology¹¹ and a systematic review.²²

Multidisciplinary approach

One study²¹ randomised 106 women with chronic pelvic pain to either standard treatment or an integrated approach. Standard treatment included comprehensive exclusion of organic causes, including routine laparoscopy, followed by attention to other causes. In the integrated approach group, laparoscopy was not performed and a gynaecologist, psychologist, physiotherapist and nutritionist assessed all the women. Management was then directed as appropriate. Evaluation 1 year later showed a significantly greater improvement in daily activities and perceptions of pain among the latter group, although pain scores were not significantly different. This

Table 76.2 Alternative therapies for dysmenorrhoea²⁷

Intervention	Nature of evidence	Conclusion
TENS	Systematic review of 7 RCTs	High- but not low-frequency TENS more effective than placebo
Behavioural therapy	Systematic review of 5 RCTs	Possible benefit but data inconsistent ²⁸
Exercise	Systematic review of 1 RCT	Possible benefit ²⁹
Acupuncture or acupressure	Systematic review of 10 RCTs	Some evidence of benefit ³⁰
Spinal manipulation	Systematic review of 2 trials	Inconclusive
Topical heat patch/pad	2 RCTs	Similar efficacy to ibuprofen and more effective than paracetamol
Magnesium	Systematic review of 3 RCTs	Some evidence of benefit but dosage uncertain ³¹
Vitamin E	Systematic review of 1 RCT	Inconclusive
Thiamine (vitamin B1)	Systematic review of 1 RCT	Some benefit with 100 mg daily
Fish oil	2 low-quality RCTs	Inconclusive
Japanese herbal therapies	Systematic review of 1 trial	Inconclusive
Chinese herbal medicine	Systematic review	Evidence of benefit ³²

study and others^{6,10,22} have highlighted the importance of a multidisciplinary approach to chronic pain [B]. A number of organisations can provide additional information and support (e.g. the Pelvic Pain Support Network; www.pelvicpain.org.uk). Pressure on multidisciplinary services may limit the availability of such facilities. A suggested plan of management for patients presenting to a general gynaecological clinic with symptoms of pelvic pain is outlined in Fig. 76.1.

Ovarian suppression

Ovarian suppression has an established role in the management of primary dysmenorrhoea and menstrual pain secondary to endometriosis and adenomyosis (see above and Chapters 77 and 78). Although there is some dispute about the existence of the condition, hormonal suppression has been advocated for women with chronic pelvic pain and dyspareunia attributed to the presence of pelvic varicosities. In a large randomised trial,³³ medroxyprogesterone acetate (MPA) (50 mg daily for 4 months), either alone or in conjunction with psychotherapy, was more effective than placebo or psychotherapy alone for the duration of therapy, but the benefit was not sustained after completion. In a subsequent study, 47 women with chronic pelvic pain and pelvic venous congestion diagnosed by venography¹⁵ were randomised to receive a 6-month course of either the GnRH agonist goserelin or MPA (30 mg daily). Both groups had improved pain scores at

the end of treatment but the improvement was sustained for 12 months afterwards only in the group who received goserelin. Ovarian suppression is also likely to benefit women with pain secondary to trapped or residual ovaries⁷ and those with obstructions to menstrual flow if surgical interventions have failed or are not appropriate.

The results of a randomised placebo-controlled trial of 3 months of treatment with the GnRH agonist depot leuprolide for women with chronic pelvic pain secondary to clinically suspected endometriosis³⁴ showed a significantly greater reduction in dysmenorrhoea, chronic pelvic pain and dyspareunia in the active treatment group. Improvements in pain occurred in some women who were subsequently found at laparoscopy not to have endometriosis. On the basis of this evidence, there seems to be a role for a trial of empirical ovarian suppression in the management of chronic pelvic pain which is cyclically exacerbated [B].

Centrally acting drugs

Regular use of NSAIDs, together with paracetamol or codeine, forms the basis of analgesic management of chronic pain. Use of opiates is not recommended outside a specialised service.⁶ Where pain control is inadequate, tricyclic antidepressants (TCAs) and anti-epileptic drugs such as gabapentinoids are commonly used in the management of chronic pain and particularly neuropathic pain.^{35,36} If, as is postulated, chronic

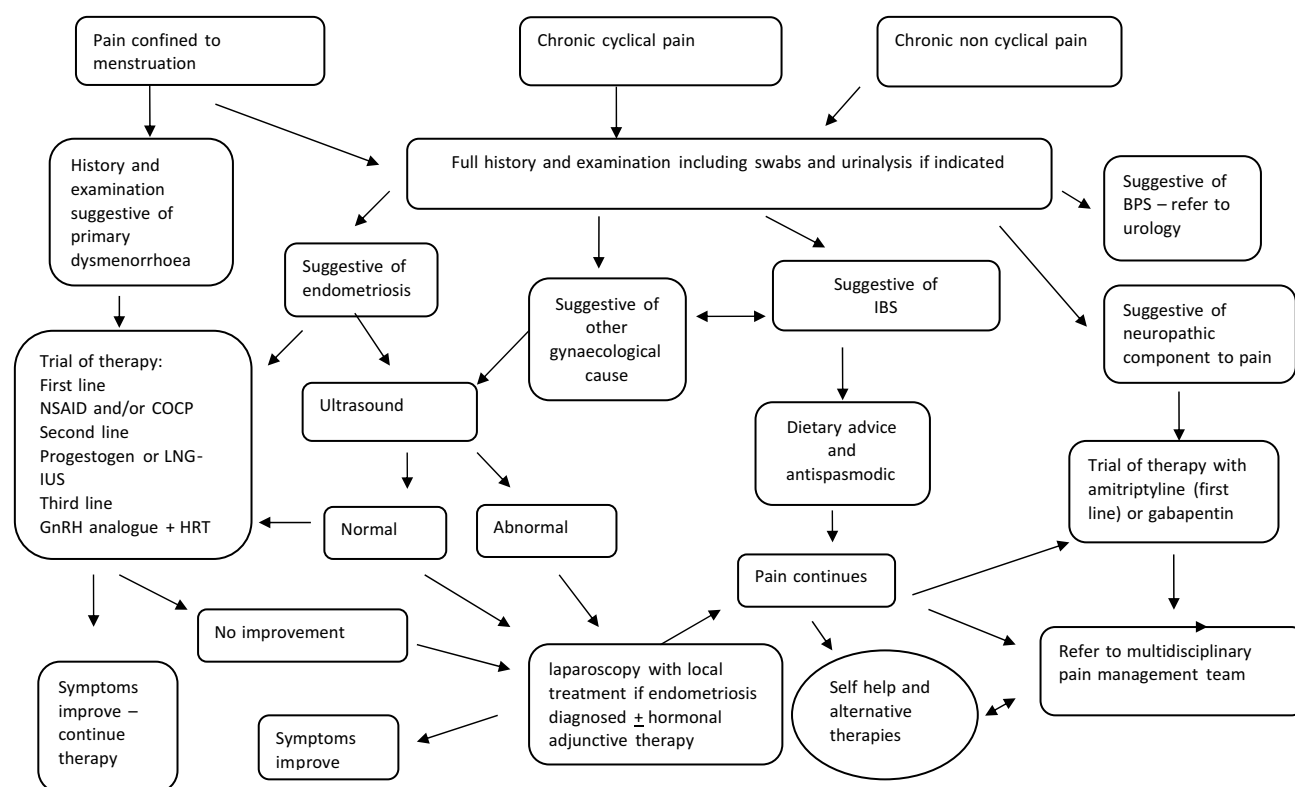

Fig. 76.1 Suggested management of dysmenorrhoea and pelvic pain in a general gynaecological setting

pelvic pain has a neuropathic component, then it is rational to try them in this setting. Amitriptyline should be started at a low dose, typically 25 mg 2 hours before bedtime (can be reduced to 10 mg if required). The drug should be slowly titrated up to effect over a period of several weeks. The target dose will be in the region of 75 mg, although many patients will not tolerate the associated side effects including dizziness, drowsiness and anti-muscarinic effects of dry mouth and blurred vision. The substitution of nortriptyline or imipramine in similar dosages may reduce the side effects, particularly sedation. The analgesic effect of amitriptyline is independent of its action as an antidepressant and other classes of antidepressants (such as selective serotonin reuptake inhibitors [SSRIs]³⁵) are ineffective for pain. With gabapentin, patients are typically started on 300 mg daily and slowly titrated up (over a few weeks) to a target dose of 600 mg three times a day. Side effects include dizziness, drowsiness, peripheral oedema and gait disturbance, although serious effects are rare. Pregabalin has a similar side-effect profile but may be better suited to individual patients. The starting dose is 75 mg twice a day, titrating up to a target dose of 300 mg twice a day.

There is limited evidence to support the use of these adjuvant agents to manage chronic pelvic pain. To date, only one small study (56 patients)^{22,37} has compared gabapentin to amitriptyline for the treatment of chronic pelvic pain. It showed that gabapentin had greater efficacy (80 per cent compared to 70 per cent improvement in pain scores at 12 months). Unfortunately, this study had no placebo arm and the significance of the effect on quality of life was not evaluated.

Nevertheless, increasing evidence supporting a neuropathic and central sensitisation component to chronic pelvic pain has led to the prescription of these agents to good effect in general practice and in multidisciplinary settings [C]. Further studies are required to determine their true efficacy in the treatment of chronic pelvic pain.

Non-gynaecological causes of pelvic pain

Because symptoms of IBS are cyclically exacerbated and there may be associated dyspareunia, women with IBS are frequently seen in gynaecological clinics and there can be diagnostic confusion with endometriosis. The conditions may also coexist, in which case management should be directed towards both.¹² If, on the basis of history and clinical examination, IBS is considered to be the main cause of pain or a contributing factor, dietary advice [C] and a trial of treatment with an antispasmodic agent such as mebeverine hydrochloride (135 to 150 mg three times daily) is appropriate [A].¹⁰ Dietary management should include regular meals and adequate fluid intake with restricted caffeine, alcohol and fizzy drinks.¹⁰ Insoluble fibre such as bran should be avoided in favour of soluble fibre such as oats or ispaghula. Constipation may be managed with laxatives (avoiding lactulose) and diarrhoea with loperamide.¹⁰ Management of IBS falls within the scope of general practice. Chronic pain associated with IBS may be resistant to these standard measures, in which case low-dose amitriptyline is a

second-line treatment [A].¹⁰ In complex cases, multidisciplinary input should be sought.

Urinary symptoms of frequency, dysuria, urgency and nocturia are frequently present in women with chronic pelvic pain, so urinary tract infection (UTI) should be excluded. BPS is usually diagnosed by cystoscopy although appearances vary according to subtypes. Input from a urologist or urogynaecologist may be required. Symptoms of BPS associated with chronic pelvic pain may benefit from treatment with amitriptyline [B].¹¹

Local treatments of myofascial trigger points and pelvic floor muscle spasms involve manual therapy by a specialist physiotherapist.^{7,11,16} Local injections of botulinum toxin have also been used to relieve pelvic floor muscle spasms.^{6,7}

Non-pharmacological therapies targeting the nervous system

Previous approaches to the management of dysmenorrhoea and pelvic pain involved surgical interruption of the sensory nerve pathways, either by removal of the nerve bundles of the hypogastric plexus which overlies the bodies of L 4 & 5 and the sacral promontory (presacral neurectomy – PSN) or ablation of the uterine nerves by division of the uterosacral ligaments (LUNA).³⁷ Both these procedures can be performed laparoscopically but PSN demands considerable surgical expertise. Although there is some evidence of benefit of PSN for uterine pain in severe endometriosis, neither technique is recommended for management of dysmenorrhoea or chronic pelvic pain, regardless of its cause³⁷[A].

Less invasive approaches target the nervous system by external electrical or magnetic stimulation³⁷ to alter neurophysiology locally at the site of pain or centrally, for example transcutaneous electrical nerve stimulation (TENS) which can be useful in the management of dysmenorrhoea. Despite some promising results, these techniques have not been fully evaluated in women with chronic pelvic pain. Direct percutaneous electrical nerve stimulation (neuromodulation) is an alternative approach which has an established role in management of overactive bladder syndrome. Both sacral nerve stimulation (SNS) and pudendal nerve stimulation (PNS) have evidence of benefit in small scale studies of women with chronic pelvic pain and one small cross-over study showed greater benefit for PNS.³⁷ PNS has also been used in the management of pudendal neuralgia. These data are very preliminary and long term follow up is lacking. Currently neuromodulation should only be undertaken in specialist centres which can provide multidisciplinary care [E].

Other surgical approaches for chronic pelvic pain

Adhesions may be seen in up to one quarter of laparoscopies for pelvic pain,⁸ usually as a consequence of previous surgery or inflammatory conditions. The mechanism of their contribution to the pain is unclear and in many cases there may be a neuropathic component. Studies evaluating surgical division of adhesions have shown minimal or no improvement of pelvic pain²² [A] with the exception of women undergoing

laparoscopic division of severe adhesions. Hysterectomy may be beneficial for secondary dysmenorrhoea attributed to endometriosis or adenomyosis but its role in chronic pelvic pain is unclear. A trial of therapy with a GnRH agonist should be undertaken before consideration of hysterectomy in such cases [E]. A review of five studies of women undergoing hysterectomy for chronic pain presumed to be of uterine origin³⁹ reported that symptoms were relieved in 83 to 97 per cent of women at 12-month follow-up [D]. However, the results of these studies showed that failure of pain relief was greatest among women with no demonstrable pelvic pathology, once again emphasising the importance of a multidisciplinary approach for women with unexplained pelvic pain.

EBM

Recommendations for the management of primary and secondary dysmenorrhoea are based on eight systematic reviews, five of which address alternative therapies. The management of chronic pelvic pain has been the subject of one systematic review, an RCOG Green-top guideline and an international guideline from the European Association of Urology.

KEY POINTS

- Primary dysmenorrhoea is experienced by more than two thirds of women and a minority are severely incapacitated.
- Investigation of suspected primary dysmenorrhoea is unnecessary unless there are atypical symptoms or abnormal findings on pelvic examination [C].
- Ultrasound is a useful non-invasive method for the detection of pelvic abnormalities [A], backed up by MRI if appearances are equivocal.
- The multifactorial nature of chronic pelvic pain should be discussed and explored from the start [B].
- Pain resulting from disturbances in the central or peripheral nervous system (neuropathic pain) is an important component of chronic pelvic pain [C].
- Laparoscopy has a limited role in the investigation of chronic pelvic pain [B].
- NSAIDs are effective for the first-line management of primary dysmenorrhoea [A].
- COCPs are effective in primary dysmenorrhoea, although much of the evidence is largely based on higher-dose formulations than those in current use [A].
- Continuous progestogens at doses which suppress ovulation [C], the LNG-IUS [B] and GnRH analogues with add-back HRT [A] can be used for the relief of primary dysmenorrhoea.
- Alternative therapies, including physical and behavioural therapy, dietary supplements (magnesium, vitamin B1) and

Chinese herbal medicine may have a role in the management of dysmenorrhoea [C].

- Chronic pelvic pain which is cyclically exacerbated may be relieved by a trial of ovulation suppression [B].
- IBS, BPS and musculoskeletal abnormalities are often present in women with chronic pelvic pain and treatment should be directed towards all the components of the problem [C].
- Centrally acting drugs such as amitriptyline and gabapentin appear to have a role in the management of chronic pelvic pain [C].
- Other classes of antidepressants are not effective in the management of chronic pain [B].
- There is insufficient evidence to support the use of pelvic nerve interruption for the relief of primary or secondary dysmenorrhoea [A].
- There is no evidence that division of adhesions relieves chronic pelvic pain, with the possible exception of severe dense avascular adhesions [B].
- Where possible, chronic pelvic pain should be managed in a multidisciplinary clinic [A].

ACKNOWLEDGEMENT

With thanks to Professor Andrew W Horne for his helpful advice during the preparation of this chapter.

Chapter 77 Endometriosis

Christine P West

MRCOG standards

Theoretical skills

- Understand the epidemiology, pathogenesis and clinical features of endometriosis.
- Be able to investigate suspected endometriosis and refer more complex cases where appropriate.
- Understand the nature, complications and adverse effects of medical and surgical management of endometriosis-associated pain.

Practical skills

- Understand the ultrasound diagnosis of endometrioma.
- Be familiar with the technique of diagnostic laparoscopy and staging of endometriosis.
- Understand the surgical techniques for treatment of mild to moderate endometriosis and endometrioma and be able to recognise and manage complications.

INTRODUCTION

Endometriosis is defined by the presence of ectopic endometrial tissue in extrauterine sites, usually within the pelvis. It is a common condition with many diverse manifestations and a clinical course that is highly variable and unpredictable. It may be asymptomatic, but most commonly presents with pelvic pain that is typically cyclical and in severe cases there may be associated bowel or bladder symptoms. The site of the lesions deep in the pelvis can also cause dyspareunia and there is a well-recognised but poorly understood association with subfertility. Endometriosis is usually regarded as distinct from adenomyosis (see Chapter 78), in which endometrial tissue is present within the myometrium.

Management should be individualised and will depend on the patient's symptoms, her age and reproductive plans. This chapter deals mainly with the management of pain in endometriosis, which has attracted a large literature and for which evidence-based management is relatively well developed.

PREVALENCE

Data from the UK General Practice Research Database¹ suggests that the prevalence of diagnosed endometriosis in women aged 15–55 years is 1.5 per cent. This is considerably lower than previous estimates based on series of women undergoing laparoscopy for various indications. In a prospective study of 1542 Caucasian women in a single Scottish centre² endometriosis was visualised in 6 per cent of women undergoing sterilisation, 21 per cent being investigated for infertility and 15 per cent being investigated for pelvic pain. Prevalence in other case series of women undergoing laparoscopy for investigation of pelvic pain has generally been higher, varying between 23 and 80 per cent.³ Women with endometriosis are more likely to have complained of abdominopelvic pain, dysmenorrhoea, dyspareunia, subfertility and menstrual bleeding disorders compared with a control population.¹

EPIDEMIOLOGY

Endometriosis is an oestrogen-dependent inflammatory condition and is thus a disease which affects women of reproductive age with regression after the menopause. It is most typically diagnosed in women aged 25–30 years but has been described in adolescents, in particular those with structural abnormalities of the reproductive tract. Factors which reduce menstruation, such as pregnancy and the use of oral contraceptives,^{2–4} reduce its prevalence while early menarche, shorter menstrual cycles and nulliparity are associated with increased prevalence. There are also reports of reduced prevalence among current smokers and women with higher body mass index (BMI).¹ Observation of regression after pregnancy formed the basis for development of hormonal therapy for disease suppression. There are no clear racial or ethnic differences but the incidence is increased 7–10-fold among first-degree relatives.²

PATHOGENESIS

It is a generally accepted theory that endometrial tissue reaches the pelvis by retrograde menstruation.³ Resulting peritoneal

tissue implants release local inflammatory mediators, such as cytokines, growth factors and prostaglandins, in response to hormonal stimulation. Haematogenous or lymphatic spread in a minority of cases may account for the rare occurrence of endometriosis at distant sites. Retrograde menstruation is observed in up to 90 per cent of women but only a minority of women develop endometriosis. It is most likely that tissue implantation is a result of failure of clearance mechanisms which may be secondary to defects in the local peritoneal immune defence system in susceptible individuals. Whatever the underlying mechanisms, it is evident that the symptoms and the progression of the disease differ considerably amongst individuals, with a poor correlation between laparoscopic appearances and clinical symptoms. Results from second-look laparoscopy in treatment trials³ have found short-term spontaneous regression of lesions in around one third of women receiving no active treatment, no change in another third and progression in the remaining third. Genetic factors appear to be relevant and these may influence local response mechanisms and the subsequent course of the disease.

Endometriomas, also known as chocolate cysts, are retention cysts which form when inflammatory adhesions develop between endometriotic deposits on the ovary and the pelvic side wall or around a superficial ovarian lesion, producing progressive inversion of the surrounding cortex. Endometriomas may be multiple and very large, when they inevitably interfere with fertility by adhesion and distortion of the Fallopian tubes.

In some women with endometriotic lesions predominantly affecting the uterosacral ligaments, marked fibrosis and scarring may develop, with infiltration of active endometriotic tissue into the rectovaginal septum or laterally to involve the ureters. Dense adhesions involving the rectum may lead to partial or complete obliteration of the pouch of Douglas. Deep infiltration may also occur on the uterovesical fold, leading to bladder involvement. It is not known why some women develop these more invasive forms of endometriosis.

The mechanism of pain in endometriosis is presumed to involve the release of inflammatory mediators. Pain related to deep lesions may be in part caused by infiltration or

constriction of nerves or may be secondary to adhesions. Development of chronic pain is thought to be attributable to a mechanism whereby endometriotic lesions may develop their own nerve supply,⁵ thereby creating a direct and two-way interaction between lesions and the CNS. Theories regarding the causation of chronic pelvic pain are discussed in Chapter 76.

MANAGEMENT

Investigation

The commonest presenting symptoms of endometriosis are dysmenorrhoea, chronic cyclical or non-cyclical pelvic pain, deep dyspareunia and infertility. Their non-specific nature makes diagnosis difficult and there is typically delay in referral from primary care¹ and confusion with other conditions, in particular pelvic inflammatory disease (PID) and irritable bowel syndrome (IBS). Dyschezia (pain with defaecation) and severe deep dyspareunia may be indicative of the presence of deep endometriosis.

Bimanual pelvic examination is important in facilitating diagnosis (Table 77.1) [C].⁶ The posterior vaginal fornix should be inspected for the presence of visible lesions. Rectal examination is useful in cases where symptoms are suggestive of rectosigmoid involvement. In many cases the examination is unhelpful and the decision to carry out further investigation is based on the history and the wishes of the patient. Levels of serum CA-125 are likely to be raised in severe disease but there is no evidence that this is useful as a screening test [A]⁶ and it can lead to confusion with malignancy.

Transvaginal ultrasound is of value in detecting ovarian endometriomas (Table 77.1) [A].⁷ It was also found to be accurate for pre-surgical detection of deep endometriosis of the rectosigmoid [A].⁸ However, evaluation of deep lesions by ultrasound is operator dependent and considerable experience is required [E]. Other imaging techniques used in the assessment of the extent of deep endometriosis are barium studies, transrectal sonography and MRI.^{6,9} Currently all appear to be

Table 77.1 Diagnosis of endometriosis

Pelvic examination findings suggestive of deep endometriosis	Ultrasound features diagnostic of endometrioma ⁶	Laparoscopic appearances of endometriosis
- Palpable induration and/or nodules on vaginal walls, uterosacral ligaments or pouch of Douglas	- Ground glass echogenicity	- Red, clear or black superficial deposits or vesicles
- Visible cysts or nodules in the posterior fornix	- 1-4 compartments	- Deeper lesions of peritoneum or ovaries (endometrioma)
- Adnexal masses	- No papillary structures with detectable blood flow	- Associated adhesions
		- Reduced ovarian mobility
		- Partial or complete cul-de-sac obliteration

of value in individual cases [D]. MRI has no advantage over ultrasound in the routine assessment of endometriomas [A]⁶ but may assist in the evaluation of deep lesions [C].

Laparoscopy for diagnosis of endometriosis

Laparoscopy, backed up by biopsy, is regarded as the 'gold standard' investigation for diagnosis of endometriosis [E]. However there is little good-quality literature assessing the value of visual diagnosis of endometriosis at laparoscopy.¹⁰ A systematic review of observational studies¹⁰ comparing visual findings with biopsy results concluded that laparoscopy is highly accurate for excluding endometriosis but a positive laparoscopy is of less value in the absence of histology. Its predictive value is higher in cases of moderate/severe disease, compared with minimal/ mild disease.

Laparoscopy must involve a two-port approach with careful inspection of the uterus and adnexae, uterovesical fold, pouch of Douglas, uterosacral ligaments, pelvic side wall and ovarian fossae [E].⁶ Where necessary, careful mobilisation of the ovaries should be attempted in order to inspect their anterior surface, as the presence of adhesions is strongly suggestive of endometriosis. The quality of laparoscopy is dependent on the experience of the surgeon carrying out the procedure and the operator must appreciate the varied appearances of endometriosis (Table 77.2). Visible evidence of endometriosis should be confirmed by biopsy [E],^{6,10} although this procedure is not without risk in inexperienced hands. Photographs or video recordings are helpful in the documentation of disease extent and use can be made of diagrams, in particular those based on the American Society for Reproductive Medicine (ASRM) classification, previously known as the American Fertility Society (AFS) classification (Table 77.2).¹¹ Although useful in research and in planning surgery, ASRM scores correlate poorly with pain symptoms [C].³ It is important to carry out

an adequate bimanual pelvic examination to detect features suggestive of deep endometriosis which may not be easily visualised laparoscopically.⁶

Laparoscopy is an invasive procedure and not without risk (Table 77.3)¹². For some patients with pain symptoms suggestive of the disease it will be preferable to undertake a therapeutic trial of hormonal suppression as initial management.⁶ All cases require an informed discussion of the various options and, for those undergoing laparoscopy, its nature and risks must be fully discussed [E]. Counselling must include discussion about the possible courses of action should endometriosis be diagnosed at the primary procedure. Best practice is to carry out surgical ablative therapy, if appropriate, at the initial laparoscopy,⁶ depending on the facilities and expertise

Table 77.3 Major complications of laparoscopy (diagnostic and minor surgical interventions). Data from a case series of 29,996 procedures¹² expressed as number (rate per 1000)

Complication	Diagnostic (n = 5983)	Minor ^a (n = 5922)
Bowel damage (all)	3 (0.5)	2 (0.3)
Haemorrhage (all):	7 (1.2)	3 (0.5)
- Major vascular	1	0
- Abdominal wall/ omentum	6	3
Urological damage (all):	1 (0.2)	0
- Bladder	1	
- Ureter		
Total	11 (1.8)	5 (0.8)
Laparotomy ^b	8 (1.3)	2 (0.3)

^a ablation of minimal/mild endometriosis, minor adhesiolysis, sterilisation, ovarian biopsy;

^b complications requiring treatment by laparotomy.

Table 77.2 ASRM (AFS) revised classification of endometriosis¹¹ scoring system

Stage	Score*	Example findings
I minimal	1-5	Superficial lesions ± filmy adhesions
II mild	6-15	More extensive superficial lesions ± adhesions ± small endometrioma (less than 1 cm)
III moderate	16-40	Likely to include deep lesions e.g. endometrioma >1 cm ± partial or complete ovarian enclosure but no more than partial obliteration of the cul-de-sac (pouch of Douglas)
IV severe	>40	Extensive disease; likely to have deep lesions (± endometrioma) and dense adhesions with complete obliteration of the cul-de-sac (pouch of Douglas)

* Score based on total extent (cm) of lesions; whether superficial or deep; presence of filmy or dense adhesions; degree of ovarian enclosure; size of endometrioma; presence of partial or complete obliteration of the cul-de-sac (pouch of Douglas)

e.g. Endometrioma 1-3 cm score 16; >3 cm score 20

- Ovarian enclosure 1-2/3 score 8; >2/3 score 16
- Complete cul-de-sac obliteration score 40

available, provided that adequate informed consent has been obtained [E].

Medical management of pelvic pain associated with endometriosis

There is a large evidence base supporting the use of medical therapy in the management of endometriosis-associated pain [A]. The majority of these therapies act by ovarian suppression and induction of amenorrhoea, resulting in inactivation of local deposits. As all the hormonal therapies have similar efficacy, their tolerability in terms of immediate and long-term side effects is important when selecting the most appropriate treatment for an individual woman [A].^{3,6} As discussed above, medical therapy may be initiated for the relief of pain symptoms in the absence of a definitive diagnosis of endometriosis. In women wishing to conceive, hormonal therapy is not appropriate, as it delays rather than enhances fertility [A].⁶ However, medical suppression may be of value in pain control, for example in women awaiting IVF [E].

Non-steroidal anti-inflammatory drugs (NSAIDs)

These offer a non-hormonal approach that is particularly useful in women trying to conceive and they are widely used in clinical practice. However, few studies have addressed their role in management of endometriosis-associated pain⁶ and evidence for their efficacy is largely based on their use in the treatment of primary dysmenorrhoea (see Chapter 76) [A].

Combined oral contraceptives

The combined oral contraceptive pill (COCP) is an effective treatment for dysmenorrhoea (see Chapter 76) and suppression or reduction of menstruation with continuous or tri-cyclic use of a COCP is commonly used for management of pain associated with endometriosis, although few randomised trials have addressed its use.^{6,13} Cyclical administration of a low-dose COCP was as effective as a gonadotrophin-releasing hormone (GnRH) agonist¹³ in the management of dysmenorrhoea and non-menstrual pain in one study, although less effective for dyspareunia [B]. Indirect evidence from a systematic review of contraceptive studies¹⁴ showed that continuous- or extended-dose regimens are marginally more effective than cyclical therapy in improving dysmenorrhoea [A]. Reduction of endometriosis-associated pain with both cyclical and continuous use of the COCP has been reported in a systematic review comparing their efficacy with that of progestogens.¹⁵ One randomised trial comparing 24 months of continuous or cyclical COCP use with no therapy¹⁶ following surgical excision of endometrioma has shown significantly lower rates of recurrence of dysmenorrhoea with continuous compared with cyclical use [B]. Overall this evidence supports the use

of combined oral contraceptives for suppression of pain in endometriosis [B]. Continuous rather than cyclical use may be preferable for pain management [B]. Administration by transdermal patch or vaginal ring can also be considered [C].⁶ Because of their relative safety, combined hormonal contraceptives are suitable for long-term use.

Progestogens

Progestogens given continuously inhibit ovulation, depending on dosage, and have direct antiproliferative effects on endometriotic implants, causing decidualisation and eventual atrophy. They have been widely used for the treatment of pain in endometriosis and are the subject of a systematic review.¹⁵ No significant difference in pain scores was found in two trials comparing DMPA (Depo-Provera 150 mg 3-monthly) with GnRH analogues. Oral progestogens including medroxyprogesterone acetate 30 mg daily, dienogest 2mg daily and desogestrel 75 mcg daily were also found to have similar efficacy when compared with GnRH analogues or oral contraceptives although numbers in the individual studies were small. Cyclical administration of progestogens was ineffective. A small non-randomised study has recently shown that low-dose norethisterone acetate 2.5 mg daily may effectively relieve chronic cyclical pain and dyspareunia in women with deep endometriosis [C].¹⁷

The most commonly reported side effect of progestogens is breakthrough bleeding, with an overall incidence of around 33 per cent¹⁵ which is not dose related. Other side effects which are likely to be dose related include weight gain, breast tenderness, bloating, headache, acne and nausea. On the basis of the evidence from the systematic review,¹⁵ continuous oral or depot progestogens can be used for suppression of endometriosis-associated pain [A] although their usefulness may be limited by side effects. Further evaluation of the role of oral desogestrel 75 mcg in endometriosis would be helpful, given its popularity as a progestogen-only contraceptive.

LNG-IUS

The levonorgestrel-releasing intrauterine system (LNG-IUS) does not suppress ovulation but acts locally on the endometrium. Its effect on extrauterine endometrial tissue is therefore locally mediated. A multicentre randomised trial comparing the LNG-IUS with a GnRH agonist¹⁸ reported no difference in pain scores after 6 months [B]. A systematic review of its use following laparoscopic treatment of endometriosis¹⁹ reported a significantly reduced incidence of recurrence of painful periods with the LNG-IUS compared with no treatment after 12 months and no significant difference when compared with a GnRH agonist. Although bleeding scores were higher with the LNG-IUS compared with the GnRH agonist, there was no difference in pain or quality-of-life assessments between the two groups. On the basis of these results, the LNG-IUS seems to have a role in the management of pain associated

with endometriosis whether as a primary treatment [B] or for prevention of recurrence of pain following surgical treatment [A].

Androgens

Gestrinone is a 19-nortestosterone derivative that also has progestogenic and antiprogestogenic actions. It has been compared with danazol and with a GnRH analogue in randomised trials.^{15,20} Reduction of pain scores was not significantly different [A], but both androgenic and hypo-oestrogenic side effects were less frequent with gestrinone. Side effects of gestrinone were reduced by lowering the dose from 2.5 mg twice weekly to 1.25 mg twice weekly without a reduction in efficacy [A].¹⁵ The reported incidence of breakthrough bleeding is much lower with gestrinone than with progestogens, making it a potentially useful alternative to other therapies [A]. However, there is a lack of information relating to its long-term safety.

Danazol is an androgenic steroid, which acts both centrally and locally to suppress steroidogenesis and induce endometrial atrophy.⁶ It induces amenorrhoea and significantly improves pain at doses of 400–600 mg daily [A] but androgenic side effects such as weight gain, limb tingling, acne, greasy skin, hirsutism and deepening of the voice are common, and atherogenic effects on lipid profiles have been reported. For this reason it is not currently recommended for endometriosis if other alternatives are available.⁶ Neither danazol nor gestrinone is associated with bone loss and therefore both are potential alternatives to GnRH analogues for women susceptible to bone loss and in whom oestrogenic add-back preparations are contraindicated (see below).

GnRH analogues

GnRH agonists down-regulate pituitary GnRH receptors leading to inhibition of follicle stimulating hormone and luteinising hormone production. This leads to gonadal suppression when administered by nasal spray or monthly or 3-monthly depot injection (Table 77.4). The intranasal route tends to be less costly, while depot administration improves compliance.

A summary of results of a systematic review of randomised controlled trials (RCTs) of GnRH agonist therapy

have demonstrated its effectiveness in the treatment of pain associated with endometriosis [A]²⁰ when compared with placebo or no treatment. Comparison with danazol and the LNG-IUS demonstrated no significant differences in clinical response but expected differences in side-effect profiles. The side effects of GnRH agonists include hot flushes, insomnia, vaginal dryness, reduced libido and headaches – all secondary to oestrogen suppression.

Longer-term use of GnRH analogues

It is usual to prescribe a GnRH analogue for an initial period of 3 months and, if effective, to continue for a total of at least 6 months prior to further review [E]. In common with other medical treatments, GnRH agonists do not produce permanent disease regression. A life-table analysis of follow-up of women treated with various GnRH agonists for 6–9 months²¹ reported a cumulative symptomatic recurrence rate of 53.4 per cent after 7 years [C]. For severe disease, the recurrence rate was 74.4 per cent, while for minimal disease it was 36.9 per cent. Therefore many women require subsequent courses of treatment and, in some cases, treatment may be long term. In this situation loss of bone mineral density is a major concern and for this reason GnRH analogues should not be given as single agents for longer than 6 months [A]. In women needing longer-term treatment, hormonal add-back therapy can be used with the object of reducing or preventing bone loss and minimising other side effects related to oestrogen deficiency. Several continuous combined HRT regimens using oral or transdermal oestrogens in combination with various progestogens have been compared with placebo in patients treated with GnRH agonists for endometriosis.²² All were effective in control of endometriosis-related pain while reducing vasomotor side effects and maintaining bone density during treatment and up to 12 months after discontinuation of treatment. However 2 years after discontinuation of treatment, bone density had recovered in the group treated with GnRH agonists alone.

Progestogens alone and calcium supplements are not effective in preventing bone loss.²² For women who cannot tolerate hormonal add-back or for whom it is contraindicated, anti-resorptive agents, such as bisphosphonates, have been used for bone protection but evidence of their efficacy to date is currently insufficient.²²

Table 77.4 Gonadotrophin-releasing hormone agonists. Data from British National Formulary indicating whether each preparation is licensed for treatment of endometriosis.

Name	Monthly depot	Licensed indication	3-monthly depot	Licensed indication	Intranasal	Licensed indication
Buserelin					300 mcg tid	Yes
Goserelin	3.6 mg SC	Yes	10.8 mg	No		
Leuprorelin acetate	3.75 mg SC/IM	Yes	11.25 mg IM	Yes		
Nafarelin					200 mcg bd	Yes
Triptorelin	3.0 mg IM	Yes	11.25 mg IM	yes		

These results support the role of add-back therapy with GnRH agonists to suppress endometriosis-associated pain when given as continuous low-dose oestrogen–progestogen combinations [A]. Tibolone is licenced in the UK for bone protection when used in conjunction with GnRH analogues although there is a lack of published data to compare its effectiveness with that of other add-back therapies and it is more costly than other alternatives.

Aromatase inhibitors

Aromatase is responsible for the conversion of androgens to oestrogens and there is evidence for its expression in endometriotic tissue.²³ It has been suggested that a feedback loop involving local induction of aromatase by prostaglandin E2 may promote oestrogen production and thereby growth of lesions. There have been some reports based on individual cases or small series²³ of a positive effect of the use of aromatase inhibitors, usually in combination with another hormonal therapy, for severe or refractory pain associated with rectovaginal endometriosis. One RCT comparing a GnRH agonist alone with a GnRH agonist plus anastrozole reported a significant improvement in pain scores over 24 months with the combined therapy. However these agents are associated with hypo-oestrogenic side effects and bone loss and thus their role in management of endometriosis has yet to be established.

Choice and duration of medical therapy

As discussed above, hormonal therapies are effective for relief of endometriosis-associated pain [A]. As all appear to have similar efficacy, their use in individual patients will depend on factors such as the degree of symptom relief, side effects and cost [E]. Because hormonal suppression merely inactivates and does not remove local disease, symptoms recur after cessation in a proportion of patients and, for some, treatment may potentially be long term. COCP, progestogens and the IUS are considerably less costly than GnRH analogues but the latter have the advantage of more reliably inducing amenorrhoea with a lower incidence of hormonally related side effects such as bloating, breast tenderness, headaches and mood changes, even with the addition of low-dose HRT. The costs of hormonal therapies used to suppress ovulation are compared in Table 79.2, Chapter 79.

Treatment with an NSAID and/or a COCP could be the first-line approach in the absence of specific indications for laparoscopy,²⁴ with use of the IUS or a continuous progestogen if oestrogenic preparations are contraindicated or give rise to side effects [E]. There is no evidence regarding the optimum duration of these therapies for endometriosis but if effective and well tolerated, evidence from contraceptive studies [A] is that all are suitable for long-term use. Women presenting to secondary care are likely to be those whose symptoms have not responded adequately to initial therapies. In such cases, treatment with a GnRH agonist would be preferable to use of

an androgenic preparation [E].⁶ A 2–3 month trial of treatment with a GnRH agonist in cases of presumed endometriosis, continued for 6 months if pain symptoms are improved, is recommended as more cost effective than initial laparoscopy with local ablation in cases of clinically suspected endometriosis,²⁴ given that the incidence of longer-term symptom recurrence is similar. However others²⁵ would challenge this approach. The role of medical therapy in women who have undergone surgical treatment is discussed below.

Adjuvant therapies

Chronic pelvic pain in endometriosis may be resistant to hormonal suppression. Increasing evidence supporting a neuropathic and central sensitisation component to endometriosis-associated chronic pain has led to the use of tricyclic antidepressants such as amitriptyline and anti-epileptic drugs such as gabapentin for the management of endometriosis-associated chronic pain [C]. These therapies are discussed in Chapter 76.

Complementary therapies

Many patients with endometriosis-associated pain seek non-conventional approaches to manage their symptoms. The evidence for the use of such therapies for primary and secondary dysmenorrhoea is reviewed in Chapter 76. Few high-quality studies have specifically addressed their role in endometriosis. A systematic review of 24 studies of the use of acupuncture concluded that only one was of sufficient quality for inclusion.²⁶ This compared auricular acupuncture with Chinese herbal medicine and demonstrated similar efficacy for mild and moderate endometriosis-associated pain but a significantly better reduction of severe pain with acupuncture [B]. Further studies are required comparing various types of acupuncture with conventional therapy.

The role of surgery for endometriosis-associated pain

Unlike medical therapies, there have been few controlled studies of surgical approaches for the management of

Table 77.5 Major complications of laparoscopic surgical procedures. Data from a case series of 29,996 laparoscopies.¹²

Procedure	Complications	Rate (%)
Major adhesiolysis ^a	22/2665	0.83
Benign cystectomy ^a	17/3908	0.44
Ablation moderate/severe endometriosis	3/1894	0.16
Deep endometriosis ^b	7/174	4.02

^a Procedures not specific to endometriosis;

^b Study published in 1998 and may not reflect current practice

endometriosis-associated pain, although the latter have gained a large literature and surgical interventions, mainly involving laparoscopy, are widely used. Because operative laparoscopy is associated with a significant risk of major complications (see Tables 77.3 and 77.5) [C]^{3,12} such interventions require critical review.

To date there have been only five RCTs of laparoscopic surgical treatment of endometriosis,²⁷ including a total of 246 women. These have compared local excision or ablation using various techniques with diagnostic laparoscopy alone (four trials) or with diagnostic laparoscopy followed by medical therapy (one trial). Presence of severe disease was generally an exclusion criterion. A systematic review of these five trials²⁷ reported a significant benefit from laparoscopic surgery [A]. Overall 75 per cent of the women who had active intervention reported an improvement in pain at 6 months, compared with 32 per cent of those following laparoscopy only. At 12 months, 73 per cent continued to report a benefit, compared with 21 per cent of the control group although the 12-month data were based on only one of the trials.

These small-scale studies, carried out in nationally recognised laparoscopic surgery centres, support the use of conservative laparoscopic surgery for the relief of pain in endometriosis [A] but more data are needed from larger studies to establish the duration of benefit and how this is influenced by the severity of the disease. No serious surgical complications were reported, but these results may not be reproducible in a more general context, in terms of both efficacy and safety [E].

Additional laparoscopic procedures that may be used for treatment of pain associated with endometriosis involve surgical interruption of pelvic nerve pathways. Laparoscopic uterine nerve ablation (LUNA) is a relatively simple procedure but was not found to confer any significant benefit when used as an adjunct to laparoscopic surgical treatment of endometriosis in three randomised trials [A].²⁸ In contrast, three trials of presacral neurectomy (PSN) as an adjunct to surgical ablation showed some benefit for dysmenorrhoea²⁸ but no significant difference in backache or lateral pain. Direct comparison of the two techniques in a single study also favoured PSN but side effects, in particular constipation and urinary urgency, were significantly higher with PSN. The latter procedure is technically demanding^{6,28} and therefore limited to highly specialised centres.

Surgical excision or ablation at the time of the initial laparoscopy is cost effective for pain management [B]²⁵ and also improves pregnancy rates in women with ASRM stage I or II (minimal or mild) endometriosis [A].⁶ Therefore, regardless of the indication for laparoscopy for assessment of suspected endometriosis, the procedure should be carried out by a gynaecologist able to carry out ablative treatment, preceded by appropriate preoperative patient assessment, counselling and consent.

Surgical management of endometriomas

Although endometriomas may be asymptomatic, their presence in association with pain is usually regarded as an indication for laparoscopic surgical intervention. Endometriomas do not usually resolve during medical suppression, although, if small, they may reduce in size and become asymptomatic. Simple drainage of an endometrioma is followed by rapid recurrence, even if it is fenestrated and irrigated [A].²⁹ A systematic review of two randomised trials of laparoscopic management of endometriomas larger than 3 cm²⁹ has indicated a higher rate of recurrence following coagulation of the inner lining of the cyst compared with excision. Laparoscopic excision is therefore the surgical treatment of choice [A]. In women with subfertility, surgical excision of endometriomas is associated with an improved chance of spontaneous pregnancy compared with drainage and coagulation [A].⁶ However cystectomy is followed by a significant and sustained fall in serum anti-Müllerian hormone,³⁰ indicating a reduction of ovarian reserve [A]. This reduction appears to be greater following removal of larger or bilateral lesions and has implications for the counselling of women undergoing surgical management of endometrioma.

Medical adjuncts to surgery

Surgical ablation is not curative and recurrence of pain is reported to be around 15 per cent at 1 year, 36 per cent after 5 years and 50 per cent by 7 years.³ There have been a number of studies addressing the role of medical adjuncts to surgery for endometriosis. There is no evidence to support their use prior to surgery [A].³¹ Drugs which suppress ovarian activity are frequently used following conservative surgery of endometriosis. Published evidence on their role is however conflicting. A systematic review of 12 RCTs which compared 3 or 6 months of ovarian suppression treatment with placebo or no treatment following surgery³¹ reported a significant reduction of pelvic pain at 12 months but no difference in its subsequent recurrence. It was concluded that there was insufficient evidence to recommend their short-term use [A]. However a systematic review of three RCTs¹⁸ concluded that insertion of a LNG-IUS at the time of surgery resulted in an 8.8 per cent incidence of painful symptoms after 12 months, compared with 38.3 per cent with no treatment [A]. Other studies have reported a significant reduction in frequency and severity of recurrent dysmenorrhoea and in recurrence of endometrioma but not dyspareunia with cyclical or continuous COCP given for 2 years following surgery [B].³² Continuous use of the COCP may be more effective than cyclical use for control of dysmenorrhoea and chronic pelvic pain.^{16,32} This evidence supports the longer-term use of hormonal contraceptives following surgery to prevent recurrence of endometrioma or dysmenorrhoea [B] where appropriate for individual women, in particular those needing contraception or planning to delay child-bearing.⁶

Management of pain in deep endometriosis

Surgical treatment of advanced disease where there are dense adhesions and deeply infiltrating lesions involving the rectovaginal septum can be effective in relieving pain [B] but requires advanced laparoscopic surgical skill and training and a multidisciplinary approach due to the potential need for bowel resection or excision of bladder or ureteric lesions.^{3,6} Appropriate presurgical assessment by imaging⁹ is essential and these procedures should only be carried out in specialist regional centres [E]. Where issues of safety arise, laparotomy still has a role in the conservative management of advanced disease [B]^{3,6} both for pain management and for preservation of fertility.

There is limited evidence for long-term efficacy of surgery for advanced disease in terms of recurrence of pain or subsequent pregnancy outcome. Long-term medical therapy may also be an appropriate option.⁶ A review of small case series and one randomised trial³³ concluded that various forms of hormonal suppression, including the LNG-IUS, relieved pain in 60–90 per cent of women with rectovaginal endometriosis [C], thereby offering a non-invasive option for women wishing to avoid surgery or for those experiencing persistent or recurrent pain following previous surgery. Use of adjuvant therapy where chronic pain is not relieved with conventional treatment is mentioned above and discussed in Chapter 76.

Definitive surgery

For women with symptomatic endometriosis who have completed child-bearing, hysterectomy with or without bilateral salpingo-oophorectomy is frequently carried out with the objective of achieving a definitive cure. However in cases of advanced disease with dense adhesions and deep lesions in the rectovaginal septum, complete removal of the disease requires a very radical approach⁶ with careful consideration of the risks. A long-term follow-up study of women undergoing surgery for pelvic pain in a regional centre where hysterectomy was accompanied by excision of all visible disease³⁴ reported that 23 per cent of those who had ovarian conservation required further surgery within 7 years of follow-up, compared with 8.3 per cent following ovarian removal. These results support the removal of ovaries in women undergoing hysterectomy for severe endometriosis [C]. Women should be counselled that hysterectomy may not be curative [E].⁶

Hormone replacement therapy and endometriosis

Following hysterectomy plus oophorectomy, or oophorectomy alone for severe endometriosis, there is a risk that use of hormone replacement therapy (HRT) may activate small

foci of residual disease.⁶ This is likely to be greater with unopposed oestrogen compared with combined oestrogen and progestogen therapy or with cyclical use of HRT. Unfortunately there is a shortage of evidence to address this issue. A systematic review³⁵ identified only two RCTs, neither of which included an oestrogen-only or a continuous combined preparation. In both, cyclical sequential administration of oestrogen and progestogen was compared with, in one trial, tibolone and in the other, placebo. There was a small incidence of endometriosis-related symptom recurrence with active treatment but not with the placebo. Symptom scores with tibolone were lower than with the combined preparation but none of the results reached statistical significance. The risk of symptom recurrence with HRT has to be balanced against the well-established sequelae of oestrogen deficiency in young women. Similarly the theoretical benefit of using an oestrogen–progestogen combination or tibolone rather than oestrogen alone needs to be balanced against the slightly greater risk of breast cancer with combined HRT. The consensus view is that continuous combined oestrogen–progestogen preparations or tibolone should be prescribed following oophorectomy [E]⁶ but individual risk factors should also be considered [E].

Psychological aspects

Addressing psychological and social issues which commonly occur in association with chronic pelvic pain may be important in resolving painful symptoms associated with endometriosis [B] (see Chapter 76). Depression, relationship breakdown and sleep disorders are common in women with chronic pain. This may be a consequence rather than a cause of their pain but specific treatment may improve the woman's ability to function. It is important that the multifactorial nature of pain is discussed and explored from the start.³⁶ The aim is develop a partnership between clinician and patient to plan a management programme.

Patient groups like Endometriosis UK³⁷ provide an excellent source of support. These groups provide self-management courses designed to teach patients how to adapt to living with a chronic condition and how to manage pain. Providing these skills may make a tangible impact on their disease and quality of life in general. These courses tackle a variety of skills including relaxation strategies, coping mechanisms for depression, cognitive symptom management skills and the role of exercise in improving symptoms. Although there is minimal evidence to support the success of a holistic approach, nutritional and exercise-based interventions are unlikely to cause detriment to patients and are associated with benefits to general health.

EBM

These recommendations are supported by one evidence-based guideline, three systematic reviews of diagnostic techniques, eight systematic reviews of medical management of endometriosis-associated pain and three systematic reviews of surgical management of endometriosis-associated pain. There have been no randomised studies comparing medical with surgical management in the relief of endometriosis-associated pain and the relative cost effectiveness of the various approaches is unclear.

KEY POINTS

- Symptoms of endometriosis include dysmenorrhoea, chronic pelvic pain, dyspareunia and infertility but are non-specific. Painful defaecation and severe dyspareunia may be indicative of deep endometriosis [C].
- Pelvic examination may be unhelpful in the presence of peritoneal disease but the presence of fixed uterine retroversion, induration, nodularity or palpable masses may be indicative of deep rectovaginal endometriosis or ovarian endometrioma [C].
- Laparoscopy is regarded as the gold standard for diagnosis of endometriosis but adequate counselling is essential prior to the procedure [E].
- Negative laparoscopy is accurate for exclusion of endometriosis but positive visual changes lack specificity unless backed up by histology [C].
- ASRM scores can be used for documentation and assessment of the extent of endometriosis but correlate poorly with pain symptoms [C].
- Where appropriate, surgical ablative therapy should be carried out at the time of the initial laparoscopy [B].
- Measurement of CA-125 is not helpful as an aid to diagnosis [A].
- Transvaginal ultrasound is useful in identifying endometriomas and can assist with detection of deep endometriosis of the recto-sigmoid [A].
- MRI should not be used routinely for assessment of endometriosis but may be useful in the assessment of deep lesions [C].
- Hormonal suppression of ovulation is effective in the management of pain associated with endometriosis [A].
- Where appropriate, a trial of empirical medical therapy can be used for symptomatic management of pain in cases of suspected endometriosis without preliminary laparoscopy [E].
- COCPs, continuous progestogens, danazol, gestrinone and GnRH agonists are all effective therapies and selection should be determined by the relative side-effect profiles [A].
- Continuous rather than cyclical use of the COCP may be more effective in control of endometriosis-associated pain. [B].
- Levonorgestrel-releasing intrauterine systems are effective for management of endometriosis-related pain [B] and for maintenance of pain control following surgical treatment [A].

- If GnRH agonists are used for longer than 6 months, add-back therapy with low-dose continuous combined HRT or tibolone should be given [A].
- Drugs used for treatment of neuropathic pain such as amitriptyline and gabapentin may have a role in the management of endometriosis-related chronic pelvic pain resistant to conventional therapies [C].
- Complementary therapies, in particular acupuncture [C], may have a role in the management of pain associated with endometriosis but evidence for their use is lacking.
- Laparoscopic surgery is effective in the treatment of pain secondary to endometriosis in experienced hands [A] but longer-term recurrence of pain occurs in around 50 per cent of women.
- LUNA is ineffective as an adjunct to surgery for the relief of endometriosis-related pain [A]. PSN may be beneficial for dysmenorrhoea but has significant side effects and should be carried out in centres with the appropriate expertise [A].
- Surgical treatment of endometriomas should be by laparoscopic cystectomy [A].
- Operative laparoscopy for advanced disease carries a significant risk [C], and cases of advanced disease should be referred to specialist centres for laparoscopic surgery [E].
- Short-term pre- or postoperative medical therapy as an adjunct to surgery is ineffective [A] but longer-term use of contraceptive preparations is effective in prevention of recurrence of endometrioma and dysmenorrhoea following surgery in women not planning to conceive [B].
- Because of a high rate of recurrence of endometriosis following both medical and surgical treatment, medical treatment may need to be intermittent or long term [C].
- If fertility is no longer an issue, hysterectomy with bilateral oophorectomy may provide a cure, but disease excision may be incomplete [C].
- Because of a risk of disease recurrence [C], low-dose combined HRT or tibolone is preferable to oestrogen-only HRT following hysterectomy with oophorectomy for endometriosis [E].
- Self-help and support groups can play an important role in pain management by teaching coping skills designed to help women adapt to living with a chronic condition [E].

ACKNOWLEDGEMENT

With thanks to Professor Andrew W Horne for his help and advice during the preparation of this chapter.

Chapter 78 Adenomyosis

Christine P West

MRCOG standards

There are no established standards for this topic but the following are suggested

Theoretical skills

- Be aware of current understanding of the epidemiology of adenomyosis and its contribution to menstrual disorders.
- Understand the clinical features that may suggest a diagnosis of adenomyosis and the medical and surgical approaches to management.

Practical skills

- Understand the role of imaging in the diagnosis of adenomyosis.

INTRODUCTION

Adenomyosis is implicated as a cause of both heavy and painful menstruation, but because the diagnosis is most often made retrospectively and based on histological appearance, most published data relate to women who have undergone hysterectomy. Information from these studies indicates that adenomyosis is frequently asymptomatic and commonly coexists with other gynaecological conditions. Histologically, adenomyosis is characterised by the presence of endometrial glands and stroma in the uterine myometrium, with surrounding myometrial hypertrophy and hyperplasia,¹ the latter often resulting in significant uterine enlargement. The lesions are seen haphazardly and at varied depths within the myometrium. There is no current consensus regarding the exact diagnostic criteria.² Although histologically similar, adenomyosis is traditionally regarded as distinct from endometriosis in terms of its epidemiology (see below) although this distinction has been challenged. Recent advances in imaging have facilitated the diagnosis and study of the condition and led to greater opportunities for clinical trials of medical and conservative management. To date, such studies have been very limited and

consequently the literature on adenomyosis remains small, as is the evidence base for its management.

PREVALENCE

Adenomyosis is present in 20–30 per cent of hysterectomy specimens,² regardless of indication. There have been some reports of a correlation between the severity of menstrual symptoms and the extent and depth of invasion of the adenomyosis but others have failed to confirm such a relationship and it seems likely that adenomyosis is commonly present as an incidental finding. A prevalence of 21 per cent was reported in an ultrasound-based study of 985 women attending a general gynaecology clinic.³ However the median age of this population was 40 years and 54 per cent were nulligravid. Small-scale studies using imaging techniques have reported appearances consistent with adenomyosis in 12 per cent of a sample of 100 healthy women⁴ and in 9 per cent of 208 women following term delivery⁵ but there have been no large-scale community-based studies of adenomyosis and thus its prevalence in a normal population of women is unknown.

EPIDEMIOLOGY

Among women who have undergone hysterectomy the presence of adenomyosis is significantly associated with increasing parity.² In the study based on ultrasound,³ age was also a significant factor, with the highest prevalence between 40 and 49 years. Many² but not all^{3,6} studies have reported an increased incidence following caesarean section (CS) and surgical evacuation for abortion or management of miscarriage. There is no consistent association with ethnicity, smoking, contraceptive use or age at menarche^{2,3,6,7} but increased risk in obese or overweight women has been reported.^{6,7} Despite this apparent association with older reproductive age, it is known that adenomyosis can occur in adolescents and young women.¹

Although women diagnosed with adenomyosis tend to be older and of higher parity than those with endometriosis and less likely to have a family history of the condition,⁷ there

have been reports of an association with endometriosis.^{3,8} The presence of adenomyosis based on MRI of a population of women attending a fertility clinic⁸ was increased in women with confirmed endometriosis compared with those without laparoscopic evidence of endometriosis but there have been no other studies of its prevalence in women attending for investigation of infertility.⁹ There has been a report that adenomyosis may be associated with obstetric complications, in particular an increase risk of preterm delivery.^{5,9}

CAUSE

The adenomyotic tissue is presumed to be derived from the endometrium by abnormal ingrowth and invagination of its basal layer^{1,2} triggered by a weakness at the endometrial–myometrial junction. Disruption of this interface was previously presumed to be caused by pregnancy-related factors such as increased intrauterine pressure or surgical trauma such as curettage or CS. However recent epidemiological data^{3,6} have thrown some doubt on this hypothesis. There is some evidence that endometrial cells in adenomyosis develop greater invasive potential and that this, together with altered myometrial contractility, results in disruption of the endometrial–myometrial junction. Altered myometrial contractility leading to retrograde menstruation may be a common link between adenomyosis and endometriosis¹ but this remains speculative. Angiogenic growth factors, genetic factors and hormonal influences are also likely to be involved.

MANAGEMENT

Investigation

Available evidence suggests that women with symptomatic adenomyosis are likely to present with heavy and painful menstruation.¹⁰ Clinically, the uterus may be bulky and tender, but both the history and the clinical findings are non-specific. Further investigation is helpful in distinguishing between adenomyosis and uterine fibroids, particularly if non-medical management is considered (see below).

Reviews of diagnostic techniques^{11,12} have concluded that transvaginal ultrasound scanning (TVS) should be used as a primary screening modality for the diagnosis of adenomyosis [B]. Various sonographic appearances have been described (Box 78.1).^{9,11,12} These changes are usually present diffusely throughout the myometrium but discrete adenomyomata are also seen^{11,12} and differ from fibroids in being elliptical rather than globular, with poorly defined borders and lack of calcification. It has been estimated that the probability of adenomyosis with an abnormal scan is 66 per cent and 9.1 per cent with a normal scan.¹²

There is no current consensus on whether one, some or all of these features should be present for diagnosis and different criteria have been used by different investigators.^{9–12}

Box 78.1 Sonographic features of adenomyosis

- Heterogeneous myometrial areas
- Globular asymmetrical uterus
- Irregular cystic spaces
- Myometrial linear striations
- Parallel shadowing
- Thickening of the anterior or posterior myometrial wall with increased or decreased echogenicity

Some authorities stipulate that three or more of these features should be present for diagnosis of adenomyosis.^{10,11}

Features of adenomyosis have also been described using MRI.^{9,10} These include diffuse or focal widening of the junctional zone and areas of low signal intensity within the myometrium corresponding to smooth muscle hyperplasia. High signal intensity foci or linear striations are also seen. However there is disagreement between observers regarding the degree of junctional zone thickening required for diagnosis.⁹ Studies comparing uterine histology with pre-surgical TVS or MRI or both have found little difference in sensitivity or specificity between the two techniques^{9,10} but MRI is less observer dependent.¹¹ It is more accurate in distinguishing adenomyosis from fibroids in larger uteri.¹¹ In keeping with ultrasound, there remains some lack of consensus on diagnostic criteria.⁹

Both hysteroscopic and laparoscopic myometrial biopsy techniques have been described^{1,13} but have limitations when compared with non-invasive imaging.

Medical management

Most women with menstrual disorders are managed symptomatically in the first instance and therapies which are effective in the management of heavy menstrual bleeding (Chapter 75), dysmenorrhoea (Chapter 76) and endometriosis (Chapter 77) should be beneficial for women with adenomyosis. These include non-steroidal anti-inflammatory drugs (NSAIDs), tranexamic acid, oral contraceptives and progestogens [E] but evidence relating to their use in adenomyosis is lacking.

LNG-IUS

There have been several small-scale studies reporting benefit from the use of the levonorgestrel-releasing intrauterine system (LNG-IUS) in women with adenomyosis.¹³ A 3-year follow-up study of 94 women¹⁴ reported a significant decrease in dysmenorrhoea and uterine volume with 53 per cent achieving amenorrhoea after the first year of treatment [D]. Overall satisfaction was 56 per cent at 1 year and 72.5 per cent at 3 years with a continuation rate of 66 per cent at 3 years. Expulsion was high, at 16 per cent. A prospective study of 95 women with adenomyosis treated with either LNG-IUS or expectant management following

endometrial resection¹⁵ reported a significantly lower rate of dysmenorrhoea and need for further treatment with the IUS. In a prospective study of 75 women randomised between LNG-IUS and hysterectomy¹⁶ levels of haemoglobin were similar at 6 and 12 months. Quality-of-life assessments were marginally better in the IUS group and there was only one IUS discontinuation, due to an expulsion. This evidence, albeit limited, supports the role of the LNG-IUS in the management of adenomyosis [B] although further data based on longer term follow-up is needed.

GnRH agonists

Pituitary–ovarian suppression with a gonadotrophin-releasing hormone (GnRH) agonist causes amenorrhoea and regression of adenomyotic foci measured by MRI [D]¹⁷ but these benefits are rapidly reversed following cessation of treatment. In theory there should be a role for longer-term use in conjunction with add-back therapy to control vasomotor side effects, such as described for fibroids or endometriosis (see Chapters 74 and 77), but evidence for this is based on small case series and case reports [D].⁹ There is a potential role for GnRH agonists as adjuncts to surgical excision of adenomyomata¹⁷ (see below).

Uterine artery embolisation

Uterine artery embolisation (UAE) is established for the management of symptomatic fibroids (see Chapter 74), and as adenomyosis and uterine fibroids may coexist, this led to some early experience of UAE in cases of adenomyosis.¹³ Small case series of women followed up for at least 2 years after UAE reported an early favourable response but this was sustained in less than 60 per cent of the women [D].^{13,18,19} A more recent retrospective study of 40 women treated by UAE for menstrual symptoms associated with adenomyosis with or without uterine fibroids reported no significant difference in outcome between women with pure adenomyosis and those with a combination of both pathologies after a median follow-up period of 40 months.²⁰ Symptoms remained controlled in 72.5 per cent of the women overall. However no patients with fibroid dominance required surgical intervention for treatment failure, compared with 52 per cent of those with pure adenomyosis and 42 per cent with predominance of adenomyosis over fibroids. There was no reported correlation between the depth or extent of the adenomyosis and the clinical outcome. On the basis of this limited information it is not possible to make a recommendation regarding the role of UAE for symptomatic adenomyosis but its presence does not appear to be a contraindication to the use of UAE in women with fibroids [D]. Further data from randomised prospective trials is clearly needed.

Surgical management

Hysterectomy is regarded as the definitive treatment for adenomyosis in women who have completed child-bearing [E] although the decision to perform a hysterectomy is usually based on the presence of other pathologies such as fibroids or because of failure of conservative management of heavy and/or painful menstrual bleeding. There is some evidence that the presence of deep lesions of adenomyosis is associated with failure of endometrial ablation [D].²¹ Use of the LNG-IUS may be preferred to endometrial ablation in this situation [E]. Evidence from one prospective study¹³ suggested that the IUS may have a role as an adjunct to endometrial ablation in the presence of adenomyosis [C] but further studies are needed. General issues relating to hysterectomy for management of menstrual disorders are reviewed in Chapter 75.

Where preservation of fertility is desired, the role of surgery is unclear. Some superficial lesions of adenomyosis close to the endometrial–myometrial junction may be suitable for endometrial ablation or resection²¹ but good-quality data are lacking. Surgical excision of adenomyomata and deeper lesions has also been described²¹ although the diffuse nature of the disease makes this challenging and, in contrast to fibroids, adenomyomata cannot easily be enucleated. This highlights the importance of accurate radiological assessment prior to any form of conservative surgery for fibroids. In one large cohort study, localised excision of adenomyosis, performed by laparotomy or laparoscopy, was followed by 6 months of a GnRH agonist or no adjunct treatment.¹⁷ The severity of menorrhagia and dysmenorrhoea declined in both groups over a 2-year follow-up period but symptom relapse was higher in the group treated with surgery alone. Pregnancy rates were over 70 per cent in both groups. However such approaches may only be applicable in specialist centres and need further evaluation.

Other treatment options

Other medical treatments including anti-progesterones and aromatase inhibitors, alone or in combination with other agents, may have a future role in management of adenomyosis but evidence is lacking. MRI-guided focused ultrasound is used successfully for treatment of fibroids (see Chapter 74) but the more diffuse nature of adenomyosis may make the application of this technique more challenging. Experience to date is based on isolated case reports¹³ and small cases series²² with varied results and it is therefore not possible to reach any conclusions about the potential use of this technique for adenomyosis.

EBM

There is little supporting evidence for the management of adenomyosis, and the above text relies largely on small non-randomised trials and cohort studies.

KEY POINTS

- Adenomyosis is present in 20–30 per cent of hysterectomy specimens and is a cause of uterine enlargement.
- Its prevalence in the general population is unclear and its role as a contributing factor to menstrual disorders is not well understood.
- There is a lack of consensus regarding the criteria for diagnosis of adenomyosis by histology or imaging.
- TVS backed up by MRI is of value as a diagnostic tool [B].
- Medical therapies such as oral contraceptives, progestogens and GnRH analogues that have proven value in management of painful and/or heavy menstruation and endometriosis are likely to be of value [D] but have not been adequately assessed in adenomyosis.
- The LNG-IUS appears to be effective for the medical treatment of adenomyosis [B]
- Endometrial ablation for treatment of heavy menstrual bleeding may have a greater failure rate in the presence of adenomyosis [D].
- Hysterectomy is effective for relief of menstrual symptoms associated with adenomyosis [D] in women who have completed child-bearing.
- UAE can be used in women with adenomyosis alone or in combination with fibroids but may be less effective in cases where the predominant lesions are those of adenomyosis [D].

Chapter 79 Premenstrual syndrome

Christine P West

MRCOG standards

There are no established standards for this topic but the following are suggested:

Theoretical skills

- Understand the definition of premenstrual syndrome and its variants.
- Understand the epidemiology of premenstrual disorders.
- Know how to assess a patient presenting with premenstrual symptoms.
- Be aware of non-hormonal approaches to management, including alternative therapies.
- Understand the nature and complications of hormonal approaches to management and their limitations.

INTRODUCTION

Adverse emotional and physical symptoms are experienced by the majority of women in the lead-up to menstruation, although they are usually mild and regarded as a normal physiological response to cyclical hormone changes. However, a substantial number of women are sufficiently distressed by their symptoms to seek medical help and a minority are severely incapacitated by them. Hormonal treatments were commonly used in the past, but premenstrual syndrome (PMS) is no longer regarded as a purely endocrine disorder and first-line management includes non-hormonal approaches. However, the symptoms are triggered by the endocrine changes of the menstrual cycle and women with severe premenstrual symptoms continue to be referred to gynaecologists for consideration of hormonal suppression when other therapies have failed. Assessment of the efficacy of treatment is complicated by the subjective nature of the diagnosis and the strong placebo effect. Prospective methods of symptom assessment are now well established and there is an expanding literature of randomised controlled trials (RCTs) covering various approaches to management, including several systematic reviews.

DEFINITIONS

Although the term premenstrual syndrome is generally used throughout published literature, it has been suggested that the criteria for diagnosis are too wide and the clinical syndrome should be renamed core premenstrual disorder.¹ Mild symptoms should be considered physiological and the diagnosis of core premenstrual disorder or PMS based on substantial impairment of personal or professional life. Various emotional and physical symptoms are associated with the condition (Table 79.1) but their pattern of occurrence is more important than their nature and combination. Severe symptoms which are predominantly psychological in nature are classified as premenstrual dysphoric disorder (PMDD)¹ by the American Psychiatric Association in its *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) although this is a research criterion not in general use outside the USA.

Because of a lack of objective tests, the diagnosis is made on the basis of detailed history taking, backed up by prospective daily symptom recording over at least two cycles. Various rating scales are available for this purpose.¹ Cyclical symptoms which are present only premenstrually should be distinguished from premenstrual magnification/exacerbation of underlying psychological, psychiatric or medical disorders. Symptoms similar to those of PMS may be induced in some women by the use of progestogens¹ for contraception, hormone replacement or management of menstrual disorders.

PREVALENCE AND EPIDEMIOLOGY

In a population-based questionnaire survey of 1083 women aged 18–46 in Goteborg, Sweden² 92 per cent reported at least one adverse symptom in the lead-up to menstruation. Seventy per cent reported changes in mood in combination with bodily swelling, and 30–40 per cent rated their symptoms as mild to moderate in intensity. Eleven per cent felt that their symptoms were severe enough to seek medical help. Such population-based studies rely on retrospective assessment and do not distinguish between symptoms present only prior to menstruation and those that are ongoing throughout the cycle. In a recent sample of 947 UK women aged 20–34 years

Table 79.1 Criteria for diagnosis of moderate–severe PMS (core premenstrual disorder)

Symptoms	Pattern	Impact
Any combination of symptoms which may include:	Precipitated by ovulation	Substantial impairment of daily personal and professional activities
Irritability	Recur in each luteal phase	No underlying physical or psychiatric disorder
Tension	Relieved by the end of menstruation	
Depression	Followed by a symptom-free week	
Anxiety		
Fatigue		
Food cravings		
Bloating		
Breast discomfort		

assessed prospectively by symptom diaries,³ 24 per cent were considered to have PMS, based on the presence of five or more symptoms scored as mild to moderate or two or more symptoms scored as severe, followed by a symptom-free period of at least 7 days. In the latter study prevalence was lower in women using any form of hormonal contraception and in those with higher educational attainment and lower perceived levels of stress. No association was found with alcohol, diet or exercise. Apparent association with age, smoking and body mass index (BMI) was abolished after adjustment for contraceptive use.

There are no well-defined demographic risk factors and although level of reporting may vary in different communities, a recent web-based survey showed prevalence to be similar across 19 countries.⁴ Premenstrual symptoms are associated with ovulatory menstrual cycles and are reported in all reproductive age groups, including adolescence⁴ although the majority of women who seek help are between 25 and 40.

CAUSES

The frequency with which these symptoms are reported by women indicate that in their milder form they are a normal manifestation of the menstrual cycle, although it is possible that those at the more extreme end of the normal range have a pathological cause. Despite their relationship with the endocrine changes of the menstrual cycle, there is no evidence for any abnormality of the hypothalamo–pituitary–ovarian axis. There have been many theories of aetiology, but current evidence suggests that PMS may be a neuroendocrine disorder caused by deficiency or abnormal function of the neurotransmitters serotonin and gamma-aminobutyric acid which may cause increased sensitivity to progesterone. This is supported by evidence that drugs which enhance serotonergic function are beneficial in its management.⁵ A reported reduction of PMS symptoms with the anti-mineralocorticoid spironolactone may be suggestive of a disorder in the renin–angiotensin–aldosterone system⁶ and forms the basis for the use of an oral contraceptive containing a progestogen

derived from spironolactone. Currently the nature of any underlying metabolic disorder remains unclear.

A study of prospective daily symptom self-assessment by women referred for specialist help because of cyclical symptoms found that PMS was confirmed in only one-third,⁷ the remainder showing premenstrual magnification of ongoing psychological symptoms or symptoms exacerbated by menstruation itself. There was a significant relationship between menstrual and premenstrual magnification and previous psychiatric disorders, marital breakdown and increased parity. Other studies have shown a relationship between self-reported PMS and personality disorders and psychosocial stress.⁸

MANAGEMENT

A detailed history should be obtained,¹ including a description of the individual symptoms and their relationship to the menstrual cycle, together with a menstrual and reproductive history, including need for contraception. Medical, social and psychiatric history should also be explored together with details of any current or previous exposure to exogenous hormones. A diagnosis of PMS based on retrospective history taking is unreliable,⁷ and prospective charting of symptoms for at least two menstrual cycles is essential in order to clarify the symptom pattern [C]. Many methods of symptom assessment are available,^{1,9} but as they are time consuming to analyse, most are only suitable for use in a specialist clinic or research setting. Simple pictorial charts are available for use in primary care.

Management of PMS has been the subject of an RCOG Green-top Guideline.⁹ Basic management lies within the scope of primary care.¹ Women with mild degrees of PMS may respond to reassurance and general advice about exercise, diet and stress reduction [E]. Referral for specialist help will depend on the severity of the problem, the experience of individual general practitioners and the expectations of the women involved. Many women referred for specialist

help will be experiencing disruption of family or professional life and have a history of previous treatment failures. Ideally, women with severe PMS should be seen in a multidisciplinary specialist clinic or at least by a gynaecologist or a psychiatrist with a particular interest in the problem, preferably in a community-based setting [E].⁹

All RCTs of treatment for PMS have shown a very marked placebo response [A]. This emphasises the importance of critical appraisal of the evidence base before recommending specific therapies. The strength of the placebo effect may reflect the positive role of detailed history taking and a sympathetic approach.

Complementary and alternative therapies

Gynaecologists should have an awareness of the evidence underlying alternative therapies in order to advise patients appropriately. There have been three systematic reviews of trials of such therapies¹⁰⁻¹² and the conclusions are summarised in the RCOG Green-top Guideline.⁹

Dietary supplements

These approaches are available over the counter and may be recommended by alternative practitioners or on the internet. Beneficial effects have been reported with calcium, calcium combined with vitamin D, magnesium and isoflavones.⁹⁻¹² However, the reviewers felt that weaknesses in methodology limited recommendations of their value [E]. Similarly, studies of nutritional supplements containing high doses of vitamins and other micronutrients have yielded inconclusive results.⁹⁻¹¹

Dietary supplements are popular because they are perceived to have fewer side effects than conventional medicines and are likely to be regarded as effective because of the strong placebo effect. However, interactions with conventional medicines should be considered, such as those associated with the use of St John's Wort.⁹ High-dose vitamin B6, used for many years for the treatment of PMS, was reported to have neurotoxic effects.¹² Evidence from a meta-analysis suggested that low doses of vitamin B6 up to 100 mg daily may be of benefit in treating premenstrual depression [C]¹² but the studies are of poor quality and other authors have challenged this conclusion.^{9,10} Evening primrose oil is licensed for treatment of premenstrual mastalgia when given at high dosage but a meta-analysis failed to find sufficient evidence to support its use for PMS.¹³

Herbal medicine

The fruit of the chaste tree (*Vitex agnus-castus*) contains a mixture of iridoids and flavonoids and some compounds similar in structure to sex steroids. Evidence from a multi-centre RCT¹⁴ has shown the active treatment to be significantly more effective than placebo for the majority of the symptoms assessed (with the exception of bloating), with an overall response rate of 53 per cent for active treatment and 24 per cent for placebo. On the basis of this evidence, *Vitex*

agnus castus fruit extract seems to be a potentially useful therapy for PMS [B] although there is no standard quality-controlled preparation available. Further investigation is in progress. Similarly, reports of benefit from the use of Chinese herbal medicine¹⁵ are limited by the lack of standard formulations. Ginkgo biloba and pollen extract have both been shown to be beneficial in small-scale studies although further data would be needed to support their use.⁹

Other alternative approaches

Massage, relaxation and aromatherapy are popular therapies for which benefit is likely to outweigh any possible harm [E], although controlled studies of their use for PMS have yielded inconclusive results.¹¹ Similarly, although advice about graded exercise is useful for general health and is often recommended for relief of PMS, the evidence is based on observational studies and small non-randomised trials [D].¹⁶

Support and self-help groups are commonly used for PMS. This approach was supported by a study in which women were managed with a package of strategies including self-monitoring, personal choice, self-regulation and environmental modification, administered within a peer support group with professional guidance.¹⁷ The actively managed group experienced greater relief of symptoms in comparison with a control group waiting for the intervention [C]. The response was also maintained during an 18-month follow-up period.

Cognitive behavioural therapy

It has been suggested that cognitive behavioural therapy (CBT) should be routinely considered for the treatment of severe PMS.⁹ A meta-analysis of five trials of CBT¹⁸ found a significant reduction in both anxiety and depression and a possible beneficial effect on behavioural changes and interference with daily living. However, the evidence was considered to be of low quality. A subsequent meta-analysis¹⁹ which also assessed pharmacological interventions concluded that the effect size for both interventions was small to medium and future research should focus more on a combination of both approaches. On the basis of this evidence, CBT can be considered to be effective for severe PMS [A] but such therapy is intensive, involving weekly sessions of individual cognitive therapy, and may not be available for many sufferers.

Selective serotonin reuptake inhibitors

SSRIs are now regarded as a first-line therapy for treatment of severe PMS, particularly in women who fulfil the criteria for PMDD.⁹ The use of SSRIs for PMS has been the subject of a systematic review⁵ of 31 trials comparing SSRIs with placebo. These included fluoxetine (n = 10), sertraline (n = 9), paroxetine (n = 9), escitalopram (n = 2) and citalopram (n = 1) given continuously (n = 20) or intermittently (n = 14) for 2–6 months. Three trials compared continuous with luteal-phase administration. The results favoured active treatment over placebo for both

behavioural and physical symptoms. The onset of effectiveness was rapid and luteal-phase-only therapy was as effective as continuous treatment. Moderate doses were more effective than low doses but side effects were also dose dependent. Nausea, fatigue, insomnia, decreased libido and sweating were the most common side effects, reported by up to 20 per cent of women.

On the basis of this evidence, SSRIs can be regarded as a first-line treatment for severe PMS [A]. Low doses given during the luteal phase of the cycle (14 days premenstrually) may optimise efficacy while reducing incidence of side effects [B].⁵ They can be given together with oral contraceptives¹ although there is no evidence for any synergistic effects. They may also be suitable for long-term use although their long-term effectiveness for PMS has not been established. Despite this evidence for their efficacy, side effects are a common reason for poor compliance and 30–40 per cent of women with severe PMS fail to respond to SSRIs. Use of these medications falls outwith the expertise of the average gynaecologist and should be prescribed in the context of a specialist clinic [E].

HORMONAL MANIPULATION FOR THE MANAGEMENT OF PMS

Although the majority of women with PMS have no identifiable underlying endocrine disorder, ovulation appears to act as a trigger factor and thus various strategies that suppress ovulation or abolish the cycle altogether have a potential role in management. Currently there are no preparations (hormonal

or non-hormonal) licensed for the treatment of PMS. The costs of the various treatments discussed in this chapter vary widely (Table 79.2) and this, together with their side-effect profiles, should be considered alongside the evidence underlying their use.

Progesterone and progestogens

Luteal-phase supplements of progesterone were widely used in the past, based on the unproven theory that PMS was secondary to a progesterone deficiency. In the UK, progesterone is available only for vaginal or rectal administration, hence the use of synthetic progestogens for this indication. However, evidence from hormone replacement therapy (HRT) studies indicates that progestogens might actually exacerbate PMS-type symptoms in susceptible individuals.²⁰

A systematic review assessed 14 RCTs of progesterone and 4 of progestogens in PMS.²¹ Overall results of meta-analysis for progesterone showed no difference compared with placebo. Results with progestogens were difficult to interpret due to the small number of studies and differences in the treatment protocols. Overall odds ratios were marginally but significantly in favour of progestogens for both physical and behavioural symptoms but drop-outs due to side effects were high. The response to progestogens may have been influenced by the fact that two of the four studies used progestogens in an ovulation-suppressing regimen. However, this evidence does not support the use of either progesterone or progestogens in the management of PMS when given during the luteal phase of the cycle [A]. While the continuous use of progestogens in ovulation suppressive doses (e.g. Depo-Provera or oral desogestrel)

Table 79.2 Costs of pharmacological treatment options for PMS (data from British National Formulary – 2014 prices)³¹ and evidence level for use. None of the treatments listed are licensed for this indication.

Treatment	3 monthly cost (range in £)	Evidence level
Non-hormonal:		
Pyridoxine hydrochloride 50–100 mg/day (vitamin B ₆)	9.24–18.48	Inconclusive
Selective serotonin reuptake inhibitors	1.44–25.50	A
Hormonal:		
Ethinylestradiol 20/30 mcg plus levonorgestrel 150 mcg or norethisterone acetate 1 mg	1.89–3.76	B
Ethinylestradiol 20/30 mcg plus desogestrel 150 mcg	6.57–10.23	B
Ethinylestradiol 30 mcg plus drospirenone 3 mg	14.20–18.93	B
Estraderm 100 mcg/24 hours + Mirena IUS	23.59	B
Estraderm 100 mcg/24 hours + oral progestogen	24.00–29.77	B
Depot medroxyprogesterone acetate	6.01	D
Desogestrel 75 mcg	4.30–8.68	None available
Danazol 200 mg bd or tid	97.32–152.10	B
Intranasal GnRH agonist + add-back HRT	157.29–174.31	A
GnRH agonist depot + add-back HRT	210.20–252.02	A

* Range covers cyclical or continuous administration (where relevant) and alternative available formulations

may be beneficial, there is lack of evidence to support this approach.

Combined oral contraceptives

The occurrence of PMS symptoms in the post-ovulatory phase of the menstrual cycle strongly suggests that any therapy that suppresses ovulation should relieve PMS. Combined oral contraceptive pills (COCPs) have the advantage of being cheap (Table 79.2) and suitable for long-term use. Earlier studies yielded varied results. Some showed a reduction in the prevalence and severity of PMS with oral contraceptive use^{22,23} while others failed to show any difference in cyclical symptoms between COCP users and non-users.²⁴

An oral contraceptive containing the progestogen drospirenone, which is derived from spironolactone and has anti-androgenic and anti-mineralocorticoid activities, may have advantages over older preparations. An initial placebo-controlled trial of drospirenone 3 mg in combination with ethinylestradiol (EE) 30 mcg (21 days out of 28 for 3 months) reported a non-significant improvement in symptoms of PMDD.²⁵

Subsequently the authors of a systematic review²⁵ concluded that a combination of drospirenone 3 mg with 20 mcg EE (two studies in which the combination was given for 24 days out of 28) was significantly more effective than placebo over a 3-month period of treatment in women with a diagnosis of PMDD. However the placebo response was 36 per cent, compared with 48 per cent for the active treatment group. This drospirenone/EE combination, given cyclically for 24 days out of 28, is licensed in the USA for treatment of PMDD but is not currently available in the UK.

The question remains whether other low-dose combined contraceptives, used conventionally or in extended regimens, may be effective for moderate or severe PMS. In a large multicentre study comparing desogestrel 150 mcg with drospirenone 3 mg, both combined with 30 mcg EE for 21 days out of 28, there was no significant difference in premenstrual symptoms after 2 years of treatment.²⁵ A pre-treatment diagnosis of PMS or PMDD was not an inclusion criterion for this study. A single-centre study²⁶ compared desogestrel 150 mcg with drospirenone 3 mg both in combination with 20 mcg EE given in extended dosage for 24 days out of 28 for 6 months. Results showed a significant improvement in premenstrual symptoms in both groups after 6 months although the response was greater in the group treated with drospirenone.

Prolongation of the contraceptive pill cycle from 21 to 24 days causes increased ovarian suppression²⁷ which may contribute to improvement of cyclical symptoms. Similarly, continuous administration is commonly used for relief of dysmenorrhoea and endometriosis (see Chapters 76 and 77) and may be beneficial for PMS. An overview of four studies of continuous use of levonorgestrel 90 mcg in combination with EE 20 mcg, including three placebo-controlled trials, reported a 30–59 per cent improvement in premenstrual

symptoms²⁸ although a large placebo effect was also observed.

Taken overall, this evidence suggests that a trial of therapy with a low-dose COCP should be considered for women with premenstrual syndrome who have no contraindications to its use [B]. Continuous use of COCP preparations may have an advantage over cyclical use [B] and both second- and third-generation formulations may be effective [B]. Strongest evidence exists for the third-generation combination of drospirenone 3 mg with 20 mcg EE administered for 24 days out of 28 for women with severe PMS [A], although evidence is limited to short-term use and this preparation is currently not available in the UK.

Transdermal oestradiol

Subcutaneous implants and transdermal estradiol patches have been used in ovulation-suppressive doses in combination with cyclical luteal-phase progestogen for the management of severe PMS. However, concerns over supraphysiological levels of estradiol due to tachyphylaxis after repeated subcutaneous implants²⁹ have favoured the use of transdermal patches. Both 200 mg and 100 mg estradiol patches, used twice weekly, suppressed ovulation and were more effective in symptom relief than placebo in cross-over studies but there were fewer oestrogenic side effects with the lower dosage.³⁰ Overall satisfaction at 8 months was around 50 per cent. Oral progestogen was given cyclically from days 17–26 for endometrial protection but information on side effects or symptom recurrence with the progestogen was lacking. These limited data support the role of ovulation-suppressive doses of transdermal estradiol for the relief of PMS [B] although information on its long-term safety in relation to breast and endometrial cancer and cardiovascular risk is required. As such preparations have not been assessed for their contraceptive efficacy, additional contraception is required [E]. Use of transdermal estradiol patches in combination with the levonorgestrel-releasing intrauterine system (LNG-IUS) for both contraception and endometrial protection is an approach that merits future investigation [E].

Oral contraceptive formulations based on estradiol (estradiol valerate or estradiol hemihydrate) in combination with newer progestogens (norgestrel acetate or dienogest) and given in extended-dose regimens have recently become available.³¹ They were developed with the objective of reducing the metabolic and thrombogenic effects of EE although their clinical relevance has yet to be established. In theory they may be useful for management of PMS although currently there are no relevant published studies. They are considerably more expensive than older oral contraceptive formulations although costs are similar to that of transdermal estradiol.

Danazol

Several studies have supported the use of danazol for PMS. At a dose of 200 mg bd in a cross-over study,³² 44 per cent of subjects on active therapy experienced a clinically significant

improvement, compared with only 8 per cent of those treated with placebo. Although effective [B], the side effects and metabolic sequelae of danazol (see Chapter 77) limit its usefulness for the long-term management of PMS.

GnRH agonists

Ovarian suppression with GnRH agonists (see Chapter 77) should eliminate PMS if the symptoms are triggered by ovulation. A meta-analysis³³ of five studies comparing a GnRH agonist with placebo reported a reduction in both physical and behavioural symptoms with the active therapy [A]. However the use of hormonal add-back is necessary for bone protection if treatment is to be long term. The meta-analysis³³ included three studies in which add-back HRT combined with a GnRH agonist was compared with the GnRH agonist alone. In two of these, add-back was with continuous oestrogen and cyclical progestogen HRT; the third used tibolone. Results showed no significant difference in efficacy with add-back HRT, although one trial reported a reduced response and a greater drop-out rate in the cyclical add-back group. On this basis, GnRH agonists should be combined with continuous combined HRT or tibolone when used for treatment of severe PMS [A].

GnRH agonists are effective in the management of severe PMS but the cost (Table 79.2) and potentially long-term nature of treatment when used with hormonal add-back should limit its use to women with severe symptoms that are socially disruptive and resistant to other forms of therapy [E].⁹ Patient selection is also important. All the women included in the trials cited above had prospectively confirmed PMS. Women with premenstrual exacerbation of ongoing symptoms do not experience symptom relief.³⁴ GnRH agonists therefore offer a useful means of further assessment of the pattern and nature of cyclical symptoms in situations in which the diagnosis is unclear or, in particular, when oophorectomy is being considered [E].

Oophorectomy

Although there have been reports of its efficacy in the literature,^{35,36} oophorectomy is not recommended for the management of PMS unless the problem is very severe and has been confirmed by prospective assessment and there has been genuine failure of conservative therapies [E].⁹ It should not be considered unless supported by a trial of ovarian suppression, preferably with a GnRH agonist [E].³³ The latter also gives an opportunity to assess the response of the patient to add-back HRT. Unless there are additional indications for hysterectomy, laparoscopic oophorectomy offers a less invasive surgical approach [E]. In women undergoing hysterectomy for other indications, a history of PMS is not a sufficient indication for concurrent oophorectomy without careful assessment [E].³⁷ as cyclical symptoms may improve following hysterectomy [B].^{38,39} Indeed, improvement of premenstrual symptoms has been reported following endometrial ablation³⁸ and insertion of the LNG-IUS,³⁹ and

these options offer a less invasive approach than hysterectomy with oophorectomy in women with heavy menstrual bleeding (HMB) who also complain of mild to moderate premenstrual symptoms.

MANAGEMENT OF WOMEN WITH PREMENSTRUAL MAGNIFICATION

There is a growing evidence base for the management of premenstrual disorders. However, eligibility for treatment trials requires prospective confirmation of the diagnosis by daily self-rating, so that the majority exclude the group of women whose management tends to be most problematic: those with premenstrual magnification of underlying psychological or psychiatric problems. The presence of high baseline postmenstrual symptom scores has been identified as one factor that leads to treatment failure with SSRIs [B]⁴⁰ and GnRH agonists [B]³⁴ and to poor response with the COCP [B].²² Women with premenstrual magnification are therefore likely to be over-represented among those who present because of treatment failure. It is important that this group is identified and the nature of the problem and the limitations of management appreciated by both the clinician and the patient so that these women are not subjected to inappropriate and over-aggressive interventions such as hormonal manipulation or even surgery. Alternative management by the multidisciplinary team or psychiatric referral may be appropriate [E].

CONCLUSION

There is a wide range of therapies that have proven efficacy for severe PMS. However, response rates to any individual therapy are rarely in excess of 50 per cent with a high response to placebo. It is important that those involved in management are aware of these limitations and of different approaches to the problem. Ideally, women with severe symptoms and those with a history of treatment failure should be managed in specialist multidisciplinary clinics. The importance of making a correct diagnosis based on adequate prospective daily symptom assessment cannot be over-emphasised.

EBM

- There are many published RCTs covering various approaches to the management of PMS, but some of those relating to alternative therapies are open to methodological criticism.
- These recommendations are based on an RCOG Green-top Guideline and nine systematic reviews or meta-analyses of PMS therapy, five of which relate to alternative or dietary approaches.

KEY POINTS

- Diagnosis of PMS should be based on detailed history taking and confirmed by at least two cycles of prospective daily symptom rating [E].
- Management of severe PMS should take place in a multidisciplinary clinic or by a specialist with a special interest in the condition [E].
- All treatment trials to date have demonstrated a strong placebo effect and the response rate to active therapy is rarely in excess of 50 per cent [A].
- Expert opinion is divided about the benefit of complementary therapies such as nutritional and herbal approaches [E]. Vitamin B₆ in doses up to 100 mg daily may be of benefit for premenstrual depression [C].
- Limited evidence supports the role of group support [C], lifestyle modification and physical interventions such as acupuncture, relaxation and exercise [D].
- Support and self-help groups are likely to have a positive role in the management of PMS [C].
- CBT is beneficial for the treatment of severe PMS [A] but availability is limited.
- SSRIs are effective for relieving both the physical and psychological symptoms of PMS [A].
- SSRIs are equally effective when given in low doses during the luteal phase of the cycle [A], and this is associated with fewer side effects [B].
- Progesterone or progestogens given during the luteal phase of the menstrual cycle are not effective for PMS [A] although ovulation suppressive regimens may be beneficial [C].
- Suppression of ovulation with a third-generation COCP containing drospirenone given for 24 days out of 28 is beneficial in the management of severe PMS [A].
- Other low-dose COCPs with both second- and third-generation progestogens may also reduce premenstrual symptoms [B], particularly if given continuously or in extended dose regimens and are cheaper than newer alternatives.
- Suppression of ovulation with transdermal estradiol combined with progestogen for endometrial protection has been shown to be beneficial in older studies [B] but information on its safety for long-term use is lacking.
- Danazol is effective for PMS [B] but is not suitable for long-term use.
- GnRH analogues are effective for severe PMS [A] and may be used in combination with low-dose continuous hormonal add-back therapy [A] but are costly and should not be used as first-line therapy [E].
- Oophorectomy may be considered in severe PMS but only when medical measures have failed, and should be preceded by a trial of GnRH agonist therapy [E].
- Women with mild to moderate premenstrual symptoms in association with HMB may benefit from use of an LUG-IUS or endometrial ablation [B].
- Lack of symptom relief following menstruation and persistence of symptoms throughout the cycle (premenstrual magnification) is an important contributor to treatment failure [B].

Chapter 80 Normal conception

Yakoub Khalaf

MRCOG standards

Theoretical skills

- Understand the processes of gametogenesis in both the male and female. These are covered in Chapter 68.
- Understand the gonadal embryology in both the male and female.
- Understand the processes of fertilisation, embryo development and implantation.
- Understand early pregnancy hormonal changes in relation to implantation and the early development of the embryo.

Practical skills

- Know the relationship between fertilisation problems and some pregnancy disorders, such as hydatidiform moles.
- Be able to discuss and investigate implantation disorders and recurrent pregnancy loss.
- Know the relationship between the perimenstrual endocrinological changes and menstrual disorders.

INTRODUCTION

The fusion of the male and female gametes is the core event in reproduction. The genetic material in the two haploid gametes combines to produce a diploid zygote. In mammals, the fusion of the gametes occurs within the female reproductive tract, and is followed by implantation and the development of the embryo into a fetus in the uterus. Gametes are produced in the gonads, which also have endocrine functions that are essential for successful reproduction. It is important to explore the embryology, anatomy and some physiological aspects of the ovary and testis in order to understand conception and infertility.

THE OVARY AND FEMALE GAMETE

The functions of the ovary are to engineer the periodic release of oocytes and to produce steroid and glycoprotein hormones.

Both functions are integrated in the continuous processes of growth and maturation of the primordial to Graafian follicle, containing the oocyte, followed by ovulation and formation of the corpus luteum. The corpus luteum regresses if pregnancy does not occur, but is maintained into the first trimester if a pregnancy occurs. The human ovary consists of three major components:

- 1 the outer cortex, the outer part of which is the tunica albuginea, and the internal part consisting of primordial follicles embedded in stromal tissue;
- 2 the inner medulla;
- 3 the rete ovarii (hilum), which is attached to the mesovarium and contains nerves, blood vessels and hilar cells, which have the potential to become active in steroidogenesis. The hilar cells are similar to the testosterone-producing Leydig cells of the testes.

The embryonic development of the ovary passes through four stages.

- 1 *The indifferent gonadal stage.* This stage lasts about 7–10 days and starts at approximately 5 weeks' gestation. It starts with the development of the gonadal ridges, which consist of consolidated coelomic projections overlying the mesonephros. At this stage, the ridges are indistinguishable as testes or ovaries. By the sixth week, the indifferent stage is completed, leaving the indifferent gonads consisting of germ cells and supporting cells derived from the coelomic epithelium and the mesenchyme of the gonadal ridge.
- 2 *The stage of differentiation.* This occurs at 6–9 weeks if the gonad is destined to be a testis.
- 3 *The stage of oogonial multiplication and maturation.* This starts at 6–8 weeks and represents the first sign of ovarian differentiation. A rapid mitotic division of the germ cells takes place, giving rise to the oogonia, and by 10–12 weeks the number of oogonia reaches 6–7 million. This is the maximal oogonial content of the gonads. From this point onwards, the germ cell content will irretrievably decrease and will be exhausted approximately 50 years later. The germ cells undergo mitosis to produce the oogonia that enter the first meiotic division and arrest in the prophase to become oocytes. This process begins at 11–12 weeks, perhaps in response to a factor or factors produced by the rete ovarii. Progression of meiotic prophase to the diplotene stage takes place throughout the rest of the

intrauterine life. The completion of the first meiotic division occurs just before ovulation, and the second meiotic division takes place at sperm penetration. As a result of the two meiotic divisions, a single haploid ovum is produced and the excess genetic material is extruded as a polar body at the completion of each meiotic division.

- 4 *The stage of follicular formation.* This starts at 14–20 weeks, when the entire follicle undergoes various stages of maturation leading to the production of the primary follicle before atresia takes place. However, ovulation does not occur in the fetal ovary.

At the onset of puberty, the germ cell mass, incorporated into primordial follicles, is usually reduced to approximately 300,000 follicles. These regularly undergo various stages of maturation, development and atresia. In all, less than 0.1 per cent of follicles will grow beyond the pre-antral stage and develop into a dominant follicle, which ovulates. This enormous attrition of primordial follicles forms part of the process of natural selection, by which only a tiny number of germ cells pass through the reproductive cycle and form a new individual.

As the dominant follicle grows, it produces oestrogens, predominantly oestradiol, and inhibins, predominantly inhibin B. These hormones synchronise the development of the endometrial lining of the uterus with that of the follicle, and prepare the pituitary for eventual triggering of the luteinising hormone (LH) surge. Once oestradiol production from the dominant follicle passes a threshold, a positive feedback is triggered at the pituitary and the LH surge occurs, leading to ovulation. Ovulation results in the physical release of the oocyte, allowing it to enter the Fallopian tube, with potential for fertilisation. The follicle then develops into the corpus luteum, the source of progesterone and inhibin A in the second half (luteal phase) of the cycle. Production of the sex steroids by the corpus luteum results in preparation of the uterus and the entire woman's body for the occurrence of conception. For this regular periodic process to occur, accurate communication between the ovary and the pituitary gland is essential.

THE TESTIS AND MALE GAMETE

The physiological responsibilities of the testis are, in principle, similar to those of the ovary i.e. the production of gametes (spermatozoa) and sex steroids (testosterone). However, sex steroid production in the male is a continuous, non-episodic process, which is independent of the development of gametes. The early embryonic stages of testicular development also follow those of the ovary, starting from the indifferent gonad stage. However, at 6–7 weeks of embryonic life of the male fetus, the production of testis-determining factor (TDF) results in differentiation of the gonads to testes. TDF is the product of a gene located on the Y chromosome. However, the male phenotype is dependent on the production of anti-Müllerian hormone and testosterone. The absence of these two factors leads

to the development of the female phenotype. Differentiation of the testis leads to the production of the spermatic cords, which include the Sertoli cells and primordial germ cells that later become the spermatogonia. The mature Sertoli cells produce androgen-binding protein and inhibin B. The former is responsible for maintaining the high local androgen environment necessary for spermatogenesis. The Leydig cells develop from the mesenchymal cells surrounding the spermatic cords. They produce testosterone, the secretion of which increases with the increase in the number of Leydig cells. The Leydig cell number reaches a peak at 15–18 weeks, after which they regress, leaving a restricted pool of cells present at birth. These cells become responsive to gonadotrophins at puberty, leading to the production of testosterone and the initiation of spermatogenesis. The spermatogonia divide mitotically to produce primary spermatocytes, which then divide meiotically to produce the haploid secondary spermatocytes. Secondary spermatocytes undergo a maturation process to produce the spermatids, then the mature spermatozoa.

The Sertoli cells influence the process of spermatogenesis and are directed by genes on the Y chromosome. Approximately 74 days are required to produce a mature spermatozoon, of which about 50 days are spent in the seminiferous tubules. After leaving the testicle, the sperm takes 12–21 days to travel to the epididymis and appear in the ejaculate

FOLLICULAR DEVELOPMENT, MATURATION AND OVULATION

Follicular development

This involves several stages, starting with the mobilisation of the dormant primordial follicles to form a cohort of growing follicles, which progress through the pre-antral, antral, and pre-ovulatory stages to produce (usually) one dominant follicle that reaches ovulation. The mechanism determining which primordial follicles and how many will be released into the pool of growing follicles in each menstrual cycle is not known. However, this may be regulated by an intra-ovarian mechanism. The number of primordial follicles released from quiescence to enter the pool of growing follicles each cycle seems to be proportional to the size of the residual pool. Therefore, the reduction of the primordial follicle pool by total or partial unilateral oophorectomy, or towards the end of reproductive life, may result in a smaller cohort of growing follicles. The onset and the time span of folliculogenesis have been controversial. Mais *et al.*² suggested that the follicle destined to ovulate is recruited in the first few days of the cycle, whereas Gougeon³ suggested that such a process occurs over a time span of several cycles, estimated to be 85 days to achieve a pre-ovulatory status. The initiation of follicular growth in the early stages is independent of pituitary control; however, without a rise in follicle stimulating hormone (FSH), these follicles are destined for atresia.

Soon after the initial resumption of maturation, the follicle develops FSH receptors and becomes capable of responding to circulating FSH. This is known as the pre-antral stage, which starts to occur towards the end of the luteal phase of the preceding cycle. FSH, aided by other autocrine/paracrine factors, initiates steroidogenesis and granulosa cell proliferation, and is also responsible for up-regulation and down-regulation of its own receptors. Therefore, the fate of each pre-antral follicle in the developing pool depends on its ability to convert an androgen microenvironment to an oestrogen microenvironment. This requires the development of aromatase within the granulosa cells that line the follicle. Once one follicle acquires sufficient aromatase to produce and secrete significant quantities of oestradiol, the remainder of the cohort stop growing and gradually become atretic.

The granulosa cell layer is separated from the stromal cells by a basement membrane called the basal lamina (lamina basalis). The surrounding stromal cells differentiate into concentric layers designated as the theca interna (closest to the basal lamina) and the theca externa (the outer portion). As the follicle develops, the theca cells develop LH receptors, leading to LH-stimulated production of androgens, which form the substrate for the production of oestrogen in the granulosa cell layer.

Under the influence of FSH and as the follicles grow, intra-follicular fluid secretion increases, to form a cavitated antral follicle. The intrafollicular fluid contains oestrogens and a variety of peptide growth factors, which provide the oocytes and the surrounding granulosa cells with an endocrine-rich environment essential for maturation and eventually ovulation.

The selection of a dominant follicle

In primates and humans, usually one follicle proceeds to ovulation and the rest of the cohort is destined for atresia. Oestradiol and inhibin B are produced in increasing amounts by the rapidly growing lead follicle in the cohort. These hormones exert a negative feedback on the pituitary, leading to a decrease in the circulating level of FSH. This in turn withdraws gonadotrophic support from the less developed follicles, but is sufficient for the continued growth of the most advanced follicle, which contains the highest number of FSH receptors. In the antral stage, the dominant follicle maintains the production of oestradiol and inhibin B, which further reduces the FSH level and seals the fate of the other less developed follicles in the cohort. The accumulation of a greater mass of granulosa cells is accompanied by advanced development of the thecal vasculature, which facilitates preferential delivery of gonadotrophins to the follicles, allowing the dominant follicle to maintain FSH responsiveness and continue to develop and function despite the decreasing levels of FSH.

In the pre-ovulatory stage, the granulosa cells enlarge, the theca cells become vacuolated and richly vascular, the oocyte resumes meiosis, and the oestradiol level continues to rise, reaching a peak approximately 24–36 hours prior to ovulation.⁴

Ovulation

The continuous production of oestradiol by the growing follicle leads to the surge in LH through a positive-feedback mechanism. The LH surge usually lasts 48–50 hours. Ovulation (follicular rupture and oocyte release) occurs 24–36 hours after the LH surge. The LH surge leads to several events essential for oocyte maturation and preparation of the endometrium for implantation. The oocyte resumes its first meiotic division, leading to the production and extrusion of the first polar body, and enters the second meiotic division, which will be completed on fusion of the sperm with the oocyte later on. This stage is essential for the oocyte to be fertilised by the sperm. Stimulation of the granulosa cells by LH leads to the production of progesterone necessary for converting the endometrium from the proliferative to the secretory phase. Furthermore, progesterone enhances the activity of proteolytic enzymes and prostaglandins to digest the follicular wall, leading to the rupture of the follicle and the release of the oocyte.

Fertilisation

The oocyte released at the time of ovulation is surrounded by granulosa cells known as the cumulus oophorus, which is separated from the actual oocyte by a layer of glycoprotein known as the zona pellucida. Within 2–3 minutes of ovulation, the oocyte (surrounded by the cumulus) is within the ampullary part of the Fallopian tube. The fertilisable life span of the human ovum is estimated to be 24–36 hours. Although several million sperm are deposited in the vagina, only about 200 will come in contact with the oocyte. For the sperm to bind with the zona pellucida, a receptor is required, which is species specific. The sperm has to undergo a process known as ‘capacitation’ in order to be able to bind with the receptor and penetrate the egg. The zona pellucida not only contains the receptors for the sperm, but also has a mechanism by which it prevents more than one sperm from entering the oocyte (polyspermy). This mechanism is known as the zona reaction.

IMPLANTATION

This is defined as the process by which the embryo attaches itself to the endometrial side of the uterine wall and gradually penetrates the epithelium to reach the circulatory system of the mother. This process requires preparation of both the endometrium and the embryo for a successful implantation to take place.

Embryo preparation

After ovulation, oestradiol and progesterone from the corpus luteum alter the molecular structure of the endometrium from proliferative to secretory. The individual components of the endometrium continue to grow, leading to tortuosity of the glands and coiling of the spiral arterioles. Intracytoplasmic

glycogen vacuoles appear and transudation of plasma occurs, contributing to endometrial secretion. The peak secretory phase is reached by 7 days post-ovulation. At this point, the endometrial cells are rich in glycogen and lipids. The receptivity of the endometrium is limited to days 16–19 (of a 28-day cycle) and it is essential that the hatched blastocyst impacts and adheres to the surface of the endometrium during this ‘implantation window’ if pregnancy is to occur.

KEY POINTS

- At the onset of puberty, the size of the primordial follicles pool is approximately 300,000 follicles.
- Once oestradiol production from the dominant follicle passes a threshold, a positive feedback is triggered at the pituitary and the LH surge occurs, leading to ovulation.
- The oestradiol level continues to rise, reaching a peak leading to the LH surge, which is followed 24–36 hours later by ovulation.
- The fertilisation life span of the released ovum is 24–36 hours.
- The zona pellucida precludes more than one sperm entering the oocyte through a mechanism known as the zona reaction.
- The embryo usually reaches the blastocyst stage by day 5 post-fertilisation with a prominent inner cell mass and trophoctoderm.

ACKNOWLEDGEMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of Hany AMA Lashen to the chapter on this topic in the previous edition of the book.

Chapter 81 Female infertility

Yakoub Khalaf

MRCOG standards

Theoretical skills

- Understand epidemiology, aetiology and pathogenesis of infertility.
- Understand clinical management and prognosis of all aspects of female fertility problems.
- Have adequate knowledge of interpretation of relevant investigations in relation to female infertility.
- Have adequate knowledge of indications and limitations of treatments for female infertility.

Practical skills

- Be able to establish a rapport with infertile couples.
- Be able to elicit the relevant history and plan the investigations.
- Be able to work within a framework alongside other healthcare professionals.
- Be familiar with the available evidence and treatment success rates when counselling patients regarding treatment options.
- Know your limitations and consider the patient's welfare.

INTRODUCTION

Infertility is defined as the inability to conceive despite regular unprotected sexual intercourse over a specific period of time, usually 1–2 years. The cumulative spontaneous pregnancy rate for a couple is approximately 57 per cent after three months, 72 per cent after six months, 85 per cent after one year and 93 per cent after two years [D].¹ Accordingly, only 50 per cent of couples failing to conceive during the first year will conceive in the second year, which justifies starting investigations for infertility after one year. However, if the physician or the patient has a reason to suspect impaired fertility, the process should be started sooner. Furthermore, if the female partner is 35 years of age or older, the investigations should not be delayed, given the rapid decline of female fecundity

after this age. Over the past three decades the introduction of IVF and the wide public interest in this aspect of infertility treatment, together with the increasing ease of obtaining information, have increased patients' expectations of infertility treatment.

EPIDEMIOLOGY

It has been estimated that infertility affects 9 per cent of couples, of whom 70 per cent suffer from primary infertility i.e. no previous conception, and 30 per cent secondary infertility i.e. have achieved a previous pregnancy (regardless of the outcome of that pregnancy). Worldwide, more than 70 million couples suffer from infertility, the majority being residents of the developing countries. The recent advances in infertility treatment and the access of patients to such information have led to early presentation of these patients and their request for treatment. This may give a false impression of an increasing infertility problem.

CAUSES OF INFERTILITY

For pregnancy to occur, there must be fertile sperm and egg, a means of bringing them together and a receptive endometrium to allow the resulting embryo to implant. A defect at any of these stages can lead to subfertility. It has been estimated that in 35 per cent of cases a male factor is the reason for infertility [C]. In the remaining 65 per cent of cases, a female factor is identified in 50 per cent of couples and no cause will be identified in the remainder [C]. The most common causes of infertility in the female are ovulatory and tubal factors. Endometriosis in its moderate to severe forms has also been linked to infertility, despite a lack of clear understanding of the connection between the two phenomena [C]. Although failure of implantation will cause infertility, it is difficult to determine whether the embryo or the endometrium is at fault in such cases. The effect of age on female fertility is not a new concept, with a gradual decline in female fertility and an increase in the miscarriage rate being observed many years before the menopause [D]. As discussed earlier, women enter the reproductive age at puberty with a pool of primordial

follicles of a pre-determined number. The size of this pool and the rate of follicular depletion are the deciding factors in the timing of the menopause. Female fertility declines after the age of 35 and declines more rapidly after the age of 40 [C]. The rate of follicular loss is inversely proportional to the size of the primordial pool i.e. the smaller the pool, the faster the rate. Delaying starting a family to the later years of reproductive life also increases the risk of developing endometriosis and the risk of miscarriage.

Anovulatory infertility

Anovulation is a frequent cause of infertility. Negative-feedback and positive-feedback mechanisms allow the ovaries to interact successfully with the hypothalamo-pituitary axis. The causes of anovulation can be classified according to the clinical findings when the level of disruption between the hypothalamic-pituitary axis and the ovary is assessed. This divides the causes of anovulatory infertility into three main categories – ovulatory dysfunction, hypogonadotrophic hypogonadism and hypergonadotrophic hypogonadism, with other less common causes considered separately.

Ovarian dysfunction

The most common presentation of anovulation is associated with normal gonadotrophin concentrations. Such normogonadotrophic anovulation is usually seen in polycystic ovary syndrome. PCOS is the most common endocrine disorder in women of reproductive age. In its classic form – a combination of oligomenorrhoea/anovulation and hyperandrogenism – it is estimated to affect >5 per cent of the female population. PCOS is also associated with a metabolic disturbance, central to which is peripheral insulin resistance and compensatory hyperinsulinaemia. Significant abnormalities in the very earliest stages of folliculogenesis may be the root cause of anovulation in PCOS.

Hypogonadotrophic hypogonadism

Failure of the pituitary gland to produce gonadotrophins will lead to lack of ovarian stimulation. There are a number of disorders of the anterior pituitary gland that lead to failure of production of FSH. These include destruction of the anterior pituitary by a tumour (e.g. a benign non-functioning adenoma or craniopharyngioma), by a pituitary inflammatory reaction as in tuberculosis, or following ischaemia as in Sheehan's syndrome. Rare congenital causes include Laurence-Moon-Biedl, Kallmann's and Prader-Willi syndromes. The pituitary can also be damaged by cranial irradiation or surgically at the time of hypophysectomy for a pituitary tumour.

Hypogonadotrophic hypogonadism will also occur if pulsatile secretion of GnRH is slowed or stopped. This is seen in hypothalamic dysfunction, commonly secondary to excessive exercise, psychological stress or anorexia nervosa.

Hypergonadotrophic hypogonadism

This occurs as a result of failure of the ovary to respond to gonadotrophic stimulation by the pituitary gland. The absence of negative feedback (by oestradiol and inhibin B) from a developing follicle results in excessive secretion of the gonadotrophic hormones FSH and LH. Concentrations of these hormones reach menopausal levels. Hypergonadotrophic hypogonadism classically results from premature ovarian failure with exhaustion of the ovarian follicle pool. A variant of the condition, resistant ovary syndrome, describes the occurrence of elevated levels of serum gonadotrophins in the presence of a good reserve of follicles. Abnormalities in the FSH receptor may produce this picture. Neither premature ovarian failure nor resistant ovary syndrome is treatable by FSH injection.

Other discrete causes

Endocrine disorders, most commonly hyperprolactinaemia and hypothyroidism, are possible causes of anovulation and should be excluded by appropriate biochemical testing.

Tubal infertility

Tubal damage underlies infertility in approximately 14 per cent of couples and 40 per cent of infertile women [C]. Any damage to the Fallopian tube can prevent the sperm from reaching the oocyte or the embryo from reaching the uterine cavity, leading to infertility and tubal ectopic pregnancy, respectively. The Fallopian tube is more than just a 'tube': a number of key events occur within the tube, including capacitation of the sperm, fertilisation and the early development of the zygote and embryo. Therefore, the Fallopian tube may maintain its patency but lose the ability to promote these other functions. Currently accepted investigations can only test tubal patency, and not its function.

The main causes of tubal damage are either pelvic inflammatory disease (PID) or iatrogenic causes. PID remains the major cause of tubal damage in the western world, with *Chlamydia trachomatis* infection the prime pathogen in most cases. Pelvic infection or abscess caused by appendicitis, other bowel disorders or septic abortion is responsible for a lesser proportion of cases. Fallopian tubes can be damaged iatrogenically either directly, as in tubal ligation for sterilisation, or indirectly as a consequence of pelvic surgery. Other rare causes of tubal damage include tuberculosis, schistosomiasis, viral infection and abdominal inflammatory disorders, such as Crohn's disease.

Endometriosis

It is apparent that severe endometriosis can lead to mechanical tubal damage due to adhesion formation caused by the pelvic endometrial deposits. However, it is less certain whether the lesser degrees of endometriosis can lead to infertility.

Both mild endometriosis and infertility are common, and may occur together as epiphenomena [C]. Endometriosis is discussed further in Chapter 77.

Uterine factors

Submucous leiomyomata, congenital uterine abnormalities, endometrial polyps and intrauterine adhesions are all potential causes of infertility. The presence of a fibroid that occludes or distorts the Fallopian tubes will lead to tubal infertility [D]. Fertility outcomes are decreased in women with submucosal fibroids, and removal seems to confer benefit. Subserosal fibroids do not affect fertility outcomes, and removal does not confer benefit. Intramural fibroids appear to decrease fertility, but the results of therapy are unclear. Distortion of the uterine cavity, by a fibroid, a septum or in the T-shaped uterus following exposure of the female fetus to diethylstilbestrol *in utero*, can lead to implantation failure and recurrent early miscarriage [D]. Such cases should be assessed individually and the likelihood of their contribution to infertility should be examined. Excessive uterine curettage after a miscarriage or abortion, especially in the presence of uterine infection, can lead to the destruction of the strata basalis endometrium. Intrauterine scarring and synechiae develop as a result, which is known as Asherman's syndrome. This condition can also result after CS, uteroplasty or myomectomy.

It has been difficult to demonstrate a relationship between endometritis and subfertility, except when the cause of endometritis is tuberculosis. In the UK, tuberculous endometritis is a rare, but increasing, cause of infertility. The effect of chlamydial endometritis on implantation remains controversial, although there is evidence that patients with tubal disease undergoing IVF have significantly lower pregnancy and implantation rates.

Unexplained infertility

Completion of standard investigation of infertility fails to reveal a cause in 15–30 per cent of cases [C]. This does not indicate absence of a cause, but rather the inability to identify it. The results of IVF have shown that there may be undiagnosed problems of oocyte or embryo quality or of implantation failure, neither of which can easily be tested unless IVF is undertaken. Unexplained infertility causes great distress to couples, who often find it harder to bear when a cause cannot be found.

INVESTIGATION OF THE FEMALE PARTNER

Investigation of infertility will usually be initiated in general practice, frequently followed by referral to a secondary or tertiary centre, where most treatments will take place. RCOG and NICE have recently published guidelines for the management

of infertility. These define the role of the medical practitioner at each level, and outline the evidence base for investigation and treatment.

History taking and examination

It is important to recognise that infertility is a problem that faces couples, and that both partners should be seen and investigated together whenever possible [E]. Consultations involving infertility require tact and sensitivity on behalf of the clinician, a quiet, private environment and sufficient clinical time to allow exploration of the couple's anxieties and explanation of available treatments, as well as classical history taking. A rapport must be established before more personal and sensitive details can be sought.

Personal and social history

The couple's ages, in particular that of the female partner, are important, as discussed earlier. The occupations of the couple, especially the male, can have an impact on their fertility. Exposure to high temperature, chemicals and ionising radiation can seriously affect sperm production [D]. If either of the partners works away from home, this may affect the frequency of sexual intercourse around the time of ovulation. Smoking, alcohol and recreational drug use can also influence fertility. Appropriate advice should be given.

Menstrual history

The age of menarche and regularity of periods are important factors. Information about the frequency and length of the menstrual cycle and any associated problems such as dysmenorrhoea or heavy menstrual loss should be sought. Irregular menstrual cycles, oligomenorrhoea and amenorrhoea are all suggestive of anovulation. If amenorrhoea is reported, enquiries should be made about any menopausal symptoms, weight loss or gain, and symptoms of hyperprolactinaemia and hypothyroidism. These patients should be investigated in specialised centres [E].

Obstetric history

The clinician should enquire about any previous pregnancies, both in the current and any previous relationships, as well as the outcome of these pregnancies. It may be wise to ask about breastfeeding and any sustained galactorrhoea at this stage. It is also important to establish if there were any difficulties encountered or treatment required prior to achieving a previous pregnancy.

Contraception

The use of the oral contraceptive pill and the long-acting progestogens can be followed by a period of amenorrhoea. In particular, use of long-acting progestogen-based contraceptives may be followed by delay in the resumption of ovulation [D]. The use of intrauterine contraceptive devices may increase

the risk of pelvic infection, especially in young nulliparous women, leading to tubal disease [D].

Past medical history

It is important to establish any previous medical disorders that may affect either fertility or pregnancy. Pre-conceptional counselling may be necessary if a serious medical condition is identified. The possible impact of prescription medications on ovulation should be investigated: for example, some antidepressants can increase prolactin secretion and NSAIDs can interfere with ovulation.

Sexual history

The clinician should enquire about the couple's frequency of sexual intercourse and associated problems, such as dyspareunia or ejaculatory dysfunction. Regular intercourse (two to three times a week) is sufficient for most couples to achieve a pregnancy. It is frequently the case that infertile couples restrict their sexual activity to the period around mid-cycle and some use commercially available ovulation detection kits to time intercourse. There is no evidence that such practices can increase fecundability, and the increase in psychological stress that results from such practices is unhelpful [C]. Sensitive enquiry concerning sexually transmitted infections should be made.

Other important points

The discussion should include advice concerning the use of folic acid and enquiry about rubella vaccination [A]. A cervical smear history should be taken and a smear offered if indicated [E]. A family history, including enquiry concerning diabetes, endometriosis and PCOS, should be taken, as this information can be useful in the diagnosis and treatment of infertility [D]. A history of familial disorder should lead to an offer of genetic counselling before starting investigation and treatment [E].

Examination of the female partner

Unless there is an indication from the patient's history that examination would be of any value in establishing the cause of infertility, there would seem to be little to be gained from routine examination. Indications from the history, for example of cyclical pelvic pain or dyspareunia, should prompt pelvic examination. Other features of the physical examination, for example detection of an asymptomatic pelvic mass, have been supplanted by transvaginal ultrasound examination.

Assessment of BMI is important, as both obesity and underweight can cause anovulation [C]. If the patient is found to be obese, central obesity can be assessed by measuring the waist:hip ratio [C].

Table 81.1 Interpretation of female infertility investigations

Test	Result	Interpretation
Progesterone (mid-luteal)	<30 nmol/L	Anovulation
		Check cycle length and timing in mid-luteal phase
		Complete other endocrine tests
		Scan for PCO
		Advise re. weight gain/loss
		May need ovulation induction
		Clomiphene should not be started without test of tubal patency
FSH (early follicular)	>10 IU/L	Reduced ovarian reserve
		May respond poorly to ovulation induction
		May need egg donation
LH (early follicular)	>10 IU/L	May be PCO
		Ultrasound to confirm
Testosterone	>2.5 nmol/L	May be PCO
		Ultrasound to confirm
Prolactin	>1000 IU/L	May be pituitary adenoma
		Repeat prolactin to confirm raised level
		Exclude hypothyroidism
		Arrange MRI/CT scan
		If confirmed hyperprolactinaemia, start dopamine agonist

Test	Result	Interpretation
HSG/HyCoSy	Abnormal	May be tubal factor
		Arrange laparoscopy and dye to evaluate further
		May be intrauterine abnormality
		Evaluate further by hysteroscopy
Laparoscopy and dye	Blocked tubes	Tubal factor
		? Suitable for transcervical cannulation, surgery or IVF (also depends on semen quality)
	Endometriosis	Endometriosis
		Assess severity, may benefit from diathermy laser
		Medical suppression not helpful for fertility
		May need IVF
Rubella	Non-immune	Offer immunisation and 1 month contraception

Laboratory investigations, endoscopy and imaging

The aim of these investigations is to assess ovulation, tubal patency and uterine factors (Table 81.1).

Ovulation

A history of regular periods usually indicates ovulation. However, a reliable marker is useful to confirm that ovulation has occurred. After the release of the oocyte and the formation of the corpus luteum, progesterone levels rise sharply, reaching a peak level approximately 8 days after the LH surge. The detection of high levels of progesterone in serum or evidence of progesterone effect can be used as a secondary marker of ovulation. Historically, the effects of progesterone on basal body temperature, endometrial histology or cervical mucus were commonly used. Measuring serum progesterone at its peak in the mid-luteal phase is a reliable, safe and inexpensive test. Levels in excess of 30 nmol/L are diagnostic of ovulation [C]; however, lower (suboptimal) levels may be due to incorrect timing of blood sampling or may be caused by a luteinised unruptured follicle. It is important to remember that the mid-luteal phase is approximately 7 days before the next expected period i.e. day 21 and day 28 in 28-day and 35-day cycles, respectively.

Commercially available urinary LH detection kits can detect the LH surge and can be used to time intercourse with ovulation induction or donor insemination treatments.

Ovarian reserve tests

Another test added to the investigation of couples with infertility includes assessment of ovarian reserve. Women with advanced age or history of prior ovarian surgery are at risk for diminished ovarian function or reserve. Given the relatively

non-invasive nature of the testing, several practitioners are including the evaluation of ovarian reserve as first-line work up for infertility. The testing includes a cycle day 3 serum FSH and estradiol level, AMH or an ultrasonographic ovarian antral follicle count. However, NICE guidelines recommend that women who have high levels of gonadotrophins should be informed that they are likely to have reduced fertility. The results of these tests are not absolute indicators of infertility but abnormal levels correlate with decreased response to ovulation induction medications and lowered livebirth rates after IVF.

Tubal patency tests

Although the Fallopian tube has functions other than as a conduit for the sperm, oocyte and embryo, it is not yet feasible to assess these functions in routine practice. Tubal patency can be assessed by three different methods: ultrasound scanning with hydrotubation; hysterosalpingography; and laparoscopy and dye hydrotubation [D].

Ultrasound scan and hydrotubation

HyCoSy (**h**ysterosalpingo **c**ontrast **s**onography) has recently been introduced as a method for studying tubal patency using ultrasonography. Ultrasonographic contrast medium is slowly injected into the uterine cavity under direct visualisation, with imaging of the cavity and of flow along the Fallopian tubes. This method does not require X-ray and allows the ultrasound assessment of the pelvic organs i.e. the uterus including the uterine cavity, tubes and ovaries. This screening method should be reserved for cases where history is not suggestive of tubal pathology. Finding a normal cavity and bilateral fill and spill of contrast is reassuring, but where there is doubt, hysterosalpingography or a laparoscopy and dye hydrotubation test should be performed.

Hysterosalpingography

Hysterosalpingography (HSG) is a simple, safe and inexpensive X-ray-based contrast study of the uterine cavity and the Fallopian tubes with a 65 per cent sensitivity and 83 per cent specificity for detecting tubal blockage. The principle of this test is to inject a radio-opaque contrast medium through the cervix into the uterus and take abdominal X-rays at intervals during and after the injection. The images should reveal the uterine outline and passage of contrast along the tubes, with free spill into the peritoneal cavity. HSG is usually carried out in the first 10 days of the menstrual cycle, to avoid disruption of an early pregnancy in the secretory phase of the cycle. It will cause period-like pain in most patients and may occasionally lead to a vasovagal attack. The main complication of HSG is flare-up of PID. The overall risk of infection from this test in the normal population is approximately 1 per cent, rising to 3 per cent in high-risk patients. Therefore, it is wise to carry out laparoscopy and dye test in high-risk patients and to use prophylactic antibiotics to cover the test. RCOG recommends routine screening for chlamydia in any patient before carrying out any intrauterine instrumentation [E]. HSG is recommended by RCOG as the primary screening procedure in low-risk patients [E].

Laparoscopy and dye test

A laparoscopy and dye hydrotubation ('lap and dye') test is the most reliable, albeit expensive, tool used to diagnose tubal subfertility. The principle of this procedure is to visualise the passage of methylene blue dye through the Fallopian tubes. The procedure enables inspection of the fimbrial ends of the tubes and the pelvic structures for the presence of endometriosis or adhesions. Combining this procedure with electrocoagulation of any endometriotic spots or adhesiolysis adds therapeutic value. Hence, it is advisable that such procedures are carried out in centres where the necessary expertise is available [E].

Laparoscopy and dye test requires general anaesthetic and carries the risk of bowel or visceral injury. It is therefore not recommended as a first-line screening test [E]. However, it should be considered in patients with a history suggestive of endometriosis, previous PID or previous pelvic surgery. Furthermore, if the HSG reports abnormal results, verification should be carried out with diagnostic laparoscopy [E].

When comparing HSG with laparoscopy, keep in mind that both procedures provide extra information in addition to the assessment of the Fallopian tubes. HSG provides information about the status of the uterine cavity, whereas laparoscopy allows inspection of the intra-abdominal cavity, excludes peritoneal disease and allows laparoscopic treatment of pelvic pathology.

Visualisation and assessment of the uterine cavity are not possible unless hysteroscopy is performed concurrently. However, the value of routine hysteroscopy is questionable [E], as the frequency of asymptomatic intrauterine lesions that are not seen on transvaginal ultrasound is low. Hysteroscopy

should probably therefore be reserved for cases where there is an indication from the history or previous investigations.

Assessment of the uterus

Uterine anatomy can be visualised by saline hysterosonography, HSG or hysteroscopy. Conventional TVS may not always provide a good-quality image of the cavity, but 3D ultrasound, when available, can provide an accurate assessment of the uterine cavity. This may outline intrauterine polyps or synechiae. Routine hysteroscopy for infertile patients has been discouraged by RCOG [E].

Postcoital test

The postcoital test provides information concerning the ability of the sperm to penetrate and survive in cervical mucus. However, reproducibility of the test is low and the false-positive rate is high. A diagnosis of an adverse cervical factor does not alter therapeutic decisions, as both 'cervical factor' and unexplained infertility are treated with intrauterine insemination or IVF. According to NICE guidelines on the management of infertility, the routine use of postcoital testing in the investigation of fertility problems is not recommended because it has no predictive value on pregnancy rate.

Management of female infertility

Any discussion about the management of infertility should begin with an explanation of the physiology of the cycle, with information about the 'fertile period'. Among healthy women trying to conceive, nearly all pregnancies can be attributed to intercourse during a 6-day period ending on the day of ovulation.

Lifestyle issues, including advice on smoking, alcohol consumption and 'fitness for pregnancy', should be raised. Further planning of treatment protocols will depend on the presumed cause of the problem.

Management of tubal infertility

Tubal infertility can be treated with tubal surgery, IVF and embryo transfer (IVF-ET) or selective salpingography. Although tubal surgery is no longer recommended for severe tubal disease since the introduction of IVF-ET, it still has a place in less severe forms of the disorder.

Tubal surgery

Successful tubal surgery requires surgical skill and experience. The decline in the number of suitable cases has reduced training opportunities, and some advocate restriction of this practice to tertiary centres to allow concentration of expertise [E]. This permits audit of outcome and estimation of realistic, single-centre pregnancy rates. Comparison between tubal surgery and IVF is difficult. The cost, success rate, complications and benefits must be assessed in every case individually. Decision making may be altered in favour of IVF by the presence of other causes of infertility, particularly male factor and

anovulation. The success rate after tubal surgery depends on the underlying disease, site of damage (proximal or distal) and patient's age. NICE guidelines have suggested that for women with mild tubal disease, tubal surgery may be more effective than no treatment. In centres where appropriate expertise is available, it may be considered as a treatment option.

The cost of a single cycle of IVF has been calculated to be comparable to that of tubal surgery and, apart from patients with mild tubal disease, the cost-effectiveness argument is in favour of IVF-ET. However, tubal surgery, if successful, offers less risk of multiple pregnancy and ovarian hyperstimulation syndrome (OHSS), and avoids the ethical issues that fertilisation *in vitro* can engender. Patients should be informed that the risk of ectopic pregnancy after tubal surgery is significantly higher than after IVF-ET [C].

Once tubal surgery is being contemplated, careful assessment of the tubes and pelvis with HSG and laparoscopy should be carried out [E]. The route of access should then be decided i.e. laparotomy or laparoscopy. Laparoscopic surgery is less costly and offers less morbidity, more technical advantages and a marginally better pregnancy rate. If pregnancy does not occur within 6–12 months of tubal surgery, reassessment of the tubes with HSG should be carried out. If the tubes remain blocked, IVF-ET is indicated. If the tubes remain patent, ovulation should be assessed and perhaps a short period of ovulation induction could be tried. This decision will depend on the patient's age and whether IVF-ET is affordable to the couple. The key issues here are to present the couple with all the available facts and to involve them in the decision-making process.

IVF-ET

Absent or irreparably damaged Fallopian tubes were the main reason for the development of IVF-ET. A lower pregnancy rate after IVF-ET in tubal-infertility couples compared to other causes of infertility has been reported. The reason is not entirely clear, but it is possible that fluid from a hydrosalpinx could be hostile to embryo development and implantation. Salpingectomy of an ultrasonographically visible hydrosalpinx should therefore be considered to improve the success rate of IVF treatment [C], although careful counselling is needed before performing salpingectomy for an infertile patient, even if the tubal damage is severe [E].

Selective salpingography and tubal cannulation

These procedures can be carried out under image intensification or at hysteroscopy. These methods were originally developed for diagnostic purposes, but were subsequently proven to be useful in treating proximal tubal damage, for which surgery yielded disappointing success rates. The outcome of these procedures in terms of regaining tubal patency is immediately known. According to NICE guidelines, for women with proximal tubal obstruction, selective salpingography plus tubal catheterisation, or hysteroscopic tubal cannulation, may be treatment options because these treatments improve the chance of pregnancy.

Management of anovulatory infertility

A number of therapeutic interventions for the induction of ovulation are available. Selecting the most appropriate method depends on the cause of anovulation. Patients with ovarian failure and resistant ovary syndrome will not respond to ovulation induction and should be offered oocyte donation [C]. Normalisation of bodyweight in underweight and obese patients can help to regain ovulation without the need for medical intervention [B]. Medical treatment of prolactinoma can also help regain normal ovulation [A]. Ovulation induction in patients with hypogonadotrophic hypogonadism can be achieved with the pulsatile administration of GnRH or by daily injection of gonadotrophin [C]. Ovulation induction in PCOS patients (80 per cent of anovular women) can be achieved by weight normalisation in obese patients [C] (40–60 per cent of PCOS patients), medical or surgical methods. The medical methods include the use of clomiphene citrate or gonadotrophins – discussed further in Chapter 84, Assisted reproduction. NICE has recommended that women with WHO group II ovulation disorders (hypothalamic pituitary gonadal dysfunction), such as PCOS, should be offered treatment with clomifene citrate (or tamoxifen) as the first line of treatment for up to 12 months because it is likely to induce ovulation [A]. Additionally, women undergoing treatment with clomifene citrate should be offered ultrasound monitoring during at least the first cycle of treatment to ensure that they receive a dose that minimises the risk of multiple pregnancy.

The surgical methods are either ovarian drilling or wedge resection. Stein and Leventhal suggested ovarian wedge resection in 1935. Their theory was that the thick tunica albuginea prevented the release of the ovum, hence the anovulation in PCOS patients. Although pregnancies resulted, the operation (performed by laparotomy) led to complications, including tubal damage and adhesion formation, and fell into disrepute. Ovarian drilling involves focal local destruction of the ovarian stroma with laser or diathermy, applied laparoscopically. The route of access reduces morbidity and postoperative complications. Ovarian drilling achieves equivalent ovulation and pregnancy rates to medical ovulation induction. Predictors of success have included LH level >10 IU/L, normal BMI and shorter duration of infertility. However, evidence suggests that ovarian drilling has less risk of multiple pregnancies and no risk of OHSS. Economic analyses of two RCTs suggest that treating women with CC-resistant PCOS by laparoscopic ovarian drilling (LOD) resulted in reduced direct and indirect costs. On the other hand, the long-term advantages and risks of ovarian drilling require further assessment. Destroying ovarian tissue inevitably leads to destruction of primordial follicles and reduction of the ovarian reserve. These anxieties have partially been resolved by studies that demonstrate that a good therapeutic response can be achieved by minimal application of energy and after reduction of the number of diathermy burns to four per ovary.

Management of endometriosis-related infertility

This depends on the severity of the condition and the presence of any other infertility factors. The two main lines of treating endometriosis are medical and surgical. Medical treatment of minimal and mild endometriosis does not enhance fertility in infertile women and should not be offered [A].

Women with minimal or mild endometriosis who undergo laparoscopy should be offered surgical ablation or resection of endometriosis plus laparoscopic adhesiolysis because this improves the chance of pregnancy [A].

As many infertile patients will undergo diagnostic laparoscopy, diathermy to endometriosis can be delivered at the same session, alleviating the need for a further anaesthetic. Women with moderate or severe endometriosis should be offered surgical treatment because it improves the chance of pregnancy [B]. Assisted reproduction has lent itself to treating endometriosis-related infertility. Whether medical or conservative surgical treatment of endometriosis before carrying out IVF-ET can improve the ovarian response and pregnancy rates remains unclear.

Management of unexplained infertility

The lack of an identifiable reason for infertility in this category makes the treatment empirical. Conservative management, ovulation induction with or without intrauterine insemination, and IVF-ET are the main approaches to managing unexplained infertility. Approximately 60 per cent of couples with unexplained secondary infertility (diagnosed after one year) achieve a pregnancy within three years of conservative management [C]. Results are less good in primary infertility. However, the woman's age should be taken into consideration when advising this line of management. Ovulation induction (or, more properly, 'augmentation') with clomiphene citrate along with timed sexual intercourse has been used frequently in patients with unexplained infertility. However, recent meta-analysis of studies in this area has not demonstrated benefit over the conservative approach [A], and treatment with clomiphene citrate carries a risk of multiple pregnancy.

A cumulative pregnancy rate of 40 per cent has been reported after controlled ovarian stimulation (COS) with gonadotrophins and intrauterine insemination [C]. The pregnancy rates after IUI alone in couples with unexplained infertility have been disappointing and its use does not appear to confer any additional benefit over expectant management. However, the advantage of IUI over timed sexual intercourse after COS has been controversial, and firm evidence is lacking. For logistic reasons, IUI may provide a better timing compared to sexual intercourse. Many centres advise two or three cycles of COS-IUI before moving to IVF-ET in this group. COS-IUI may be less stressful, less physically demanding and less costly per attempt than IVF.

IVF-ET in unexplained infertility has diagnostic as well as therapeutic value, as it provides information about fertilisation

and egg and embryo quality. Owing to its high cost, IVF-ET is usually seen as a last resort in unexplained infertility. The cost of three cycles of COS-IUI is comparable to that of one IVF-ET cycle, with the latter offering a better pregnancy rate [D].

Gamete intrafallopian transfer (GIFT) used to be the treatment of choice for patients with unexplained infertility. However, IVF-ET, with its diagnostic potential, has superseded this modality. Although GIFT offered a high pregnancy rate, the ectopic pregnancy risk was also high [C], and the treatment requires general anaesthesia and laparoscopy in order for gametes to be placed within the ampulla of the Fallopian tube. This method has largely been supplanted by IVF-ET.

Management of uterine factor infertility

Congenital defects, leiomyomas and intrauterine adhesions and polyps are the only treatable uterine factors. However, before offering surgical treatment, the impact of such findings on the couple's fertility should be carefully assessed [E]. Myomectomy can be carried out either laparoscopically or by laparotomy with similar postoperative pregnancy rates [A]. Entry into the uterine cavity should be avoided if possible, and adhesion barriers and microsurgical technique should be used to reduce the risk of postoperative adhesions. The risk of a scar rupture during pregnancy is less if the endometrial cavity remains intact at myomectomy [D], although some fibroids cannot be removed without breach of the cavity. Post-operative adhesions can have a detrimental effect on tubal patency.

Submucous fibroids can successfully be resected hysteroscopically, depending on the size of the fibroid and its degree of protrusion into the uterine cavity. The risk of tubal damage with this procedure is minimal, but there is a risk of haemorrhage, uterine perforation and endometrial scarring leading to intrauterine adhesions. Hysteroscopic division of intrauterine adhesions and excision of polyps are usually straightforward, with low morbidity. Assisted reproductive technology is not applicable to uterine factor infertility. However, treatment of a uterine factor should be considered if failure of implantation seems to be the only cause of an unsuccessful IVF-ET treatment [E].

EBM

- There is no evidence that ovulation detection kits and temperature charts increase the chance of conception.
- There is no evidence that thorough physical examination of every patient is necessary.
- The postcoital test is of limited value with regard to discriminating between couples achieving and not achieving a pregnancy.
- Drug treatment is ineffective in the treatment of endometriosis-related infertility.
- Ovarian stimulation and IUI are effective in the management of mild male factor and unexplained infertility

KEY POINTS

- Around 9 per cent of couples are affected by infertility and half of them seek help.
- The most important determinant of a couple's fertility is the woman's age.
- Delaying starting a family until later life not only reduces fertility, but also increases the risk of miscarriage.
- PCOS is the most common cause of anovulatory infertility.
- Ovulatory disorders are the most common cause of female infertility.
- PID and iatrogenic causes are the main reasons for tubal infertility.
- *Chlamydia trachomatis* is the most common pathogen leading to PID in the western world.
- Unexplained infertility represents approximately 15–30 per cent of cases.
- Careful history taking is a very important starting point to the investigation of infertility.
- The mid-luteal phase is approximately 7 days from the next menstrual cycle, which is important when measuring serum progesterone levels for ovulation detection.
- Ablation of minimal and mild endometriosis adds a therapeutic dimension to a diagnostic procedure

ACKNOWLEDGEMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of Hany AMA Lashen to the chapter on this topic in the previous edition of the book.

Chapter 82 Male infertility

Yakoub Khalaf

MRCOG standards

Theoretical skills

- Understand epidemiology, aetiology and pathogenesis of male infertility.
- Understand clinical management and prognosis of male factor infertility.
- Understand indications, limitations and interpretation of relevant investigations.

Practical skills

- Be able to take a history and examine the male partner with regard to infertility investigations.
- Be able to interpret and understand the seminal analysis report.

INTRODUCTION

The impact of male factor on a couple's fertility is difficult to quantify other than in cases of absolute azoospermia or severe oligozoospermia/asthenozoospermia. In other words, any man with motile normal spermatozoa in his ejaculate should be credited with some degree of fertility. Women undergoing donor insemination treatment have a higher probability of pregnancy if they are partners of azoospermic men than if they are partners of oligozoospermic men. This reflects the fact that a degree of compensation can exist between the female and male partners. Accordingly, in most circumstances, it is easier to define male fertility than infertility. The ability to make a woman pregnant or father a child can be considered evidence of the male's fertility. There are many causes of male infertility, although primary testicular disorders are most commonly responsible.

AETIOLOGY

Primary testicular disease

The majority of cases of male factor infertility lie in this category. The pathogenesis of testicular dysfunction is poorly understood,

with no obvious predisposing factors being identifiable in more than 50 per cent of cases. Recent studies have linked azoospermia and severe oligozoospermia to microdeletions of genes on the Y chromosome, which appear to be involved in at least some cases of 'idiopathic' male infertility [D]. Other causes of failure of spermatogenesis include testicular maldescent, particularly if left uncorrected until puberty, testicular torsion, trauma or infection, neoplasm and effects of subsequent chemotherapy, haemosiderosis and Klinefelter's syndrome [D]. Mumps orchitis and severe epididymo-orchitis are the main inflammatory causes of testicular damage [D]. Other chromosomal anomalies can also lead to male infertility; however, Klinefelter's syndrome remains the only relatively commonly seen anomaly. Azoospermic and severely oligozoospermic men should have chromosomal karyotyping before their sperm is used for intracytoplasmic sperm injection (ICSI) in order to counsel the couple adequately about the risk of transmission of a chromosomal disorder (commonly deletion or translocation) to the offspring [E].

Obstructive male infertility

Obstruction can occur at any level of the male reproductive tract from the rete testis and the epididymis to the vas deferens. Obstruction can be due to congenital, inflammatory or iatrogenic causes. Desire for fertility following vasectomy is common. Congenital absence of the vas is also fairly common, being the cause of azoospermia in approximately 10 per cent of cases [D]. Bilateral congenital absence of the vas is seen in carriers of genes for cystic fibrosis [C], and pre-treatment screening of both partners is essential to avoid the possibility of cystic fibrosis in the offspring.

Endocrinological causes of male infertility

Endocrinopathies are rarely identified in cases of male infertility. The more common conditions seen in this category include hypogonadotrophic hypogonadism, and thyroid and adrenal disease [D]. Although rare, these conditions should be diagnosed, as their treatment is straightforward and can restore fertility. Hyperprolactinaemia in men can lead to impotence, but has little effect on sperm production [C].

Auto-immune causes

Approximately 12 per cent of men have anti-sperm antibodies [C]. This can lead to decreased sperm motility and may impede the binding of the spermatozoon to the zona pellucida of the oocyte, hindering fertilisation. Low levels of anti-sperm antibodies are not thought to have a significant impact on fertility [D]. The reason why some men develop anti-sperm antibodies is not known, although damage to the testis following trauma and surgery (resulting in disruption of the blood–testes barrier) can be found in many cases.

Drugs

Drugs taken for medicinal and recreational purposes can affect sperm production and/or function. Alcohol, cigarettes, opiates and marijuana can suppress spermatogenesis and affect sperm function [D]. Anabolic steroids, antifungal drugs, sulfasalazine and corticosteroids also affect spermatogenesis. The effect of most of these drugs is reversible. In contrast, chemotherapy can cause permanent damage to spermatogenesis. Other drugs, including antidepressants, sedatives and antihypertensives, can lead to male infertility by causing erectile dysfunction.

Environmental factors

Exposure to heat, chemicals and ionising irradiation can damage sperm production, and it is important to enquire about the male partner's occupation. Evidence for the extent of the effects of environmental toxins on male fertility is lacking. Although epidemiological studies have demonstrated a decline in sperm quality in the developed world, it is difficult to extrapolate from these population-based data to individual cases. However, it seems sensible to advise the avoidance of excessive heat and exposure to chemicals such as paints, organic solvents, lead-based products and pesticides in oligospermic/asthenospermic subfertile men.

Varicocele

Varicocele is a dilatation of the veins along the spermatic cord in the scrotum. Dilatation occurs when valves within the veins along the spermatic cord obstruct normal blood flow, causing a backflow of blood. The mechanisms by which varicoceles would affect fertility have not yet been explained, and neither have the mechanisms by which surgical treatment of the varicoceles might restore fertility. It occurs in both fertile and infertile men, although the incidence seems to be higher among infertile men [C]. The impact of varicocele on male fertility remains controversial. Increased testicular temperature (which is unfavourable for spermatogenesis) has been suggested as a mechanism of action in these cases, but surgical or radiological correction of the disorder is not thought to improve the chances of conception [A].¹ Additionally, there is no increase in pregnancy rates following varicocele treatment

compared to no treatment in subfertile couples in whom varicoceles in the man is the only abnormal finding.

Ejaculatory disorders

Retrograde ejaculation, in which sperm enter the bladder rather than the penile urethra at ejaculation, can follow from neurological disorders, diabetes or bladder neck or prostate surgery. Failure of ejaculation due to neurological disorders, medication or psychological difficulties is a rare cause of male infertility and the most difficult to treat. Most men with such problems require sperm freezing (usually by surgical sperm retrieval) and assisted conception treatment.

INVESTIGATION OF THE MALE

All referrals to an infertility clinic should be seen as a couple, with concurrent investigation of the male and female partners. A routine semen analysis can be performed before seeing the couple in the clinic. A normal result can provide a degree of reassurance to the male partner, and erectile and ejaculatory problems can usually be excluded by a sensitively taken medical history. If the seminal parameters are abnormal, further investigations should be instigated. It is important to elicit from the history any of the causes of male infertility mentioned above. This should be followed by examination of genital development, the testicles, the epididymis and the vas deferens. Any of the aforementioned reversible causes can usually be corrected, and advice regarding smoking, alcohol and substance abuse should be given. Testicular cooling by wearing boxer shorts or taking cold baths is probably of little value, although occupational exposure to extreme heat should be avoided.

Semen analysis

The value of a diagnostic test depends on its sensitivity (ability to identify disease), specificity (ability to identify normality) and reproducibility (obtaining similar results each time the test is carried out). The wide overlap of the results of the various components of a semen analysis between fertile and infertile men reduces the sensitivity and specificity of routine semen analysis as a test of infertility. Moreover, the large biological variation seen in the quality of sperm in repeated tests on the same individual limits the reproducibility of semen analysis as a diagnostic test. Routine semen analysis should be performed according to criteria established by the WHO in order to achieve standardisation (Table 82.1). The test assesses several measures of sperm quality, some of which are more sensitive in identifying infertile men than others. The WHO-recommended method of semen analysis includes determination of the volume of ejaculate, concentration, motility and percentage of morphologically normal forms. Semen analysis can be carried out manually or using computer-assisted sperm analysis (CASA). Several population-based studies have

Table 82.1 Reference values from the updated WHO guidelines (2010)

volume	Lower reference limit
Semen volume (ml)	1.5 (1.4–1.7)
Total sperm number (10 ⁶ per ejaculate)	39 (33–46)
Sperm concentration (10 ⁶ per ml)	15 (12–16)
Progressive motility (PR, %)	32 (31–34)
Sperm morphology (normal forms, %)	4 (3.0–4.0)
Vitality (live spermatozoa, %)	58 (55–63)
pH	≥7.2

produced statistical correlation between the different semen parameters and fertility potential in men. It is also important to remember that these values are not the minimum requirement to achieve a pregnancy; therefore they are referred to as 'reference' and not 'normal' values.

Many other tests of semen quality have been devised. These include biochemical analysis of the seminal fluid and detection of anti-sperm antibodies. Biochemical analysis of the seminal fluid can provide information about the prostate, seminal vesicles and epididymis. Zinc, fructose, carnitine and acid phosphatase have all been studied, but are not thought to impart useful diagnostic or prognostic information. The detection of anti-sperm antibodies using the immunobead or mixed antibody reaction (MAR) test may alter treatment and continues to be performed in most centres.

Sperm function tests

The functions of the sperm *in vivo* are to negotiate the cervical mucus, reach the ampullary part of the Fallopian tube in sufficient numbers, undergo capacitation and finally fertilise the egg. However, routine semen analysis does not test these functions. Therefore several tests, known as 'sperm function tests', have been developed in tertiary centres. These tests are still of academic rather than practical value and have become less significant following the introduction of IVF treatments, which circumvent most of the steps necessary for fertilisation *in vivo*. Their role in routine infertility investigations has yet to be established. Some of these tests are listed in Box 82.1 and the interested reader can refer to the WHO manual for more details.

Other tests

Unexplained severe sperm abnormality including azoospermia merits further investigation. The objective of such

Box 82.1 Sperm function tests

- Objective assessment of motility
- Hypo-osmotic swelling test
- Tests for sperm nuclear maturity
- Measure of acrosome status
- Acrosome reaction and acrosin activity
- Hamster zona-free oocyte penetration
- Human sperm zona binding and penetration

tests is to identify whether azoospermia is due to a primary testicular disorder or an outflow obstruction. Obstructive azoospermia is usually associated with normal concentration of FSH in serum, as the testes continue to function normally. In contrast, disorders of spermatogenesis result in interruption of the gonadal–pituitary feedback loop with elevation of serum FSH. Measurement of FSH can thus be useful in the investigation of azoospermia. Testosterone, luteinising hormone and sex hormone-binding globulin (SHBG) can complement the investigations. Serum inhibin B is performed as a marker of spermatogenesis in some tertiary centres and also in research settings. Ultrasound scan of testes (with or without Doppler) can be used to rule out structural abnormalities and malignancies. Invasive investigation using testicular biopsy can assess the extent of damage to the spermatogenesis and identify whether it is possible to obtain testicular sperm for use in ICSI, even if the patient is azoospermic. Karyotyping and cystic fibrosis gene screening are necessary if a chromosomal abnormality is suspected or to assess the carrier status for cystic fibrosis genes in patients with congenital absence of the vas. However, the modern management of male infertility and the introduction of ICSI treatment has reduced the need for extensive investigations, especially in less severe cases of oligozoospermia or athenozoospermia. Where an endocrinological reason is suspected, the diagnosis should be made, as the treatment strategy in these cases differs from the usual treatment modalities for male infertility (Fig. 82.1).

Examination of the male partner

In the presence of a normal semen analysis, there is little to gain from examination of the male. On the other hand, in severe male factor infertility and especially in azoospermic men, examination is warranted to help establish the cause of the problem. Both general and genital examinations should be undertaken. The objectives of the general examination are to assess the level of masculinisation and to detect any stigmata of chromosomal abnormality, inguinal hernia or relevant surgical scars, gynaecomastia or evidence of systemic illnesses. The genital examination should include assessment of the testes, epididymis and vas deferens and detection of any scrotal swellings or varicocele. If the history suggests penile

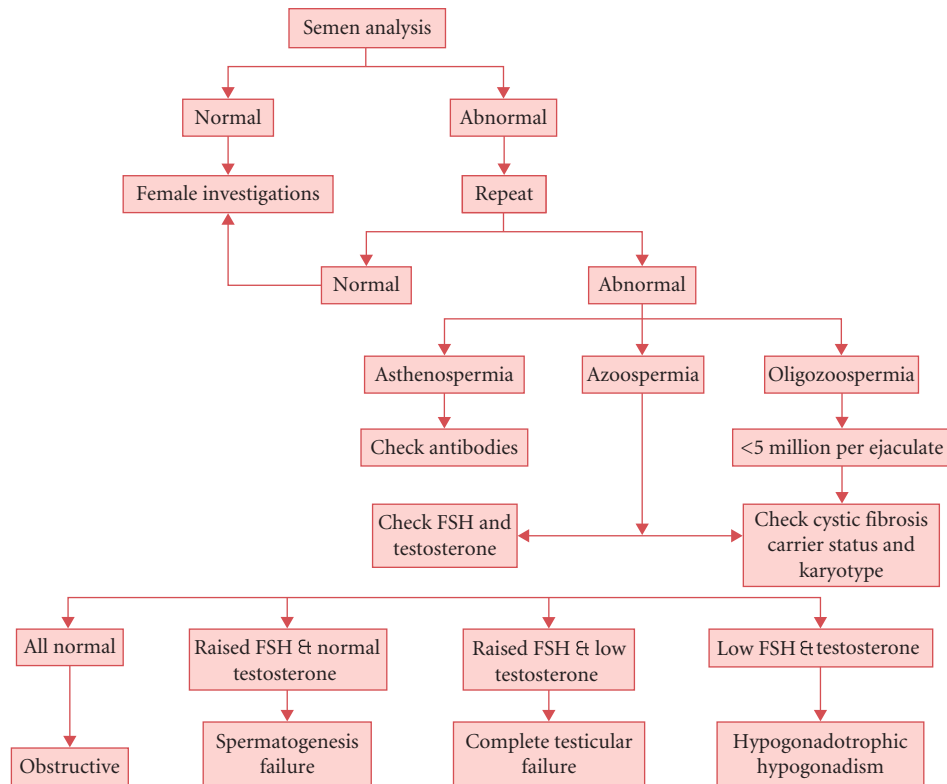

Fig. 82.1 Investigations of male infertility. FSH, follicle-stimulating hormone

or prostatic problems, it is advisable to refer for a urological opinion. The examination should be carried out in standing and supine positions in a warm private room. The testicular axis, volume and consistency should be assessed with a Prader orchimeter to measure the testicular volume. It should be noted that testicular volume is related to ethnic origin, weight and height and there is normally a small difference between the left and right testicles. For Caucasian men the normal volume is above 12 mL per testis. The consistency of the testicles can also be assessed. A soft consistency is associated with impaired spermatogenesis. Examination of the epididymis should assess its position in relation to the testicle, volume, any tenderness and any nodularity or swellings. Normally, the epididymis is small and may not be palpable. The vas should have no thickenings or nodules. Careful examination for the presence of the vasa is essential in azoospermic men, especially if the testicular volume is normal. Scrotal examination for varicocele should be carried out in the standing position. If any other scrotal swelling is palpable, the patient should be referred for a urological opinion. Testicular maldescent in infancy is associated with an increased risk of testicular cancer in later life. Such patients may present to an infertility clinic for investigation of oligospermia. They should be apprised of this risk and taught to self-examine. Similarly, tissue collected at testicular biopsy that is used to obtain sperm for ICSI in azoospermic men should also be sent for histological examination

(for example, to exclude sertoli-only syndrome). Ideally testicular sperm retrieval should be performed in an-HFEA registered clinic with facilities for cryopreservation.

MANAGEMENT OF MALE INFERTILITY

Until recently, men with primary testicular dysfunction or obstructive azoospermia were unable to reproduce. IVF and micromanipulation of sperm now offer these men the opportunity to father children and have become the mainstay in the treatment of male factor infertility. The treatment of male factor infertility, including the use of donor insemination, is discussed in Chapter 84, Assisted reproduction. However, some more traditional methods of treatment merit consideration.

Varicocelectomy

This procedure refers to the ligation of varicocele, which was carried out both prophylactically and therapeutically for many decades. Varicocele repair does not seem to be an effective treatment for male or unexplained subfertility [A]. The modern management of infertility has made the procedure redundant, removing the opportunity for further randomised trials to investigate its value.

Management of endocrine disorders

Hypogonadotrophic hypogonadism, often in association with Kallmann's syndrome, has been successfully treated with pulsatile GnRH or human menopausal gonadotrophins and hCG to restore spermatogenic drive and hence fertility. Initiation of spermatogenesis can take several months and treatment can become costly.

Men with idiopathic semen abnormalities should not be offered anti-oestrogens, gonadotrophins, androgens, bromocriptine or kinin-enhancing drugs because they have not been shown to be effective [A].

Management of anti-sperm antibodies

Many empirical therapies have been suggested for men with anti-sperm antibodies. The use of condoms and corticosteroids and intrauterine insemination of washed spermatozoa are some examples [A]. The value of all these modalities has been controversial, and IVF-ET and ICSI are currently the methods of choice in these cases. Donor insemination can be an alternative for financial reasons.

Reversal of vasectomy

Vasectomy reversal can be carried out successfully, with up to an 80 per cent chance of a subsequent pregnancy. The chance of success is inversely proportional to the length of time since the vasectomy was carried out. Although the integrity of the vas deferens can be restored in most cases, anti-sperm antibodies are common after vasectomy and reversal, and are probably the major bar to conception. In these cases and in those whose operation has failed, IVF with ICSI is the recommended treatment. A growing number of centres are offering collection and storage of sperm from the epididymis at the time of vasectomy reversal, for subsequent use in ICSI treatment if the reversal operation fails.

EBM

- The use of gonadotrophin drugs in hypogonadotrophic hypogonadal men is an effective treatment [B].
- The use of bromocriptine in men with sexual dysfunction as a result of hyperprolactinaemia is effective [B].
- Testicular biopsy should only be undertaken in tertiary centres [E].
- Vasectomy reversal is an effective treatment [A].
- Anti-oestrogens, androgens and bromocriptine are not effective in improving sperm quality [C].
- The use of steroids in the treatment of anti-sperm antibodies is ineffective and further validation is required [B].

- Surgery on the male genital tract should be undertaken only in centres where expertise is available [E].
- Men found to have abnormal chromosomal analysis (14 per cent in azoospermia and 7 per cent in severe oligozoospermia should receive genetic counselling.
- Testosterone replacement can result in oligozoospermia and/or reversible azoospermia and is therefore contraindicated in management of male infertility.

KEY POINTS

- Semen analysis is an appropriate starting point in the investigation of the male partner.
- If a severe sperm abnormality is found, clinical examination and bacteriological and endocrinological tests should be undertaken.
 - Tact and sensitivity are important when obtaining a history, examining patients and discussing abnormal results with them.
 - If reversal of vasectomy is to be undertaken, efforts should be made to obtain epididymal sperm for freezing and future use in case of operation failure.
- There is a considerable variability in sperm quality when assessed in the same individual over time.
- Semen analysis, unlike many modern investigative tests, is operator dependent. Adequate training of the operators is therefore essential to minimise both intra-observer and inter-observer variation.
- The andrology laboratory should be subject to external and internal quality assessments.

ACKNOWLEDGMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of Hany AMA Lashen to the chapter on this topic in the previous edition of the book.

Chapter 83 Unexplained infertility

Smriti Bhatta and Siladitya Bhattacharya

MRCOG Standards

Theoretical

- Understand how to reach a diagnosis of unexplained infertility.
- Understand the factors linked to unexplained infertility.
- Be familiar with the different management approaches.
- Be aware of the high risk of obstetric complications in subfertile women

Practical

- Arrange the investigations required for the diagnosis.
- Be aware of the higher chance of natural conception in couples with unexplained infertility.
- Understand the place of expectant management, ovulation induction, IUI and IVF in managing these couples.

INTRODUCTION

Infertility is defined as the inability to conceive after one year of unprotected intercourse. Standard investigations performed as part of an initial work-up include semen analysis, serum mid-luteal progesterone level to confirm ovulation, and a tubal patency test. These tests are normal in about 25 per cent of couples in whom the cause of infertility is deemed to be unexplained.¹ As the decision to undergo a panel of investigations is prompted by an expectation of finding a specific cause which is amenable to targeted treatment, unexplained infertility as a concept is difficult for couples to accept.

The suitability of the term 'unexplained infertility' has been questioned as the diagnosis is dependent on the number, nature and quality of tests used. Unexplained infertility does not exclude the possibility of a number of putative causes which are undetectable by standard tests.

These include tubal transport problems, mild ovulatory dysfunction, poor gamete and embryo quality, luteal-phase deficits, implantation abnormalities and immunological causes. While absence of a precise diagnosis is intellectually and emotionally unsatisfactory, routine use of a larger panel of tests would be logistically challenging without necessarily having an impact on management, which is heavily reliant on assisted reproduction to bypass known and unknown causes.

POSSIBLE CAUSES OF UNEXPLAINED INFERTILITY

Human conception is a complex series of events that involves an interaction between the egg and sperm, fertilisation and implantation of the embryo. Any overt or hidden factors that interfere with these events can lead to infertility. A number of possible causes for unexplained infertility are listed in Box 83.1. Many of these are subtle in nature and few are actually treatable at the present time.

Box 83.1 Factors which can contribute to unexplained infertility

Ovarian

- Poor ovarian reserve in older women
- Poor oocyte quality
- Luteinised unruptured follicle

Peritoneal

- Mild endometriosis
- Altered macrophage and immune activity

Endometrial

- Abnormal T-cell and natural killer cell activity
- Abnormal endometrial perfusion
- Abnormal secretion of endometrial proteins

Male factors

- Reduced acrosome reaction, oocyte binding and zona penetration

Embryo

- Genetic and chromosomal abnormalities

MANAGEMENT

Absence of conception within 12 months does not equate to sterility, and in the absence of any obvious barriers to infertility, a significant proportion of couples with unexplained infertility can expect to become pregnant without active treatment.² In particular, where the duration of infertility is short and the female partner is young and/or has had a previous pregnancy, the prognosis is good. However, lack of a specific diagnosis has traditionally encouraged the use of a variety of empirical treatments in the management of unexplained infertility. Commonly used treatments include clomiphene citrate, intrauterine insemination with or without controlled ovarian stimulation, and IVF. Factors affecting treatment success are female age, parity and duration of infertility.

Expectant management

EBM

Managing the couples expectantly is the first-line approach in good-prognosis patients due to high chances of natural conception [B]² and due to cost effectiveness [A]. However, couples prefer the treatment option [B].^{4,5}

Expectant management is the first-line approach for couples with unexplained infertility of relatively short duration where the female partner is young. In an observational Dutch study, 81 per cent (356/437) of couples with unexplained infertility had an ongoing pregnancy within five years of diagnosis, with 74 per cent (263/356) of pregnancies being conceived naturally.²

Table 83.1 provides data from two other studies on spontaneous livebirth rates in couples undergoing expectant management in different settings.

Accurate prediction of the chances of conception can be useful in counselling patients and avoiding unnecessary treatment. A popular prediction model³ has identified the factors associated with live birth, of which the most important are female age, duration of infertility and previous pregnancy. Female age less than 35 years and duration of infertility of less than two years are associated with higher odds of natural conception.

During expectant management, couples are advised to follow healthy lifestyle habits, maintain optimal weight

Table 83.1 Chance of spontaneous conception

Author	Livebirth rate at 12 months	Livebirth rate at 36 months	Setting
Collins <i>et al.</i> 1995	14.3%	33%	Tertiary care
Snick <i>et al.</i> 1997	27.4%	60%	Primary care

and continue regular sexual intercourse in order to maximise chances of conception. However, this approach is not always appealing to many couples who equate active medical treatment with higher success rates. A Scottish RCT⁴ comparing clomiphene or IUI with expectant management found that women randomised to clomiphene citrate (159/170, 94%) and IUI (155/162, 96%) found the process of treatment more acceptable than those randomised to expectant management (123/153, 80%) ($p = 0.001$ and $p < 0.001$, respectively).

Expectant management is cost effective compared to active treatment. Data from a Dutch study⁵ on long-term follow-up of couples with an intermediate prognosis, randomised to a six-month period of either expectant management or superovulation and IUI, found an estimated saving of 2616 euros in those managed expectantly, with no difference in pregnancy rates between the two groups. The period of expectant management needs to take into account the age of the female partner, but many would consider waiting for two years before moving on to active treatment.¹

EBM

Clomiphene use is costly and does not shorten the time to pregnancy or increase the livebirth rate as compared to expectant management [A].^{4,5,6}

Clomiphene citrate

Oral clomiphene citrate therapy has been commonly used for management of unexplained infertility. It is thought to correct subtle ovulatory dysfunction. Clomiphene is a selective oestrogen receptor modulator (SERM) that inhibits the negative feedback effect of oestrogen on the hypothalamus, resulting in increased gonadotrophin secretion and induction of ovulation. It can lead to multiple ovulation and is associated with a risk of multiple pregnancy. Treatment is usually initiated with a dose of 50 mg once daily from days 2–6 of a menstrual cycle, although higher doses have been used. Common side effects of clomiphene include hot flushes, abdominal discomfort or blurring of vision. Concerns regarding potential risk of ovarian cancer have not been confirmed. Clomiphene has been popular because it is inexpensive, non-invasive and needs less clinical monitoring.

In a large RCT⁴ comparing clomiphene with expectant management in unexplained infertility, livebirth rates were comparable in both groups (OR 0.79, 95% CI 0.45–1.38), suggesting no benefit with clomiphene use. The number needed to treat for harm with clomiphene citrate was 33 (i.e. treating 33 more women with clomiphene would yield one less livebirth compared to expectant management). Also, there was no significant difference in time to pregnancy leading to livebirth with clomiphene ($P = 0.41$) compared with expectant management (Fig. 83.1).

Fig. 83.1 Time to pregnancy leading to live birth in expectant management compared to treatment (clomifene and IUI) Bhattacharya *et al.*⁴

A Cochrane review⁵ on clomifene use in unexplained infertility did not show any improvement in pregnancy rates with clomifene after pooling data from two trials (OR 1.03, 95% CI 0.64–1.66).

Cost effectiveness of empirical clomifene use has been evaluated based on data from a large trial.⁶ Cost per livebirth was £72 after expectant management and £2611 after treatment with clomifene, suggesting clomifene to be less cost effective than expectant management.

EBM

IUI in a natural cycle does not increase the livebirth rate compared to expectant management [A].^{4,7} IUI with ovarian stimulation is more effective than IUI alone but increases the risk of multiple pregnancy [A].⁷

Intrauterine insemination

Intrauterine insemination has been widely used as a fertility treatment for unexplained infertility. It involves preparation of a semen sample in the laboratory to isolate spermatozoa with high motility. The prepared sample is then loaded into a narrow catheter and introduced within the uterine cavity at around the time of ovulation. Theoretically, this allows sperm to bypass any hostile cervical factors and increases the number

of motile sperm within the upper genital tract. Ovarian stimulation increases the number of available oocytes and therefore increases the risks of multiple pregnancy.

IUI in a natural cycle involves monitoring urinary or serum LH from day 10 to day 12 of the treatment cycle to detect LH surge. Insemination is performed 20–30 hours after detection of an LH surge. In stimulated cycles (IUI + ovarian stimulation [SO]), clomifene or gonadotrophins are used to promote ovulation from more than one (ideally two) mature follicles. hCG is administered to trigger ovulation and IUI is scheduled 36–40 hours later.

A Scottish multicentre trial comparing unstimulated IUI to expectant management over a 6-month period⁴ did not find a statistically significant difference in livebirth rate between the two groups (OR 1.46, 95% CI 0.88–2.43). The NNT was 17, suggesting that 17 women would need to undergo IUI over six months to achieve one extra livebirth.

Table 83.2 presents a summary of the available evidence from RCTs for the effectiveness of IUI treatment.

In an economic evaluation of a large multicentre trial,⁶ the cost effectiveness of IUI was compared to expectant management. The cost per livebirth was £1487 compared to £72 for expectant management. The study concluded that IUI was unlikely to be cost effective in an NHS setting.

Stimulated IUI cycles can be associated with a high multiple pregnancy rate. A recent multicentre Dutch study¹⁰ randomised 605 couples with unexplained and mild male factor infertility to 3 cycles of IVF elective single embryo transfer (IVF e-SET), 6 cycles of modified natural cycle IVF (MNC IVF) and 6 cycles of IUI with COH to evaluate if the alternative treatment strategies have reduced multiple pregnancy rates compared to stimulated IUI. This found that the multiple pregnancy rates were low and comparable across the three groups.

IVF

IVF is increasingly used as a definitive treatment for unexplained infertility. The rationale behind using IVF is that it can bypass known and unknown causes associated with unexplained infertility, but it is expensive and is associated with the risks of multiple pregnancy and ovarian hyperstimulation syndrome.

Table 83.2 IUI in unexplained infertility compared to expectant management and IVF

Treatment	Comparison group	Study	Effectiveness (odds of livebirth)
Stimulated IUI	Natural cycle IUI	Cochrane review ⁷	OR 2.07, 95% CI 1.22–3.50
Stimulated IUI	Timed intercourse in stimulated cycle	Cochrane review ⁷	OR 1.59, 95% CI 0.88–2.88
Unstimulated IUI	Expectant management	Cochrane review ⁷	OR 1.60, 95% CI 0.92–2.78
Stimulated IUI	Expectant management	Dutch multicentre RCT ⁸	OR 0.82, 95% CI 0.45–1.49
Stimulated IUI	IVF	Cochrane review ⁹	OR 1.09, 95% CI 0.74–1.59

EBM

IVF is more effective than expectant management and IUI [A]⁹ and is offered to couples with unexplained infertility of more than two years' duration.

IVF is offered to women with unresolved unexplained infertility who have been trying for more than two years. However, the contribution of IVF to pregnancy rates in couples with unexplained subfertility is around 13 per cent compared to a higher proportion of pregnancies from IVF in couples with tubal factor, endometriosis and male factor infertility (45, 45 and 37 per cent, respectively).¹¹ Use of ICSI technique for fertilisation has shown improved fertilisation rates when compared to conventional IVF in couples with unexplained infertility.¹²

IVF appears to be more effective compared to other treatment strategies. Table 83.3 shows data from a Cochrane review⁹ to support this.

One study used a mathematical model to compare the cost effectiveness of offering primary IVF therapy with IUI cycles and IVF.¹³ The study found that for a cohort of 100 couples, six cycles of IUI would cost an extra £172,200, providing an opportunity for an additional 54 IVF cycles and 14 live births. The conclusion was that a primary strategy of IVF was more cost effective than IUI followed by IVF.

PREGNANCY AFTER UNEXPLAINED INFERTILITY

Subfertile women are at a higher risk of obstetric complications even after adjusting for the influencing factors like age and parity. A study specifically investigating obstetric outcome in women with unexplained infertility found higher rates of obstetric complications in this group, including pre-eclampsia, preterm labour, placental abruption, and induction of labour and emergency caesarean section.¹⁴ The explanation for this remains unclear.

Table 83.3 Efficacy of IVF compared to IUI and expectant management

Treatment	Comparison group	Study	Effectiveness (odds of live birth)
IVF	Expectant management	Cochrane review ⁹	OR 22, 95%CI 2.56–189.37
IVF	IUI	Cochrane review ⁹	OR 1.96, 95%CI 0.88–4.36
IVF	Stimulated IUI	Cochrane review ⁹	OR 1.09, 95% CI 0.74–1.59

EBM

Pregnancies following unexplained infertility have higher risks [B].¹⁴

KEY POINTS

- Unexplained infertility is a diagnosis of exclusion after confirmation of ovulation, tubal patency and normal semen analysis.
- Introducing additional tests to identify the potential causes is not cost effective and is unlikely to change management.
- Unexplained infertility is associated with higher chances of natural conception compared with other causes of infertility.
- Expectant management is recommended in younger couples with shorter duration of infertility.
- Clomiphene and unstimulated IUI are not effective.
- IUI with ovarian stimulation is more effective than IUI alone.
- IVF may be offered after two years of expectant management and appears to be more effective in comparison with other treatment strategies.

Chapter 84 Assisted reproduction

Abey Eapen and Arri Coomarasamy

MRCOG standards

Theoretical skills

- Have good knowledge of the indications and treatment options for assisted reproductive techniques.
- Be aware of the risks associated with ART.
- Have a brief knowledge of the laboratory procedures.
- Appreciate the emotional, physical and financial stress involved and be aware of the social, ethical and legal implications associated with ART.
- Have a brief knowledge of the HFEA and practice code.

Practical skills

- Be able to organise appropriate investigations and offer counselling.
- Be able to identify and counsel individuals/couples regarding treatment options, risks and success rates.
- Be able to diagnose and manage ovarian hyperstimulation syndrome.
- Be able to liaise with a multidisciplinary fertility team.

INTRODUCTION

ART represents a wide range of treatment options used for management of women or couples diagnosed with infertility. The most widely used option is IVF. Human IVF treatments started as early as the 1940s, but without success. In 1976, the first IVF pregnancy was documented, albeit an ectopic.¹

The first livebirth following 'test tube conception' occurred in 1978. Louise Brown was born in the UK following a natural cycle of IVF treatment supervised by Robert Edwards (physiologist) and Patrick Steptoe (gynaecologist). Successful IVF treatment followed in Australia, USA, Sweden and France and then worldwide.

The two major breakthroughs since inception of IVF treatment are considered to be controlled ovarian stimulation (COS) and intracytoplasmic sperm injection (ICSI). Advances in diagnosis, therapy, intervention (e.g. TVS) and laboratory techniques have resulted in a gradual increase in ART success rates over the years.

EPIDEMIOLOGY

An estimated 1 in 7 couples (approximately 3.5 million in the UK) have difficulty conceiving, and many of these couples have IVF treatment. Every year about 12,000 babies are born using assisted conception treatment in the UK,² representing approximately 2 per cent of all babies born every year.

Latest HFEA data show 49,636 women had a total of 64,600 cycles of IVF and 2379 women had a total of 4611 cycles of donor insemination (DI) in 2013 in the UK. Worldwide, about 1 million babies have been born as a result of ART.

INDICATIONS FOR ART

There are multiple indications for ART, including long-standing unexplained infertility (Table 84.1).

HUMAN FERTILISATION AND EMBRYOLOGY AUTHORITY

In the UK, the HFEA provides licensing and monitoring for clinical and research activities using human gametes and embryos. Clinics performing any form of assisted conception techniques will need to be registered with the HFEA and are identified by a unique HFEA reference number. The HFEA provides impartial and reliable information to the public and publishes a league table with individual clinics' success rates and statistics associated with each aspect of ART.

Table 84.1 Indications for ART

Female	Male	Couple
Tubal factor	Ejaculatory dysfunction	Long-standing primary or secondary unexplained subfertility
Moderate to severe endometriosis	Sub-optimal sperm variables	HLA matching for offspring with rare disorders
Low ovarian reserve	Azoospermia	Screening for genetic disorders (in those with a strong family history)
Age-related subfertility	Gay couples	Medical indications (surrogacy in cases of contraindications to pregnancy, anatomical abnormalities or following egg/embryo freezing in women with cancers)
Premature ovarian failure	Medical indications (malignancies or chronic debilitating illnesses)	
Single woman		
Lesbian couple		

KEY POINTS

- The HFEA replaced the Warnock committee (1982) and the HFEA 1990 Act came into force in 1991.
- Disclosure of donor information regulation (2004) allowed removal of donor anonymity allowing details about oocyte and sperm donors (registered after 1 April 2005) to be passed on to the offspring.
- As per HFEA data from 2013, a total of 78 licensed clinics conducted IVF treatment and a total of 75 conducted donor inseminations in the UK.

COUNSELLING

Counselling includes information provision by care providers and impartial advice by independent counsellors, as well as genetic and psychosexual counselling.

Counselling by clinicians: This involves explaining the options available to the couple, helping them to decide the right treatment by discussing the risks, benefits and success rates associated with the treatment options.

Counselling by a trained professional: Offering impartial advice to the individual before, during or after the assisted conception process is a requirement for ART clinics registered with HFEA. Implication counselling to help with emotional issues, to discuss needs/legal rights of donor conceived children and to help decision making is always encouraged (even though not mandatory) for individuals and couples using donor gametes or embryos. In special circumstances, counselling services are used by clinicians to assess the emotional and social circumstances of the individual or couple requesting treatment. This is an integral part of the process to ascertain the welfare of the (unborn) child.

Genetic counselling: Risk of transmission of genetic disorders through ART has implications for the welfare of the unborn child. It is important to counsel the woman or couple regarding the risk of transmission to the offspring. Some couples may benefit from pre-implantation genetic diagnosis.

KEY POINTS

- Assisted conception treatments can entail significant emotional and physical stress. Many patients make use of support services and alternative therapies such as hypnosis, holistic therapies and acupuncture (most commonly used).
- In spite of the advances in ART over the decades, the majority of treatment cycles result in a negative outcome.
- Individuals who wish to start a family after multiple failed ART attempts have the option to consider adoption or fostering.

ASSISTED REPRODUCTIVE TECHNIQUES

Although numerous options are available, the commonest assisted conception treatment is IVF. The various techniques and their indication(s) are summarised in Table 84.2.

A TYPICAL IVF TREATMENT CYCLE

A typical IVF cycle involves pituitary suppression, superovulation, monitoring ovarian stimulation and oocyte maturation, oocyte retrieval, sperm insemination and fertilisation, embryo transfer, luteal-phase support and confirming outcome of

Table 84.2 Assisted conception techniques

Technique	Explanation/indication(s)
IUI	Intrauterine insemination of sperm in the 'right place' (womb) at the 'right time' (around the time of ovulation)
	Commonly used treatment option in unexplained subfertility or in cases where the male partner is diagnosed with ejaculatory dysfunction
IUI-DS	IUI treatment using donated sperm
	Commonly used treatment option for treating single women, lesbian couples or heterosexual couples where the male partner is diagnosed with aspermia
GIFT	Gamete intra-fallopian tube transfer where retrieved oocytes and sperm are laparoscopically placed in the fallopian tubes
	Not widely used due to invasive nature, risks and low success rates
ZIFT	Zygote intra-fallopian transfer where the fertilised embryo is laparoscopically placed in the fallopian tube
	Not widely used due to invasive nature, risks and low success rates
IVF: standard insemination	Insemination of retrieved oocytes in a Petri dish using the standard insemination with sperm
	Indications: tubal factor infertility, unexplained infertility and other indications
IVF with ICSI	Intracytoplasmic sperm injection using microinjection technique where a single sperm is injected into the retrieved oocyte
	Indication: male factor infertility
IVF with ICSI using IMSI	ICSI insemination technique using morphologically selected sperm with high-magnification microscope
	Indication: severe male factor infertility
IVM	In-vitro maturation where immature oocytes are retrieved and matured in the laboratory and then inseminated with sperm using ICSI technique
	Indication: polycystic ovaries, to reduce the risk of OHSS
FET	Frozen embryo transfer where transfer of frozen embryos is performed in a natural cycle or a hormonally manipulated cycle
	Indication: in cases where the embryos were electively frozen to reduce the risk of OHSS, due to endometrial abnormalities, or for other reasons (e.g. surplus embryos after a fresh treatment cycle)
IVF with oocyte donation	IVF using donated oocytes and sperm from husband/partner
	Indications: low ovarian reserve or premature ovarian failure
IVF using sperm donation	IVF treatment using donated sperm
	Indication: male partner with aspermia
IVF using embryo donation	IVF treatment using donated embryos
	Indication: cases where there is combined female and male factor or in cases of repeated IVF failures
IVF using surrogacy	Transfer of embryos to a surrogate mother
	Indications: anatomical abnormalities or medical indications

treatment. Careful coordination of physiological events both *in vivo* and *in vitro* is crucial. A multidisciplinary team involving clinicians, nurses, embryologists and administrators is needed to provide effective care. UK regulations require an assessment of the welfare of the (unborn) child. Furthermore, it is mandatory that both partners are screened for HIV, hepatitis B surface antigen, hepatitis core antibody and hepatitis C before they undergo IVF treatment.

The most important factor determining the outcome of an IVF cycle is age of the female partner. The livebirth rate per treatment started in the UK ranges from 33 per cent (for under 35 years) to 5 per cent (43–44 years). Success rates range widely between different ART clinics.

Pituitary suppression

Pituitary suppression or 'down-regulation' is often used to prevent premature release of eggs in an IVF cycle. Pituitary suppression can be achieved with either GnRH agonists or antagonists.

GnRH agonists are synthetic peptides that interact with the GnRH receptors resulting in an initial surge in FSH and LH ('flare effect') which is followed by down-regulation once all the receptors are engaged. With continuous use ovarian down-regulation occurs in about 10–14 days resulting in endogenous gonadotrophin suppression. Side effects include hypo-oestrogenic side effects, hot flushes and headaches.

GnRH antagonists are peptide molecules which result in immediate blockage of GnRH without the flare-up effect. This helps to reduce the duration of treatment protocols. An antagonist protocol has the added advantage of enabling the use of GnRH agonists for final oocyte maturation; there is emerging evidence to suggest a reduction in the risk of OHSS with such an approach. Side effects include mild anaphylactic reactions due to release of histamine although this is rarely encountered with newer preparations.

Superovulation

The aim of superovulation is to achieve multifollicular development to allow harvesting of multiple eggs which are needed for IVF treatment. Superovulation can be achieved using various treatment protocols by prescribing combinations of hormonal preparations.

Oral medications such as clomiphene have a limited role in superovulation for IVF treatment. Natural or recombinant FSH injections are commonly used for superovulation. Human menopausal gonadotropins (hMG) contain urinary FSH and LH. Another preparation is purified urinary FSH. Technical difficulties, urinary protein contamination and initial concerns of unreliable dosing led to development of recombinant FSH (rFSH) which is 99 per cent pure FSH. Recombinant human FSH is produced from a Chinese hamster ovary cell line. The superiority of recombinant FSH versus urinary FSH is a much debated topic³ but meta-analysis of RCTs suggests similar clinical pregnancy and livebirth rates.⁴

Recent studies suggested no increased risk of ovarian, uterine, cervical or breast cancer associated with ovarian stimulation medications. Previously some studies suggested borderline ovarian changes with long-standing high-dose clomiphene citrate; however, recently a cohort study confirmed there is no risk of borderline ovarian changes with any ovulation induction agents including clomiphene.^{5,6}

Monitoring ovarian stimulation

Advances in transvaginal scanning along with Doppler assessment and 3D scanning techniques have changed ART practice significantly. Monitoring is routinely done to assess follicular response; this involves evaluating each ovary to document the number and size of growing follicles. The endometrium is also assessed to ensure appropriate endometrial development.

During this phase, there is a risk of OHSS, one of the most serious complications of IVF treatment.

Oocyte maturation

As endogenous LH release would have been suppressed in an IVF cycle (with GnRH agonist or antagonist), exogenous LH or an equivalent drug is required to achieve final oocyte

maturation. The most commonly used agent is hCG, which has a similar chemical structure to LH. Recombinant LH preparations have equal efficacy to hCG but are rarely used.⁷ The 'final trigger' injection of HCG or LH is administered 34–36 hours before oocyte retrieval.

Oocyte retrieval

Oocyte retrieval is generally performed via the transvaginal route under ultrasound guidance. A single or double lumen needle is passed through the lateral vaginal fornix to puncture the ovarian follicles and drain the follicular fluid. Care is taken to keep the aspirated fluid at body temperature and it is passed to the embryology lab for microscopic analysis to identify oocytes. Most frequently the risk is vaginal bleeding (venous or small arterial) which settles down with pressure. Very rarely this procedure can be associated with intraperitoneal bleeding, infection, bowel perforation and also failure to retrieve any oocytes. Oocyte retrieval can be performed using general anaesthesia or conscious sedation with or without local anaesthesia.

Sperm insemination and fertilisation

Oocytes are inseminated on the same day as oocyte retrieval using standard or ICSI techniques by using a fresh or frozen sperm sample produced by the male partner. Surgical collection of sperm is needed in cases of unexpected azoospermia in the ejaculated sample or if the male partner is unable to produce a fresh sample on the day of oocyte retrieval.

The day after insemination, oocytes are checked for presence of two pronuclei (one from the oocyte and one from the sperm) confirming normal fertilisation. Oocytes with no evidence of fertilisation or abnormal fertilisation are discarded. The remaining embryos are further incubated to allow development.

Embryo transfer

Embryos are transferred as cleavage embryos (Day 2 or Day 3) or at blastocyst stage (Day 5 or Day 6) (Fig. 84.1). Embryo transfer (ET) is done via a trans-cervical route using a polypropylene catheter and is usually straightforward, with no discomfort to the woman. Ultrasound-guided (trans-abdominal, performed by an assistant) ET provides reassurance for both the woman and the clinician. Utmost care is taken to avoid the catheter tip disturbing the uterine fundus which may trigger subendometrial–myometrial contractions. Trans-myometrial embryo transfer (TM-ET) is reserved for difficult cases. In the UK, women under the age of 40 can have a maximum of two embryos transferred and women over the age of 40 can have a maximum of three embryos transferred (using own oocytes). However the HFEA, along with NICE, recommends an elective single embryo transfer policy to reduce the risk of multiple pregnancy.

Fig. 84.1 a) Day 3 embryo with 8 cells. b) Early blastocyst. c) ICSI technique (a single sperm seen inside the pipette). (By courtesy of CARE Fertility Group, UK.)

Luteal phase support

The most commonly used medication is progesterone in the form of tablets, pessaries or injectable preparations. Even though not routinely used, some clinicians prefer to use additional hCG injections or oestrogen preparations. In cases of hormonally manipulated FET treatment, luteal-phase supplementation using progesterone and oestrogen is mandatory as the ovarian activity is suppressed by pituitary suppression. Once a pregnancy is established, luteal-phase support can be withdrawn at about 8–12 weeks when the early placenta takes over the function of pregnancy maintenance.

Confirming outcome of treatment

For those women who achieve an ET, a urinary or serum pregnancy test is performed 16 days post oocyte retrieval. If the test is positive, this corresponds to 4 weeks of gestation. In most cases luteal phase is extended until confirmation of viability which is by ultrasound assessment. In ART settings, this is routinely performed between 6 and 7 weeks of gestation (4–5 weeks after embryo transfer).

RISKS WITH ART

Other than specific procedure-related risks mentioned earlier, there may be risks for the offspring. There may be an association between ART and risks of developmental delay, low birthweight, birth defects, imprinting disorders, lower genital tract abnormalities (male offspring) and genetic transmission of Y-chromosome abnormalities. However, other factors such as maternal age, twin pregnancy and other epigenetic factors may also play a role.

A key risk of multiple ET is multiple pregnancy, which is associated with numerous obstetric and neonatal complications. ESET should be recommended whenever appropriate.

EMBRYO CRYOPRESERVATION

Women having surplus embryos can opt for embryo freezing after appropriate HFEA consents from both partners. Embryos can be frozen at the fertilisation stage, cleavage stage (Day 2/3) or at the blastocyst stage (Day 5/6). Embryo thaw survival rates are better when they are frozen at earlier stages of development. With advancement in vitrification or 'flash freezing'

KEY POINTS

- A typical IVF cycle involves pituitary suppression, superovulation, monitoring ovarian stimulation, oocyte maturation, oocyte retrieval, sperm insemination and fertilisation, embryo transfer, luteal-phase support and confirming outcome of treatment.
- Pituitary down-regulation can be achieved using GnRH agonists or antagonists.
- Superovulation can be achieved by urinary or recombinant FSH preparations.
- Trigger injection is administered 34–36 hours prior to oocyte retrieval.
- Oocyte retrieval can be performed by a transvaginal or laparoscopic approach.
- Sperm insemination is performed on the same day as oocyte retrieval.
- Embryos are transferred at cleavage or at blastocyst stage.
- In the UK, a maximum of two embryos may be transferred under the age of 40 and a maximum of three embryos over the age of 40.
- The most commonly used agent for luteal-phase support is progesterone.
- The greatest risks with ART are OHSS and multiple pregnancy.

process, better survival rates are observed. Women who suffer complications following oocyte retrieval, those with suboptimal endometrial quality or those at higher risk for OHSS should have their embryos frozen and should proceed with FET at a later date. They should be counselled about a small chance of a failed thawing process. Embryo cryopreservation is also undertaken to preserve fertility when one partner (in a stable relationship) is diagnosed with a significant medical condition or malignancy which may impact on their future fertility potential (Chapter 92).

Chapter 85 Polycystic ovary syndrome

Adam H Balen

MRCOG standards

Theoretical skills

- Understand the definition and epidemiology of PCOS.
- Have a good understanding of the short- and long-term complications associated with PCOS.
- Develop a good appreciation of the psychological and metabolic consequences of PCOS.

Practical skills

- Be able to interpret the various investigations for PCOS and related conditions.
- Have good knowledge of management options, particularly for anovulation.

INTRODUCTION

Polycystic ovary syndrome is the most common endocrine disorder to affect women during their reproductive years.¹ The symptoms of PCOS include menstrual cycle disturbance and features of hyperandrogenism (hirsutism, acne, alopecia), with associated fertility problems, obesity and psychological issues. There is significant heterogeneity of presentation, such that signs and symptoms manifest across a spectrum and their severity may vary. Ovarian hyperandrogenism is thought to have genetic origins with amplification in some by hyperinsulinaemia secondary to insulin resistance, which in turn may be promoted by obesity. The primary presenting complaint itself is subject to change depending on the age and needs of the patient; for example acne may be a primary concern during adolescence whereas reduced fertility may be the main concern for an older woman. PCOS may also be associated with an increased risk of an individual developing type 2 diabetes, the metabolic syndrome and endometrial cancer.^{1,2} The symptoms of

PCOS may have a profound impact on psychological well-being.³ Options for treatment include lifestyle advice and a range of therapies depending upon the constellation of an individual's problems.⁴

PCOS appears to be underdiagnosed and, as a result, patients may not be managed appropriately.⁵ Furthermore, management of PCOS may require the collaboration of a variety of healthcare professionals ranging from primary care physicians, gynaecologists, reproductive specialists, endocrinologists, diabetologists, dermatologists, dieticians and psychologists. In some clinics important components of the syndrome may not be considered; for example gynaecological problems in a dermatology clinic or metabolic problems in a gynaecology clinic. We have recently assessed a cohort of women presenting with features of PCOS in our hospital to infertility, gynaecology, dermatology and endocrine clinics.⁵ Participants were assessed for symptoms and signs of PCOS and underwent a full endocrine and metabolic profile and a pelvic ultrasound scan. A significant difference between the four clinic groups existed with regards to frequency distribution of presenting symptoms as might have been expected with, for example, those in the dermatology clinic having more hirsutism and those in the gynaecology clinic a greater frequency of menstrual disturbance. It was striking that 81 per cent were overweight, 34 per cent had previously undiagnosed impaired glucose tolerance (IGT) and 9 per cent were found to be diabetic. This study emphasises the importance of understanding the full spectrum of PCOS as it presents to different specialty clinics. Not only is the syndrome underdiagnosed but so too are the significant associated morbidities such as IGT and type 2 diabetes.

DEFINING PCOS

In 2003 the European Society of Human Reproduction and Embryology (ESHRE) and the American Society of Reproductive Medicine (ASRM) held a consensus meeting in Rotterdam. They proposed that the diagnosis of PCOS should be made, once appropriate investigations have been

performed to exclude other causes of menstrual disturbance and androgen excess, if two out of three criteria are met – the so-called ‘Rotterdam Criteria’:¹

- 1 the presence of clinical or biochemical features of hyperandrogenism;
- 2 oligo-ovulation or anovulation (in other words a menstrual cycle disturbance);
- 3 polycystic ovaries on ultrasound.

This definition of PCOS requires the exclusion of specific underlying diseases of the adrenal or pituitary glands (e.g. hyperprolactinaemia, acromegaly, congenital adrenal hyperplasia, Cushing’s syndrome, androgen-secreting tumors of the ovary or adrenal gland) which could predispose to similar ultrasound and biochemical features and also the exclusion of other causes of menstrual cycle irregularity secondary to hypothalamic, pituitary or ovarian dysfunction.

Box 85.1 outlines the clinical features, potential long-term sequelae and endocrine disturbances seen in women with PCOS. Tables 85.1 and 85.2 outline the investigations that are commonly performed and results expected and Table 85.3 outlines the gonadotrophin and oestradiol profiles that can be expected in different clinical scenarios.

There is considerable heterogeneity of symptoms and signs amongst women with PCOS and for an individual these may change over time. Polycystic ovaries can exist without clinical signs of the syndrome, expression of which may

Box 85.1 The spectrum of clinical manifestations of PCOS

Symptoms

- Hyperandrogenism (hirsutism, acne, alopecia)
- Menstrual disturbance
- Infertility
- Obesity
- Asymptomatic, with polycystic ovaries on ultrasound scan

Possible late sequelae

- Type 2 diabetes mellitus
- Dyslipidaemia
- Hypertension
- Cardiovascular disease
- Endometrial carcinoma

Serum endocrinology

- ↑ Androgens (testosterone and androstenedione)
- ↑ LH, normal FSH
- ↑ Fasting insulin (not routinely measured; insulin resistance assessed by GTT)
- ↓ Sex hormone binding globulin, results in elevated ‘free androgen index’ (FAI)
- ↑ Oestradiol, oestrone
- ↑ Anti-Müllerian hormone

Table 85.1 Investigations for PCOS

Test	Normal range (may vary with local laboratory assays)	Additional points
Testosterone (T)	0.5–1.8 nmol/L	It is unnecessary to measure other androgens unless total T >5 nmol/L
SHBG	16–119 nmol/L	Insulin suppresses SHBG, resulting in a high FAI in the presence of a normal total T
Free androgen index: T x 100/SHBG	<5	
Oestradiol	Usually normal, measurement is unhelpful to diagnosis	Oestrogenisation may be confirmed by endometrial assessment
LH	2–10 IU/L	Elevated in 40% of women with PCOS, especially those who are slim
FSH	2–8 IU/L	FSH and LH best measured during days 1–3 of a menstrual bleed. If oligo-/amenorrhoeic then random samples are taken
Prolactin	<500 mU/L	Measure if oligo-/amenorrhoeic
Thyroid function, TSH	0.5–5 IU/L	Measure if oligo-/amenorrhoeic
Fasting insulin	<30 mU/L	Not routinely measured; insulin resistance assessed by GTT, see Table 85.2
Pelvic ultrasound	More than 12 follicles (cysts) 28 mm in diameter per ovary	To assess ovarian morphology and endometrial thickness; trans-abdominal scan satisfactory in women who are not sexually active
AMH	35 pmol/L	Not universally accepted and still debated; has been suggested as a biochemical marker for the polycystic ovary

Table 85.2 Definitions of glucose tolerance after a 75 g glucose tolerance test

	Diabetes mellitus	Impaired glucose tolerance	Impaired fasting glycaemia
Fasting glucose (mmol/L)	≥7.0	<7.0	≥6.1 and <7.0
2 hour glucose (mmol/L)	≥11.1	≥7.8 and ≤11.1	<7.8

Table 85.3 Gonadotrophin and oestradiol profiles in different clinical scenarios

Ovarian failure	↑ FSH	↑ LH	↓ Oestradiol
Hypothalamic or pituitary failure	↓ FSH	↓↓ LH	↓ Oestradiol
PCOS	n/↓ FSH	n/↑ LH	n/↑ Oestradiol
Mid-cycle, pre-ovulatory	↑ FSH	↑↑ LH	↑ Oestradiol

be precipitated by various factors, most predominantly an increase in bodyweight.

Debate continues regarding the reliability and reproducibility of the various tests that we have at our disposal, whether ultrasound or biochemical. Raised serum levels of LH, testosterone and androstenedione, in association with low or normal levels of FSH and abnormalities of oestrogen secretion, are variable findings and sometimes the endocrine profile may be normal. It is thought that the hyperandrogenism is driven by LH in slim women and in overweight women by insulin, which acts as a 'co-gonadotrophin' and amplifies the effect of LH.

ULTRASOUND

Polycystic ovaries are commonly detected by pelvic ultrasound, with estimates of the prevalence in the general population being in the order of 20–33 per cent.⁶ The morphology of the polycystic ovary was also defined in the ESHRE/ASRM consensus as an ovary with 12 or more follicles measuring 2–9 mm in diameter and/or increased ovarian volume (>10 cm³).⁷ With improvements in the resolution of ultrasound technology it has more recently been suggested that the threshold number of follicles to define a polycystic ovary should be increased and that the biochemical marker of anti-Müllerian hormone may be even more precise than ultrasound, although a figure has not been universally accepted.

EPIDEMIOLOGY AND PREVALENCE

Estimates of the prevalence of PCOS are greatly affected by the nature of the population which is being assessed. Populations of women who are selected on the basis of the presence of a symptom associated with the syndrome (e.g. hirsutism, acne and menstrual cycle disturbances) would be expected to demonstrate a prevalence greater than that which exists in the general population. The prevalence of PCOS in the general population has not been definitively determined and appears to vary considerably between populations that have been

studied and the diagnostic criteria being employed and has ranged from 4 per cent to 26 per cent.⁶

PCOS tends to run in families, although there is not a single gene or pathway that causes the syndrome; however there may be genetic factors that affect expression and presentation – whether because of racial differences in the colour and distribution of hair or variations in hormone production and receptor activity. For example women from the Far East (e.g. Japan) with PCOS do not present with excess bodily or facial hair despite having dark hair and elevated testosterone levels, whereas those from Mediterranean countries or South Asia with similar hormone profiles may have profound hirsutism. There may be profound ethnic variations in the presentation of PCOS, for example South Asian women in the UK with PCOS have greater insulin resistance and more severe symptoms of the syndrome than white Caucasians with PCOS. These variations in the overt features of PCOS (symptoms of hyperandrogenism, menstrual irregularity and obesity) in women of South Asian descent are linked to the higher prevalence and degree of insulin resistance in South Asians. Type 2 diabetes and insulin resistance have a high prevalence among indigenous populations in South Asia, with a rising prevalence among women. Type 2 diabetes also has a familial basis, inherited as a complex genetic trait that interacts with environmental factors, chiefly nutrition, commencing from fetal life.⁸

PCOS AND METABOLIC ABNORMALITIES

Women with PCOS are characterised by the presence of insulin resistance, central obesity and dyslipidaemia, which appears to place them at a higher risk of developing diabetes as well as cardiovascular disease. There are a number of environmental factors that may influence the expression of the syndrome, in particular a tendency to insulin-resistant states induced by overeating and under-exercising. A plausible hypothesis for the survival of PCOS in the population is that of the 'thrifty phenotype/genotype' whereby in times of famine, individuals who have a tendency to obesity preserve the population by maintaining fertility, while those of normal

bodyweight fall below the threshold bodyweight for fertility. This might explain the greater prevalence of PCOS among South Asians in the UK, where there is relatively greater nutrition and thus the right environment to express PCOS. In addition the 'thrifty phenotype' hypothesis suggests that insulin resistance *in utero* results as an adaptation to impaired nutrition and then persists through to adult life and is then amplified by overnutrition (obesity).

Women who are obese, and also many slim women with PCOS, will have insulin resistance and elevated serum concentrations of insulin (usually <30 mU/L fasting). We suggest that a 75 g oral GTT be performed in women with PCOS and a BMI >30 kg/m², with an assessment of the fasting and 2-hour glucose concentrations (Table 85.2). It has been suggested that South Asian women should have an assessment of glucose tolerance if their BMI is greater than 25 kg/m² because of the greater risk of insulin resistance at a lower BMI than seen in the Caucasian population.

Although the insulin resistance may occur irrespective of BMI, the common association of PCOS and obesity has a synergistic deleterious impact on glucose homeostasis and can worsen both hyperandrogenism and anovulation. It has been suggested that rather than BMI itself it is the distribution of fat that is important, with android obesity being more of a risk factor than gynaecoid obesity. Hence the value of measuring waist:hip ratio, or waist circumference, which detects abdominal visceral fat rather than subcutaneous fat. It is the visceral fat which is metabolically active and when increased results in increased rates of insulin resistance, type 2 diabetes, dyslipidaemia and hypertension. Waist circumference should ideally be less than 79 cm, whilst a measurement that is greater than 87 cm carries a significant risk. Exercise has a significant effect on reducing visceral fat and reducing cardiovascular risk – indeed a 10 per cent reduction in bodyweight may equate with a 30 per cent reduction in visceral fat.

HEALTH CONSEQUENCES OF PCOS

Cardiovascular disease and diabetes

Young women with PCOS who are obese have a 10–20 per cent risk of IGT and, if left untreated, have an approximately 50 per cent chance of developing type 2 diabetes in the next five years. Obesity and metabolic abnormalities are recognised risk factors for the development of ischaemic heart disease (IHD) in the general population, and these are also recognised features of PCOS. There have been a few studies that have tried to assess the long-term risk for women with PCOS and, interestingly, whilst diabetes has been associated with increase in mortality, death rates from cardiovascular disease have not been found to be higher than the normal population.⁹

Endometrial cancer

Endometrial adenocarcinoma is the second most common female genital malignancy but only 4 per cent of cases occur

in women less than 40 years of age. The risk of developing endometrial cancer has been shown to be adversely influenced by a number of factors including obesity, long-term use of unopposed oestrogens, nulliparity and infertility. Women with PCOS who are amenorrhoeic have unopposed oestrogen secretion as, in the absence of ovulation, progesterone is not released by the ovary and so the endometrium is not shed as a menstrual bleed. The endometrium may then become hyperplastic and endometrial hyperplasia may progress to cystic glandular hyperplasia with atypical cellular changes and in time lead to endometrial adenocarcinoma. The true risk of carcinoma in women with PCOS, however, is difficult to ascertain but is thought to be increased approximately three-fold compared with the normal population.⁹ It is therefore important that women with PCOS shed their endometrium either monthly or at the very least every 3 months, which can be achieved either by cyclical administration of a progestogen or a COCP. Another option is to consider a progestogen-secreting intrauterine system such as the Mirena®.

PCOS does not appear to increase the risk for carcinoma of the breast or ovary.

MANAGEMENT OF PCOS

Psychological support and quality of life

The symptoms typically associated with the condition have also been shown to lead to a significant reduction in health-related quality of life (HRQoL). HRQoL is a multi-dimensional, dynamic concept that encompasses physical, psychological and social aspects that are associated with a particular disease or its treatment. Therefore any management of the woman with PCOS needs to consider and understand the negative impact this condition may have upon these psychosocial parameters. For example, although the management of hirsutism may be considered as a purely cosmetic issue, excessive facial hair has been shown to be one of the major causes of marked psychological stress in women with PCOS, often caused by embarrassment about the excessive hair growth. Infertility and weight issues have also been found to affect other social and psychological parameters. Infertility can cause tensions within the family, altered self-perception, and problems at work. Whilst obesity worsens the symptoms, the metabolic scenario conspires against weight loss and many women experience frustration in attempts to lose weight and suffer from low self-esteem and poor body image.⁹

Obesity

The management of women with PCOS should be focused on the patient's particular problems. Obesity worsens both symptomatology and the endocrine profile and so obese women (BMI >30 kg/m²) should be encouraged to lose weight, by a combination of calorie restriction and exercise. Weight loss improves the endocrine profile and the likelihood of ovulation and a healthy pregnancy. There is no evidence

that women with PCOS benefit from a specific diet compared with obese women without PCOS. The right diet for an individual is one that is practical, sustainable and compatible with her lifestyle. There does not appear to be a particular diet that is most appropriate for women with PCOS. It is sensible to reduce glycaemic load by lowering sugar content in favour of more complex carbohydrates and to avoid fatty foods. Meal replacement therapy or low-calorie diets may be appropriate; it is often helpful to refer to a dietitian, if available. An increase in physical activity is essential, preferably as part of the daily routine. Thirty minutes per day of brisk exercise is encouraged to maintain health, but to lose weight, or sustain weight loss, 60 to 90 minutes per day is advised. Concurrent behavioural therapy improves the chances of success of any method of weight loss. Furthermore there are no medications that have been shown to assist with long-term weight reduction. Bariatric surgery is used increasingly because of the global epidemic of obesity and certainly has a role in the management of obese women with PCOS. It is recommended by some that anyone with a BMI of more than 40 kg/m² should be referred for consideration for bariatric surgery. If there are co-morbidities, such as diabetes, then the BMI cut-off for surgery is lower at 30–35 kg/m².

Menstrual irregularity

The simplest way to control the menstrual cycle is the use of a low-dose COCP. This will result in an artificial cycle and regular shedding of the endometrium. It is also important once again to encourage weight loss. As women with PCOS are thought to be at increased risk of cardiovascular disease a 'lipid-friendly' combined contraceptive pill should be used. The third-generation oral contraceptives are lipid friendly but present the potential disadvantage of venous thromboembolism, particularly in overweight women. Dianette® and Yasmin® are both COCPs that respectively contain the anti-androgens cyproterone acetate and drospirenone, which is a derivative of spironolactone, although any COCP will help suppress ovarian hyperandrogenism and concurrently achieve an elevation in SHBG production and thereby help suppress the free androgen levels. Alternatives to the COCP include a progestogen, for example medroxyprogesterone acetate (Provera®), for 12 days every 1–3 months to induce a withdrawal bleed, or simply the insertion of a Mirena® intrauterine system.

In women with anovulatory cycles the action of estradiol on the endometrium is unopposed because of the lack of cyclical progesterone secretion. This may result in episodes of irregular uterine bleeding, and in the long term endometrial hyperplasia and even endometrial cancer (see above). An ultrasound assessment of endometrial thickness provides a bioassay for oestradiol production by the ovaries and conversion of androgens in the peripheral fat. If the endometrium is thicker than 10 mm a withdrawal bleed should be induced and if the endometrium fails to shed then endometrial sampling is required to exclude endometrial hyperplasia or malignancy.

Hyperandrogenism and hirsutism

The bioavailability of testosterone is affected by the serum concentration of SHBG. High levels of insulin lower the production of SHBG and so increase the free fraction of androgen. Elevated serum androgen concentrations stimulate peripheral androgen receptors, resulting in an increase in 5-alpha reductase activity directly increasing the conversion of testosterone to the more potent metabolite, dihydrotestosterone. Symptoms of hyperandrogenism include hirsutism and acne, which are both distressing conditions. Hirsutism is characterised by terminal hair growth in a male pattern of distribution, including chin, upper lip, chest, upper and lower back, upper and lower abdomen, upper arm, thigh and buttocks. A standardised scoring system, such as the modified Ferriman and Gallwey score, should be used to evaluate the degree of hirsutism before and during treatments.

Treatment options include cosmetic and medical therapies. As drug therapies may take 6–9 months or longer before any improvement of hirsutism is perceived physical treatments including electrolysis, waxing and bleaching may be helpful whilst waiting for medical treatments to work. For many years the most 'permanent' physical treatment for unwanted hair has been electrolysis. It is time consuming, painful and expensive and should be performed by an expert practitioner. Regrowth is not uncommon and there is no really permanent cosmetic treatment but the last few years have seen much development in the use of laser and photothermolysis techniques. Repeated treatments are required for a near-permanent effect because only hair follicles in the growing phase are obliterated at each treatment.

Eflornithine (Vaniqua®) has been recently developed as a topical treatment for hirsutism. It works by inhibiting the enzyme ornithine decarboxylase in hair follicles and may be a useful therapy for those who wish to avoid hormonal treatments but may also be used in conjunction with hormonal therapy.

Any COCP is likely to help improve symptoms of hyperandrogenism. An effective therapy is Dianette® which contains ethinyloestradiol (35 µg) in combination with 2 mg synthetic progestogen cyproterone acetate which is antigonadotrophic and anti-androgenic. The anti-androgen effect reduces sebum excretion in 2–3 months and results in clinical improvement in acne in 4–6 months. Medical regimens should stop further progression of hirsutism and decrease the rate of hair growth. Therapy for acne should aim to lower sebum excretion, alter follicular cell desquamation, reduce propionibacteria and reduce inflammation.

Spironolactone is a weak diuretic with anti-androgenic properties and may be used in women with hirsutism and/or acne in whom the COCP is contraindicated, at a daily dose of 25–100 mg. If using anti-androgen therapy, adequate contraception is important in women of reproductive age as transplacental passage of anti-androgens may disturb the genital development of a male fetus. Other anti-androgens such as ketoconazole, finasteride and flutamide have been tried, but are not widely used in the UK for the treatment of hirsutism in women due to their adverse and potentially serious side effects.

MANAGEMENT OF INFERTILITY IN PCOS

PCOS accounts for approximately 80–90 per cent of women with anovulatory infertility, which in turn comprises about a third of those attending the infertility clinic. Various factors influence ovarian function and fertility, the most important being obesity. A patient's weight correlates with both an increased rate of cycle disturbance and infertility secondary to disturbances in insulin metabolism. Monitoring treatment is also harder in obese women because their ovaries are more difficult to see on ultrasound scans, thus raising the risk of missing multiple ovulation and multiple pregnancy. National guidelines in the UK for managing overweight women with PCOS advise weight loss, preferably to a BMI of less than 30 kg/m², before commencing drugs for ovarian stimulation. Hypersecretion of LH is found in 40 per cent of women with PCOS and is associated with a reduced chance of conception and an increased risk of miscarriage, possibly through an adverse effect of LH on oocyte maturation. Elevated LH concentrations are more often found in slim women with PCOS, whilst those who are overweight are more likely to be hyperinsulinaemic.

Strategies to induce ovulation include weight loss, oral anti-oestrogens (principally clomiphene citrate), parenteral gonadotrophin therapy and laparoscopic ovarian surgery. There have been no adequately powered RCTs to determine which of these therapies provides the best overall chance of an ongoing pregnancy when used as first-line therapy. Women with PCOS are at risk of OHSS and so ovulation induction has to be carefully monitored with serial ultrasound scans. The realisation of an association between hyperinsulinaemia and PCOS has resulted in the use of insulin-sensitising agents such as metformin, although results have been disappointing.^{4,10}

Carefully conducted and monitored ovulation induction can achieve good cumulative conception rates and, furthermore, multiple pregnancy rates can be minimised with strict adherence to criteria that limit the number of follicles that are permitted to ovulate.

Clomiphene citrate therapy

Prior to commencing ovulation induction therapy it is important to comprehensively investigate the couple, with a full endocrine profile, assessment of rubella immunity and tubal patency together with a semen analysis (see Chapter 82). The anti-oestrogen clomiphene citrate (CC) has traditionally been used as first-line therapy for anovulatory PCOS. CC therapy is usually commenced on day 2 of the cycle and given for 5 days. If the patient has oligo/amenorrhoea it is necessary to exclude pregnancy and then induce a withdrawal bleed with a short course of a progestogen, such as medroxyprogesterone acetate 20 mg/day for 5 to 10 days. The starting dose of CC is 50 mg/day, for 5 days beginning on days 3–5 of the menstrual cycle (the first day of bleeding is considered day 1 of the cycle). If the patient has not menstruated by day 5

and she is not pregnant, a progestogen-induced withdrawal bleed should be initiated. The dose of CC may be increased to 100 mg if there is no response. Doses of 150 mg/day or more appear not to be of benefit. If there is an exuberant response to 50 mg/day, as in some women with PCOS, the dose can be decreased to 25 mg/day. Discontinuation of CC therapy should be considered if the patient is anovulatory after the dose has been increased up to 100 mg/day. If the patient is ovulating conception is expected to occur at a rate determined by factors such as the patient's age. CC induces ovulation in approximately 70–85 per cent of patients and approximately 60–70 per cent should be pregnant by six cycles of therapy.

CC may cause an exaggeration in the hypersecretion of LH and have anti-oestrogenic effects on the endometrium and cervical mucus. All women who are prescribed CC should be carefully monitored with a combination of endocrine and ultrasonographic assessment of follicular growth and ovulation because of the risk of multiple pregnancies, which is approximately 10 per cent. Clomiphene therapy should therefore be prescribed and managed by specialists in reproductive medicine.

If pregnancy has not occurred after 6–9 normal ovulatory cycles it is then reasonable to offer the couple assisted conception (i.e. IVF). Patients with anovulatory infertility who are resistant to anti-oestrogens may be prescribed parenteral gonadotrophin therapy or treated with laparoscopic ovarian surgery. The term 'clomiphene resistance, strictly speaking refers to a failure to ovulate rather than failure to conceive despite ovulation, which should be termed 'clomiphene failure'.

Gonadotrophin therapy

Gonadotrophin therapy is indicated for women with anovulatory PCOS who have been treated with anti-oestrogens if they have failed to ovulate or if they have a response to clomiphene that is likely to reduce their chance of conception (e.g. persistent hypersecretion of LH, or anti-oestrogenic effect on cervical mucus).

In order to prevent the risks of overstimulation and multiple pregnancy, a low-dose step-up regimen should be used with a daily starting dose of 25–50 IU of FSH or hMG. This is only increased after 14 days if there is no response and then by only half an ampoule every 7 days. Treatment cycles using this approach can be quite long – up to 28–35 days – but the risk of multiple follicular growth is low and the multiple pregnancy rate should be less than 5 per cent. It can be extremely difficult to predict the response to stimulation of a woman with polycystic ovaries; indeed this is the greatest therapeutic challenge in all ovulation induction therapies. The polycystic ovary is characteristically quiescent, at least when viewed by ultrasound, before often exhibiting an exuberant and explosive response to stimulation. It can be very challenging to stimulate the development of a single dominant follicle.

Ovulation is triggered with a single subcutaneous injection of hCG 5000 units, when there has been the development of

at least one follicle of at least 17 mm in its largest diameter. In order to reduce the risks of multiple pregnancy and OHSS, the exclusion criteria for hCG administration are the development of a total of two or more follicles larger than 14 mm in diameter. In overstimulated cycles hCG is withheld, and the patient counselled about the risks and advised to refrain from sexual intercourse. The cumulative conception and livebirth rates after 6 months should be 65–70 per cent and 55–60 per cent, respectively. If conception has failed to occur after six ovulatory cycles in a woman younger than 25 years or after 12 ovulatory cycles in women older than 25, then it can be assumed that anovulation is unlikely to be the cause of the couple's infertility and assisted conception (usually IVF) is now indicated.

Complications of ovulation induction

Women with PCOS are at an increased risk of developing OHSS. This occurs if many follicles are stimulated, leading to ascites, pleural and, sometimes, pericardial effusions with the symptoms of abdominal distension, discomfort, nausea, vomiting and difficult breathing. Hospitalisation is sometimes necessary in order for intravenous fluids (colloids preferable to crystalloids) and heparin to be given to prevent dehydration and thromboembolism. Although this condition is rare it is a potentially fatal complication and should be avoidable with appropriate monitoring of treatment.

Multiple pregnancy is the other undesirable side effect of fertility therapy, first because of the increased rates of perinatal morbidity and mortality and second because of the devastating effects on the family of caring for a large number of babies. High-order multiple pregnancies (quadruplets or more) result almost exclusively from ovulation induction therapies. Gonadotrophins should be given in low doses to women with anovulatory infertility and strict criteria employed before the administration of the ovulatory trigger.

Insulin-sensitising agents

It is logical to assume that therapy that achieves a fall in serum insulin concentrations should improve the symptoms of PCOS. The biguanide metformin both inhibits the production of hepatic glucose, thereby decreasing insulin secretion, and also enhances insulin sensitivity at the cellular level. In the last decade many studies have been carried out to evaluate the reproductive effects of metformin in patients with PCOS. Initial studies appeared to be promising, suggesting that metformin could improve fertility in women with PCOS; however, more recent large RCTs have observed no benefit from metformin as either first-line therapy or in combination with other drugs.¹¹

Surgical ovulation induction

An alternative to gonadotrophin therapy for clomiphene-resistant PCOS is laparoscopic ovarian diathermy, which

involves burning four 'holes' into each ovary with a diathermy probe. This has replaced the more invasive and damaging technique of ovarian wedge resection. Laparoscopic ovarian diathermy is free of the risks of multiple pregnancy and ovarian hyperstimulation and does not require intensive ultrasound monitoring. Furthermore, ovarian diathermy appears to be as effective as routine gonadotrophin therapy in the treatment of clomiphene-insensitive PCOS, although it does take longer to conceive and often additional therapy with CC or gonadotrophins is required after surgery if ovulation is not occurring.¹² In addition, laparoscopic ovarian surgery is a useful therapy for anovulatory women with PCOS who fail to respond to clomiphene and who persistently hypersecrete LH, or who live too far away from the hospital to be able to attend for the intensive monitoring required in gonadotrophin therapy. Surgery does, of course, carry its own risks and must be performed only by fully trained laparoscopic surgeons.

IVF in women with polycystic ovaries

IVF is not the first-line treatment for PCOS, but many patients with the syndrome may be referred for IVF, either because there is another reason for their infertility or because they fail to conceive despite ovulating (whether spontaneously or with assistance) – i.e. their infertility remains unexplained. Furthermore, approximately 30 per cent of women have polycystic ovaries as detected by ultrasound scan. Many will have little in the way of symptoms and may present for assisted conception treatment because of other reasons (for example tubal factor or male factor). When stimulated, these women with asymptomatic polycystic ovaries have a tendency to respond sensitively and are at increased risk of developing OHSS. Care must therefore be taken and there is evidence of reduced risk if protocols using a GnRH antagonist are employed.

PREGNANCY OUTCOMES

Women with PCOS may conceive naturally or, if they have anovulatory infertility, by ovulation induction (OI). In addition to anovulation there may be other factors that contribute to subfertility in women with PCOS including the effects of obesity, metabolic, inflammatory and endocrine abnormalities on oocyte quality and fetal development. Women who are obese are also more likely to experience miscarriage and pregnancy complications. A number of studies have compared pregnancy outcomes between women with PCOS and controls and have found that women with PCOS demonstrated a significantly higher risk of developing gestational diabetes, pregnancy-induced hypertension, pre-eclampsia, adverse neonatal outcomes and preterm birth.¹³ Their babies had a significantly higher risk of admission to a NICU and a higher perinatal mortality, unrelated to multiple births. The potential mechanisms for these

problems include obesity, altered glucose metabolism and disturbances in uterine blood flow and so careful monitoring of pregnancy is required.

CONCLUSIONS

PCOS is one of the most common endocrine disorders. It may present, at one end of the spectrum, with the single finding of polycystic ovarian morphology as detected by pelvic ultrasound. At the other end of the spectrum, symptoms such as obesity, hyperandrogenism, menstrual cycle disturbance and infertility may occur, either singly or in combination. Ovarian dysfunction leads to the main signs and symptoms and the ovary is influenced by external factors, in particular the gonadotrophins, insulin and other growth factors, which are dependent upon both genetic and environmental influences. There are long-term risks of developing diabetes and possibly cardiovascular disease in addition to the risk of endometrial hyperplasia and adenocarcinoma secondary to unopposed oestrogen. Therapy should be tailored to an individual's symptoms and needs, which may change over her lifespan.

KEY POINTS

- PCOS is the commonest endocrine disorder in women (prevalence 15–20%).
- PCOS is a heterogeneous condition. Diagnosis is made by two out of three of the following: menstrual disturbance; hyperandrogenism (clinical or biochemical); the ultrasound detection of polycystic ovaries. Appropriate investigations are required to exclude other causes of menstrual irregularity or hyperandrogenism.
- Management is symptom orientated.
- If obese, weight loss should be encouraged to improve symptoms, reproductive function and long-term health. A GTT should be performed if the BMI is $>30 \text{ kg/m}^2$ (or $>25 \text{ kg/m}^2$ if from South Asia).
- Menstrual cycle control is achieved by cyclical oral contraceptives or progestogens or a Mirena intrauterine system can be used to protect the endometrium.
- Ovulation induction may be difficult and require progression through various treatments which should be monitored carefully to prevent multiple pregnancy.
- Hyperandrogenism is usually managed with the COCPs Dianette or Yasmin. Alternatives include spironolactone. Flutamide and finasteride are not routinely prescribed because of potential adverse effects. Reliable contraception is required with anti-androgen therapy.
- Insulin-sensitising agents (e.g. metformin) appear to be of limited, if any, benefit may be prescribed when there is impaired glucose tolerance.

Chapter 86 Hirsutism and virilism

Mostafa Metwally and William Ledger

MRCOG standards

Theoretical skills

- Have knowledge of physiology of androgen production in the female.
- Have knowledge of the physiology of normal hair growth.
- Know the warning symptoms and signs that alert to significant pathology.

Practical skills

- Be able to quantify the severity of hirsutism using the Ferriman–Gallwey score.
- Be able to differentiate between hirsutism and hypertrichosis.
- Be able to request appropriate investigations for hirsutism/virilism.
- Be able to examine for other signs of virilism.

the thick pigmented hair normally present on the face, limbs, axilla and pubic area. It is this hair that is androgen dependent and is influenced by genetic and racial factors.

Hair growth is a dynamic process and can be divided into three distinct phases. The relative duration of these different stages influences the length and appearance of hair in different parts of the body:

- 1 *Anagen*: This is the growing phase during which active mitotic division occurs in the basal matrix. This stage is relatively long in areas such as the scalp where hair appears to be continuously growing. Similarly, facial hair also has a long growth phase, which is why the effects of therapy require six to nine months before becoming apparent.¹ Consequently, the focus of hirsutism treatment is to shorten this phase.²
- 2 *Catagen*: During this phase, hair growth ceases and the hair follicle prepares to enter the resting (telogen) phase.
- 3 *Telogen*: During this resting phase, the hair is short and loosely attached to be ultimately expelled as the follicle again enters the anagen phase and a new hair starts growing.

HIRSUTISM

Definition

Hirsutism is defined as male pattern hair growth in a female as a result of increased androgen production or increased skin sensitivity to circulating androgens. Hirsutism must be differentiated from hypertrichosis, which is a generalised non-sexual (vellus) hair growth that may be hereditary, or due to various medications or malignancies. It is important to recognise that hirsutism in itself is not a diagnosis but rather a manifestation of a large spectrum of abnormalities; so a careful search for the underlying cause is essential.

The physiology of hair growth

Adults have two types of hair, vellus and terminal. Vellus hair is the fine lightly pigmented hair that covers most areas of the body during the prepubertal years, while terminal hair is

Incidence

It is difficult to state exactly the prevalence of hirsutism since it is highly variable depending on the studied ethnic group, being higher in those of African or Mediterranean origin. The condition, however, is believed to affect 5–10 per cent of women of reproductive age.³

Female androgens and hair growth

Pivotal to the understanding of hirsutism is an understanding of the metabolism of androgens in the female and how they can affect hair growth. Female androgens are produced by two sources, namely the ovaries and adrenal glands. The ovaries produce testosterone and androstenedione, whilst the adrenals produce androstenedione and dehydroepiandrosterone (DHEA). Testosterone in the ovary is produced by the theca cells under the control of LH and insulin acting through IGF-1. Testosterone is then converted by the granulosa cells

to oestradiol. This transition of the ovarian environment from androgen dominant to oestrogen dominant is vital to normal ovulation and ovarian function. In conditions such as PCOS where this process is disturbed, there is a relative increase in ovarian androgen production. Adrenal androgens are also peripherally converted to testosterone, which then circulates in two forms, an inactive form bound to SHBG and a metabolically active free form. To stimulate hair growth, free testosterone needs to be further metabolised at the level of the hair follicle into a more active form, DHT, by the enzyme 5 α reductase. Consequently, hirsutism can be caused by any of the following disturbances:

- Increased production of adrenal or ovarian androgens: Adrenal androgens can increase in Cushing's syndrome, delayed-onset congenital adrenal hyperplasia and androgen-producing adrenal tumours. However, the most common cause in clinical practice is an increased production of ovarian and, to a lesser extent, adrenal androgens as a result of PCOS.
- An increase in the free fraction of testosterone due to a decreased concentration of SHBG despite normal testosterone production. Decreased SHBG can occur due to increased insulin concentrations in women with insulin resistance, which again is a common finding in women with PCOS.⁴
- An increased local activity of 5 α reductase. Two forms of this enzyme exist, type 1 and type 2. Type 1 is mainly present in the sebaceous gland, while type 2 is found mainly in the hair follicle. Relative activity of these isoenzymes can lead to a discrepancy between the severity of hirsutism and acne in women with hyperandrogenism.⁵ In women with PCOS – especially those who are obese or are insulin resistant – insulin and IGF act to stimulate this enzyme.
- Iatrogenic hirsutism can be caused by the administration of certain medications, such as danazol, androgen therapy, sodium valproate and anabolic steroids.

Clinical assessment of hirsutism

History

A detailed history should include the following:

- The severity and duration of hirsutism, as well as the presence of any other symptoms of virilisation. Rapidly progressive virilisation or severe hirsutism point to the possibility of a more ominous cause, such as an ovarian or adrenal tumour.
- Associated menstrual disturbances or history of infertility may point to chronic anovulation as a result of PCOS.
- History suggestive of other related medical conditions, such as Cushing's syndrome or hypothyroidism.
- Medications such as steroids, androgen therapy or danazol.

Examination

- Evaluation of the severity of hirsutism is commonly performed using the Ferriman–Gallwey scoring system.

The score includes an evaluation of nine androgen-sensitive body areas. Each area is assigned a score from 0 to 4 and the scores are then added. A minimal score of 8 is required for the diagnosis of hirsutism. The disadvantages of this method are that it does not account for focal hirsutism. In addition, it ignores some androgen-sensitive areas, such as the buttocks and sideburns.¹

- General examination may show other manifestations of androgen excess, such as acne or signs of virilisation (e.g. clitoromegaly, male pattern balding).
- The presence of velvety, pigmented skin patches (acanthosis nigricans) in the groin, neck or axillae may point to associated insulin resistance. The combination of hirsutism together with acanthosis nigricans and insulin resistance is a hereditary condition known as HAIR-AN syndrome. It is possibly due to an insulin receptor defect and can be associated with severe hirsutism.⁶
- Pelvic examination in severe cases may reveal the presence of a pelvic mass (androgen-producing ovarian tumour).

Investigations

- Testosterone concentrations: The need to measure testosterone concentrations in patients with mild isolated hirsutism is debatable, since over half of these women will have normal concentrations and results are unlikely to influence treatment.¹ Testosterone concentrations also correlate poorly with the severity of hirsutism due to individual variations in hair follicle response. Testosterone measurements are however indicated in women with other symptoms, such as menstrual irregularities, infertility, severe hirsutism or in the presence of virilism. Measurement of the free androgen index is particularly useful since it reflects changes in SHBG as well as testosterone. Obese and PCOS patients may have an elevated FAI when the testosterone concentrations are normal due to a decrease in SHBG. High testosterone concentrations (>5 mmol/L) may suggest an androgen-producing tumour. DHEA concentrations may also be measured and if markedly elevated may suggest an adrenal cause.
- Baseline 17-OH progesterone measurements should be performed to screen for suspected cases of late-onset CAH. Equivocal results will need a short Synacthen test to confirm the diagnosis. After measurement of baseline 17-OH progesterone concentrations, the patient is given an intramuscular injection of 250 mg of Synacthen and measurements are taken again after 1 hour. A significant rise in 17-OH progesterone concentrations is diagnostic of CAH.
- Tests for insulin resistance (75 g GTT and insulin concentrations) are particularly important in PCOS and obese patients.
- Dexamethasone suppression test and 24-hour urinary free cortisol for suspected cases of Cushing's syndrome.
- Pelvic imaging may show the presence of polycystic ovaries or an androgen-producing ovarian tumour. More detailed imaging (CT and MRI) may be required in cases

of suspected androgen-producing ovarian or adrenal tumours. In cases where imaging is negative, selective venous sampling from the ovarian and adrenal veins may be performed.

VIRILISM

Hirsutism may occur together with other symptoms of defeminisation in a condition known as 'virilism'. Other signs and symptoms include secondary amenorrhoea, male pattern baldness, clitoromegaly and deepening of voice. The condition usually indicates significant pathology, including the following:

- Androgen-producing ovarian and adrenal tumours: This should be suspected in the presence of progressive severe virilisation.
- Adult onset CAH: This is most commonly due to 21-hydroxylase deficiency, leading to a blockage of the production of 11-deoxycortisol from 17-OH progesterone with a consequent diversion of steroidogenesis to the androgen pathway.
- XY females with functioning testicles will usually present around the time of puberty with primary amenorrhoea and signs of virilisation. The diagnosis can be confirmed with karyotyping.
- Iatrogenic, due to androgen therapy or the use of danazol to treat endometriosis.
- Cushing's syndrome and acromegaly.

Treatment

In addition to treatment of the excessive hair growth, treatment should be directed to the likely cause. For example, weight loss in obese PCOS patients may improve hirsutism through a decrease in ovarian androgen production, an improvement in insulin resistance and an increase in SHBG (see Chapter 85, Polycystic ovary syndrome). Treatment of hirsutism can prevent or slow further hair growth but will not treat the already existent hair growth, which will need to be physically removed using a variety of methods, including electrolysis, plucking, waxing, shaving and laser removal. Targeting the hair follicles in the anagen stage can lead to permanent hair removal.⁵

Pharmacological agents

Oral contraceptive pill

The oral contraceptive pill (OCP) is usually the first line of therapy, particularly for those requiring contraception or for those with menstrual irregularities.¹ The OCP acts by increasing SHBG thus decreasing the free testosterone fraction. Other actions include antagonising LH-stimulated androgen production by the theca cells, a mild decrease in adrenal androgen production and a mild blockage of the androgen receptors.¹ Pills with an oestrogen-dominant effect, such as those containing desogestrel, gestodene or norgestimate, should be used. Levenorgestrel can oppose the

oestrogen-driven increase in SHBG, while norethisterone is an androgen derivative. Pills containing these two progestogens should therefore be avoided. Dianette® is an OCP that contains the progestogen cyproterone acetate (2 mg), which also has an anti-androgenic effect through gonadotrophin inhibition and increased hepatic clearance of androgens. Cyproterone acetate in higher doses (50–100 mg/day) can also be used, but needs to be combined with an effective contraceptive due to the risk of feminisation of a male fetus should pregnancy occur. Cyproterone acetate has a long half-life and therefore can be combined with ethinyl oestradiol in a reverse sequential regimen which involves the administration of ethinyl oestradiol 25–50 µg/day from day 5 to day 25 and cyproterone acetate in the first ten days (days 5–15). After improvement, the dose of cyproterone acetate can be decreased (5 mg/day).¹ The efficacy of cyproterone acetate combined with ethinyl oestradiol compared to placebo has been demonstrated in a Cochrane review.⁷

Similar to Dianette is Yasmin®, containing the progestogen drospirenone which has an anti-androgen effect through inhibition of ovarian androgen production, as well as blockage of androgen receptors similar to the effect of spironolactone from which it is derived.⁵ A recent RCT compared two OCPs containing either drospirenone or cyproterone acetate and showed them to be similarly effective.⁸

Androgen antagonists

These medications are usually used as second-line monotherapy or in combination with the OCP in severe cases. They should be used in combination with an effective contraceptive to avoid feminisation of a male fetus. They include the following:

- Spironolactone: This is the most commonly used anti-androgen due to its relative safety and demonstrated effectiveness.⁹ Spironolactone acts by blockage of the androgen receptors and by inhibition of 5 α reductase. The effect of spironolactone is dose dependent¹ and side effects include diuresis and postural hypotension in early stages, as well as menstrual irregularities and, rarely, hyperkalaemia.¹
- Flutamide: This is a potent androgen receptor antagonist that can result in hepatotoxicity. Hence, it should only be used with caution and under tertiary care supervision. The dose varies from 250 to 500 mg/day.¹ Flutamide alone has been shown to have similar efficacy to a combination of spironolactone and Dianette.^{10,11}
- Finasteride: This is an inhibitor of 5 α reductase that is used at a dose of 5 mg/day. It can result in mild gastrointestinal disturbances, as well as dry skin and decreased libido.⁵ The most important concern, however, is its teratogenicity and hence the importance of effective contraception.

Eflornithine

Eflornithine (Vaniqa®) is a topical antiprotozoal drug that acts locally to inhibit hair follicle ornithine decarboxylase enzyme that is essential for hair growth, and can result in visible improvement within a few weeks. However, on discontinuation of treatment, hair growth returns. It can also result

in obstruction of the sebaceous glands and hence worsening of acne. Vaniqa has been shown to enhance the effect of laser treatment for hair removal.^{12,13}

Insulin sensitising agents

Metformin has been shown to improve ovulation rates in women with PCOS (Chapter 85), and may also improve hirsutism through an improvement in insulin resistance. A recent meta-analysis has shown that metformin has similar efficacy to an OCP containing 2 mg cyproterone acetate and 35 µg of ethinyl oestradiol.¹⁴ On the other hand, other studies have shown little or no benefit from the use of metformin.¹⁵

GnRH agonists

GnRH agonists can be used to suppress pituitary gonadotrophins and ovarian activity in severe resistant cases. However, treatment is associated with significant menopause-like symptoms and prolonged treatment can lead to loss of bone mineral density.

Surgical treatments

Surgical approaches include the treatment of identifiable causes, such as hypophysectomy for Cushing's syndrome, adrenal suppression for CAH and surgical removal of ovarian and adrenal tumours.

A therapeutic approach to hirsutism is summarised in Fig. 86.1.

KEY POINTS

- Polycystic ovary syndrome is the most common cause of hirsutism.
- Weight loss in obese patients may improve hirsutism.
- Virilism usually indicates significant pathology.
- The oral contraceptive pill is the most commonly used single therapy for hirsutism.

Chapter 87 Amenorrhoea and oligomenorrhoea

Mostafa Metwally and William Ledger

MRCOG standards

Theoretical skills

- To know the definitions of amenorrhoea (primary and secondary) and oligomenorrhoea.
- To know the different causes for amenorrhoea/oligomenorrhoea.
- To know how to diagnose premature ovarian failure.

Practical skills

- To be able to approach systematically, and arrange suitable investigations for, a case of amenorrhoea/oligomenorrhoea.
- Understand the principles of management of a case of amenorrhoea/oligomenorrhoea, including the management of fertility problems.

DEFINITIONS

Amenorrhoea

Amenorrhoea is the absence of menses. Based on the previous occurrence of menstruation, amenorrhoea is divided into primary and secondary.

- **Primary amenorrhoea:** Menstruation has not occurred by the age of 14 in the absence of secondary sexual characters or by the age of 16, even if secondary sexual characters are present.
- **Secondary amenorrhoea:** Periods have not occurred for six months.

Oligomenorrhoea

This is defined as infrequent menstruation, where the duration between periods is more than 35 days.

CAUSES OF AMENORRHOEA

It is important to remember that amenorrhoea and oligomenorrhoea are symptoms and not a final diagnosis. The occurrence of regular menses requires a coordinated interaction between the hypothalamus, pituitary, ovaries and the outflow tract (uterus and vagina). A disturbance at any of these levels can lead to amenorrhoea (Fig. 87.1).

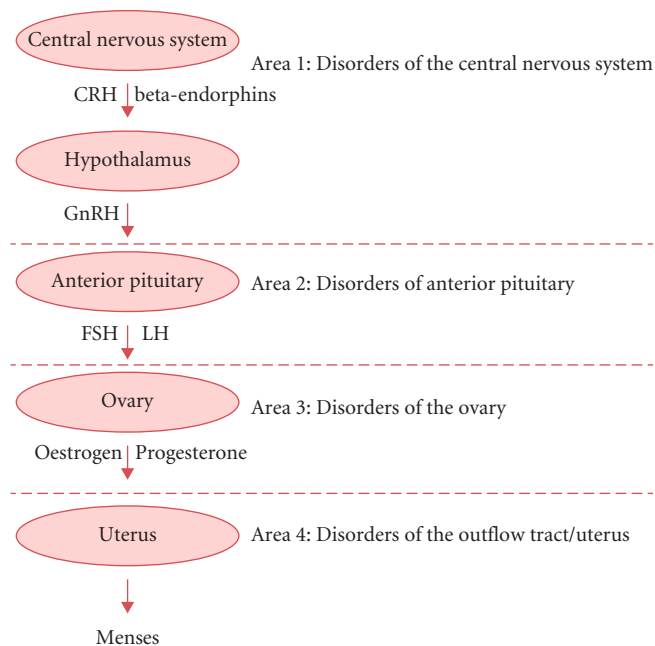

Fig. 87.1 Different compartments that may be involved in occurrence of amenorrhoea

Hypothalamus (normal or low gonadotrophins)

- **Congenital:** Kallman syndrome is a condition associated with congenital absence of GnRH secretion from the arcuate nucleus. Since GnRH-producing cells develop in the

olfactory area, Kallman syndrome can be associated with defective olfactory development manifesting with anosmia.

- **Trauma:** This may be physical trauma, such as in the case of head injuries, or psychological trauma, such as in cases of severe emotional stress.
- **Inflammation:** For example, encephalitis and meningitis.
- **Neoplastic:** Hypothalamic and other brain tumours.
- **Iatrogenic:** chemotherapy or radiotherapy for malignant or auto-immune disorders
- **Weight related:** Leptin is one of the adipokines (a range of proteins secreted by white adipose tissue) that can influence the hypothalamus and is involved in various aspects of female reproductive function. Leptin has a stimulatory effect on the hypothalamus and may be responsible for signalling information to the brain on the critical amount of fat stores that are necessary for GnRH secretion and activation of the hypothalamic–pituitary–gonadal axis.¹ Rising levels of leptin have also been associated with the initiation of puberty in animals and humans, possibly acting in concert with gonadotrophins and the growth hormone axis.² This is further supported by the occurrence of amenorrhoea associated with a drop in body fat, seen in eating disorders such as anorexia nervosa which can affect about 0.7 per cent of teenage girls,³ and in strenuously exercising athletes.⁴

Exogenous recombinant leptin replacement has been shown to improve reproductive and neuroendocrine function in women with hypothalamic amenorrhoea.⁵

In contrast, obesity is often associated with elevated serum or follicular fluid leptin levels, raising the possibility of relative leptin deficiency or resistance which may explain the poor reproductive performance in such conditions.²

Pituitary: (normal or low gonadotrophins)

- **Congenital:** Mutation of the β -subunit of FSH.⁶
- **Trauma:** After surgical removal of pituitary tumours.
- **Neoplastic:** Micro-adenomas producing prolactin, macro-adenomas or an extra-pituitary tumour compressing the pituitary stalk and hence leading to hyperprolactinaemia due to interference with dopamine (prolactin inhibitory factor).
- **Sheehan syndrome** is a condition of hypopituitarism due to ischaemic necrosis of the pituitary after massive post-partum haemorrhage. The first hormones to be affected are the gonadotrophins and growth hormone followed by ACTH and finally TSH.

Ovarian: (normal or raised gonadotrophins)

- **Congenital:** Complete androgen insensitivity in an XY female.
 - Turner syndrome (XO) presents with primary amenorrhoea, while women with mosaic Turner (XX/XO) may present with secondary amenorrhoea.

- Other forms of abnormal gonadal development may also present with primary or secondary amenorrhoea, such as cases of gonadal dysgenesis (pure or mixed).
- Resistant ovary syndrome is a condition that can present with premature menopause. The condition is characterised by a normal cohort of primordial follicles and absence of auto-immune disease. The condition can be due to a defect in the gonadotrophin receptors.⁷

- **Trauma:** Radiotherapy, chemotherapy and surgical removal.
- **Inflammation:** Rarely severe genital tuberculosis causes ovarian damage.
- **Neoplastic:** A variety of benign or malignant ovarian tumours.
- **Polycystic ovarian syndrome:** This is discussed in more detail in Chapter 85.
- **Early ovarian insufficiency (EOI, previously termed premature ovarian failure):** (see Chapter 91) This is characterised by cessation of ovarian function due to depletion of the follicular cohort before the age of 40 years. Gonadotrophins are raised in the menopausal range. The cause is usually idiopathic, in 74–90 per cent of cases,⁸ but may be associated with a variety of auto-immune conditions, chromosomal abnormalities (such as mosaic Turner), galactosaemia and carriers of fragile X pre-mutation. The occurrence of premature menopause should prompt the search for chromosomal abnormalities associated with the presence of a Y chromosome due to the high risk of malignant tumours in these gonads.

Outflow tract (normal gonadotrophins)

- **Congenital:** Congenital absence of the uterus is due to faulty development of the Müllerian ducts (Meyer–Rokitansky–Kuster–Hauser syndrome). Since the Müllerian and Wolffian ducts are closely related, this condition is often associated with developmental abnormalities in the urinary tract. Other developmental abnormalities that present with primary amenorrhoea include imperforate hymen and transverse vaginal septum. These two conditions lead to cryptomenorrhoea, where cyclic bleeding and pain occur every month, but the bleeding is not revealed. Eventually haematocolpos and haematometra occur and commonly present with acute urinary retention due to stretching of the urethra.
- **Trauma:** Surgical removal (hysterectomy) or over-curettage of the endometrium.
- **Inflammation:** Postpartum or post-abortive infection.

Both surgical trauma and inflammatory destruction of the basal endometrial layer will lead to the formation of intra-uterine adhesions (Asherman syndrome).

INVESTIGATIONS

Clinical examination, particularly in cases of primary amenorrhoea, may reveal physical characteristics of Turner syndrome, outflow obstruction and allow for examination of secondary sexual character development. According to the findings, investigations may be required at this stage including karyotyping or gonadotrophin measurement.

Other preliminary tests include exclusion of pregnancy, which is a must in all cases of secondary amenorrhoea. Thyroid function tests will exclude thyroid disorders, although it is a rare cause of amenorrhoea. Prolactin measurement is needed to exclude hyperprolactinaemia as the cause.

Progesterone challenge test

An oral progestogen given for 5–10 days will usually induce a withdrawal bleed if the endometrium has been primed by endogenous oestrogen. A positive withdrawal bleed therefore establishes the cause as anovulation (e.g. PCOS), while a negative withdrawal bleed is an indication for addition of oestrogen to the progestogen. A positive bleed with estrogen and progestogen means that the ovary is not producing adequate oestrogen (hypogonadism). This may be due to ovarian (hypergonadotrophic hypogonadism) or central deficiency of FSH/LH (hypogonadotrophic hypogonadism). The two conditions can be differentiated by measurement of gonadotrophin concentrations. On the other hand, a negative withdrawal bleed is an indication for investigation of the outflow tract (e.g. hysteroscopy to diagnose and treat Asherman syndrome, ultrasonography or MRI to investigate obstructive outflow lesions or Müllerian abnormalities).

Pituitary imaging

Imaging of the sella turcica using CT or MRI is indicated in women with significantly elevated prolactin concentrations.

Investigations for women with premature ovarian failure

The diagnosis is usually established by finding a raised FSH concentration in the menopausal range. The test should be repeated since fluctuations in FSH concentrations can occur and are associated with intermittent episodes of ovarian activity. However, other tests of ovarian reserve may be more accurate and include measuring AMH and inhibin B concentrations. Both these hormones are produced by the existing cohort of follicles and decrease with diminished ovarian reserve. However, AMH has the advantage of not fluctuating with the different phases of the cycle and therefore can

be measured at any time. Other tests that may be indicated after the diagnosis is established include karyotyping, screening for autoantibodies, galactosaemia and fragile X syndrome permutations.

TREATMENT

This should be directed to the cause and depends on the patient's current desire for fertility.

Specific pathologies that will require intervention include:

- Hysteroscopic resection of intrauterine adhesions in cases with Asherman syndrome. In one series, the conception rate after treatment ranged from 33 to 58 per cent, depending on the severity of adhesions.⁹
- Removal of space-occupying pituitary or brain tumours.

The majority of pituitary micro-adenomas, however, can be managed conservatively with a dopamine agonist. For women with hyperprolactinaemia not due to a pituitary adenoma, dopamine agonists can lead to resumption of ovulation and menstruation.

- Treatment of feeding disorders and normalisation of bodyweight.
- Surgical correction of outflow tract obstruction, e.g. incision of an imperforate hymen.
- Correction of thyroid disorders.

Treatment depends on whether fertility is required. Where fertility is not required, regular withdrawal bleeds may be induced using cyclic oestrogen/progestogen therapy (e.g. oral contraceptive pill [OCP]). Women who suffer from chronic anovulation should be treated with a cyclic oestrogen/progestagen or a progestogen alone to protect the endometrium against the effects of prolonged unopposed oestrogen stimulation. The OCP or another form of combined HRT should also be used for women with POF to protect the bone density and avoid the unpleasant side effects of oestrogen deficiency.

Where fertility is required in anovulatory women, the primary method of ovulation induction depends on the level of the defect:

- PCOS (see Chapter 85).
- Oocyte donation offers the best chance for conception in women with premature ovarian failure. Natural conception, although rare (<10 per cent lifetime odds),¹⁰ can still occur due to unpredictable late resumption of ovarian activity. There are also reports of successful ovulation induction after suppression of FSH using ethinyl oestradiol.^{11–13}
- Women with pituitary or hypothalamic causes of amenorrhoea (hypogonadotrophic hypogonadism) are treated with gonadotrophins (FSH and LH) or less commonly with pulsatile GnRH administration using a subcutaneous pump.

KEY POINTS

- Amenorrhoea and oligomenorrhoea can arise from a disturbance at the level of any of the key structures controlling the menstrual cycle.
- Pregnancy should always be excluded in a patient presenting with secondary amenorrhoea.
- Premature ovarian failure should prompt the search for underlying pathologies, although most cases remain unexplained.
- In women with premature ovarian failure not requiring fertility, treatment should be directed to the prevention of the long-term health consequences of oestrogen deficiency.
- Contraception should still be advised for women with premature ovarian failure not desiring pregnancy, since spontaneous pregnancy can still occur, albeit rarely.
- Measurement of anti-Müllerian hormone (AMH) is a better test of ovarian reserve than follicle-stimulating hormone.

Chapter 88 Menopause

Tina Sara Verghese, Jenny Williamson and Lynne Robinson

MRCOG standards

Theoretical skills

There is no established standard for this topic, but we would suggest the following points for guidance:

- Have good knowledge of the hypophyseal–pituitary–ovarian axis.
- Have knowledge of the epidemiological factors determining the age at menopause.
- Have knowledge of symptoms and health risks associated with the menopause.
- Have awareness of the risks and benefits of HRT.
- Have some knowledge of alternatives to HRT.

Practical skills

- Be able to take an appropriate history.
- Be able to diagnose menopause and arrange investigations as necessary.
- Be able to initiate referral to secondary or tertiary care for management if appropriate.

INTRODUCTION

Menopause is defined as the permanent cessation of menstruation. In the UK the mean age for menopause is 52 years. With the increase in life expectancy, a woman will live more than a third of her life beyond the menopause. Menopause is a natural phenomenon where the ovaries cease to produce significant amounts of oestrogen due to the depletion of ovarian follicles. Perimenopause is a period of change leading up to the last menstrual cycle. Menopause is retrospectively diagnosed with certainty after twelve months of amenorrhoea. The British Menopause Society and Women's Health Concern recommend that women should be able to seek advice during the climacteric and menopause periods and be able to discuss the benefits and limitations of various therapies including HRT.

EPIDEMIOLOGY

The age of menopause appears to be genetically determined. Factors that may contribute to early menopause include smoking, chemotherapy and pelvic radiation. Women who have had surgery on their ovaries or have had hysterectomy despite preservation of their ovaries may experience early menopause. Premature ovarian insufficiency is described as menopause before the age of 45 years, affecting approximately 5 per cent of the population and 1 in 100 women under the age of 40 years.

PHYSIOLOGY

Menopause is due to the depletion of ovarian follicles secondary to apoptosis or programmed cell death. Along with changes in the hypothalamic and pituitary hormones, the ovary fails to respond to the pituitary hormones (for more physiological details please refer to Chapter 91 on the subject of premature ovarian insufficiency). For more detailed description of the physiology of the reproductive tract please see Chapter X.

VASOMOTOR SYMPTOMS

The underlying cause for hot flushes during menopause is still uncertain. The hypothesis is that falling oestrogen and progesterone levels cause a change in the thermoregulatory centre of the hypothalamus.¹ This is thought to result in a transient peripheral vasodilatation mainly affecting skin blood vessels, presenting as hot flushes lasting a few seconds. If prolonged, these can progress to a sweat. Hot flushes and sweats affect approximately 75 per cent of women during perimenopause and early menopause.² The severity is variable. A Cochrane review incorporating 24 double-blind, randomised placebo control studies found that oral oestrogen or combined oestrogen and progestogen HRT greatly reduced the frequency and severity of these symptoms.³ Data obtained from nine trials demonstrated a reduction in hot flush

frequency for HRT compared with the placebo; the difference was statistically significant in eight of the trials.^{4–7}

Women initiating HRT may experience some symptoms such as transient breast tenderness, mild headaches and fluid retention, sometimes described as bloating. The overall withdrawal rate is low.

SEXUAL FUNCTION

There is a significant decline in sexual function including libido, arousal, orgasm and satisfaction around the time of the menopause. Treatment options such as androgens may be considered in conjunction with HRT.

Tibolone has a weak androgenic effect which can have a beneficial effect on mood and libido. Tibolone exhibits a combination of oestrogenic, progestogenic and androgenic activities. In patients with a surgical menopause, RCTs have demonstrated that transdermal therapy is beneficial in improving sexual function and activity. There may also be cardiovascular benefits for women.⁸ Testosterone gels are available albeit only as a male product. These are unlicensed for use in women but can be used if titrated to an appropriate dose (for more physiological details please refer to Chapter 91). Androgenic side effects and risks are minimal and reversible if testosterone levels are maintained within the female physiological range.

UROGENITAL SYMPTOMS

Oestrogen treatment can be used to reduce thinning of the vaginal and pelvic tissues. This may help to reduce or prevent symptoms of cystitis and may aid postoperative recovery after uro-gynaecological procedures. The different preparations of topical HRTs (creams, pessaries, tablets and the oestradiol vaginal ring) all appear equally effective for treating vaginal atrophy.

Estradiol vaginal tablets when used for 12 months at 10 µg daily for 2 weeks followed by twice weekly for 52 weeks resulted in a total annual oestradiol exposure of only 1.14 mg and did not stimulate the endometrium in postmenopausal women to any significant level.⁹ There were no cases of endometrial hyperplasia or carcinoma in these women.¹⁰ There is therefore no indication for the addition of progestogen treatment for endometrial protection when a twice-weekly vaginal oestrogen preparation is used.

CARDIOVASCULAR DISEASE

In the UK, one in ten women die from coronary heart disease.¹¹ The mortality rate from this disease is higher than from any gynaecological or breast cancers. Postmenopausal women are 2–3 times more prone to having a heart attack when compared to premenopausal women. Oestrogen reduces atheroma

formation and has a favourable influence on cholesterol and lipoprotein metabolism along with maintaining the smooth muscle and collagen elasticity.

Prior to 2002, observational studies suggested that HRT was beneficial, showing a reduction in risk of cardiovascular disease, osteoporosis and colon cancer.¹² Critics suggested that the 'healthy well' were more likely to use HRT and therefore randomised trials were needed to find out if HRT was in fact cardioprotective.¹²

In 2002, the primary outcomes from the Women's Health Initiative (WHI) trial reported no cardiovascular benefit from the combined arm of HRT.¹³ Subsequent analysis of this study published in 2007 now identifies that the timing of administration may be of significance.^{14,15} Starting HRT many years after menopause can result in harm which is not seen when commenced in the immediate postmenopausal years. The Danish Osteoporosis Prevention study found that if HRT was started soon after menopause and continued for a prolonged period, there was no increase in adverse events such as stroke, heart failure, myocardial infarction or mortality. In addition the results also showed no increase in breast cancer or other cancers.¹⁶ In this study, 17-beta oestradiol and norethisterone were the hormones used rather than conjugated equine oestrogen (CEE) which was used in the WHI study. 17-beta estradiol, both alone and in combination with norethisterone, appears to be less thrombogenic.¹⁷ In contrast to CEEs which maintain the postmenopausal oestrone:oestradiol ratio, 17-beta estradiol maintains the premenopausal ratio. This may help to explain to some degree the differing results of the WHI trial compared with subsequent trials.

HRT has been found to have a positive effect on lipid metabolism. Combination therapy can lower the cholesterol levels and improve endothelial function. There is some evidence of benefit to metabolic parameters including lipids, insulin, glucose and body fat distribution with oestradiol and dydrogesterone combinations.¹⁸ However, given the uncertainties in the evidence, HRT cannot be recommended for primary or secondary prevention of ischaemic heart disease.

STROKE

The incidence of stroke in women immediately post menopause is low but increases with age. The indication for HRT is symptom relief and studies which have identified an increased risk of stroke tend to be on women in whom HRT has been commenced later in life. The WHI study found an increase of 30–40 per cent in stroke risk in women on oestrogen alone or a combination of oestrogen with progestogens.¹⁹ However, re-analysis of the data showed a smaller increase of stroke in women who commenced HRT aged 50–59 years. The Nurses Study, which aimed to evaluate the risk of stroke in women of various age groups on HRT, found that the age-adjusted RR of overall stroke for current users on oestrogen alone when compared with women who never used HRT was 1.33 (95% CI 1.13–1.55). In women on combined therapy, the

RR was 1.17 (95% CI 0.96–1.42).²⁰ The HERS study (Heart and oestrogen progestogen study) reported no increase in incidence of stroke in women on HRT and a recent open-label randomised trial found no increase in stroke after 16 years' follow-up of HRT users who commenced treatment around the time of their natural menopause.¹⁶

HRT, if required, should be cautiously started in low doses in women above the age of 60 with high risk for stroke or thromboembolism. This group of women may benefit from transdermal hormonal patches. Low-dose hormone therapy may be preferable for women with significant risk factors.

OSTEOPOROSIS

Osteoporosis accounts for about 35 per cent of bone fractures. Osteoporosis mainly affects the spine, hip, distal forearm and proximal humerus. In 2010, the calculated direct costs due to fractures were estimated to be €29 billion in the five largest EU countries – France, Germany, Italy, Spain and the UK.^{21–23} Dual energy X-ray absorptiometry (DXA) is the most inexpensive method of measuring bone density, involving low radiation exposure. Bone mineral density (BMD) is most often described as a T- or Z-score, both of which are units of standard deviation. The T-score describes the number of SDs by which the BMD in an individual differs from the mean value expected in young healthy individuals. Osteoporosis is based on the T-score for BMD assessed at the femoral neck and is defined as a value for BMD 2.5 SD or more below the young female adult mean (T-score less than or equal to -2.5 SD).^{24,25} The Z-score is mostly used in children and adolescents. A computer-based algorithm known as FRAX (www.shef.ac.uk/FRAX/) calculates the 10-year probability of a major fracture (hip, spine, humerus or wrist fracture). The variables used to calculate fracture risk are age, BMI and risk factors such as prior fragility fracture, family history, smoking, ever use of long-term oral glucocorticoids, rheumatoid arthritis, secondary causes of osteoporosis and alcohol consumption.

HRT has been shown to be very effective at maintaining and preventing bone loss in both spine and hips and should be considered in women who are at risk of osteoporosis and require symptomatic relief from climacteric symptoms.

Other drugs can be used to prevent bone density loss. Raloxifene (selective oestrogen modulator) prevents bone loss. The risk of vertebral fractures is reduced by 30–50 per cent in postmenopausal women on raloxifene (Multiple Outcomes of Raloxifene Evaluation – MORE trial).²⁶ However raloxifene can cause vasomotor symptoms. Bisphosphonates are also used to prevent bone loss and are inhibitors of bone resorption, acting by reducing the recruitment and activity of osteoclasts and increasing their apoptosis.

In contrast to HRT, there are no long-term outcome data with these treatments and there may be an increase in atypical fractures and osteonecrosis of the jaw with bisphosphonate use.

BREAST CANCER AND HORMONE THERAPY

Studies such as the WHI trial and the Million Women study have reported an increase in the risk of breast cancer, especially for women on combined hormone therapy.^{27,28} The Million Women study stated a varied relative risk of breast cancer depending on the type of HRT used and this was significantly greater in users of combined therapy ($p < 0.001$).²⁸ The study estimated that 10 years' use of HRT resulted in 5 (95% CI 3–7) additional cases of breast cancer per 1000 users of oestrogen-only preparation and 19 (95% CI 15–23) additional cases of breast cancer per 1000 users of combined HRT.²⁸ The study had several design flaws resulting in unreliable findings. A critique of the Million Women study identified that the participants were recruited from a national breast screening programme and this could have led to a detection bias.²⁹ Furthermore, cancers detected at the outset were not excluded, women on HRT were more likely to attend, and the rapid onset of breast cancer suggested by the researchers did not fit with the biological course of the disease. The findings did however indicate that the risks were greater with combined HRT than with oestrogen-only preparations or tibolone.

Women who have had a personal history of breast cancer are often the women with the most troublesome menopausal symptoms because of anti-oestrogen treatments and therefore present a real clinical dilemma. Following breast cancer treatment, many women experience hot flushes, night sweats, sexual dysfunction and poor sleep. Two thirds of breast cancers are oestrogen receptor-positive where treatment to block the effects of oestrogen results in profound vasomotor symptoms along with urogenital atrophy. Aromatase inhibitors in the postmenopausal woman inhibit the peripheral conversion of androgen to oestrogen, while tamoxifen, usually given to the pre- and perimenopausal woman, acts as an oestrogen receptor blocker.

Clonidine, a centrally acting alpha-adrenergic agonist, is the only licensed non-hormonal treatment for vasomotor symptoms. Selective serotonin reuptake inhibitors (SSRIs) and serotonin noradrenaline reuptake inhibitors (SNRIs) in low doses are unlicensed but have been evaluated and found to reduce symptoms of hot flushes to some extent. Short-term studies of women with breast cancer have found SSRIs (paroxetine, fluoxetine, citalopram) and SNRIs (venlafaxine, desvenlafaxine) more effective than placebo.³⁰ Some SNRIs and SSRIs induce CYP2D6 and may interfere with the breakdown of tamoxifen. Citalopram and venlafaxine may be better alternatives in breast cancer patients on tamoxifen.³⁰

Gabapentin (up to 900 mg/day in divided doses) is also unlicensed for this use but can help reduce hot flushes in breast cancer patients.³¹ It has a rapid onset of action. In an RCT by Reddy *et al.* gabapentin has exhibited equivalent efficacy to oestrogen in reducing hot flushes.³²

For some breast cancer survivors the use of HRT will be a quality-of-life decision. The main concern of the clinician is that there may be a dormant occult breast cancer cell which

would become activated by the use of oestrogenic stimulation although evidence for this is conflicting.³³⁻³⁷ The stage at diagnosis, the oestrogen receptor status of the original tumour and the length of time since diagnosis are all relevant to the discussion. Patients with tiny screen-detected tumours may have an excellent prognosis and reduced incidence of disseminated metastases.³⁸ Initiating HRT immediately after cancer treatment would not be recommended. Patients who have suffered vasomotor symptoms relentlessly, and for whom many years have elapsed since their initial breast cancer treatment, may wish to evaluate HRT on a quality-of-life basis.³⁹ Discussion on the use of HRT in these women is best carried out with multidisciplinary team input. Studies on breast cancer patients using HRT have been conflicting and the use of tibolone identified recurrence in the ER+ cases but not in the ER- cases.⁴⁰

ENDOMETRIAL CANCER

Furness *et al.*⁴¹ reported that unopposed oestrogen therapy increases the risk of endometrial hyperplasia at any dose and duration between 1 and 3 years. The WHI study reported no increase in incidence of endometrial cancer for women on HRT (RR 0.83, 95% CI 0.29–2.32).⁴² The risk is decreased by adding progestogens either sequentially or in a lower dose continuously. Sequential combined oestrogen and progestogen therapy for more than five years is associated with a very small risk of endometrial cancer and continuous combined regimens actually confer a lower risk of endometrial cancer than for non-HRT users. Combined continuous regimens are suitable for women who have had at least 12 months of sequential therapy, one year or more after their last menstrual period or two years or more if they are under 50 years. Sequential regimens are more suited to perimenopausal or prematurely menopausal women. In patients who have undergone a subtotal hysterectomy it is important to establish that there is no remaining endometrium before prescribing oestrogen-only HRT; using sequential HRT initially post surgery can help to establish this if there is doubt. In the event where there is no bleeding with a sequential regimen, unopposed oestrogen HRT is safe.

OVARIAN CANCER

The WHI study found that there was no increased risk of incidence of ovarian cancer for women on HRT.²⁷ Contrary to this study, the Danish National Cancer registry reported that women on unopposed oestrogen or combined HRT for more than eight years had a small but significant increase in the incidence of ovarian cancer. Data on HRT use after ovarian cancer are limited. A systematic review including randomised and observational studies found that there was no increased risk of recurrence.⁴³

CONTRAINDICATIONS TO HRT

There are few absolute contraindications to HRT. These include current breast cancer, current thromboembolism, active liver disease and SLE with renal involvement.

Conditions such as previous venous thromboembolism, hypertension, obesity and migraine can all be managed alongside prescribing HRT treatment. HRT is not known to increase blood pressure although conjugated oestrogens can be linked with an idiosyncratic rise in blood pressure. When hypertension is controlled with appropriate medication, HRT can be used concurrently.

Patients with previous thromboembolism should be adequately assessed in conjunction with a haematologist, but may be suitable for transdermal treatment started in a gradual fashion to minimise a procoagulant effect. A similar approach may be employed for migraine or seizure sufferers.

DURATION OF TREATMENT

The theory surrounding the 'window of opportunity' would suggest that HRT is most beneficial in the first 10 years after the age of natural menopause. However, many women continue to experience marked vasomotor symptoms well into their sixties and even seventies and therefore duration of treatment will vary from patient to patient. Each patient should be individually assessed and consideration should be given to their symptoms. Prolonged HRT treatment can be employed in many women safely but medication should be regularly reviewed and lower doses used if tolerated (see Table 88.1).

Table 88.1 Indications for various types of hormone replacement therapy

Type of HRT	Indications
Oestrogen only	Women without a uterus + subtotal hysterectomy (if adequate resection margin)
Sequential HRT	Premature ovarian insufficiency Last menstrual period (LMP) <12 months ago
Continuous combined HRT	>12 months sequential HRT 1 year post LMP if >50 years old 2 years post LMP if <50 years old
Oestrogen + Mirena IUS	Women with uterus preferring IUS to systemic progestogens Women requiring HRT + contraception Women with pre-existing IUS requiring HRT

A full discussion about the risks and uncertainties in the evidence is essential, particularly for women who wish to continue HRT beyond five years since treatment initiation.

NON-HORMONAL TREATMENT

There are limited clinical data on non-pharmacological treatments such as behavioural interventions, exercise and acupuncture. Acupuncture has been found to be less effective than oestrogen in management of hot flushes but more beneficial than placebo. A recent systematic review of non-hormonal therapies for hot flushes did not support the efficacy of red clover products (predominantly promensil).⁴⁴ There are mixed results on the use of soy isoflavones. Placebo-controlled RCTs of vitamin E succinate (800 IU/day) in breast cancer did not show promising results. Despite the long-term safety concerns of HRT, there are few data on non-hormonal therapies. SNRIs/SSRIs, clonidine and gabapentin are often used to control vasomotor symptoms but clonidine is the only one of these products licensed for this use.

KEY POINTS

- Menopause symptoms are often debilitating.
- It is essential that we adequately inform women of the risks and benefits of HRT.
- In recent years, lower doses of oestrogen have become available and we now know that lower doses of oestrogen adequately protect bone density.
- HRT does not appear to increase the risk of cardiovascular disease in women started on HRT within 10 years of menopause.
- Although there are uncertainties in the evidence, the available data suggest an increase in the risks of breast cancer, stroke and venous thromboembolism with HRT use.
- HRT remains one of the most effective strategies available to provide relief of vasomotor symptoms and protect bone density.

Chapter 89 Miscarriage

James Hounslow and Ying Cheong

MRCOG

- To have a good understanding of early pregnancy physiology and pregnancy loss.
- To be able to diagnose and treat miscarriage, both medically and surgically.
- To understand the use of ultrasound in the assessment of early pregnancy and diagnosis of miscarriage, including its limitations.
- To be able to communicate effectively and sensitively with patients.

INTRODUCTION

Miscarriage is the most common complication of early pregnancy. Its effects are both physical and psychological, and may be immediate or long term in their nature. The incidence of clinical miscarriage is around 10–15 per cent. This risk of miscarriage is highest in the first trimester of pregnancy and decreases to 2–7.5 per cent once a viable fetus is identified on ultrasound.^{1–3} Recurrent miscarriage, defined as the spontaneous loss of three or more consecutive clinical pregnancies, is a separate clinical entity requiring specialist investigations and management covered elsewhere in the book and therefore will not be dealt with in this chapter.

Historically miscarriage was associated with significant maternal morbidity and mortality. Fortunately maternal death from miscarriage is rare in the developed world, with

0.3 deaths per 100,000 estimated pregnancies in the CMACE report of 2006–08.

DEFINITION AND EPIDEMIOLOGY

Seventy per cent of spontaneous human pregnancies are lost prior to live birth. From the time of conception to implantation 30 per cent of conceptions are lost, a further 30 per cent are lost between the time of implantation and the date of the first missed period, and another 10 per cent are lost as a recognised miscarriage;⁴ in other words, overall only 30 per cent of conceptions will result in a live birth.

Hence, human reproduction is far from efficient. Losses from spontaneous pregnancies can be pre-clinical or clinical. Pre-clinical or occult pregnancy losses will include pregnancies where implantations were initiated with (biochemical) or without detectable circulating hCG (implantation failure).

The term ‘miscarriage’ refers to a spontaneous loss of pregnancy before the fetus reaches viability. The definition of viability can vary depending on the context of discussion but in the UK, miscarriage is defined as the loss of a pregnancy before 24 weeks of gestation. After 24 completed weeks, pregnancy loss is legally defined as stillbirth. The term clinical miscarriage is applied when there is either ultrasound or histological evidence that a failed intrauterine pregnancy is or has been present. Clinical miscarriage may be either early (<12 weeks’ gestation) or late (>12 weeks’ gestation). A pregnancy that is demonstrated by a raised urinary hCG or serum β -hCG, but that fails before ultrasound or histological evidence of the pregnancy, is defined as a biochemical loss (Table 89.1).

Table 89.1 Differential diagnosis of early pregnancy loss

Diagnosis	Presentation	Cervical findings	Ultrasound	Action
Biochemical pregnancy	Initially +ve then –ve urinary pregnancy test or serum hCG	Os closed	Not performed	No further action required
Pregnancy of unknown location (PUL)	+/- Pain; +/- bleeding	Os closed	No intra- or extrauterine pregnancy or retained products of conception (RPOC) identified	β -hCG follow up and re-scan as appropriate

Diagnosis	Presentation	Cervical findings	Ultrasound	Action
Threatened miscarriage	Bleeding; +/- pain	Os closed	Gestation sac + yolk sac +/- fetal pole/cardiac activity	Reassure, offer re-scan if fetal pole/cardiac activity not seen
Delayed miscarriage (missed miscarriage)	May be asymptomatic/incidental finding; +/- pain or bleeding	Os closed	Gestation sac >= 25 mm with no fetal pole OR fetal pole >= 7 mm with no cardiac activity	Explain diagnosis of miscarriage and explain options (expectant/medical/surgical)
Inevitable miscarriage	Bleeding; +/- pain	Os open	Gestation sac + yolk sac +/- fetal pole/cardiac activity	Explain diagnosis of miscarriage and explain options (expectant/medical/surgical)
Incomplete miscarriage	Bleeding; +/- pain	Os open; +/- products within cervix/vagina	RPOC	Explain diagnosis of miscarriage and explain options (expectant/medical/surgical)
Complete miscarriage	Bleeding (settling); +/- pain	Os closed	Intact midline endometrial echo or RPOC of <15 mm diameter AND previous ultrasound evidence of intrauterine pregnancy	Reassure and discharge to GP follow-up

MECHANISMS, CAUSATION AND RISK FACTORS IN EARLY CLINICAL MISCARRIAGE

The embryo or the endometrium?

It is generally accepted that sporadic early pregnancy loss represents a physiological phenomenon, selecting out conceptions which have significant and serious structural and/or chromosomal problems.⁴ This assumption is borne out by studies which demonstrate that a large proportion of early clinical miscarriage is affected by either an abnormal karyotype or abnormal fetal morphology, or both. One study has demonstrated that 85 per cent of fetuses observed by embryoscopy prior to uterine evacuation had fetal malformations and in the same group an abnormal karyotype was demonstrated in 75 per cent.⁵

The endometrium also contributes to embryo selection and a failure of this process can lead to implantation failure or recurrent pregnancy loss. Compared to controls, the endometrium of women with recurrent miscarriages can be overly receptive to low-quality embryos; such 'super fecundity' facilitates the implantation of embryos that normally fail to implant only to result in a clinical miscarriage further on.⁶

Risk factors for miscarriage

Various risk factors are known to modulate one's risk of miscarriage. These include high maternal⁷ and/or paternal⁸

age, history of previous miscarriage,⁹ history of infertility,¹⁰ extremes of BMI, uterine malformations, alcohol consumption and a recent change of partner.¹¹ There is also an association of an increased risk of miscarriage with many chronic medical conditions including diabetes, epilepsy (with or without treatment), cystic fibrosis and heart disease.

Maternal age is associated with a wide variation in the incidence of clinical early miscarriage, from 10 per cent in women aged 20–24 to 51 per cent in women aged 40–44.⁷ The increase in the incidence of early pregnancy loss with age is largely related to the increased rate of aneuploidy.

Alcohol consumption both pre-conception and in the first three months of pregnancy is associated with an increased risk of miscarriage.¹² Alcohol has a dose-dependent effect on the risk of miscarriage, with those drinking more than 4 drinks per week being 2.8 times more likely to miscarry.¹³

Caffeine intake has previously been implicated as a cause of miscarriage, but recent data suggest there is only an increased risk of miscarriage where the mother had been drinking >7 cups of coffee per day, which suggests moderate caffeine intake does not increase the risk of miscarriage as previously thought.¹⁴ Unless the mother's caffeine intake is very high it is therefore unlikely that reducing or omitting intake will reduce her risk of miscarriage.

There is conflicting evidence as to whether smoking is a risk factor for miscarriage, with a large prospective study being unable to demonstrate an association,¹⁵ although a recent study demonstrated harm.¹⁶

There is a three-fold increase (5–15 per cent) in the prevalence of congenital uterine malformations when

comparing women with recurrent miscarriage to an unselected control group.¹⁷ A meta-analysis has shown that a septate uterus increases the rate of first-trimester miscarriage, again nearly three-fold with an RR of 2.89.¹⁸ It is however unclear as to whether resection of the uterine septum is beneficial.

There is an association between hypothyroidism and increased risk of miscarriage. Meta-analysis of results from 19 cohort studies showed more than a tripling in the odds of miscarriage in the presence of thyroid antibodies (OR 3.9, 95% CI 2.48–6.12).¹⁹ It is unclear if correction of TSH by means of T₄ (levothyroxine) improves outcomes and at the time of writing the TABLET RCT is investigating whether low-dose levothyroxine improves pregnancy outcome in patients who are euthyroid but with elevated TSH.²⁰

Whilst studies have suggested a biologically plausible immunological basis for miscarriage, interventions relating to immunomodulation, such as steroid immunosuppression, allogeneic lymphocyte immunisation, intravenous immunoglobulin administration, TNF α antagonists and granulocyte colony-stimulating factor, are largely non-evidence based and not recommended for standard use.

While thrombophilias are associated with an increased risk of recurrent miscarriage, it is unclear whether a causative association with sporadic miscarriage exists.

TYPES OF CLINICAL EARLY MISCARRIAGE

Until the 1990s the term ‘spontaneous abortion’ was in general use by gynaecologists and other medical professionals. This term can cause significant distress due to its similarity to induced abortion (termination of pregnancy) and should therefore not be used in clinical practice. The current classification of miscarriage can also cause distress to patients and relatives if care is not exercised in its explanation as part of the delivery of bad news. Terms used should be explained in language appropriate to the patient, for example avoiding the use of missed miscarriage and instead explaining a diagnosis of delayed miscarriage. The clinical presentation, examination findings and ultrasound findings are shown in Table 89.1.

A patient presenting with a suspected history of miscarriage should first be clinically assessed by way of a medical history and examination. A suggested clinical pathway for management of these patients is depicted in Fig. 89.1. It would be appropriate to arrange a transvaginal scan in order to assess the state of the pregnancy. A TVS offers a good sensitivity and specificity for the diagnosis of miscarriage although in the event that a TVS is not immediately available to the clinician, and/or the patient is cardiovascularly unstable or bleeding heavily, it is appropriate to perform, with consent, a speculum and pelvic examination to assess the severity of bleeding and to remove any products of conception from the cervical os. In rare instances, where cervical shock occurs as a result

of distension of the cervix by products of conception, rapid removal of this tissue with the aid of a speculum and a pair of sponge forceps can be life saving.

A definitive diagnosis may not be made at the first ultrasound, and in such cases appropriate follow-up should be planned. If an intrauterine pregnancy is confirmed by the presence of a gestation sac and yolk sac then follow-up should be with a further ultrasound, appropriately timed to assess progression (7–14 days).

If the location of the pregnancy is uncertain then biochemical testing for serum β -hCG is appropriate. If the level of hCG rises sub-optimally, one should suspect the differential diagnosis of ectopic pregnancy (not dealt with in this chapter). A consistently declining β -hCG suggests a failing pregnancy. Serum biochemistry, either progesterone or β -hCG, should not be used to distinguish between viable and non-viable pregnancy as it is not possible to reliably discriminate between the latter two on biochemistry alone without an ultrasound diagnosis.

Provided the patient is haemodynamically stable at the time of assessment then it is appropriate to continue any further investigations required on an outpatient basis. A minority of patients will need admission to the gynaecology ward directly from their initial assessment, either for a period of observation or if immediate surgery is planned. If there is evidence of haemodynamic instability then fluid resuscitation is appropriate and consideration should be made as to the availability of blood products should they be required (Fig. 89.1).

MANAGEMENT OF DIAGNOSED MISCARRIAGE

The management of miscarriage should be individualised, taking into account the wishes of the woman as well as the clinical situation. In most instances expectant, medical or surgical management will be appropriate, although availability of these management options will depend on local provision. If the patient is haemodynamically unstable, or the pain cannot be adequately controlled, or there are concerns about infection/sepsis, then surgical management is usually indicated.

Rhesus D prophylaxis

The use of anti-D immunoglobulin for the prevention of RhD sensitisation is now well established in the UK. In order to prevent avoidable sensitisation, it is important to ascertain the patient’s blood group and treat with anti-D Ig when indicated. Those opting for surgical management at any gestation, or medical or expectant management beyond 12⁺⁰ weeks should receive anti-D if they are rhesus negative and have not been previously sensitised. Those receiving medical management before 12⁺⁰ weeks’ gestation should be considered for anti-D prophylaxis. Women with a diagnosis of threatened miscarriage but continued bleeding beyond 12⁺⁰ weeks’ gestation should also be treated.²¹

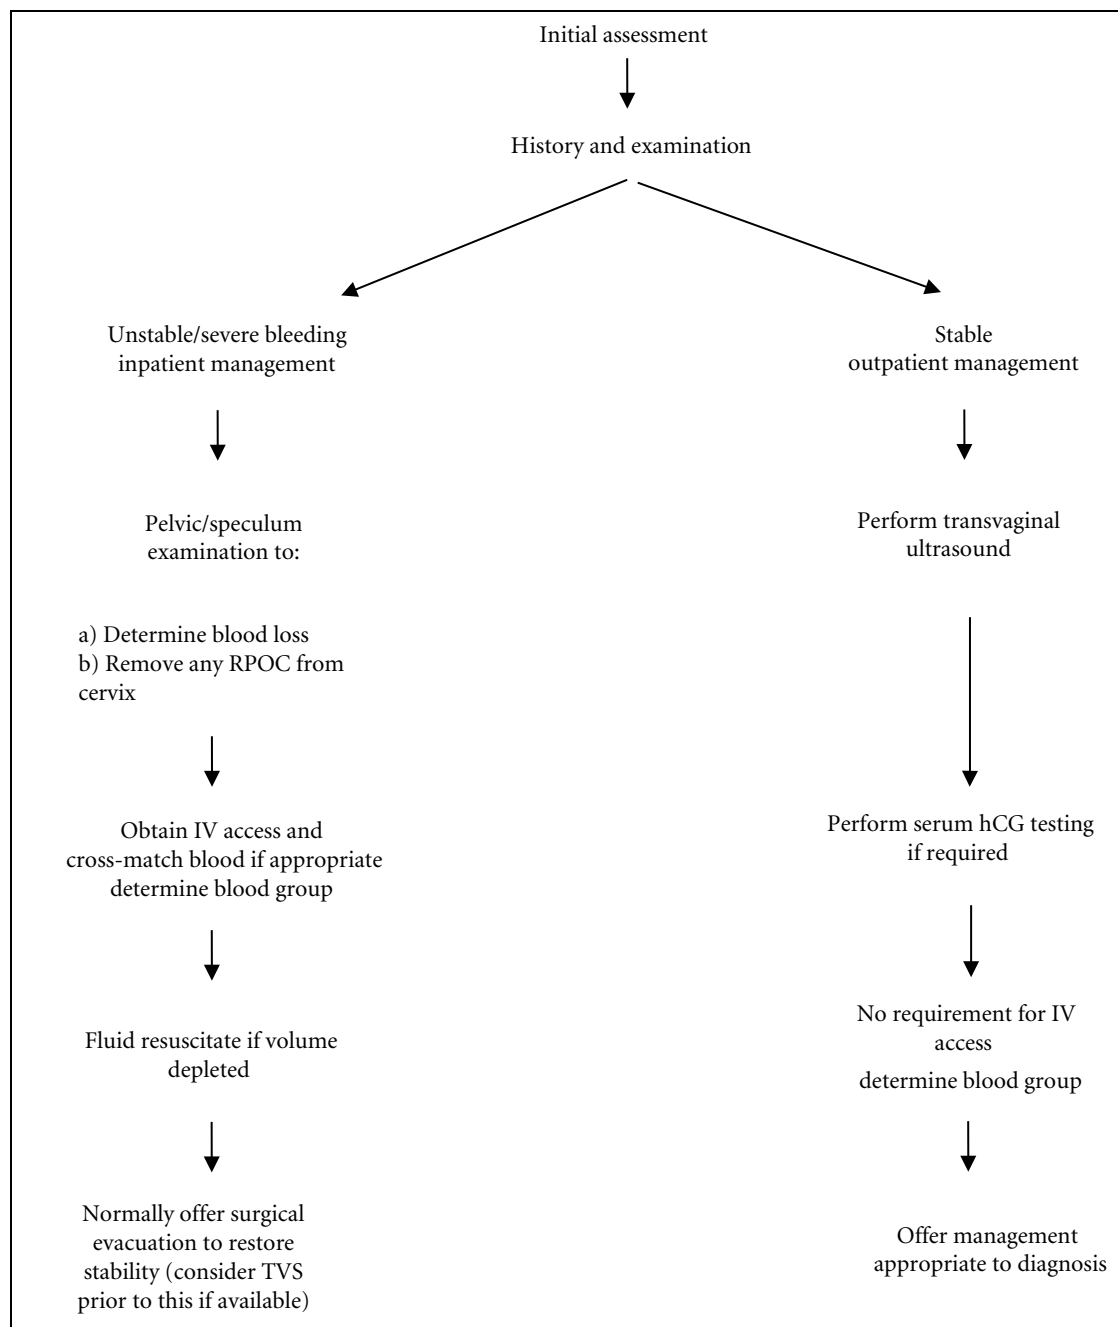

Fig. 89.1 The initial assessment of a woman with a possible diagnosis of miscarriage

Expectant management

NICE recommends that expectant management should be used for 7–14 days from a confirmed diagnosis of miscarriage unless this is unacceptable to the woman or expectant management is not clinically appropriate, for reasons such as high risk of haemorrhage or suspected infection.²² Expectant management is an appropriate management to offer for women diagnosed with a pregnancy of uncertain viability (where the diagnosis is unclear) and threatened miscarriage.

An observational study of 1096 women diagnosed with first-trimester miscarriage evaluated the uptake and outcome of expectant management. This study demonstrated a high take-up of expectant management (70 per cent) and patient satisfaction rates of around 90 per cent with this management option.²³ The same study found that expectant management is more successful for incomplete miscarriage (84%, 185/221) compared with delayed (missed and anembryonic) miscarriage (56%, 129/230) at 14 days from diagnosis.

Expectant management may continue provided that the woman remains clinically well, has no signs of infection and is not compromised by the bleeding. The duration of this management can be greater than eight weeks, provided of course that the patient remains happy with this choice of management.

Follow-up is usually with ultrasound to assess whether the miscarriage has completed, as well as clinical assessment of the patient.

Medical management

Medical management involves the use of the prostaglandin analogue misoprostol to induce uterine contractions, resulting in the delivery of the pregnancy vaginally. There are several protocols being used currently regarding the dose of misoprostol used, the route of administration and whether to use mifepristone (an oral antiprogesterone). Meta-analysis of these differing protocols has allowed NICE to make the following recommendations:²² mifepristone should not be routinely used as there is no significant increase in the success rate of treatment; misoprostol should be administered vaginally, at a dose of 800 µg for missed miscarriage or 600 µg for incomplete miscarriage; and where vaginal administration is not acceptable or wished by the patient, oral administration of the same dosage should be offered.

Success rates are similar to expectant management, with an overall success rate of around 80 per cent achieved within a shorter timescale.²⁴ Medical management is more likely to be successful for incomplete miscarriage than delayed miscarriage, as is the case for expectant management. It is currently uncertain as to whether expectant or surgical management is the most effective and/or cost-effective way to continue the management of patients with RPOC post medical management with misoprostol. The MisoREST trial is investigating this at the time of writing.²⁵

Surgical management

Surgical management remains the treatment of choice for patients who are haemodynamically unstable, who show signs of sepsis, or who are not suitable for medical or expectant management either through patient preference or other medical co-morbidities.

Vacuum (suction) aspiration is preferable to sharp curettage as it is associated with significantly less blood loss, less postoperative pain and a shorter duration of procedure. It has a failure rate of 1–5 per cent.^{26–28}

There is a risk of uterine and cervical trauma with surgical management. Uterine perforation occurs in up to 1:250 cases.²⁷ In such cases of suspected uterine perforation it is common to perform a laparoscopy to assess the injury and facilitate any repair that is necessary.

Intrauterine adhesions form in up to 40 per cent of patients undergoing surgical management for miscarriage²⁹ but it is

uncommon for this to manifest in long-term fertility problems or menstrual disorders.

Which management option to recommend?

Expectant and medical management have the benefits of avoiding planned surgery and anaesthesia; however they are associated with a higher failure rate and a higher chance of needing emergency surgery due to either unacceptable bleeding or pain.^{30,31}

The incidence of local pelvic infection following surgical evacuation of the uterus is around 3 per cent, and comparable with both medical and expectant management.³²

Reassuringly the long-term follow-up of women undergoing any of the three management options for miscarriage shows no significant difference in the livebirth rate five years post miscarriage, at 79 per cent (298/454) for both medical and expectant management and 82 per cent for surgical management (192/235).³³

There is no 'one size fits all' miscarriage management strategy, and as a result care should be individualised. Clinicians who are providing advice to patients must therefore take into account their wishes, their medical history, local provision of services and the patient's ability to access those services along with the current clinical situation.

PREVENTION OF MISCARRIAGE

- 1 Progesterone: Although commonly used in many countries, there is still insufficient evidence to suggest the routine use of progesterone to prevent/reduce the risk of miscarriage.³⁴
- 2 Other pharmacological/alternative interventions: There is no evidence of reduction in the risk of miscarriage with the use of:
 - multivitamins;
 - oestrogen supplementation;
 - uterine muscle relaxants;
 - hCG;
 - complementary medicine.
- 3 Non-pharmacological interventions: As previously discussed, the evidence for smoking as a direct risk factor for miscarriage is inconsistent. As there are significant health benefits to stopping smoking, a recommendation that smokers stop smoking is appropriate.

Addressing concerns about maternal alcohol consumption is appropriate. Increased or even moderate alcohol intake is associated with an increased risk of miscarriage, and in an ongoing pregnancy with fetal alcohol syndrome. For those planning pregnancy the current recommendation is to avoid alcohol.¹²

Bed rest has historically been recommended as a treatment for threatened miscarriage; however there are no data to support its use.³⁵

- 4 Embryo selection: There is currently no evidence to suggest that screening embryos prior to implantation helps with reducing the risk of miscarriage.

KEY POINTS

- Significant morbidity or indeed mortality from miscarriage is fortunately now rare in the UK.
- Diagnosis is by TVS combined (when appropriate) with hCG follow-up.
- Expectant, medical or surgical management of miscarriage will be safe management options for the majority of women with a diagnosis of miscarriage. Management will therefore depend on patient preference and local availability.
- Surgical management (evacuation of products of conception – ERPC) remains the mainstay of treatment in women who are haemodynamically unstable.

Chapter 90 Ectopic pregnancy

Ghada Salman, Davor Jurkovic

MRCOG standards

Knowledge criteria

- Understanding of epidemiology, aetiology, pathogenesis and clinical features of ectopic pregnancy.
- Prognosis after ectopic pregnancy and pregnancy of unknown location.
- Identification and assessment of evidence.

Theoretical skills

- Clinical presentation and assessment.
- Indications and limitations of investigations.
- Biochemical: serum β hCG and progesterone.
- Radiological: ultrasound.

Practical skills

Understanding of management options:

- Conservative management;
- Medical management;
- Surgical management.

INTRODUCTION

Ectopic pregnancy is a major health problem and an important cause of morbidity and mortality in women of reproductive age. Ruptured ectopic pregnancy can cause severe intra-abdominal bleeding which may require emergency life-saving surgery. The UK CEMACH reported a maternal mortality rate (MMR) of 0.2 per 1000 ectopic pregnancies or 0.3 per 100,000 maternities.¹

Serious adverse outcomes, however, tend to occur only in a small minority of women and they are often caused by delays in reaching the correct diagnosis. Over half (54 per cent) of deaths caused by ectopic pregnancies have been attributed to substandard clinical care. It is therefore important that all health professionals are familiar with the risk factors, clinical signs and symptoms of ectopic pregnancy to ensure timely

referrals to secondary care. The burden of the disease is also considerable due to the high costs of diagnostic investigations and treatment.^{1,2}

Improvements in diagnosis and management are therefore needed to prevent avoidable deaths from ectopic pregnancies. Better clinical care should also help to reduce physical and psychological morbidity associated with ectopic pregnancy, improve future fertility outcomes and reduce the costs associated with repeated hospital follow-up visits and admissions.^{1,3,4}

DEFINITION OF ECTOPIC PREGNANCY

Ectopic pregnancy is defined as any pregnancy that implants outside the uterine cavity. Most of the ectopic pregnancies implant within the Fallopian tubes (93–97 per cent) of which the majority are found within the ampullary part.⁵ Implantation of pregnancy in the interstitial part of the Fallopian tube occurs in 2.5 per cent of cases. Despite their relative rarity, these interstitial pregnancies are responsible for about a fifth of all deaths caused by ectopic pregnancies in the UK.¹

In about 5–7 per cent of ectopic pregnancies, the implantation occurs outside the Fallopian tubes. Most of these pregnancies are located within the uterine wall but outside the endometrial cavity and they include intramural, cervical and caesarean scar pregnancies. Other reported sites for ectopic pregnancy include ovarian and abdominal pregnancies.⁶ Cornual pregnancies are those located in rudimentary, non-communicated cornua of anomalous uteri. Although these pregnancies are located within the uterine cavity, they follow the clinical course of ectopic pregnancy and they typically result in late rupture. For that reason cornual pregnancies tend to be classified as a form of ectopic pregnancy. Spontaneous heterotopic pregnancy, i.e. concomitant intra- and extrauterine pregnancy, occurs in 0.3–0.8 per cent of women of reproductive age and 1–3 per cent of pregnancies following assisted reproduction.⁷

EPIDEMIOLOGY

True prevalence of ectopic pregnancy is difficult to ascertain as the figures in the literature vary. Three commonly used denominators to express prevalence of ectopics are number of births, number of pregnancies and number of women of reproductive age (15–44 years) in the population. The reported prevalence is also influenced by the variations in diagnostic facilities between different countries. The worldwide prevalence of ectopic pregnancies is believed to be around 1–2 per cent per number of pregnancies.⁸

In the UK nearly 12,000 ectopic pregnancies are diagnosed each year, which gives an incidence of 1.1 per cent. The reported incidences in some of the other countries are shown in Table 90.1.^{9–15} There are very wide variations in the reported figures which are more likely to reflect methodological differences between the studies rather than a true incidence of ectopics. The UK statistics have also suggested that the rate of hospital admission for ectopic pregnancies is around 1.5 per 100 deliveries (1.5 per cent).¹

The UK MMR due to ectopic pregnancies is approximately 0.02 per cent, which is significantly lower compared to developing countries where the reported MMRs are between 1 per cent and 3 per cent.^{1,15} Table 90.2 shows the incidence and mortality rates of ectopic pregnancies in the UK since 1991.

Table 90.1 The reported incidence of ectopic pregnancies in several countries around the world

Country	Ectopic pregnancies/1000 deliveries
UK ⁹	3–16
USA ¹⁰	4–16
Australia ¹¹	16–17
Norway ¹²	14–22
Finland ¹³	6–26
Ghana (Africa) ^{14,15}	11–46

Table 90.2 The incidence and mortality rates of ectopic pregnancies in the UK from 1991–2008 (adapted from reference 1)

Years	Estimated pregnancies (n)	Estimated ectopic pregnancies (n)	Ectopic pregnancies/1000 pregnancies	Number of deaths	Mortality rate/10000 maternities
1991–93	3141667	30160	9.6	9	3.9
1994–96	2917391	33550	11.5	12	5.5
1997–99	2878012	31946	11.1	13	6.1
2000–02	2736364	30100	11.0	11	5.5

2006–08	3139315	35495	11.3	6	2.6

AETIOLOGY AND PATHOPHYSIOLOGY

Most ectopic pregnancies develop abnormally slowly which could be due to inadequate blood supply to these gestations outside the endometrial cavity. This results in inappropriate signalling to the corpus luteum, leading to low progesterone production. Tubal ectopic pregnancies often stop growing and may eventually undergo regression and spontaneous resolution. Alternatively they may continue to develop, causing distention of the Fallopian tube accompanied by invasion of the trophoblastic tissue into the tubal mucosa. This may eventually result in tubal rupture and intra-abdominal bleeding. In some women tubal ectopic pregnancy is expelled spontaneously into the peritoneal cavity through the fimbrial end of the Fallopian tube, which is referred to as tubal miscarriage.⁷

In normal pregnancy fertilisation of the mature ovum occurs in the ampullary part of the Fallopian tubes, thus any abnormalities of the tubal morphology or function can lead to impaired migration of the fertilised egg. It has been hypothesised that damage to the tubal mucosa is the main cause of tubal ectopic pregnancy. This could result in internal scarring of the Fallopian tube that interferes with the transfer of the embryo, or to a mucosal defect that encourages implantation of the fertilised ovum in the tube. Other theories suggested that malfunction of the tubal smooth muscle because of an altered oestrogen:progesterone ratio could be a causative factor behind ectopic pregnancy.^{16–18}

The pathophysiology behind ectopic pregnancies in the absence of tubal pathology remains unclear. One possible explanation is the poor quality of the morula, while others have claimed that that ectopic pregnancy might represent a chromosomally abnormal pregnancy. However a study by Goddijn *et al.*¹⁷ has demonstrated that the rate of chromosomally abnormal ectopic pregnancy was not higher than those obtained from intrauterine pregnancies. The effect of the male factor has also been suggested in the aetiology of ectopic pregnancy but there is not enough available evidence to support this.^{17,19,20}

RISK FACTORS

A number of risk factors for ectopic pregnancy have been reported in observational studies (Box 90.1). Evidence of

Box 90.1 Risk factors for ectopic pregnancies**High risks**

Tubal pathology
 Previous ectopic pregnancy
 Previous tubal surgery
 In utero diethylstilbestrol

Smoking

Moderate risks

History of pelvic infection
 Infertility/sub fertility
 Multiple sexual partners
 Advanced age

tubal pathology, history of previous ectopic pregnancy, previous tubal surgery, and in-utero diethylstilboestrol were found to be strongly associated with ectopic pregnancy in a recent meta-analysis of studies, while previous history of genital infection (PID, chlamydia, gonorrhoea), infertility, subfertility and multiple sexual partners were moderately associated with risk of ectopic pregnancy [A].²¹ Another large study of all ectopic pregnancies diagnosed in one region of France showed history of infection and smoking to be the most important risk factors; however, around 24 per cent of women who were diagnosed with ectopic pregnancy had no known risk factors [C].²² It has been postulated that the main adverse effect of smoking is on the motility of ciliated tubal epithelium, resulting in delayed transport of the fertilised ovum, leading to implantation in the Fallopian tubes. Smoking could also affect other aspects of fertility causing delayed ovulation, fertilisation and implantation. A dose-effect relationship between smoking and ectopic pregnancy has been suggested with a higher rate of ectopic pregnancy when more than 20 cigarettes were smoked per day.²²

It has been suggested that about a third of ectopic pregnancies are a result of tubal infection or previous surgery. Although several types of micro-organisms can cause PID, chlamydia infection appears to be the main causative agent.^{21,23} The incidence of tubal damage after one episode of PID was determined to be about 8 per cent but this increases to 19.5 per cent after two episodes and 40 per cent after three episodes. The risk of tubal damage was also related to the severity of salpingitis even with one episode, increasing from 0.6 per cent for mild to 6 per cent for moderate and 21.4 per cent for severe salpingitis [C].²⁴

In women with previous ectopic pregnancy, the risk of recurrent ectopic pregnancy is higher than in the general population and it increases further with every successive occurrence. In one study the ORs for having an ectopic pregnancy were 3 (95% CI 1.8–5.7) after one previous ectopic and 16 (95% CI 4.4–47.7) after two previous ectopic pregnancies.²⁵ An association between advanced maternal age and ectopic pregnancy has also been demonstrated in different studies. The OR for having an ectopic pregnancy can be doubled for women over 35 years of age (OR 1.4) and it is four times higher in women

over 40 (OR 2.9) when compared to younger women less than 20 years of age (OR 0.6).²² This could be explained by potentially higher exposure to risk factors, increased incidence of chromosomal abnormalities of the conceptus and age-related changes of tubal function [C].^{26,27}

Generally, the use of contraception prevents all types of pregnancy including ectopic pregnancy but failure of certain contraceptive methods is associated with increased risk of ectopic pregnancy. In women who become pregnant following tubal ligation, the risk of ectopic pregnancy is particularly high. In a multicentre prospective cohort study the 10-year cumulative probability of ectopic pregnancy after tubal sterilisation was 7.3 per 1000 procedures.²⁸ The risk is also significantly increased with an intrauterine contraceptive device *in situ* (IUCD). A meta-analysis of studies has shown that in women with current IUCD use, when compared to pregnant controls, there is an increased risk of ectopic pregnancy (OR 10.6, 95% CI 7.66–14.74) while past IUCD use only mildly increases the risk of ectopic pregnancy (OR 1.4, 95% CI 1.23–1.59) [A].²⁹ Although the risk of ectopic pregnancy is 6–10 per cent in women with failure of progesterone-only pills, the risk of ectopic pregnancy for women who have failure of oral contraceptive pills, emergency hormonal pills and the barrier method is similar to the risk of women not using any type of contraception.^{30,31}

Women with a history of infertility and especially those treated with superovulatory drugs or undergoing IVF are at a higher risk of ectopic pregnancy (4–5 per cent) and heterotopic pregnancies (1–3 per cent) when compared to women conceiving naturally. The most probable explanation is the shift of the embryo from the uterine cavity back into the Fallopian tubes.^{32–34}

CLINICAL PRESENTATION

Clinical presentation of ectopic pregnancy is variable and is largely determined by the location of the pregnancy. In general, ectopic pregnancies implanted closer to the uterus tend to develop further and present with more severe clinical symptoms. The more common types of tubal ectopics that develop in the ampullary part of the tube are unlikely to grow beyond the very early stages, therefore causing less serious symptoms.

The most common presentations in women with ectopic pregnancies are vaginal bleeding, pelvic pain and amenorrhoea. However in one study around one third of women did not present with this triad.³⁵ Vaginal bleeding is usually an early presentation that happens soon after a missed period and can vary from mild brownish vaginal spotting to period-like fresh bleeding. Occasionally vaginal bleeding may be heavy and associated with passage of a cast of endometrial tissue. This can lead to incorrect diagnosis of menstrual period or miscarriage. Abdominal pain typically occurs after the onset of vaginal bleeding. Location, type and intensity of pain can also be variable. It can be localised to one side or present as generalised abdominal pain, dull or sharp, crampy or continuous, at the ipsilateral or contralateral site to the ectopic pregnancy. Occasionally the woman might complain of upper abdominal pain or rectal pressure and/or pain on defaecation. The

pain that women with ectopic pregnancy experience usually occurs due to tubal distension, as a result of blood entering the peritoneal cavity from the fimbrial end or tubal rupture. The severity of the pain does not always correspond to the amount of blood loss into the peritoneal cavity. On the other hand, pain referred to the shoulder usually reflects irritation of the diaphragm and is a sign of a major bleed.³⁵⁻³⁹ However, up to 9 per cent of women diagnosed with ectopic pregnancy do not complain of any abdominal pain.⁴⁰

Nausea, vomiting and diarrhoea occasionally occur with severe intra-abdominal haemorrhage and can lead to erroneous diagnosis of gastrointestinal, urinary tract or other acute gynaecological conditions and delay the diagnosis of potentially life-threatening intra-abdominal bleeding.^{1,6} Four of the six women who died from ectopic pregnancies in this last triennium complained of diarrhoea, dizziness or vomiting as the presenting symptoms.¹ A key recommendation from the 2006–2008 CEMACH report, as with the previous report, was that the diagnosis of ectopic pregnancy should be considered in all women of reproductive age with sudden onset of severe gastrointestinal symptoms.¹

DIAGNOSIS

Physical examination

There is little evidence to support the diagnostic benefit of internal examination in women presenting in early pregnancy with abdominal pain or vaginal bleeding. In routine clinical practice, however, vaginal examination using speculum and bimanual palpation is still often used as a part of the diagnostic work-up for ectopic pregnancies. The findings of tenderness on moving the cervix or adnexal mass and/or tenderness and vaginal bleeding are all non-specific signs and can present in different early pregnancy complications, gynaecological and non-gynaecological conditions. In addition most ectopic pregnancies are too small to be felt clearly on bimanual examination and uterine size assessment is rarely helpful in making the diagnosis.^{39,41,42}

Vaginal examination is generally uncomfortable for pregnant women, even for those with a normal intrauterine pregnancy. Applying pressure on a swollen Fallopian tube could result in rupture of the ectopic pregnancy; however, there is little evidence to support this assertion. In addition about 36 per cent of women will lack adnexal tenderness on pelvic examination. Referral of women with suspected ectopic pregnancies for ultrasound examination when available is suggested prior to vaginal examination. Signs of haemorrhagic shock might be also present such as high pulse rate, low blood pressure, pallor and low urine output.^{35,39,41,42}

Recent NICE guidelines on the management of pain and bleeding in early pregnancy recommend that clinicians should be offering a pregnancy test to all women of reproductive age as part of their clinical assessments, even when symptoms are non-specific.⁴

Developments in ultrasound technology and improvements in the sensitivity of laboratory investigations have greatly added to the accuracy of non-invasive diagnosis of ectopic pregnancy. Ultrasound scans (especially transvaginal examination), and biochemistry investigations (quantitative serum β hCG testing and progesterone) are now considered as necessary investigations when evaluating women with pain or vaginal bleeding during early pregnancy.

Ultrasound

The first report describing ultrasound criteria for the diagnosis of ectopic pregnancy was published in 1969.⁴³ The introduction of the transvaginal ultrasound in the assessment of women in early pregnancy has greatly improved the diagnosis of ectopic pregnancy and it is now considered the diagnostic method of choice. In addition studies have demonstrated that it is an acceptable diagnostic tool for women presenting with early pregnancy complications such as pain or bleeding.^{44,45}

A meta-analysis of the accuracy of ultrasound demonstrated a sensitivity of 99 per cent (95% CI 96.6% to 100%) with specificity of 71 per cent (95% CI 60% to 80%) when it was used as the diagnostic tool in North American emergency departments [A].⁴⁶ The presence of other factors such as increased BMI, uterine fibroids or adnexal lesions such as ovarian cysts can make visualisation of the adnexa difficult and cause delay in the diagnosis of ectopic pregnancy. NICE in its guideline has advised offering women attending an early pregnancy assessment service or emergency gynaecology service a TVS to identify the location of the pregnancy and check its viability.⁴

Despite the fact that transabdominal ultrasound is still used in some places, the benefit of using this approach is doubtful. The visualisation of intrauterine pregnancy can be challenging when the pregnancy is smaller than 6 or 7 weeks' gestation. It is also difficult for operators to clearly visualise or exclude ectopic pregnancies with certainty. It is therefore not surprising that high false-negative and false-positive rates were reported when transabdominal ultrasound examination was used in women with suspected early pregnancy complications.^{41,47}

Transvaginal sonography has been shown in many studies to have a better sensitivity (87–99 per cent) and specificity (94–99 per cent) for the diagnosis of ectopic pregnancy [C].⁴⁸⁻⁵⁰ The additional advantage of TVS examination is that it allows guided palpation of the pelvic organs, which helps to assess their mobility and to determine the site of tenderness. The transabdominal route, however, may be helpful in women with large fibroid uteri or other pelvic pathology, such as adenomyosis or ovarian cysts.^{47,51,52}

The accuracy of ultrasound examination in detecting ectopic pregnancy depends largely on the experience of the operator and the quality of the ultrasound machine. In the hands of an experienced operator, the location of pregnancy can be determined from a single ultrasound examination and about 75–80 per cent of clinically significant ectopic pregnancies are detected at the initial examination with a further 20–25 per cent detected at subsequent ultrasound scan

assessments.^{50,53,54} However, the detection of ectopic pregnancy on ultrasound is also dependent on its size at the time of presentation. A study comparing the diagnosis of ectopic pregnancy at first visit with serum hCG levels has shown that women with a clear diagnosis of ectopic pregnancy on TVS had a higher level of β hCG and more advanced gestational age when compared to women in whom the pregnancy could not be visualised (pregnancy of unknown location or PUL).⁵³

The following morphological criteria can help to identify ectopic pregnancy when seen on ultrasound outside the uterine cavity:^{55,56}

- 1 gestational sac surrounded by a hyperechoic ring with or without a yolk sac;
- 2 gestational sac with an embryo with or without cardiac activity (Fig. 90.1);
- 3 solid tubal swelling or inhomogeneous adnexal mass separate from the ovary.

The second morphological type is very specific to ectopic pregnancy, whilst the risk of misdiagnosis is higher when the sac is empty or in cases where there is an inhomogeneous mass. Using these criteria, the efficiency of TVS in diagnosing ectopic pregnancy was 96 per cent using diagnostic laparoscopy as the reference standard.⁵⁷ In a study by Cacciatore *et al.*,⁵⁸ where the visualisation of an adnexal mass was used for the diagnosis of ectopic pregnancy, a specificity of 99 per cent was demonstrated. The presence of an adnexal mass that is separate from the ovary on TVS has also been demonstrated by observational studies to be a good indicator of ectopic pregnancy.⁴⁹ This was further confirmed by a meta-analysis of studies comparing different morphological criteria for the diagnosis of ectopic pregnancy, which concluded that the presence of an inhomogeneous mass separate from the ovary had a high specificity of 98.9 per cent, a sensitivity of 84.4 per cent with a 96.3 per cent positive predictive value and negative predictive value of 94.8 per cent [A].⁵⁹

A number of other ultrasound findings have been suggested to facilitate detection of ectopic pregnancy, but they are

not specific enough to be used in clinical practice. The presence of blood or blood clots in the pelvis is highly suspicious of ruptured ectopic pregnancy and should be differentiated from free fluid in the pouch of Douglas, which is a common finding in women with a normal intrauterine pregnancy. But consideration needs to be given to other possibilities of echogenic fluid in the pelvis such as rupture of a haemorrhagic ovarian cyst. An important distinction needs also to be made between the intrauterine gestational sac in normal pregnancy and the presence of a pseudosac as a result of small bleeding within the uterine cavity in women with ectopic pregnancy. The diagnostic criteria are as listed in Table 90.3. Problems can also arise in women with congenital uterine abnormalities and large uterine fibroids. In those cases a careful and systematic approach to the ultrasound examination helps to visualise the site of the pregnancy. The use of transabdominal and 3D ultrasound may help in these cases to determine the shape of the uterine cavity. In addition, in symptomatic women, especially those who have conceived after IVF treatment or with the use of superovulation drugs, it is important to exclude the presence of heterotopic pregnancy. Heterotopic pregnancies need also to be excluded in spontaneous pregnancy when more than one corpus luteum is present.^{50,60-62}

Surgical and histopathological diagnosis

Traditionally, the diagnosis of ectopic pregnancy used to be made by surgery and then confirmed by histological examination of the excised specimen, usually a Fallopian tube containing the suspected ectopic pregnancy. However, in modern practice the diagnostic role of surgery is declining as an increasing proportion of ectopic pregnancies are managed more conservatively. In recent years laparoscopy has replaced open surgery to diagnose and treat ectopic pregnancies.⁶³ Although laparoscopy is still perceived by many as the gold standard for the diagnosis of ectopic pregnancy, its diagnostic accuracy has never been properly tested. In an observational study 4.5 per cent (2/44) of women reported to have no evidence of ectopic

Fig. 90.1 A pelvic ultrasound image showing a gestational sac (arrow) containing an embryo with cardiac activity documented on colour Doppler examination. The sac is located behind the uterus (UT) and medial to the left ovary which contains a corpus luteum (CL)

Table 90.3 Diagnostic criteria for the distinction between intrauterine gestational sac in normal pregnancy and the presence of pseudo sac as a result of small bleeding within the uterine cavity in women with ectopic pregnancy

	Early gestational sac	Pseudo sac
Location	Eccentric, appears on one side of the cavity line within the endometrium	Central, along the endometrial cavity line
Shape	Regular, usually round	Elliptical shaped, can change contour during scan
Borders	Double decidual sign or double echogenic ring	Single layer
Colour flow pattern	Vascular peripheral flow can be demonstrated	Relatively avascular

pregnancy at the time of initial laparoscopy were subsequently diagnosed with an ectopic pregnancy [D].⁶⁴ At laparoscopy, unruptured tubal ectopic pregnancy appears as a well-defined swelling of the Fallopian tube. However, the diagnosis is not always straightforward especially in cases of small ectopic pregnancy or ectopics located in the interstitial part of the tube. The diagnosis of ectopic pregnancy can also be difficult in women with extensive pelvic adhesions that prevent clear visualisation of the tubes.^{63–65} Histopathology can confirm the diagnosis of ectopic pregnancy after surgical treatment of ectopic pregnancy where chorionic villi are detected within the Fallopian tubes or other excised specimen. However, difficulty can arise when there is a complete tubal miscarriage or tubal rupture as it might not be possible to identify chorionic villi in the salpingectomy specimen and in these women, follow-up with serum β hCG measurements is advisable to ensure complete resolution of the ectopic pregnancy. A recent prospective study showed that histological examination failed to identify the presence of chorionic villi in 5 per cent of women with ultrasound, biochemical and surgical evidence of tubal ectopics.⁶⁶

Another proposed surgical procedure to diagnose ectopic pregnancy is to perform dilatation and curettage. The theory behind it is that finding chorionic villi on histology will help to exclude ectopic pregnancy. This approach is of limited value, as although the presence of heterotopic pregnancy is uncommon, it cannot be excluded. In addition it was shown that the majority of women who had no chorionic villi on histological examination of the uterine cavity content had no ectopic pregnancies on diagnostic laparoscopy.⁶⁷

Biochemical diagnosis

Serum human chorionic gonadotrophin

Serum β hCG is the most commonly used hormone in the assessment of women in whom ultrasound findings are non-diagnostic. Single and serial measurements of serum β hCG have been used to try to facilitate non-invasive diagnosis of ectopic pregnancy but it is rarely possible to determine the location of pregnancy on the basis of changes in maternal β hCG concentrations alone.^{68,69} A single serum β hCG measurement will usually give an indication of when a singleton normal intrauterine pregnancy should be visualised on transvaginal or transabdominal ultrasound scan in a woman with a healthy uterus. Several studies have reported different discriminatory β hCG levels above which a normal intrauterine pregnancy should be detectable on ultrasound scan. The most commonly used cut-off values to detect a normal intrauterine pregnancy on TVS are 1000–1500 IU/L and 6500 IU/L when transabdominal scan is used.^{47,70}

However, discriminatory or cut-off values for β hCG should be interpreted with caution. It has been shown in one study that more than 50 per cent of ectopic pregnancies detected on ultrasound had β hCG levels less than 1000 IU/L. In addition in many women who suffered complete miscarriages, serum β hCG levels remained high due to its long half-life of 24–36 hours.^{71,72}

Serial β hCG measurements are considered more useful. An abnormal or slow increase in β hCG levels has been traditionally used to predict ectopic pregnancies. Although it is true that the sub-optimal β hCG rise indicates that the pregnancy is likely to be abnormal, it cannot discriminate reliably between intrauterine miscarriage and ectopic pregnancy. It has also been demonstrated in some studies that in 10–20 per cent of ectopic pregnancies, serum β hCG increases normally.^{73,74}

The usefulness of measured β hCG in detecting pregnancy location was questioned in a recent meta-analysis. A single serum β hCG level was shown to be a poor test to diagnose ectopic pregnancy, and the results were only slightly better when serial measurements were performed [A].⁷⁵

Progesterone

Progesterone production from the corpus luteum depends largely on the rate of β hCG increase in early pregnancy. The half-life of progesterone clearance is about 2 hours, which is shorter than the 24- to 36-hour half-life of β hCG. This means that it can respond rapidly to any change in the β hCG level. As a result its level can be used as an indicator of β hCG dynamics and behaviour in early pregnancy.⁷⁶

While serum progesterone levels can be used to predict whether the pregnancy is in progression or regression, it has been shown by different studies that it should not be used to speculate about its location.^{77,78} A meta-analysis by Mol *et al.*⁷⁹ has demonstrated that a single measurement of progesterone level can help to identify women at risk of ectopic pregnancy [A]. It has been shown by several authors that serum progesterone <20 nmol/L reflects fast decreasing β hCG levels in maternal blood and thus can be used to predict failing pregnancy with a sensitivity of 94 per cent and specificity of 91 per cent. Progesterone levels >60 nmol/L indicate a normal increase in β hCG levels and are often associated with normal viable intrauterine pregnancy. The dilemma is when the progesterone level is between 20 and 60 as this is usually a reflection of an abnormal pregnancy that could be either ectopic or miscarriage, and further follow-up is warranted to reach the final diagnosis. The benefit of routine measurement of serum progesterone is that it can reliably diagnose pregnancies in regression and thus can reduce by 50–60 per cent the need for follow-up scans and serial β hCG measurements in pregnant women with non-diagnostic scan findings.^{71,80–84}

PREGNANCY OF UNKNOWN LOCATION

Pregnancy of unknown location is a term used to describe the ultrasound scan when pregnancy is not visualised inside or outside the uterine cavity in women with a positive pregnancy test. Studies suggest that in 8–31 per cent of women presenting with mild clinical symptoms of early pregnancy complications ultrasound will not identify the location of the pregnancy. The percentage of PUL cases will depend on the skills of the ultrasound operator, the quality of the ultrasound equipment

and the route of ultrasound examination (transvaginal or transabdominal).^{54,85} Recent meta-analysis has concluded that the diagnostic accuracy of serum β hCG strategies in women with PUL did not provide enough data to detect the outcome of these pregnancies and whether they will end up with viable intrauterine pregnancies, failing pregnancies or ectopic pregnancies [A].⁷⁵ It has also highlighted the need for further properly conducted prospective studies.

The majority of women with PUL either have a normal pregnancy that is too small to be seen on the scan or have already suffered a miscarriage. A minority of women with PUL are eventually diagnosed with ectopic pregnancies. In about 50–70 per cent of PULs serum β hCG will decline eventually to non-pregnant level and further routine follow-up is not required.⁷⁵ Several studies have demonstrated that a declining serum β hCG level on serial measurements, or a single low initial reading of serum progesterone, can help to identify a woman in whom pregnancy is undergoing spontaneous resolution regardless of its location. When serum β hCG levels decline rapidly by >13 per cent over 48 hours or when the initial serum progesterone is ≤ 20 nmol/L the risk of women requiring any form of medical intervention is very low.^{86–95}

In published observational studies [C–D] the outcome of 44–69 per cent of PULs was a resolution with expectant management; the remainder were early intrauterine pregnancies that miscarried. Ectopic pregnancy was eventually diagnosed in 14–28 per cent of cases.^{71,96–98} Women with minimal or no symptoms of ectopic pregnancy should be managed expectantly with follow-up in two to three days. Active intervention should be considered if clinical symptoms of ectopic pregnancy occur or serum β hCG levels continue to rise. Further follow-up with ultrasound and/or repeat measurement of biochemical markers needs to continue until the correct diagnosis is reached.^{75,99} If women with PULs are managed expectantly, serial serum β hCG measurements should be performed until the levels are less than 20 IU/L. In addition, women need to be given clear information regarding the follow-up plans and the importance of compliance; they also need to be within easy access of the hospital treating them. However, a very small minority of women will have the diagnosis of persistent PUL despite follow-up scans and serial β hCG measurements. The ideal management for these cases is not known but expectant management or the use of systemic methotrexate in women with mild symptoms is reported to be successful.^{89,99} NICE in its recent guideline has advised that in women with PUL on scan, attention needs to focus on their symptoms more than β hCG results. Follow-up also needs to continue until the location of the pregnancy becomes known but consider a repeat scan for women with a serum β hCG level greater than or equal to 1500 IU/L.⁴

MANAGEMENT

The improvements in the quality of diagnostic ultrasound and urine pregnancy tests in recent years have facilitated early and better diagnosis of ectopic pregnancy and the development of

conservative management strategies. Tubal pregnancy can be managed surgically (laparotomy or laparoscopy), medically using methotrexate (local or systemic) and more recently through the expectant approach. However, management must be tailored to the clinical condition and future fertility requirements of individual women.

Surgical management

Surgery is still considered the main treatment for tubal ectopic pregnancies in many parts of the world, especially in cases with significant internal haemorrhage. With recent advances in minimally invasive surgery, the laparoscopic approach has become the treatment modality of choice in haemodynamically stable women, over the open approach.^{100,101} A meta-analysis showed that laparoscopic procedures are associated with lower blood loss during the operation, shorter operative time and hospital stay as well as less postoperative pain [A].¹⁰² Laparotomy, however, may be safer than the laparoscopic approach if there is a major intraperitoneal bleed in which achieving immediate haemostasis is essential. An experienced laparoscopic surgeon may be able to perform the procedure and achieve haemostasis relatively quickly but this might not be applicable in all cases and laparotomy should be considered to stop the internal bleeding in a short period of time. The laparoscopic approach might also not be possible if the operator lacks surgical skills or if the approach is hampered by severe pelvic adhesions or large uterine fibroids.^{103,104}

NICE and RCOG in their guidelines have advised that surgical treatment of ectopic pregnancy should be carried out laparoscopically whenever possible, taking into account the condition of the woman and the complexity of the surgical procedure. However, the surgeons providing care to women with ectopic pregnancy should be competent in performing laparoscopic surgery.^{4,89}

Salpingotomy or salpingectomy

Salpingectomy (partial or complete removal of the Fallopian tube) and salpingostomy/salpingotomy (linear opening of the Fallopian tube with removal of ectopic pregnancy tissue and preservation of the tube) whether through laparoscopic approach or laparotomy can both be used to surgically treat ectopic pregnancy. Until recently there was no clear evidence whether laparoscopic salpingotomy with tubal conservation offers any advantages over salpingectomy. A recent open multicentre RCT (ESEP study)¹⁰⁵ analysed 446 women with tubal ectopic pregnancies who were randomly allocated over seven years to either salpingotomy or salpingectomy. The cumulative ongoing pregnancy rate by natural conception was 60.7 per cent after salpingotomy and 56.2 per cent after salpingectomy (fecundity rate ratio 1.06, 95% CI 0.81–1.38) [B]. While persistent trophoblast occurred significantly more frequently in the salpingotomy group than in the salpingectomy group, the numbers of repeat ectopic pregnancies did not differ significantly. The authors concluded that salpingotomy

did not improve the cumulative rates of ongoing pregnancy by natural conception in women with tubal pregnancy and a healthy contralateral tube, but it was associated with an increased risk of persistent trophoblast. The results from another recent RCT (DEMETER trial)¹⁰⁶ had shown a similar result with regard to the cumulative ongoing pregnancy rates (HR 1.13, 95% CI 0.73–1.74) [B].

The choice of surgical technique is largely determined by the condition of the contralateral tube and the desire for future fertility. Currently, the consensus is that tubal conservation should be attempted if the woman desires further pregnancies and there is evidence of contralateral tubal damage at laparoscopy. In the presence of a healthy contralateral tube, salpingectomy can be performed with the woman's consent.^{4,6,89} However if salpingotomy is performed, women should be informed that having a salpingotomy there is a 20 per cent chance of further treatment such as methotrexate and/or a salpingectomy and that a post-operative follow-up with serial serum β hCG measurements is required to ensure that all active tissue has been removed.^{4,63}

NICE⁴ also recommend offering surgery as a first-line treatment to women with ectopic pregnancies who are unable to return for follow-up after methotrexate treatment or who have any of the following:

- 1 significant pain;
- 2 adnexal mass of 35 mm or more;
- 3 an ectopic pregnancy with a fetal heartbeat visible on an ultrasound scan;
- 4 serum β hCG level of 5000 IU/L or more.

Surgery should not be delayed in women showing signs of hypovolaemic shock. TVS examination when appropriate can confirm the presence of ruptured ectopic and intra-abdominal bleeding in cases with uncertain diagnosis; however it is important to intervene rapidly in these cases to achieve haemostasis which is crucial to resuscitate and treat those women.^{89,107}

Medical management with methotrexate

Methotrexate is a folic acid antagonist which interferes with DNA synthesis and inhibits cell proliferation in fast-growing tissues such as trophoblasts. Its side effects are dose related and they include conjunctivitis, inflammation of the gastrointestinal mucosa, impaired liver function and bone marrow suppression.¹⁰⁸

Medical treatment with methotrexate is one of the options in treating stable asymptomatic women with small, unruptured ectopic pregnancy. In clinical practice, ectopic pregnancies suitable for methotrexate treatment usually account for about 25–30 per cent of all ectopic pregnancy cases.^{109,110} However caution must be used when giving methotrexate as its use in a misdiagnosed intrauterine pregnancy can have serious adverse effects resulting in a miscarriage. Should the pregnancy continue there is a high risk that the fetus could be malformed. The other problem is the risk of tubal rupture

and the need for blood transfusion, which occur significantly more often in women treated with methotrexate than in those who had surgical treatment. This and the need to delay future pregnancy for a minimum of three months might make methotrexate a less attractive option for women.¹⁰⁹

Methotrexate treatment is usually given as an injection of 50 mg/m² or 1 mg/kg IM. Follow-up requires women to attend for several visits and have measurements of serum hCG until they clear (<20 IU/L). Repeat ultrasound scans might also be required in women who start to experience abdominal pain to exclude ruptured ectopic and intra-abdominal haemorrhage.^{89,102} This has been further enforced in the recent NICE guideline,⁴ which suggests that systemic methotrexate could be offered to women who fulfil the following criteria:

- 1 no significant pain;
- 2 serum hCG level less than 1500 IU/L;
- 3 with unruptured ectopic pregnancy, measuring less than 35 mm and with no visible heartbeat activity;
- 4 no intrauterine pregnancy on ultrasound scans;
- 5 able to continue with follow-up visits;
- 6 methotrexate is an acceptable option.

Women with unruptured small ectopic pregnancies (<35 mm in size and no visible heartbeat) and with serum hCG between 1500 IU/L and 5000 IU/L can still be offered the choice of methotrexate if they have no significant pain and are able to return for follow-up visits. In addition all women who choose methotrexate treatment need to be informed that there is a chance of requiring further intervention and they may need to be urgently admitted if their symptoms worsen. Furthermore follow-up with serum β hCG measurements needs to continue after treatment until a negative result is obtained.¹¹¹

A randomised trial of systemic methotrexate versus laparoscopic salpingostomy has shown that in haemodynamically stable women with unruptured ectopic pregnancies there is no significant difference in overall treatment success between the medical and surgical group (RR 0.98, 95% CI 0.87–1.1) [B].¹⁰⁹ However a meta-analysis of four randomised trials showed that a single dose of systemic methotrexate was significantly less successful than laparoscopic salpingotomy (OR 0.38, 95% CI 0.20–0.71) [A].¹¹¹ Methotrexate treatment was also cost effective only in women requiring a single injection and with initial serum β hCG concentrations <1500 IU/L but becomes more expensive in women presenting with β hCG above that level who often require multiple injections.^{111,112}

In a double-blind study, more than one dose of methotrexate was required in 25–31 per cent of women [B].¹¹³ This is in agreement with other studies which also showed that more than one dose of methotrexate was required in about 14–26 per cent of women [B–C].^{110,114–116}

Expectant management

Several observational studies have suggested a high success rate for expectant management in selected cases of ectopic

pregnancies that present with low β hCG levels [C].^{66,117} Most clinicians however do not feel comfortable with the concept of expectant management of ectopic pregnancy and would still consider some form of treatment, whether surgical or medical. In addition there are few existing data to compare expectant management of ectopic pregnancy with other forms of treatment. The first randomised trial that compared expectant management with systemic methotrexate showed similar success rates in both arms of the study. The trial was of limited value, however, as methotrexate was administered orally at a dose much lower than that used in standard clinical practice.¹¹⁸

A more recent trial compared expectant and medical management in women diagnosed with ectopic pregnancies with serum β hCG levels <1500 IU/L and those with PULs and serum hCG 2000 IU/L. Again there was no difference in the success rate between the two arms of the study. The authors concluded that methotrexate, which is potentially a harmful drug, could be withheld in these women [B].¹¹⁹

Expectant management has important advantages over medical treatment. In addition to avoiding the side effects of methotrexate, it also follows the natural course of ectopic pregnancies which is a self-limiting process that will eventually result in tubal miscarriage or resolution. However, expectant management requires prolonged follow-up, which could lead to anxiety in the woman and her carer.^{120,121}

To minimise the risk of failure, many authors have used strict criteria, such as low serum β hCG levels, to select women for expectant management, which could explain the high success rate in some of these reports, reaching 70–80 per cent [C–D].^{66,122,123} Published studies have suggested that by using less strict selection criteria for expectant management, 40–49 per cent of tubal ectopics can resolve spontaneously [C].^{66,117,124} This observation could reflect the increased sensitivity of modern ultrasound equipment, which enables the detection of very small ectopics that might have been missed in the past. In general, expectant management can be offered to clinically stable women with clear ultrasound diagnosis of small (<3 cm) non-ruptured ectopic pregnancy without fetal cardiac activity and with serum β hCG levels less than 1500 IU/L at the initial presentation. According to the current literature the success of expectant management in these cases can reach 67–88 per cent [C].^{66,89} Clinically stable women who fit the criteria should be given the choice of surgical, medical or expectant management but their personal and medical history, in addition to their compliance with a follow-up visit, must be taken into consideration. Detailed information of the management options and their long-term outcomes will help women to choose the path of their treatment.

CONCLUSION

The diagnostic challenges and serious risks of ectopic pregnancy make this condition an important cause of maternal morbidity and mortality worldwide.

Recent advances in ultrasound diagnosis and the availability of highly sensitive urinary pregnancy tests have contributed to more accurate and timely diagnosis of ectopic pregnancies. Many of these pregnancies are small and are destined to resolve spontaneously without interventions. This has advanced the care of women with ectopic pregnancy to include non-surgical treatment options. Selection criteria when managing women conservatively, such as small ectopic pregnancy, low serum β hCG concentrations and no intraperitoneal haemorrhage, will help to avoid risk of complications. However, women with conservative management will remain at risk for tubal rupture and therefore careful follow-up including serial blood tests is important to ensure women's safety.

TVS has revolutionised the diagnosis of ectopic pregnancy and should be considered as the diagnostic test of choice for women presenting with problems such as bleeding and/or pain in early pregnancy, while serum biochemistry and laparoscopy should be considered as secondary tests in women with inconclusive findings on ultrasound scans.

RECOMMENDATIONS FOR CLINICAL PRACTICE

- When considering conservative treatment for tubal ectopic pregnancy, patients should be given detailed information about the success rate, side effects and complications.
- When considering conservative treatment, women need to comply with follow-up and adjust their lifestyle to minimise the risk of complications.
- In both medical and expectant management, follow-up with serum β hCG concentrations should continue until the level becomes undetectable.
- Anti-D prophylaxis should be given to all rhesus-negative women who require surgical treatment of ectopic pregnancy.
- Future pregnancy should be delayed for at least three months after completion of medical treatment because of the risk of teratogenicity of methotrexate.

Chapter 91 Premature ovarian insufficiency

Nowmi Zaman, Jenny Williamson and Lynne Robinson

MRCOG standards

Theoretical skills

There is no established standard for this topic, but we would suggest the following points for guidance:

- Have a good knowledge of the hypophyseal–pituitary–ovarian axis.
- Understand the aetiologies which may lead to premature ovarian insufficiency (POI).
- Know about first-line investigations for POI.
- Know how to manage POI, including psychological and fertility aspects.
- Be aware of new screening techniques for POI.

Practical skills

- Be able to take an appropriate history.
- Be able to initiate appropriate investigations to enable a diagnosis and/or tertiary referral.

INTRODUCTION

Premature ovarian insufficiency is now the preferred term for a premature menopause or ovarian failure. It occurs in 1 per cent of women under 40 years.¹ The condition is characterised by primary or secondary amenorrhoea, raised gonadotrophins and hypo-oestrogenism. The British Menopause Society recommends that POI definition uses an age cut-off of less than 45 years.¹ The term ‘ovarian failure’ suggests that it is an irreversible condition. In fact, ovarian follicular function fluctuates in 50 per cent of women with POI and 5–10 per cent of women may eventually conceive. The term ‘failure’ may convey a sense of hopelessness – a better term may therefore be dysfunction or insufficiency.

The main effects of POI include subfertility, climacteric symptoms and early onset of osteoporosis and cardiovascular disease.

Over recent years there has been concern about the safety of hormone replacement therapy (HRT) and therefore many women have not received the oestrogen replacement they require. However, most of the evidence regarding HRT applies

to women who achieve menopause at the usually expected age, and not those with POI. Women who suffer from POI would have normally been expected to produce endogenous oestrogen at that age and therefore it is logical to replace this until at least the age of the natural menopause.

HYPOPHYSEAL–PITUITARY–OVARIAN AXIS

The hypothalamus is part of the diencephalon at the base of the brain and forms part of the floor of the third ventricle. It synthesises hormone-releasing hormones, which are released from the median eminence into the hypophyseal portal system which carries them to the anterior pituitary gland. The releasing hormones are: thyrotropin-releasing hormone (TRH), corticotrophin-releasing hormone (CRH), dopamine, growth hormone-releasing hormone (GHRH), gonadotrophin-releasing hormone (GnRH) and somatostatin. Oxytocin and vasopressin are also released (Fig. 91.1).

GnRH is a decapeptide and is released from the medial basal hypothalamus by the process of neurosecretion (Fig. 91.1). It is released in a pulsatile manner with a pulse frequency of 90 minutes in the follicular phase and modified by the feedback of follicle-stimulating hormone (FSH) and oestrogen.

The anterior pituitary glands secrete FSH, luteinising hormone (LH), prolactin, thyroid-stimulating hormone (TSH), growth hormone (GH), corticotrophin (ACTH) and melanocyte-stimulating hormone (MSH).

FSH and LH are glycoproteins and both consist of two subunits, alpha and beta. The alpha subunit is common to FSH, LH, TSH and human chorionic gonadotrophin (HCG). The beta subunits are hormone specific although the beta subunits of LH and HCG are very similar. FSH and LH are synthesised and secreted in response to GnRH.

LH and FSH are secreted in a pulsatile manner every 1–3 hours, with the frequency and amplitude of pulses varying throughout the menstrual cycle, greatest in early follicular phase and least in luteal phase. The amplitude is maximal during the pre-ovulatory surge when the pulsatile secretion of LH is more marked than that of FSH.

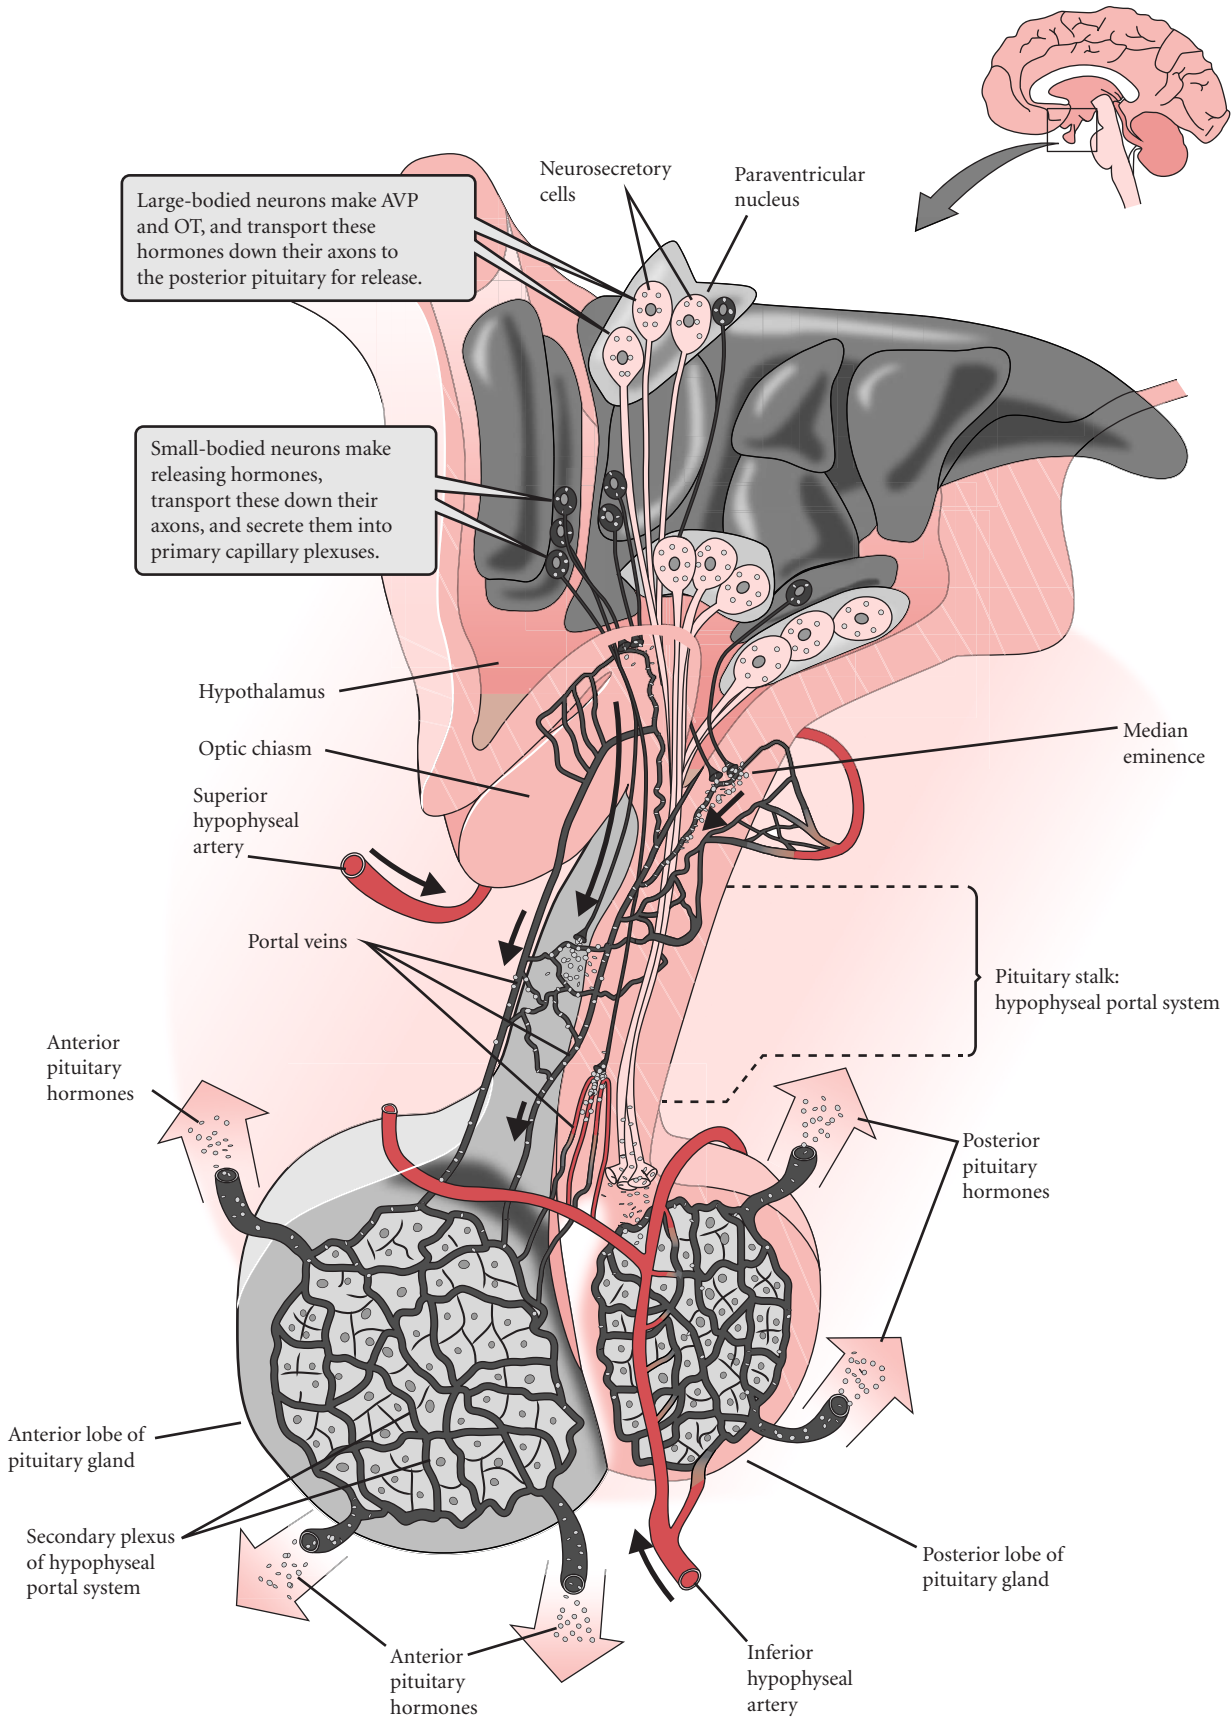

Fig. 91.1 The hormonal pathway in the hypothalamus and pituitary (reproduced from Boulpaep, Ernie, Boron, Walter. *Medical Physiology*, Elsevier, 2003, with permission)

MECHANISMS FOR CONTROL OF GONADOTROPHIN SECRETION

Gonadotrophin secretion is controlled by the positive and negative feedback of oestrogen and progesterone. During the follicular phase, oestradiol exerts a positive feedback effect and initiates the mid-cycle surge. In the luteal phase, oestradiol exerts negative feedback and suppresses gonadotrophin secretion.

Oestrogen

There are three naturally occurring oestrogens. Oestradiol is produced by the ovary, oestriol by the placenta and oestrone by peripheral conversion of androgens in the subcutaneous fat. Oestrogen has actions on the ovary, endometrium, breast, cervix and central nervous system (CNS).

Progesterone

Progesterone is produced and released by the adrenal cortex (2–3 mg/day), ovary (20–30 mg/day) and placenta. It has a very short half-life; 90 per cent is metabolised by the liver within 25 minutes. Progesterone exerts its effect throughout the reproductive tract but also increases the respiratory rate and suppresses T-cell function.

Androgens

Androgens are produced by the adrenal glands, ovary and through peripheral conversion. Dehydroepiandrosterone, androstenedione and testosterone are produced by the ovary. The daily production of testosterone is 0.2–0.3 mg/day. Fifty per cent of this is from peripheral conversion of androstenedione, 25 per cent from the ovary and 25 per cent from the adrenals. Ovarian androgens enhance the atresia of small follicles.

FOLLICULAR DEVELOPMENT

Primordial follicles are comprised of a primary oocyte and pre-granulosa cells. Females have approximately 300,000 primordial follicles at puberty. There are three phases of follicular growth: pre-antral, peri-antral and antral.

Pre-antral and peri-antral phases occur during the three cycles before ovulation. It takes 85 days for a pre-antral follicle to develop to a mature follicle ready for ovulation. Between 10 and 30 dormant primordial follicles become active each day and they appear to be programmed to begin the maturation process on a particular day. The majority will die at some stage during development and only a small number reach the correct stage of development at the critical time to continue their development.

PREVALENCE

It is estimated that POI affects 5 per cent of women under 45 years of age,^{2,5} 1 per cent of women under 40, 0.1 per cent of women under 30 and 0.01 per cent of women under 20.^{1,3-5} Hispanic and African-American women reach menopause a little earlier, and Chinese and Japanese women a little later than the average Caucasian woman.⁶ Steadily improving cure rates of childhood and adolescent cancers are likely to increase the numbers of young women with POI. In addition, the awareness of genetic susceptibility to cancers, such as from *BRCA1* and *BRCA2* genes, will lead to young women having prophylactic oophorectomies and therefore experiencing early menopause.

AETIOLOGY

In many women, a cause is not established. Identifiable causes of POI include genetic, infectious, autoimmune and metabolic factors. Women are born with around seven million oocytes but during their reproductive lifespan will only release up to 500 oocytes. Therefore POI may be due to a lower number of follicles present in the ovary or an increased rate of follicle loss. Another possibility is that abnormal pairing during meiosis may result in oocyte apoptosis.⁷

Genetic causes

Genetic causes of POI include X-linked, deletions and translocations, fragile X and autosomal dominant gene mutations.

The most common X-linked disorder is Turner syndrome (XO). This is rare (1:2500 female births) but is a well-recognised cause of POI. Females tend to have 'streak' ovaries due to follicular atresia.⁸

Deletions are more common than translocations and it is the proximal deletions which tend to induce ovarian failure. A deletion in Xq13 results in primary amenorrhoea while a deletion in Xp11 can lead to either primary or secondary amenorrhoea. The critical region for normal ovarian function has been proposed to be Xq13–26.⁹

Fragile X has a well-known association with POI. The *FMR1* pre-mutation is found in 5 per cent of all women with POI.¹⁰ There is an expansion of 50–200 copies of the CGG repeats in the 5' untranslated region of the *FMR1* gene. Fragile X syndrome is due to the CGG expansion and results in POI in the female carriers and developmental deficiencies in the males.

Finally, mutations in the *FOXL2* gene can lead to POI.

Infectious causes

Viral or bacterial infection may lead to POI. Long-term ovarian function can be adversely affected by infections such as mumps, cytomegalovirus (CMV) or human

immunodeficiency virus (HIV) as well as severe pelvic inflammatory disease (PID) and pelvic tuberculosis.¹¹

Autoimmune causes

The prevalence of autoimmune conditions in women with POI has been reported to be 10–20 per cent,¹² suggesting an association between autoimmune conditions and POI. Anti-ovarian antibodies are occasionally detected in both type 1 (hypoparathyroidism, Addison's disease, mucocutaneous candidiasis) and type 2 (Addison's disease, hypothyroidism, type 1 diabetes) polyglandular autoimmune syndromes.¹¹ Autoimmune ovarian failure associated with thyroid dysfunction may occur in the absence of positive antibodies, but this may be due to lack of detection by current assays.¹¹

Metabolic causes

There is a high prevalence of POI in patients with galactosaemia. Affected individuals have mutations of the galactose 1-phosphate uridylyltransferase gene.¹³ Ovarian insufficiency in these individuals is considered to be a result of the accumulation of galactose which disturbs the migration of the germ cells from the urogenital ridge to the gonad in fetal life.¹¹

Iatrogenic causes

POI of iatrogenic origin can be as a result of ovarian damage secondary to surgery, chemotherapy or radiotherapy.¹¹ As more women are now surviving childhood malignancies, iatrogenic causes of POI will form a greater proportion of the causes contributing to POI in the future.

Idiopathic causes

POI is idiopathic in 74–90 per cent of cases.³ It is unknown whether these cases are truly 'idiopathic' or due to as yet undiscovered genetic, immunological or environmental factors.¹¹

HISTORY AND EXAMINATION

As with the diagnosis of any condition it is important to take a history and where appropriate carry out a physical examination of the patient.

History

- Last spontaneous menstrual cycle;
- Prior infection, surgery, radiotherapy, or chemotherapy;
- Family history of POI;

- History of autoimmune disorders;
- Symptoms of hypothyroidism;
- Symptoms of adrenal insufficiency such as hypotension and hyperpigmentation.

Physical examination

- Signs of hypo-oestrogenism such as dry skin and vaginal atrophy;
- Signs of autoimmune diseases e.g. Addison's disease and hypothyroidism.¹⁴

DIAGNOSIS AND INVESTIGATIONS

Diagnosis of POI can be difficult as FSH levels can fluctuate markedly. Generally, estimation of FSH levels is recommended in women with secondary amenorrhoea with or without menopausal symptoms.^{5,15} Serial levels are useful and in general two or three measurements at 6-week intervals, in addition to oestradiol levels, help to confirm the diagnosis. It is important not to 'label' a young woman with the diagnosis of POI on the basis of one blood test as levels can fluctuate widely and it is a psychologically distressing diagnosis.

As autoimmune disease is linked with POI, an autoantibody screen and thyroid function tests are useful to aid diagnosis. If these show positive results, further investigation may be warranted, including tests for adrenal function, such as a synacthen test, renal function and a CT scan.

Karyotyping of the patient should be done to exclude any genetic cause of POI unless the reason for the condition is obvious e.g. previous chemotherapy or irradiation.

A pelvic ultrasound scan can be helpful as it may show small ovaries with little or no follicular activity.

A bone mineral density scan (DEXA) is a very useful investigation even if the patient is only recently menopausal. This is because the patient's peak bone mass may not have been achieved hence knowing a baseline bone density can help to counsel the patient regarding the risk of bone fractures and HRT. For those patients who are reluctant to commence HRT, it may be critical in helping them make a decision.

PREDICTION OF POI

It is currently not possible to predict which women will develop POI and therefore screening is not helpful. However, antral follicle count and anti-Müllerian hormone (AMH) are tests currently used to assess ovarian reserve. AMH, produced by developing antral follicles, is not currently used to predict or diagnose POI but a low AMH, indicating reduced ovarian reserve, may indicate that POI is more likely.¹⁶ FSH is more commonly used to assess ovarian function with regard to the menopause but the levels fluctuate and therefore it is advisable to do several measurements.

RISKS ASSOCIATED WITH POI

There is increasing awareness that POI can lead to earlier than expected serious health consequences contributing to increased morbidity and mortality. These include cardiovascular disease, osteoporosis, cognitive impairment including dementia and parkinsonism, psychological effects, impaired sexual function and subfertility. POI is associated with an overall 50 per cent increase in mortality when compared with women with menopause at age 52–55 years.¹⁹ However, early menopause does appear to offer a protective effect on the development of breast malignancy.

Cardiovascular disease

Bilateral oophorectomy has been associated with increased cardiovascular risk and premature death and the younger the age at oophorectomy the greater the increase in risk.²⁰ In those with POI under the age of 40 years, increased risk of mortality from ischaemic heart disease is up to 50 per cent when compared with those with a menopause at the age of 52–55 years.¹⁹ The underlying pathophysiology of this is likely to be hypo-oestrogenism contributing to enhanced progression of atherosclerosis.^{21,22} Women with POI have been shown to have atherosclerosis as a result of impaired endothelial function.²³ Hypo-oestrogenism contributes to dyslipidaemia,²⁴ reduced insulin sensitivity²⁵ and metabolic syndrome.²⁶ A reduction in the increased risk for the development of cardiovascular disease can be achieved by commencing oestrogen replacement shortly after surgical or natural menopause at a young age.^{27–29} This is usually given as HRT or synthetic ethinyl oestradiol in the form of the combined contraceptive pill.

Some progestogens have been associated with a negative impact on cardiovascular risk factors by affecting lipid profiles, vasomotion³² and carbohydrate metabolism.³³ Micronised progesterone combined with transdermal oestrogen has been associated with a reduction in the incidence of new-onset diabetes and has a neutral or beneficial effect on blood pressure in postmenopausal women.³⁴ In one study, for women with a uterus, the use of micronised progesterone produced the most favourable cardiovascular effects.³⁵ A recent meta-analysis has also demonstrated reassuring effects on lipids, glucose, insulin and body fat distribution with oral oestradiol and dydrogestrone combinations.³⁶

These studies have not been conducted on prematurely menopausal women and there is a lack of evidence to guide clinical practice in this group of patients. There is an ongoing clinical trial examining the effects of micronised progesterone and medroxyprogesterone acetate, both used with transdermal oestradiol, on the cardiovascular system, lipid profile and coagulation cascade in women with POI.³⁷

Osteoporosis

Numerous studies have shown that bone loss accelerates following menopause. The earlier in life that menopause occurs, the lower the bone density will be later in life³⁸ and this is associated with a significantly higher overall fracture risk.³⁹ Even in women who undergo bilateral oophorectomy after natural menopause, the risk of osteoporotic fracture may be increased compared with women with intact ovaries.⁴⁰ This could be due to the fact that postmenopausal ovaries still secrete testosterone. Analysis of DEXA scans performed at diagnosis of POI show 3.6 per cent of women have bone density within the osteoporotic range and 25.9 per cent have osteopenia.¹⁷ However, the usual bone density T-score classifications for osteoporosis have not been designed for use in young women and the recently developed FRAX tool (<http://shef.ac.uk/FRAX/index.htm>) for assessing fracture risk is not recommended for use in women under 40 years.¹⁷

Oestrogen therapy reduces the risk of osteoporosis and subsequent fractures.⁴¹ All patients should also be encouraged to take regular weight-bearing exercise and have a calcium-rich diet, with consideration of calcium and vitamin D supplementation if deficient. HRT is the most effective intervention for preventing bone loss in women with POI.¹⁷ The long-term effect of bisphosphonates and subsequent non-union of fractures is unknown as these agents have a long half-life and can affect bone metabolism for many years. Non-hormonal treatments including bisphosphonates, strontium or raloxifene can be used in women who have osteoporosis and cannot tolerate or refuse HRT but these preparations are not used or licensed to prevent bone loss in those with a normal bone density. Higher-than-usual doses of oestrogen for the relief of symptoms are often required by young women. However, adequate bone protection can be achieved with even low-dose HRT regimens.⁴²

Cognitive function

It has been suggested that patients with early menopause may be at increased risk of dementia or reduced cognitive function; however, definitive conclusions regarding the risk of cognitive impairment in POI cannot yet be drawn due to a lack of data in women under the age of 40 years and in those with non-surgical causes of POI.¹⁷ In the Mayo Clinic Cohort Study of Oophorectomy and Aging, women who underwent bilateral oophorectomy and consequently had POI had an increased risk of cognitive impairment or dementia compared with controls (hazard ratio [HR] 1.33, 95% CI 0.98–1.81; $p = 0.07$). The risk was greatest in the younger individuals and women under age 43 years had the highest risk (HR 1.74, 95% CI 0.97–3.14; $p = 0.06$).⁴³ Evidence suggests that there may be a neuroprotective effect of oestrogen and that the effect may be age-dependent.^{43,44}

Parkinsonism

Women with a premature surgical menopause appear to have an increased risk of parkinsonism compared with controls (HR 1.80, 95% CI 1.00–3.26; $p = 0.05$), and the risk increased with younger age at oophorectomy (test for linear trend; $p = 0.02$).^{45,46}

Psychological effects

The diagnosis of POI can have devastating, long-lasting psychological effects. Patients with POI have been shown to have increased levels of anxiety, depression, psychological distress and decreased overall wellbeing, compared with control groups.^{47–48} They also have perceived lower levels of social support.⁵⁰ Studies have shown that in both HRT and non-HRT users there are high levels of psychological distress. This throws light on the importance of managing the psychological aspect of POI. Support groups include the Daisy Network (www.daisynetwork.org.uk) and Women's Health Concern (www.womens-health-concern.org) and patients should be made aware of these.¹⁷

Sexual function

Women with POI have been shown to have decreased levels of sexual fulfilment, reduced arousal, less frequent sexual encounters and increased pain.⁴⁹ Complex psychosexual impairment is likely to develop, particularly in the younger POI patients.⁵¹ In addition to adequate oestrogen replacement and where necessary additional androgen replacement, psychosexual counselling may be required in the management of sexual dysfunction in selected cases.¹⁷

Associated endocrine and autoimmune conditions

POI is often associated with other autoimmune disorders, with 20 per cent of idiopathic POI patients presenting with another autoimmune condition.⁵² These include hypothyroidism (25 per cent), Addison's disease (3 per cent), diabetes mellitus (2.5 per cent), Crohn's disease, vitiligo, pernicious anaemia, systemic lupus erythematosus (SLE), rheumatoid arthritis and myasthenia gravis. Patients should be tested for autoimmune antibodies, including anti-ovarian and anti-adrenal antibodies.⁵³

Subfertility

Some women with POI may have irregular periods with occasional resumption of ovarian function. Spontaneous pregnancies occur in 5–10 per cent of those karyotypically normal women with idiopathic POI.¹⁸ Although there may be future developments in fertility treatment such as storage of ovarian tissue and subsequent reimplantation of tissue or in-vitro

maturation of oocytes for those who are at risk of POI, in-vitro fertilisation (IVF) using donor oocytes remains the mainstay of treatment for women who wish to conceive.¹⁷

MANAGEMENT

In the management of POI it is of paramount importance to provide patients with adequate information about the condition and explain the long-term health consequences, the use of oestrogen replacement and the effect of POI on the patient's fertility.¹ In idiopathic POI patients with normal karyotype there is a 5–10 per cent chance of spontaneous ovarian activity and the possibility of spontaneous pregnancy must be explained. Symptomatic women requiring HRT, yet still hoping for a natural conception, may choose sequential HRT as it is not contraceptive and in those women who wish to avoid pregnancy, effective contraceptive advice should be provided.¹⁸ In women with POI, contraception is advised for 2 years after the last menstrual period.

The most important aspect of management is ensuring adequate hormone replacement. Oestrogen should be replaced until at least the age of 50 years and if the uterus is still present, progesterone needs to be added for endometrial protection, either as a sequential or continuous combined preparation. An alternative to this is the Mirena coil. The license for this as the progesterone arm of HRT is for 4 years in the UK (5 years in other countries).

HRT can be administered orally or transdermally and the combined oral contraceptive pill (COCP) can also be used as oestrogen replacement. There is limited evidence of the benefit of HRT over the COCP but transdermal oestrogen and micronised progesterone may confer some benefits including lowering of systolic blood pressure.⁵⁴ However, for some the COCP may be more acceptable as it makes the younger patients feel more 'normal' among their peers.

Vaginal oestrogens can be used along with HRT and this localised oestrogen can significantly help vaginal dryness and improve sexual function. Even for patients with relative contraindications to oestrogens, this can be considered as the absorbed dose is very low.

HRT in the form of oestrogen can help libido but if a trial of standard HRT adequately improves all other symptoms except libido then androgens can be considered to improve libido.^{55,56} This can be administered as tibolone which is a selective oestrogenic activity regulator with oestrogenic, progestogenic and androgenic effects. Unfortunately in the UK there are no testosterone preparations licenced for use in women. However testosterone gel can be safely titrated for use in women by using one third of a 5 g tube of gel on alternate days. Implants of testosterone are scarce but can be used 6 monthly. Testosterone replacement appears to improve insulin resistance, muscle strength and functional cardiac capacity^{57,58} and no adverse events. Prior to using testosterone it is best to take a thorough sexual history as lack of libido can be multifactorial.

Patients need psychological support and websites such as the Daisy Network can be useful. A repeat DEXA in 3–5 years after commencing treatment can be considered and annual follow-up should be arranged.

Fertility issues also need to be addressed and the options for fertility treatment include donor oocyte treatment, fostering and adoption. If POI can be predicted, as in the case of women undergoing cancer treatment, then oocyte preservation can be considered. The options for pre-pubertal girls are more limited but there is increasing interest in ovarian tissue freezing with a view to ovarian tissue reimplantation or in-vitro maturation but the latter is still a research tool. There have been some livebirths worldwide from ovarian tissue reimplantation.⁵⁹

KEY POINTS

- POI is characterised by primary or secondary amenorrhoea, raised gonadotrophins and hypo-oestrogenism in women less than 45 years of age.¹
- POI affects 5 per cent of women under 45,² 1 per cent of women under 40, 0.1 per cent of women under 30 and 0.01 per cent of women under 20 years.^{1,3-5}
- Causes of POI include: genetic, infectious, autoimmune, metabolic, idiopathic and iatrogenic.
- In addition to FSH and oestradiol levels, important investigations at presentation include pelvic ultrasound, autoantibody screening, karyotyping and chromosomal analysis and assessment of bone density.¹⁷
- POI has been associated with a 50 per cent higher mortality from ischaemic heart disease when compared with women with menopause at age 52–55.¹⁹
- HRT relieves menopausal symptoms, conserves bone mass and there is evidence of cardiovascular benefit. It should be continued until at least the average menopausal age.
- Although ovarian follicular function fluctuates in 50 per cent of women with POI and 5–10 per cent of women may eventually conceive, IVF using donor oocytes remains the mainstay of treatment for women who wish to conceive.¹⁷

Chapter 92 Fertility preservation

Hoda Harb and Arri Coomarasamy

MRCOG standards

There are currently no MRCOG standards for this subject. The following are suggested:

- Understand who should be offered cryopreservation of sperm, oocytes, embryos and ovarian tissue.
- Be able to counsel patients on options for fertility preservation.

INTRODUCTION

It is estimated that currently 1 in 1000 young adults (25–35 years) have survived childhood cancer. The five-year survival rates with haematological malignancies, breast cancer, testicular cancer and other cancers that affect young people are in the range of 90–95 per cent. Treatment for these cancers, however, is often highly detrimental to both female and male reproductive function. Thus the concern is no longer only to save lives from cancer, but also to ensure improved quality of life, which often includes preserving fertility.^{1,2}

Although this chapter will focus mainly on patients with cancer, some treatments for non-cancerous conditions (e.g. long-term methotrexate therapy) can result in damage to reproductive organs, and the options discussed for fertility preservation should therefore also be considered for these patients.

There are two key aspects to fertility preservation:

- 1 Minimisation of the effect of cancer treatment on fertility;
- 2 Provision of effective options for storage of gametes, embryos or indeed germinal (e.g. ovarian) tissues.

The commonest cancer in women of reproductive age is breast cancer; other cancers of note in this age group are leukaemia, lymphoma, melanoma, cervical and ovarian cancers. In men, the commonest cancers during reproductive years are leukaemia, Hodgkin's lymphomas and testicular germ cell tumours.³ Semen analysis may be abnormal in men with

germ cell tumours. Furthermore, there is evidence that the integrity of sperm DNA is affected even before initiation of cancer therapy in men with Hodgkin's lymphomas and testicular cancers.⁴

The type of cancer, its stage, its biological features and patient factors have an influence on prognosis and treatment. The treatment may be a combination of surgery, chemotherapy and radiotherapy.

CHEMOTHERAPY

Chemotherapy and the ovary

Chemotherapy, particularly with alkylating agents like cyclophosphamide, is highly toxic to the primordial follicles in the ovary (Table 92.1). Histological studies of human ovaries following chemotherapy treatment have shown ovarian atrophy and global loss of primordial follicles.^{5,6} The ovarian cortical stromal cells are mostly replaced with collagen and the ovary shrinks in size. The extent of the effect of chemotherapy on ovarian reserve will depend on the drug(s) used, dose, age and the baseline ovarian reserve of the patient. Factors associated with the development of acute ovarian failure are increased age at the time of treatment, diagnosis of Hodgkin's

Table 92.1 Drugs associated with significant gonadotoxic effects

Group	Drug
Alkylating agents	Cyclophosphamide
	Chlorambucil
	Mustine
	Melphalan
Vinca alkaloids	Vincristine
	Vinblastine
Antimetabolites	Cytarabine
Others	Cisplatin

disease, increased radiation doses (particularly >10 Gy), and exposure to alkylating agents (specifically procarbazine and cyclophosphamide).

Chemotherapy and the testis

Germinal epithelium of the testis is very sensitive to the detrimental effects of chemotherapy. Men can be rendered oligospermic or azospermic. The degree to which the testicular function is affected is dose and agent dependent. Following higher cumulative doses of gonadotoxic chemotherapy, Leydig cell dysfunction may also become apparent.⁷ As a result, testosterone production is affected, with the risk of developing osteoporosis, erectile dysfunction and cardiovascular disease.

RADIOTHERAPY

Radiation and the ovaries

Radiotherapy, particularly if directed to the pelvis, can adversely affect ovarian reserve. The extent of damage is related to the radiation dose, age at the time of treatment and fractionation schedule.^{8,9}

Radiation and the uterus

Uterine function may be impaired following radiation to the pelvis as a consequence of disruption to uterine vasculature and musculature elasticity, impaired blood flow and endometrial damage. The clinical consequences are increased risk of miscarriage, lower birthweight, premature delivery and fewer livebirths.^{10,11}

Radiation and the testis

Radiation doses as low as 0.1–1.2 Gy can impair spermatogenesis, with doses over 4 Gy causing permanent azospermia.¹²

MANAGEMENT

Management of cancer patients requires a multidisciplinary approach consisting of a close partnership between the oncologist and fertility specialists, with the patient, partner and family at the centre of a treatment plan that prioritises not only the prolongation of life, but which considers quality of life and the psychological, physical and social wellbeing of the patient. The role of counsellors in supporting patients and family is important.

Oncologists and medical specialists should:

- be aware of options for fertility preservation;
- offer referral to a fertility specialist for counselling prior to commencement of treatment.

Once a referral is received, a fertility specialist will consider the following issues:

- 1 history: including age, menstrual history, pregnancies, fertility wishes, and whether or not the patient has a partner/spouse;
- 2 cancer: location, biology of the tumour, stage, prognosis, potential for metastasis in ovary, proposed treatment, and foreseeable long-term effects;
- 3 time available for fertility preservation – possibility or impossibility of delaying the start of treatment;
- 4 patient's general condition;
- 5 baseline ovarian reserve.

Conservative fertility-sparing treatment for early invasive disease, such as hormonal treatment of early endometrial cancer, may be possible in some patients. Ovarian transposition can be considered where irradiation of the pelvis becomes necessary, for example in the management of cervical cancer, to reduce the dose of radiation to the ovaries.

Controlled ovarian stimulation and cryopreservation of oocytes or embryos

This is the most established female fertility preservation method (Table 92.2). It requires approximately 2 weeks to complete the treatment to the oocyte retrieval stage. A working partnership with a fertility clinic should be established so that rapid referral can be made and the patient seen expeditiously to avoid delay (RCOG Scientific Impact Paper No. 35, 2013).

Cryopreservation of embryos

Embryo cryopreservation following IVF is a routine procedure in fertility clinics and is the method of choice with the greatest chance of success; however it is only an option if there is a male partner or if donor sperm is acceptable to the woman or couple. It is estimated that of the 3 million children born by IVF, 15–20 per cent were conceived following transfer of cryopreserved embryos. However, there are limited data on its success rates in the context of fertility preservation in women with gynaecological cancers.

Cryopreservation of oocytes

When embryo cryopreservation is not feasible or desired, women who have the time to undergo a stimulation cycle should be offered oocyte cryopreservation. Oocyte cryopreservation is technically challenging due to the size and structural complexities of oocytes. Effectiveness of oocyte preservation is limited by the number of oocytes that can be obtained, as *each* oocyte carries a 3–5 per cent chance of resulting in a successful pregnancy. A recent meta-analysis evaluating the age-specific probability of livebirth with oocyte cryopreservation found that livebirths continued to occur as late as ages 42 and 44 years with slowly frozen and vitrified oocytes, respectively.¹³

Table 92.2 Fertility preservation options available for girls and women

Group	Pre-pubertal girls	Post-pubertal girls	Women
Fertility preservation options	Cryopreservation of ovarian tissue and ovarian transplantation when fertility is required	COS and preservation of oocytes	COS and preservation of embryos
		Cryopreservation of ovarian tissue and ovarian transplantation	COS and preservation of oocytes
		GnRH agonist co-treatment during chemotherapy	Cryopreservation of ovarian tissue and ovarian transplantation
			GnRH agonist co-treatment during chemotherapy
Considerations	Transplantation carries the potential risk of reintroduction of cancer cells	COS introduces delay in cancer treatment	For creation of embryos, sperm is required
	IVM may become an option in the future	Oocyte cryopreservation may not be as effective as embryo cryopreservation	If the male withdraws consent in the future, the woman is unlikely to be able to use the embryos
	Consenting issues		
COS, controlled ovarian stimulation; IVM, in-vitro maturation.			

Cryopreservation of ovarian tissue

Cryopreservation and transplantation of ovarian cortex may be the only option for fertility preservation in pre-pubertal girls or in women who need cancer treatment within the minimum of 2 weeks required for COS. With several live-births reported from various countries, this option is gradually moving from the experimental phase to clinical practice.¹⁴ Generally, no more than 50 per cent of one of the ovaries is removed in a day-case laparoscopic procedure, and thin slivers of the cortex are prepared and cryopreserved.¹⁴ If the woman becomes menopausal following her cancer treatment, she may have the ovarian cortical tissue transplanted when she decides to try to conceive a pregnancy.

Cryopreservation and transplantation of ovarian tissues are best carried out in specialised and centralised facilities. One of the major concerns regarding cryopreservation of ovarian tissue is the risk of ischaemic damage to the tissue pending transplant and revascularisation. Also, there is a theoretical possibility of transplantation reintroducing malignant tumour cells. IVM and xenotransplantation are both experimental, but may offer a way of dealing with this risk in the future.

GnRH agonist co-treatment during chemotherapy

Suppression of folliculogenesis with GnRH analogue during chemotherapy has been proposed to provide ovarian protection. Research evidence on the effects of GnRHa co-treatment during chemotherapy has yielded conflicting results.^{15–18}

A systematic review on this subject identified 16 controlled studies, of which 5 were of randomised design.¹⁵ Meta-analysis of all the studies found a statistically significant reduction in the risk of premature ovarian failure with GnRHa co-treatment (RR 0.26, 95% CI 0.14–0.49). However, the advantage of GnRHa was primarily found in the non-randomised studies, with the randomised studies showing conflicting results, with only 3/5 studies indicating benefit with the use of GnRHa co-treatment. A more recent meta-analysis of seven randomised trials¹⁹ comparing GnRHa co-treatment with chemotherapy in premenopausal women found that the number of patients with resumption of spontaneous menstruation was statistically significantly greater in the GnRHa co-treatment patients (OR 2.83, 95% CI: 1.52–5.25).

There are at least three ongoing randomised studies that may allow us to draw a firm inference on the role of GnRHa co-treatment in the future. In the meantime, it would be reasonable to offer a woman GnRHa treatment during chemotherapy.

Sperm banking

Men should be offered the opportunity to bank sperm before cancer treatment (Table 92.3). Spermatogenesis occurs at a median age of 13.4 (range 11.7–15.3) years. Post-pubertal males will ordinarily be capable of ejaculation and can provide sperm for storage. In males who cannot ejaculate or who are too young, electro-ejaculation, epididymal sperm aspiration or testicular sperm extraction may be performed. Cryopreserved material is usually stored for an initial period of 10 years; however,

Table 92.3 Fertility preservation options available for boys and men

Group	Pre-pubertal boys	Post-pubertal boys	Men
Fertility preservation options	There are no established procedures	Electro-ejaculation or masturbatory ejaculation and sperm banking	Ejaculatory sperm banking
		SSR and sperm banking	SSR and sperm banking
Considerations	Experimental: stem cell extraction and later repopulation of the testis	Consenting issues	
SSR, surgical sperm retrieval.			

continued storage of cryopreserved sperm, beyond 10 years, should be offered to men who remain at risk of significant infertility. Testicular tissue cryopreservation from prepubescent males remains experimental.

Pregnancy in cancer survivors

Depending on the type of cancer and gonadotoxic treatment the patient received, oncologists may recommend that cancer survivors wait at least a year before attempting pregnancy,²⁰ although optimal timing of conception after treatment remains uncertain.²¹

The Childhood Cancer Survivor Study (CCSS),²² including 3531 survivors and 1366 female sibling controls, found that 292 (64 per cent) of 455 participants with self-reported clinical infertility achieved a pregnancy, although survivors had an increased time to pregnancy compared with their siblings. The analysis, however, did not include women with ovarian failure and the proportion of infertile survivors achieving pregnancy is expected to have been lower if this group was included. The study also showed that the risk of non-surgical premature menopause in childhood cancer survivors was higher in survivors than in their siblings, with a cumulative incidence of 8 per cent by 40 years of age.²³

Fertility after chemotherapy depends primarily on ovarian reserve for a woman. Ovarian assessment can be performed in a number of ways (Box 92.1). The most commonly used test is the FSH level, although AMH and antral follicle count (AFC) are increasingly being used.

Women should be counselled regarding reproductive options including natural conception, or assisted reproduction using stored gametes or donor gametes. If a woman is found to have a reduced ovarian reserve, or if natural conception does not occur, fertility specialists should have a low threshold to move to assisted reproduction. Women should also be counselled about other options including surrogacy and adoption.

Box 92.1 Assessment of ovarian reserve

Assessment of ovarian reserve

- Follicle-stimulating hormone, measured between day 2 and day 5 of cycle
- Serum anti-Müllerian hormone, at any stage of the menstrual cycle
- Sonography: total antral follicle count
- Sonography: ovarian volume
- Response to ovarian stimulation

KEY POINTS

Background:

- Young patients with many cancers have excellent survival prognosis, and may request fertility preservation.
- The effect of chemotherapy on ovarian function and fertility will depend on the drug(s) used, dose, duration of treatment, age of the patient and baseline ovarian reserve.
- Radiotherapy, particularly if directed to the pelvis, can affect fertility.

Management:

- Multidisciplinary team approach.
- Fertility preservation options will be determined by the pubertal stage of the patient, baseline ovarian reserve, time available for fertility preservation, and whether the patient is in a stable relationship with a partner who can offer sperm for the creation of embryos.
- Clinicians should inform patients about options for fertility preservation *prior* to starting potentially gonadotoxic treatment.
- Fertility preservation options are:
 - Pre-pubertal girls: ovarian tissue storage and transplantation;
 - Post-pubertal girls: COS and oocyte storage; ovarian tissue storage; GnRH α co-treatment during chemotherapy;

- Women: COS and embryo storage; COS and oocyte storage; GnRHa co-treatment during chemotherapy;
- Pre-pubertal boys: no established options;
- Post-pubertal boys: sperm banking (sperm obtained from masturbation, electro-ejaculation or surgical sperm retrieval);
- Men: sperm banking.
- Ovarian tissue storage and transplantation: generally no more than 50 per cent of one ovary is removed for storage; storage and transplantation should be carried out in specialised and centralised facilities.
- COS: requires approximately 2 weeks to complete treatment to the oocyte retrieval stage.
- There is contradictory evidence on the role of GnRHa co-treatment to reduce gonadal toxicity during chemotherapy. Results of on-going randomised trials are awaited.

Chapter 93 Psychosexual medicine

Susan V Carr

MRCOG standards

Theoretical skills

- Revision of knowledge of genital anatomy and the female sexual response.
- To understand the concept of sexuality.
- To know the definition of sexual disorders.
- To know the prevalence of sexual problems.

Practical skills

- To be able to recognise and acknowledge a sexual problem in a patient.
- To be comfortable in communicating about sexual matters.
- To be aware of the emotional elements of the condition.
- To be able to offer strategies for treatment.

INTRODUCTION

Women's sexual difficulties include problems of function, such as pain on intercourse and dyspareunia, and problems of desire, such as loss of libido. Any woman presenting to a gynaecologist complaining of a sexual problem should have a routine clinical history and examination and any indicated tests, followed by treatment. There are, however, a significant number of women who have no organic lesions, yet continue to experience sexual difficulties which have major negative effect on their lives.

Psychosexual medicine is the area of medicine which deals with sexual difficulties in patients, recognising the emotional and relationship aspects of the problem.¹

WHAT IS SEXUALITY?

Sexuality is a biopsychosocial phenomenon. It is composed of gender identity, sexual orientation and sexual knowledge, attitudes and behaviour. Gender identity and sexual orientation

are mainly organically determined, but sexual knowledge, attitudes and behaviour are shaped by many external factors, and can change over the course of a woman's lifetime.

THE HUMAN SEXUAL RESPONSE

The physiological sexual response depends not only on intact vascular, endocrine and neurological pathways, but also on sensory input. Bancroft² describes this as the 'Psychosomatic Circle of Sex', the fundamental concept of mind-body interaction, on which the discipline of psychosexual medicine is based. Female responsiveness is a result of sensory input through the peripheral nerves of the somatic and autonomous nervous systems, as well as through the cranial nerves and psychogenic stimulation. The frontal and temporal lobes all have a role to play in mediating the sexual response. The precise details of the processing of afferent information within the spinal cord and brain still remain unclear.³

Genital motor responses include vasocongestion and vaginal lubrication. During sexual penetration the vagina lengthens, the labia increase in fullness, the uterus draws back and the clitoris retracts. At orgasm there is also contraction of the uterine and pelvic muscles.

PREVALENCE OF SEXUAL PROBLEMS

According to Laumann,⁴ in a US-based population study, 43 per cent of females and 37 per cent of men at some time have a problem with sex. Of these, a third of women had loss of libido, 25 per cent were inorgasmic and around 20 per cent had loss of vaginal lubrication and did not enjoy sex. In 2004 similar figures were reported, also showing that the incidence of these problems increases with age.⁵ This is shown in another study where 26.7 per cent of pre-menopausal women had low sexual desire, but that figure increased to 52.4 per cent in naturally menopausal women.⁶ Menopausal women comprise the group who have the highest prevalence of sexual problems worldwide. Roos in 2012 reported that 37 per cent of women in a general gynaecology/urogynaecology clinic had sexual problems but only 17 per cent volunteered this information spontaneously.⁷

There is also a high prevalence of sexual problems in women with gynaecological cancer, significantly more than in a control population.⁸ These problems are multifactorial and, of necessity, require a multimodal treatment approach.⁹

VAGINISMUS

In a population-based survey, vaginismus was seen in 6 per cent of the 37.9 per cent of women who reported sexual problems¹⁰ (see Box 93.1).

Box 93.1 Case scenario: clinical presentation of vaginismus

Lucy, age 32, had been married for 5 years to James. She presented at her GP surgery saying that she hadn't been able to become pregnant. The GP noticed that she had never had a smear test. She said she would make an appointment to have it done. She was in good health, had a regular menstrual cycle and was not using contraception. All blood tests were normal. He referred her to the local hospital for investigations.

When Lucy attended the hospital she became very distressed at the mention of a vaginal examination or scans, and was unable to tolerate any form of genital examination.

It then became clear that she had never had sex, and had primary vaginismus.

After psychosexual counselling and physiotherapist-guided vaginal trainer therapy (dilators), she was able to have penetrative sex.

Vaginismus is defined as recurrent involuntary spasm of the musculature of the outer third of the vagina which interferes with sexual penetration of any kind. Primary vaginismus is diagnosed when nothing has ever entered the vagina. In this condition the vagina is healthy, and a deep-seated fear of sexual penetration triggers involuntary muscle contraction, making penetration impossible. The vaginismus precedes the pain, which only occurs on attempted penetration.

Secondary vaginismus occurs often after vulvovaginal trauma such as infection, childbirth, malignancy or its treatment, or sexual trauma such as rape or abuse. It is thought that the memory or expectation of pain on penetration causes involuntary muscle spasm resulting in vaginismus.

Although vaginismus is classified as a pain disorder, its clinical presentation is very different. Women with vaginismus can often orgasm easily, and express desire for sex. They report more sexual desire and less difficulty with lubrication compared to women with dyspareunia.¹¹

Diagnosis of vaginismus

Primary vaginismus will be diagnosed mainly on the history. A good general and gynaecological history should be taken. A woman who has never had penetration of any kind, despite

wishing to, may have vaginismus. These women may be 'cervical smear avoiders'. They are frequently too embarrassed to disclose that they are unable to have sex.

Good questions to ask include 'Have you ever used tampons?' and 'Have you ever had sex?'

A vaginal examination should then be offered, to assess not only the degree of vaginismus but also the acceptability of any vaginal examination.

- 1 Offer vaginal examination, and observe the woman's reaction to this offer.
- 2 If refused, then accept her decision.
- 3 If accepted, proceed with single digital examination only, not a speculum examination.
- 4 Only proceed if the patient is comfortable, and assess the degree of vaginal spasm.

In most cases even digital examination at this stage is unsuccessful. This is a positive diagnostic sign for vaginismus.

Treatment of vaginismus

A recent Cochrane review on the subject of interventions for vaginismus was only able to include five controlled trials. The authors stated that, although uncontrolled case series of sex therapy and desensitisation appear promising, in controlled trials there was no difference between systematic desensitisation and any of the control interventions.¹² They also highlighted the lack of research in this area.

There are excellent psychodynamic and behavioural treatment options which are widely accepted by specialists working in the field, but due to the paucity of research, most evidence is derived from expert opinion, based on grading of available research, committee discussion, public presentations and debate.

There are various modes of treatment for this condition, which is mainly of psychogenic origin.

Psychosexual therapy

Using short-term, focused and reflective doctor–patient interactions, the psychosexual approach offers a starting point for assessment of the problem, and addresses emotional aspects of the condition. It is the mainstay of treatment, and can be used in conjunction with other treatment options. A multidisciplinary approach is frequently recommended¹³ in order to simultaneously address the psychogenic as well as the physical aspects of the condition.

Behavioural therapy

Sex therapy is a commonly used form of treatment for women with a partner.¹⁴ This approach follows modified Masters and Johnson programmes of couple therapy.¹⁵ The technique 'reteaches' a couple how to touch and interact sexually, sets boundaries which facilitate trust and acts as a vehicle for communication about intimate issues. This approach is useful to both heterosexual and same-sex couples. A success rate of over 90 per cent is reported in those who continue therapy.¹⁶

Biofeedback therapy

Physiotherapist-aided vaginal training and biofeedback therapy are effective.¹⁷ A combination of increasing knowledge and awareness of genital anatomy combined with vaginal self-insertion of graduated trainers can prove very effective but may take up to 2 years to achieve success; there is rarely a quick fix.

Cognitive behavioural therapy

CBT is also an effective mode of treatment¹⁸ which can achieve positive effects on sexual intimacy and communication, and has been successfully conducted online.¹⁹

Botulinum toxin A therapy

There is some evidence of success in using intravaginal injections of botulinum toxin for vaginismus. This may hold true for treatment of refractory patients,²⁰ but to date there is a lack of placebo-controlled randomised clinical trials on which to base the approach.

Individual case treatment is usually dependent on what options are available locally. If the condition is accurately diagnosed and referred appropriately to a relevant trained professional, the cure rate is over 90 per cent.

DYSPAREUNIA

Dyspareunia is pain on sexual intercourse (see Box 93.2). This applies to any form of sexual vaginal penetration, not only with the penis, but other objects such as fingers or sex toys. Deep dyspareunia is more likely to have an organic cause and should be thoroughly investigated before psychosexual diagnosis is considered.

Vulvar pain syndromes, such as vulvodynia and vestibulodynia, may also present as dyspareunia.

In many women there may be a clear organic explanation, such as post-menopausal vaginal dryness, vulvar skin lesions, endometriosis, infection or the physical sequelae of childbirth. In cases where any obvious physical or hormonal

Box 93.2 Case scenario: clinical presentation of dyspareunia

Maya, age 28 and para 0+1, had been treated for chlamydia. She had been living with Carlos for 6 months when she was referred to the gynaecologist, saying that sex, particularly on penetration, had become painful. This difficulty was beginning to negatively affect their relationship. She said there were no other problems.

Indications from clinical and bacteriological examinations were normal. The gynaecologist expected Maya to be relieved by these results, but when she was discharged from the gynaecology clinic she began to cry. After further discussion she was referred to a sexual difficulties clinic, where she was able to discuss the underlying, unresolved emotional issues about her previous pregnancy loss, sexual infection and current relationship.

She cancelled her gynaecology review appointment, because the dyspareunia had resolved.

disruption has been treated but the pain on sex persists, then a psychogenic element must be considered.

Treatment of dyspareunia

- 1 Take a careful history including sexual and psychosocial issues.
- 2 Treat any underlying condition.
- 3 If the problem remains unresolved then consider a psychogenic origin and offer psychosexual assessment.
- 4 Refer the patient to a physiotherapist experienced in sexual difficulties if necessary following psychosexual assessment.

LOSS OF LIBIDO

There are no physiological markers for the loss of libido (loss of sexual interest and desire). The severity of the condition may be judged by the attitude of the patient towards her lack of sexual feelings. To some women, the loss of libido causes no difficulty; it is only those who would like to recover who are likely to seek clinical assistance (see Box 93.3, 93.4).

Loss of libido is associated with menopause, and post-menopausal women worldwide are the population group most likely to suffer from sexual problems. This is especially true in young women with acute, surgical menopause.

Treatment of loss of libido

- 1 Elicit and listen to the patient history, including sexual, social and relationship issues. The timing of presentation may be important.
- 2 Treat any underlying clinical condition, including any menopausal effects.
- 3 If anything in the history is suggestive of psychosocial problems underlying the loss of libido, or if hormonal treatment is unsuccessful, then offer referral for psychosexual counselling.

Box 93.3 Case scenario: clinical presentation of loss of libido

Renee is a 54-year-old woman and has been with her current partner, Louisa, for the past 7 years. Previously she was married to Tom and has 3 children in their 20s. At first Renee was embarrassed to disclose her sexual orientation to her gynaecologist, but after careful prompting she became comfortable in discussing her loss of libido.

Renee had experienced a very active sex life with Louisa, but since menopause 2 years ago her vagina had been dry, and she began to avoid sex because of vaginal discomfort. She lost any interest in sex. She wanted to improve sexual relations for both of them although Louisa insisted that the problem did not affect her commitment to a life together.

The gynaecologist treated Renee with vaginal oestrogen. Sex became more comfortable, and the situation resolved.

Box 93.4 Case scenario: clinical presentation of loss of libido

Marina, in good health at age 54 and para 4+0, presented at the menopause clinic with loss of libido.

She said things were difficult with Robert, her husband of 30 years, since she experienced menopause.

She requested 'Tablets and a check-up, please.'

After many repeat appointments and changes of HRT, the loss of libido did not improve. When asked if there was anything else wrong, Marina finally broke down and admitted there were other problems with her and Robert. She was offered the opportunity to see a psychosexual counsellor, with whom she admitted longstanding inter-relationship violence. Marina's loss of libido resulted from this difficulty and was further exacerbated by the menopause.

Marina persuaded her husband to engage in couple counselling, and things improved a little.

The only strong evidence for the use of testosterone to recover libido is confined to post-menopausal women also receiving HRT and with no previous underlying problems.²¹ Transdermal testosterone is effective, but any additional treatment such as oral or vaginal dehydroepiandrosterone remains controversial.²²

ORGASMIC DISORDERS

The female orgasm is defined as a sensation of intense pleasure creating an altered state of consciousness accompanied by the contraction of pelvic striated circumvaginal musculature, uterine/anal contractions and myotonia that resolves sexually induced vasocongestion and induces feelings of wellbeing and contentment.²³

Orgasmic disorder, or anorgasmia, is the absence of orgasm following a phase of normal sexual excitement, causing frustration²⁴ which can lead to distress. Commonly psychological, cultural and emotional factors are at play. A patient may maintain a good libido and interest in sex, yet be unable to 'let go' and lose herself in the sexual act.

Female orgasmic disorder is reportedly the second most common female sexual disorder worldwide, with a prevalence of 24 per cent in the US.²³

Treatment of orgasmic disorders

- 1 Take a comprehensive sexual and psychosocial history, and determine the time of onset and circumstance of the condition.
- 2 Exclude any rare organic causes, such as multiple sclerosis; if there are any indicators of an organic cause,

such as gradual onset in a previously orgasmic woman, then indicated investigations should be conducted.

- 3 Refer the patient for psychosexual assessment.
- 4 Treatments such as basic sexual education, simple masturbation techniques and Kegel exercises may be helpful.
- 5 CBT may alleviate the anxiety of the patient, and assist the behavioural route to cure.

To date, no pharmacological agents have been proven to cure anorgasmia.²³

COMMUNICATION

It is impossible to diagnose and treat a sexual problem if neither the gynaecologist nor the patient will mention it. Studies indicate that as many as 80 per cent of non-oncology general gynaecology patients would like the subject to be broached, but the enquiry is made by practitioners in only around one third of cases.²⁵ It may be difficult for a patient to ask about sex, especially as a result of gender, age and cultural barriers.²⁶ It is therefore up to the gynaecologist to make a simple enquiry about sex as part of the routine consultation. Simple questions such as 'Do you have a partner?', 'Are they male or female?' and 'Do you have any problems with sex?' will give the patient 'permission' to discuss the subject if she wishes.

KEY POINTS

- Sexual problems are common and amenable to treatment (options are varied).
- Patients may be reluctant to bring up the topic but good communication with the patient is essential.
- Psychosexual medicine addresses emotional as well as physical aspects of the problem.
- Treatment for vaginismus should be based on available research evidence and expert opinion, committee consensus and public debate: there is no good evidence for surgical intervention.
- Dyspareunia is multifactorial: emotional as well as organic causes must be considered and a multidisciplinary approach is optimal.
- Post-menopausal women worldwide are the population group most likely to suffer from loss of libido, but menopause is not the only cause.
- Orgasmic disorders may result from psychological, cultural and emotional factors.
- Good communication skills and knowledge of conditions, treatment and referral options will enhance practitioner confidence in the field of sexual problems, leading to good patient outcomes.

Urogynaecology and Sexual Health and Wellbeing

This page intentionally left blank

Chapter 94 Assessment of lower urinary tract function

Angie Rantell

MRCOG standards

Theoretical skills

- To understand the indications and limitations of investigations including:
 - microbiological examination of urine
 - quantification of urine loss
 - urodynamic investigations
 - videocystourethrography
 - urethroscopy
 - imaging of upper and lower urinary tract and the pelvic floor.
- To be aware of the national continence policy.

Practical skills

- To be able to take a urogynaecological history.
- To be confident in your ability to perform cystourethroscopy when indicated and correctly interpret your findings.
- To be able to interpret frequency volume charts, uroflowmetry and cystometry traces and residual volume measurement.
- Have observed tertiary assessment of complex lower urinary tract disorders.

INTRODUCTION

Lower urinary tract symptoms (LUTS) are common and can be due to a wide variety of underlying mechanisms. It is therefore important to approach the investigation of such symptoms in a logical and objective manner. An accurate and detailed history and examination provide a framework for diagnosis. However, it is important to recognise that different underlying conditions can cause the same urinary symptoms and that the medical history alone is a poor predictor of pathophysiology.

HISTORY

According to the International Continence Society (ICS)/International Urogynaecology Association (IUGA) (2010), symptoms are any morbid phenomenon or departure from the normal in structure, function or sensation, experienced by the woman and indicative of disease¹ or a health problem that may lead her to seek help from healthcare professionals.¹ Symptoms may be volunteered by the patient or described during the patient interview. In general, LUTS cannot be used to make a definitive diagnosis.

Although urinary symptoms alone do not lead directly to a diagnosis, this should in no way detract from the central importance of the medical history in assessing a woman who presents with urinary problems. Listening to any patient is important, and an appropriate history should be obtained in a targeted and methodical manner. Not only will this enable the woman's own words to be turned into a graduated list of symptoms, but it will also provide information about how the woman's quality of life is affected by the condition. There are a number of ways in which a woman can ameliorate her urinary symptoms through behavioural changes. When taking a history, it is important to elucidate these restrictions and adaptations in order to gain a proper impression of the morbidity of the disorder. For example, by severely restricting fluid intake and never venturing far from a toilet, it is possible that a woman could greatly reduce the number of episodes of leaking. However, these adaptations do not lessen the severity of the disorder, or the need for appropriate treatment that will reduce this social restriction.

Urinary symptoms are valuable in directing further management by guiding the investigator in his or her choice of additional tests. Investigations may produce a diagnosis that is inconsistent with the problems complained of by the woman. It is very important to establish which problems bother her most, so that management can be targeted at these problems. This can only be done by taking the time to listen to the patient's description of her urinary symptoms in her own words. To ensure that a complete picture of

lower urinary tract symptoms is gained, it is often useful to question the patient about individual symptoms. This can take the form of a questionnaire or a series of structured questions, and ensures that important features of the history are not omitted because the woman is unable to describe a symptom or is too embarrassed to mention it.

LUTS can be grouped into three main areas. These reflect disorders of different aspects of bladder and urethral function. That function is to store urine in a low-pressure reservoir until such time as it is socially convenient to void, when the bladder should be efficiently emptied to completion. The first group of symptoms reflects abnormal storage, the second group includes symptoms associated with abnormal voiding or post-micturition symptoms and the final group relates to abnormal bladder sensations (Table 94.1).

Table 94.1 Classification of urinary symptoms into groups

Group	Symptoms
Urinary incontinence symptoms	Stress urinary incontinence
	Urgency urinary incontinence
	Postural urinary incontinence
	Nocturnal enuresis
	Mixed urinary incontinence
	Continuous urinary incontinence
	Insensible urinary incontinence
	Coital incontinence
Bladder storage symptoms	Increased daytime urinary frequency
	Nocturia
	Urgency
	Overactive bladder syndrome
Sensory symptoms	Increased bladder sensation
	Reduced bladder sensation
	Absent bladder sensation
Voiding and post-micturition symptoms	Hesitancy
	Slow stream
	Intermittency
	Straining to void
	Spraying (spitting) of urinary stream
	Feeling of incomplete bladder emptying
	Need to immediately re-void
	Post-micturition leakage
	Position-dependent micturition
	Dysuria
	Urinary retention

URINARY SYMPTOMS

All the following definitions are as defined by ICS/ IUGA (2010).¹

Urinary incontinence symptoms

Urinary incontinence

Urinary incontinence is the complaint of any involuntary leakage of urine. It is important to consider factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage and whether or not the individual seeks or desires help because of urinary incontinence. Urinary leakage may need to be distinguished from sweating or vaginal discharge.

Stress urinary incontinence

Stress urinary incontinence is the complaint of involuntary loss of urine on effort or physical exertion (e.g. sporting activities), or on sneezing or coughing. The leakage of urine is usually in small, discrete amounts, coinciding with the physical activity. It is important to distinguish the subjective symptom of stress incontinence from the objectively demonstrated diagnosis of urodynamic stress incontinence, which can only be made following urodynamic assessment.

Urgency urinary incontinence

Urgency urinary incontinence is the complaint of involuntary loss of urine associated with urgency. It is frequently described as an inability to reach the toilet in time, and women suffering from this symptom often restrict their social activities to ensure that they are constantly near a toilet. Typical triggers for urgency incontinence include hearing running water, opening the front door (latch-key incontinence) and sudden changes in temperature. Urgency incontinence can present in different symptomatic forms e.g. as frequent small losses between micturitions or as a catastrophic leak with complete bladder emptying.

Postural urinary incontinence

The complaint of involuntary loss of urine associated with a change of body position, for example, on standing from a seated or lying position. This is a common symptom, the mechanism of which is not fully understood. It is uncertain whether it should be linked to stress urinary incontinence or urgency urinary incontinence.

Nocturnal enuresis

Enuresis means any involuntary loss of urine. Nocturnal enuresis is the complaint of loss of urine occurring during sleep. It can be primary or secondary. Primary nocturnal enuresis starts in infancy and can persist in adulthood. Secondary nocturnal enuresis occurs when the nocturnal incontinence restarts following a period of night-time continence. It is

important to distinguish enuresis from night-time urgency incontinence, in which the woman is awoken by urgency and leaks before reaching the toilet.

Mixed urinary incontinence

Mixed urinary incontinence is the complaint of involuntary leakage associated with urgency and also with effort or physical exertion or on sneezing or coughing. It is important to differentiate urodynamic mixed incontinence (the presence of urodynamic stress incontinence and detrusor overactivity based on urodynamic observations) from the symptoms of overactive bladder with stress or urgency incontinence.

Continuous urinary incontinence

The complaint of continuous involuntary loss of urine. This is a common symptom, the mechanism of which has not been adequately researched and it is uncertain whether it is linked to stress or urgency incontinence.

Insensible urinary incontinence

The complaint of urinary incontinence where the woman has been unaware of how it occurred. This can often be confused with a watery vaginal discharge or increased sweating in the vulval area.

Coital incontinence

The complaint of involuntary loss of urine with coitus. This can be further divided into incontinence occurring with penetration, with intromission and at orgasm.

Bladder storage symptoms

Increased daytime frequency

Increased daytime frequency is the complaint by the patient that micturition occurs more frequently during waking hours than previously deemed normal by the woman. A normal frequency is around four to seven times per day but this symptom is subjective to the patient and a frequency of six voids a day may be normal for one woman, but bothersome for another.

Nocturia

Nocturia is the complaint of interruption of sleep one or more times because of the need to micturate. Each void is preceded by and followed by sleep. It is important to establish whether the woman wakes due to the desire to pass urine or for other reasons (e.g. insomnia, breathing problems) and is going to the toilet as she is awake.

Urgency

Urgency is the complaint of a sudden compelling desire to pass urine which is difficult to defer. If this desire is not relieved it may result in urgency incontinence.

Overactive bladder syndrome

Overactive bladder syndrome (OAB) can be defined as urinary urgency, usually accompanied by frequency and nocturia, with or without urgency incontinence, in the absence of urinary tract infection or other obvious pathology.

Sensory symptoms

Increased bladder sensation

The complaint that the desire to void during bladder filling occurs earlier or is more persistent than that previously experienced. Suprapubic bladder pain on filling is a significant symptom and, if it persists, it is an indication for a cystoscopy and bladder biopsy. Inflammation of the bladder, such as bladder pain syndrome, stones, bladder tumours, endometriosis and pelvic infections are associated with this symptom.

Decreased bladder sensation

The complaint that the definite desire to void occurs later than that previously experienced despite awareness that the bladder is filling. This can lead to bladder over-distension, if women are not advised to void at regular intervals.

Absent bladder sensation

The complaint of both the absence of the sensation of bladder filling and a definite desire to void. It is usually due to denervation caused by spinal injury or pelvic trauma. It leads to infrequent micturition and a large-capacity bladder and is often associated with overflow incontinence.

Voiding and post-micturition symptoms

Hesitancy

Hesitancy is the term used when an individual describes difficulty or delay in initiating micturition. It is not uncommon for most women to experience this occasionally. Even in those women who complain of persistent hesitancy, only a small minority are found to have outflow obstruction. The other causes of persistent hesitancy include poor detrusor contractility and a lack of coordination in the normal neurological control of micturition (detrusor sphincter dyssynergia).

Slow stream

Slow stream is the complaint that the urinary stream is perceived as slower compared to previous performance or in comparison with others. Urinary flow rate is dependent on the total volume voided, the pressure generated by the detrusor muscle, and outflow resistance. In order to differentiate between these causes, urodynamic investigations need to be undertaken. Bladder outflow obstruction is rare in women who have not undergone previous surgery. Other causes of poor urinary stream include an underlying neurological condition and a pelvic mass.

Intermittency

This is the term used when the individual describes urine flow which stops and starts, on one or more occasions, during micturition.

Straining to void

Straining to void describes the intensive effort needed (by abdominal straining, Valsalva or suprapubic pressure) to either initiate, maintain or improve the urinary stream. Straining to empty the bladder is suggestive of voiding difficulty. Like the other symptoms in this category, it can be the result of a number of different disorders affecting bladder contractility, as well as outflow resistance. Raising intra-abdominal pressure by a Valsalva manoeuvre exerts increased intravesical pressure to aid bladder emptying. Suprapubic pressure may be used to initiate or maintain urine flow. The Credé manoeuvre is used by some spinal cord injury patients. The urinary flow produced is characteristically intermittent and prolonged.

Spraying (splitting) of the urinary stream

The complaint that the urine passage is a spray or split rather than a single discrete stream. For women who describe this symptom it is important to perform a vaginal examination to rule out pelvic organ prolapse and labial hypertrophy.

Feeling of incomplete bladder emptying

Feeling of incomplete emptying is the complaint that the bladder does not feel empty after micturition. It does not always correlate with the presence of a significant urinary residual. Similarly, women with large residuals are often unaware of it. This sensation can also arise as a result of an open bladder neck, abnormal bladder sensation, and a cystocele acting as a urinary sump.

Need to immediately re-void

The complaint that further micturition is necessary soon after passing urine. This is slightly different from double voiding which occurs at the same visit to the toilet to ensure complete bladder emptying.

Post-micturition leakage

The term used when an individual describes the involuntary loss of urine immediately after she has finished passing urine, usually after rising from the toilet in women. This symptom is associated with a collection of fluid left in the bladder after voiding, such as is found with a cystocele. It is also seen where there is a separate reservoir of urine, such as a urethral diverticulum, which fills up during voiding and subsequently drains.

Position-dependent micturition

The complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying e.g. leaning forwards or backwards on the toilet or voiding in

the semi-standing position. This can be particularly common in women with a large cystocele or after incontinence surgery.

Dysuria

Dysuria is described as burning or other discomfort during micturition. It is most frequently associated with a UTI or urethritis, but can also be caused by inflammatory bladder conditions such as bladder pain syndrome. The discomfort can also be external such as vulvar dysuria.

Urinary retention

The inability to pass urine despite persistent effort. This can be a chronic or acute condition and can be due to many reasons such as constipation/faecal impaction, pelvic mass (e.g. large fibroid uterus) or an acontractile or underactive detrusor muscle. It should be managed with either intermittent catheterisation or in the short term an indwelling catheter, and an underlying cause should be sought and treated.

Other urinary symptoms**Haematuria**

The presence of blood in the urine is always significant and should not be ignored. The commonest cause is a UTI but if it persists after appropriate antibiotic treatment it warrants investigation of the upper urinary tract with ultrasound or an intravenous urogram (IVU) and of the lower tract with cystoscopy and urine cytology.

PHYSICAL EXAMINATION

Abdominal and pelvic examinations form an essential part of the assessment of any woman who presents with urinary tract symptoms. Depending upon the medical history, there may be certain additional aspects of the physical examination that require particular attention. If there are any symptoms that point to a possible neurological cause, it is important to perform a screening neurological examination. The patient's mobility and mental state affect her ability to react to her symptoms and it may be appropriate to test these formally as part of the examination, as they will influence management. Similarly, an assessment of motivation and manual dexterity is important in determining the treatment most likely to prove effective.

As part of the gynaecological examination, the condition of the vulval skin should be noted. There may be signs of erythema, oedema and inflammation from chronic exposure to urine (incontinence-associated dermatitis). This can cause pain and discomfort and increase the risk of developing pressure sores. Vulval and vaginal atrophy may also be noted. Because of the close proximity of the lower urinary and genital tracts in the female, the presence of pelvic organ prolapse can have an important bearing on urinary symptoms and their management. This is best assessed in the left lateral position, using a Sims' speculum and asking the patient to

cough and bear down. It is important to note that in order to demonstrate stress incontinence during examination, the bladder needs to be reasonably full, which is often not the case. Speculum examination should be complemented by performing a digital examination with the woman standing, legs abducted and performing a Valsalva manoeuvre. This gives a more accurate impression of the size and origin of any prolapse that is present. The grade of prolapse can be classified subjectively as mild, moderate or severe or graded according to the ICS pelvic organ prolapse quantification (POP-Q) score. While performing a vaginal examination in a woman who complains of leaking urine, it is important to assess the degree of anterior vaginal wall mobility and note any scarring that may be present, as this will influence the most appropriate choice of continence surgery. In addition, the anterior vaginal wall should be examined for any mass that may be a urethral diverticulum or cyst. Pelvic masses, such as ovarian cysts or uterine enlargement, can cause urinary symptoms and need to be excluded by bimanual examination. If this cannot be done with confidence, for example in the obese patient, a transvaginal ultrasound scan should be considered. For some women, a rectal examination may be indicated to further assess pelvic organ prolapse and to rule out faecal impaction.

It is important to ensure that informed consent has been gained and that all examinations are performed in line with RCOG guidelines.²

INVESTIGATIONS

The bladder has been described as an ‘unreliable witness’. Although urinary symptoms provide a framework for diagnosis, they do not on their own allow an accurate impression to be formed of the underlying pathology. This may lead to inappropriate treatment being given and is especially important if surgical management is being considered, as the effects of surgery are irreversible. Investigations can be divided into

Table 94.2 Investigations of lower urinary tract disorders

Basic investigations	Midstream urine specimen
	Frequency–volume chart
	Pad test
Specialist investigations	Uroflowmetry
	Subtracted cystometry
	Videourodynamics
	Ambulatory urodynamics
	Urethral pressure profilometry
	Leak-point pressures
	Neurophysiological studies
	Radiological imaging
	Ultrasonography
Endoscopy	

basic tests, which all gynaecologists should be capable of performing and interpreting, and more complex investigations that require specialist expertise to perform (Table 94.2).

Midstream urine specimen

A midstream urine specimen must be taken for microscopy, culture and sensitivity from all women presenting with urinary symptoms. Bacteriuria is considered to be significant if >10⁵ organisms/mL of urine are reported. It is important to rule out a UTI before going on to perform more invasive investigations. The presenting LUTS can be exacerbated or entirely caused by a bacterial infection, and effective treatment with appropriate antibiotics may be all that is required. If it proves necessary to proceed to urodynamic studies, it is important to ensure that there is not an infection already present, which would lead to unrepresentative findings and the risk of an ascending urinary infection of the upper tracts. In some situations, such as investigating a patient with recurrent UTIs, it is necessary to request cultures for ‘fastidious organisms’ such as *Mycoplasma hominis*, *Ureaplasma urelyticum* and *Chlamydia trachomatis*.

Frequency–volume chart

This is also known as a bladder diary or micturition time chart (Fig. 94.1). The patient is asked to record on a standard time sheet the volume of all fluid consumed and of all urine passed, as well as indicating any episodes of urgency and incontinence. The value of this simple, non-invasive tool is often overlooked, which is unfortunate as, if filled in conscientiously, it provides a good indication of fluid input and a natural volumetric record of bladder function.

An accurately filled-out chart provides invaluable information about the patient’s voiding function in her natural environment and adds objectivity to the medical history (Box 94.1).

Frequency–volume charts can be completed prior to the initial hospital consultation to triage care and determine the urgency and complexity of the condition. They provide a useful form of feedback to the practitioner and the patient so that they can objectively evaluate the effectiveness of any therapy, for example in women undergoing bladder training for

Box 94.1 Information that can be derived from a frequency–volume chart

An idea of the normal functional bladder capacity, which should be fairly consistently around 300–500 mL. Frequent voids of variable amounts throughout the day imply bladder overactivity or behavioural adaptation to symptoms

A volumetric summary of diurnal urinary frequency and nocturia
Quantification of total fluid intake and its distribution throughout the day

A semi-objective evaluation of the severity of urinary incontinence and associated or provocative events

Health Questionnaire (KHQ), International Consultation on Incontinence Questionnaire (ICIQ), Bristol Female Urinary Tract Symptoms (BFLUTS), Overactive Bladder Questionnaire (OAB), Urogenital Distress Inventory (UDI) and Incontinence Impact Questionnaire (IIQ). These are available through the International Consultation on Incontinence website³ and further information is available in the RCOG document on measuring outcomes in gynaecology.⁴

Pad test

The objective demonstration of leaking is essential in reaching a diagnosis of urinary incontinence. A pad test provides a simple, non-invasive, objective method for detecting and quantifying urinary leakage. Various protocols exist for performing a pad test. To obtain a representative result, especially for those who have variable or intermittent urinary incontinence, the test should be as long as possible in circumstances that approximate those of everyday life. It should be conducted in a standardised fashion so that results are comparable and reproducible. This allows the effect of treatment to be objectively assessed in a non-invasive manner.

The ICS has produced guidelines for a standardised 1-hour pad test.⁵ The patient wears a pre-weighed pad or sanitary towel, drinks 500 mL of water and rests for 15 minutes. She then performs 30 minutes of moderate exercise, such as stair climbing and walking. The remaining 15 minutes are spent performing more provocative exercises, including coughing vigorously, bending over, hand washing and running. At the end of 1 hour, the pad is removed and re-weighed. An increase of >2 g is considered a significant loss. A weight gain of >10 g is categorised as severe incontinence.

The standard 1-hour ICS pad test has been shown to have good reproducibility, and reliably differentiates normal from abnormal continence mechanisms. However, the short period of study and lack of a standardised bladder volume before starting the test mean that there is a significant false-negative rate.

Long-term protocols also exist in which the patient is given several pre-weighed pads to be worn at home for periods of 12, 24 or 48 hours. The used pads are collected in sealed plastic bags and reweighed at the end of the specified period to determine total urine loss. The extended pad test is particularly useful to confirm or refute leakage in those patients complaining of incontinence that has not been demonstrated on urodynamic studies.

Recent studies have shown that pad tests bear little relationship to the underlying urodynamic diagnosis but there is a positive relationship with symptom severity.⁵ According to NICE guidelines the pad test should not be used for routine assessment of urinary incontinence.⁶

Methylene blue test

For women who are unable to differentiate urinary leakage from vaginal discharge, or in cases of possible vesico-vaginal or urethra-vaginal fistula, a methylene blue test can be

performed. During this test, a solution of 0.9% saline and methylene blue is instilled into the patient's bladder to half the cystometric capacity. Gauze swabs are then placed into the upper, mid- and lower vagina and a pre-weighed pad into the patient's underwear. They are then asked to mobilise for 1 hour and perform provocative exercises. At the end of the test, patients are asked to void and then each vaginal swab is removed. Staining on the pad represents urinary leakage. Blue on the lower vaginal swab may represent urethro-vaginal reflux or contamination from the test. Blue on the mid-vaginal swab may be indicative of a urethro-vaginal fistula and on the upper vaginal swab could suggest a vesico-vaginal fistula. A heavy vaginal discharge can also be assessed from this test. During the instillation of methylene blue into the bladder, it is important to ensure that there is no contamination of dye on to the labia or vagina as this will give false-positive results from the test. Fig. 94.2 demonstrates the placement of swabs during the test.

Uroflowmetry

Uroflowmetry is the simplest and one of the most useful investigations in the assessment of voiding dysfunction. It consists simply of measuring urinary flow over time and allows a rapid and non-invasive analysis of the normality or otherwise of flow rate. When combined with the measurement of residual urine volume by ultrasound or catheterisation, it provides information on the efficiency of micturition in emptying the bladder. One or more symptoms of voiding disorder are commonly described in women complaining of urinary tract disorders, and it is important to diagnose or eliminate voiding difficulty. This is particularly so when treatment is being considered for incontinence. Both surgical treatment of urodynamic stress incontinence and drug treatment for detrusor overactivity have the potential to cause voiding difficulty. Therefore pre-treatment uroflowmetry and the measurement of residual urine are essential.

Indications

Uroflowmetry should be regarded as a screening test for voiding difficulty in all women with symptoms of lower urinary tract dysfunction. It is important to appreciate that urinary

Fig. 94.2 Diagrammatic representation of methylene blue test

flow is dependent upon a number of factors, including detrusor contractility, neurological coordination of sphincter relaxation, and outflow patency. Uroflowmetry on its own cannot successfully distinguish between the causes of voiding dysfunction.

Methods

There are several different physical principles that can be utilised to provide an accurate assessment of flow. The following three methods are in common use.

- 1 *Gravimetric method.* The rate of change of the weight of the voided urine in the collecting jug is converted into a flow rate (Fig. 94.3).
- 2 *Rotating disc method.* A known amount of power is required to keep a rotating disc spinning at a constant rate. Voided fluid is directed onto the disc, increasing its inertia. The flow rate is proportional to the amount of extra power that is required to keep the disc spinning at a constant rate.
- 3 *Capacitance dipstick.* A metal capacitor strip is attached to the side of the flowmeter. As urine accumulates in the container, the electrical capacitance of the dipstick changes and from this the rate of flow can be calculated. It should be noted that the environment in which the woman performs the flow rate recording will have a considerable influence on the results. It is important that every effort is made to make the patient feel as comfortable and relaxed as possible, and that privacy and dignity are maintained at all times.

Interpretation

The definitions for urine flow rate measurements have been standardized by the ICS and should be expressed in millilitres per second (Fig. 94.4).

Fig. 94.3 (a) Gravimetric flow meter

The two most useful parameters are the maximum flow rate and the voided volume. The maximum flow rate is partially dependent on the voided volume, as this determines how distended the bladder muscle fibres are. For this reason, small voided volumes of less than 150 mL are insufficient to obtain an accurate impression of flow, and the test needs to be repeated.

The third major factor to consider when interpreting flow rate is the pattern of flow, in particular whether flow is continuous or intermittent. A normal flow curve is bell shaped and characterised by a rapid rise to maximal flow. A prolonged, intermittent flow curve is suggestive of voiding dysfunction, with the patient using abdominal straining to achieve bladder emptying. The results must always be interpreted within the context of the clinical situation, and the limitations of the study should be recognised. These include the reliability of the apparatus, and the ability of the staff interpreting the trace in recognising artefact. More information concerning the cause of voiding difficulty is provided by the addition of simultaneous pressure measurements as part of cystometry (pressure flow studies).

Factors influencing urine flow rate

The peak flow rate (PFR) is highly dependent on voided volume, as has already been discussed. Most commonly, a minimum accepted PFR of 15 mL/s is used. Urine flow rates are higher in women than in men for a comparable voided volume. Age and parity have not been shown to have a significant effect on urine flow rates in asymptomatic women. As might be expected, there is a progressive decline in flow rate with increasing grades of pelvic floor prolapse, especially uterine prolapse and cystourethrocele.

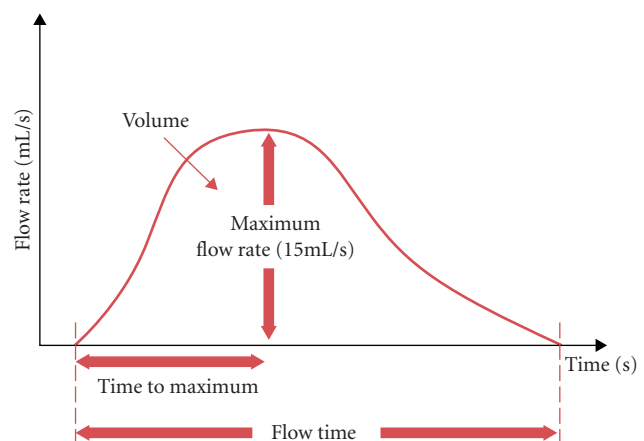

Fig. 94.4 Diagrammatic representation of urinary flow rate with standardised ICS terminology. Voided volume: total volume expelled via the urethra; the area beneath the flow-time curve. Maximum flow rate: maximum measured value of the flow rate. Flow time: the time over which measurable flow actually occurs. If flow is intermittent, the time intervals between flow episodes are not included. Average flow rate: volume voided divided by the flow time. Time to maximum flow: elapsed time from onset of flow to maximum flow

Altered detrusor function influences flow rate by determining the contractile force with which urine is expelled. In addition, bladder neck and urethral anatomy influence urine flow by affecting outflow resistance. To distinguish between these two major causes of voiding dysfunction, more complex urodynamic tests are required in which simultaneous pressure/flow measurements are taken.

Subtracted cystometry

Cystometry is the method by which the pressure–volume relationship of the bladder is assessed during filling and voiding. It involves the simultaneous measurement of intravesical and intra-abdominal pressures. Electronic subtraction of the intra-abdominal pressure from the intravesical pressure enables the detrusor pressure to be calculated and compared with changes in bladder volume and flow rate. Cystometry aims to characterise detrusor and urethral function during the filling and voiding phases (Table 94.3). It can be useful, when learning to interpret cystometrograms, to break down the functions of the detrusor and urethra by phases of the micturition cycle.

Indications

When access to investigations is limited, it is reasonable to manage patients with clear-cut symptoms empirically with conservative treatment, provided that cystometry is subsequently performed in those in whom empirical treatment fails. Certainly surgical treatments should never be considered without urodynamic assessment, as the inappropriate selection of surgery can have disastrous and largely irreversible consequences for the patient. If a policy of urodynamic screening on all women with lower urinary tract symptoms is not practised, selective testing should certainly be considered in the investigation of:

- symptoms that have failed to respond to empirical conservative measures;
- a patient being considered for any form of incontinence surgery if there is a clinical suspicion of detrusor overactivity;

- voiding difficulties;
- mixed symptoms e.g. frequency, urgency and stress incontinence;
- previous unsuccessful incontinence surgery;
- suspected neuropathic bladder disorders.

The last two complex groups are better investigated by videourodynamics, as this yields valuable information about the anatomical structure of the urinary tract, as well as the dynamic function.

A good urodynamic practice comprises three main elements:⁷

- 1 A clear indication for and appropriate selection of relevant measurements and procedures;
- 2 Precise measurement with data quality control and complete documentation;
- 3 Accurate analysis and critical reporting of results.

There is a document available detailing minimum standards for urodynamic practice in the UK.⁸

Methods

It is important that cystometric diagnoses are related to the patient's symptoms and physical findings at the time of the investigation. The aim is to reproduce the presenting symptoms that cause the woman concern, so that a diagnosis can be made and appropriate treatment planned. Terminology and standards are defined by ICS/IUGA.¹ This allows cystometric data to be compared among different centres and used in research trials.

Modern multichannel cystometry requires two pressure transducers (to measure the abdominal and intravesical pressures), an electronic subtraction unit (to derive the detrusor pressure), an amplifying unit and a display or printout (Fig. 94.5). Three types of pressure transducers are available: a fluid-filled or air-charged pressure line inserted into the bladder or rectum and connected to an external transducer, and a solid microtip pressure transducer placed directly inside the body. The difference between the two is largely cost and convenience of use. Fluid-filled lines are generally disposable, whereas microtip pressure transducers are reusable and need sterilisation between patients. Local infection control policies

Table 94.3 Cystometry

Phases of cycle	Urethra	Detrusor
Filling	Should remain closed and competent but can: be incompetent due to physical stress, but without an associated rise in detrusor pressure (stress incontinence); be incompetent as a direct result of an involuntary rise in detrusor pressure (detrusor overactivity)	Should remain relaxed/stable throughout filling but can: show abnormal involuntary contractions (detrusor overactivity); show a gradual rise in pressure with filling (low compliance)
Voiding	Should be appropriately relaxed but can: be constricted, leading to outflow obstruction (obstructed cause)	Should contract efficiently under voluntary instruction but can: be under-active or acontractile (possible neuropathic cause); show high-pressure contractions (if overactive or needing to overcome an outflow obstruction)

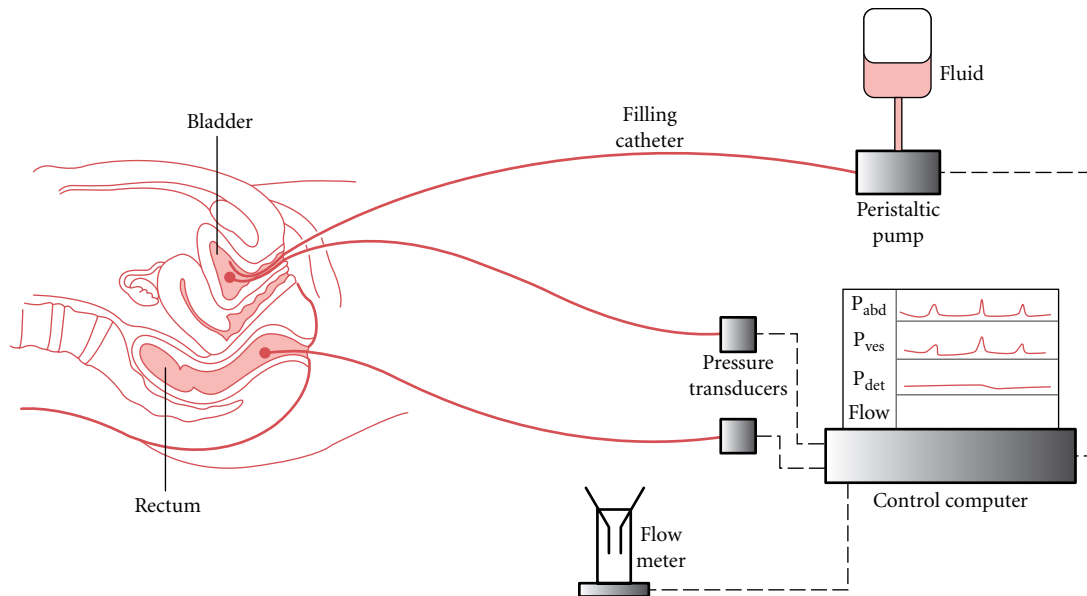

Fig. 94.5 Schematic diagram showing the position of the pressure catheters and the measurements recorded during subtracted cystometry. The following measurements are made:

- Free-flow rate and residual urine are measured at the start of the test by means of a flow meter and subsequent urethral catheterisation.
- Intra-abdominal pressure (P_{abd}) is measured with the rectal pressure catheter. Alternatively, this could be measured with a pressure catheter in the vagina or colostomy stoma.
- Intravesical pressure (P_{ves}) is measured with a pressure catheter in the bladder via the urethra or suprapubic route.
- Detrusor pressure (P_{det}) is derived from continuous electronic subtraction of intra-abdominal from intravesical pressure ($P_{det} = P_{ves} - P_{abd}$) and displayed concomitantly.
- Filling volume is recorded by a peristaltic pump connected to the system or calculated manually.
- Flow rate is measured by a flow meter allowing simultaneous pressure-flow analysis.
- During filling, the patient is asked to indicate her first FDV and when she experiences an SDV. This is taken as bladder capacity.
- In addition, it is important to explain to the patient the relevance of expressing her sensations (such as urgency) during the test so that the cystometry trace can be annotated. This helps to interpret the findings

should be adhered to. All pressure measurements are made in centimetres of water (cmH_2O).

Prior to inserting the pressure catheters, the patient is asked to void on the flow meter to allow the measurement of a free flow rate. The presence of any residual urine on subsequent urethral catheterisation is noted. The pressure catheters are then inserted and calibrated. Quality control is an essential part of performing cystometry if valid conclusions are to be drawn from the investigation. The system is checked for adequate subtraction by asking the patient to cough at regular intervals. An equal pressure rise should be observed in both the abdominal and intravesical pressure traces, which should cancel out to leave the detrusor pressure unchanged. Once the integrity of the pressure readings has been checked and the system zeroed to atmospheric pressure, filling can commence.

0.9% saline at room temperature is instilled into the bladder at a predetermined rate under the control of a peristaltic pump. This is usually in the range of 25–100 mL/min, depending on the indication for cystometry. This rate should be reduced to a slower filling rate closer to the normal physiological range when assessing patients with neuropathic bladders. During filling, the patient is asked to indicate her first

desire to void (FDV) and when she experiences an uncontrollable strong desire to void (SDV). Any rise in detrusor pressure is noted and whether this is associated with the sensation of urgency or leaking. Filling is discontinued once there is a sustained SDV. This volume is taken as cystometric bladder capacity and is usually in the range 400–600 mL. Filling can occur when the patient is in the supine, sitting or standing position.

At the end of filling, the patient is asked to stand, to assess whether there is a postural rise in detrusor pressure, and to cough several times. More strenuous stimuli, such as star jumps, can be performed if leakage is not demonstrated by coughing in women who complain of this symptom in their history. The presence of any leakage is noted and whether a stable trace or an associated rise in detrusor pressure accompanies this. Provocative tests for detrusor overactivity are performed at this stage and the patient may be asked to listen to running water, wash her hands or heel bounce to try to induce leakage. Finally, the patient transfers back on to the flow meter, with the pressure catheters still *in situ*. She is instructed to void and the detrusor pressure and urine flow rate are measured simultaneously to provide a simultaneous pressure/flow analysis.

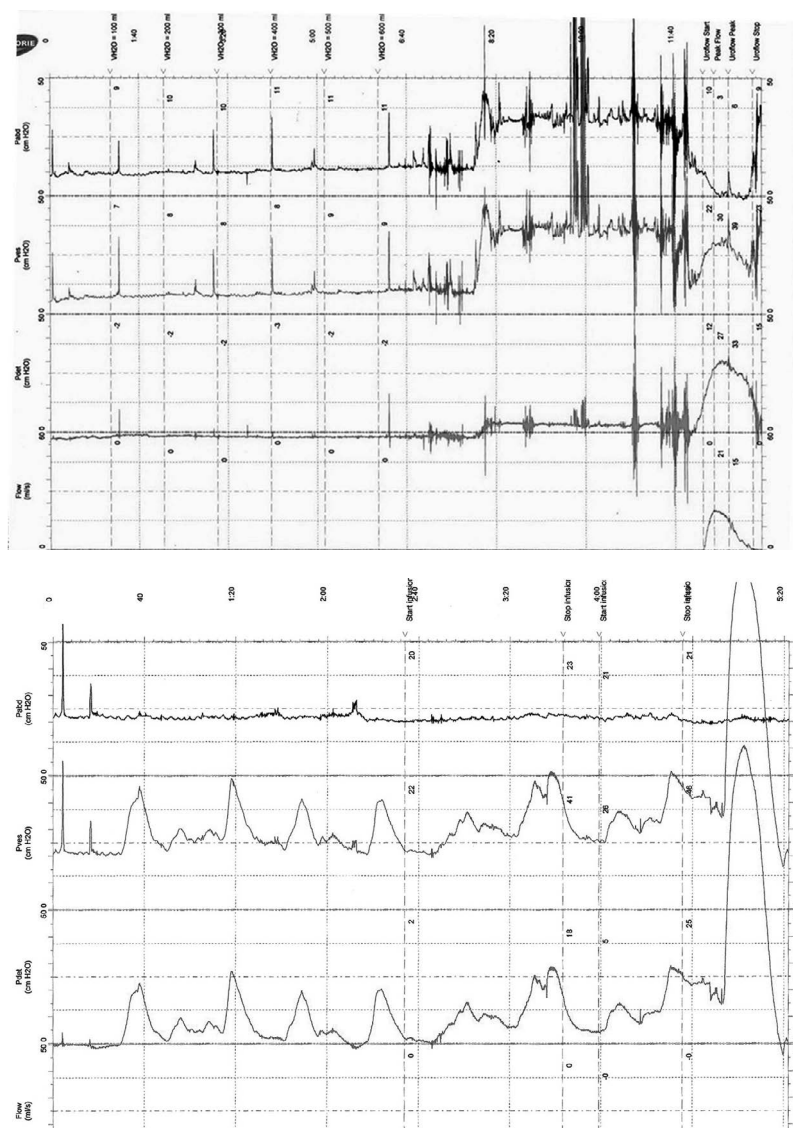

Fig. 94.6 Part of a cystometrogram trace showing detrusor overactivity. Note that intra-abdominal pressure is stable while the intravesical pressure line shows an involuntary detrusor contraction

Interpretation

As has been previously discussed, it is vital that the cystometric findings are evaluated in the light of the woman's symptomatology. The following are normal cystometric parameters:

- Filling cystometry:
 - residual urine <50 mL;
 - capacity (taken as SDV) >400 mL;
 - absence of uninhibited detrusor contractions during filling;
 - negligible rise in detrusor pressure on filling; this should be <15 cm H₂O for a filling volume of 500 mL.
- Voiding cystometry:
 - no leakage on coughing or performing exercise;
 - no provoked detrusor contractions as a result of precipitating factors, such as postural changes, hand washing or coughing;

- a maximum voiding detrusor pressure of <50 cm H₂O, with a maximum flow rate >15 mL/s for a volume voided of >150 mL.

By considering urethral and detrusor function during the filling and voiding phases of cystometry, abnormalities can be systematically classified (Fig. 94.6). The presence of involuntary detrusor contractions, during filling or on provocation, that the patient cannot suppress is diagnostic of detrusor overactivity. If there is a gradual rise in detrusor pressure during filling to >15 cm H₂O, but without phasic contractions, this is termed 'low compliance'. This can be artefactual owing to superphysiological or fast bladder filling. If there is a neurological condition present, such as multiple sclerosis, this is often accompanied by marked low compliance. If leakage occurs on coughing, with an associated rise in intra-abdominal pressure but in the absence of abnormal detrusor activity, urodynamic stress incontinence is diagnosed.

Fig. 94.7 Examples of structural and functional abnormalities seen by fluoroscopy. a) urethro-vaginal reflux, b) vesico-uretic reflux into a transplanted kidney, c) urethral diverticulum, d) multiple bladder diverticulae, trabeculation and right sided vesico-ureteric reflux, suggestive of a neurogenic bladder

Videourodynamics

Videourodynamics offers the facility to simultaneously study the anatomical structure and the pressure/flow characteristics of the lower urinary tract. This is achieved by using contrast medium rather than saline to fill the bladder during cystometry, and radiologically screening the bladder and urethra intermittently throughout the procedure. The combination of these approaches results in the videocystourethrogram (VCU), which is regarded as the 'gold standard' for assessing lower urinary tract disorders. Most patients can be adequately investigated using simpler techniques, but VCU does offer several advantages over cystometry alone for the investigation of complex cases in tertiary centres. The addition of radiological

screening provides valuable additional information relating to bladder morphology, the degree of bladder base support and function of the bladder neck during coughing, the presence of vesico-ureteric reflux (which may be present in up to 7 per cent of incontinent patients) and the site of outflow obstruction (Fig. 94.7).

Clinical situations in which VCU offers significant advantages over simple cystometry include the following:

- Women in whom previous incontinence surgery has failed, as the position and mobility of the bladder neck can be assessed at rest and on straining. When combined with urethral pressure profilometry (UPP), an experienced investigator can infer information about the relative

contributions of bladder neck hypermobility and sphincter deficiency as the causes of continued stress incontinence.

- Neurological lower urinary tract dysfunction. VCU is required to adequately assess the complex dysfunction seen in neuropathic bladders and to provide a framework for treatment. It is important to look for the presence of vesico-ureteric reflux in this group of women.
- Assessment of voiding difficulties or symptoms suggestive of an anatomical lesion, such as a urethral diverticulum.

Technique

The technique is identical to that used for routine subtracted cystometry, except that the investigation is performed in a room set up for radiological X-ray screening. Uroflowmetry, measurement of urinary residual and the insertion of pressure catheters are the same as for subtracted cystometry. Radio-opaque contrast is used to fill the bladder. X-ray screening takes place if the woman complains of leaking during filling and then during provocative coughing. This allows assessment of the degree of bladder neck opening, the severity of leakage and the extent of bladder-base descent. The presence of vesico-ureteric reflux, bladder trabeculation and diverticulae is noted. The woman then commences voiding and, once normal flow has been established, she is asked to interrupt it. This should result in cessation of flow and urine being 'milked back' from the proximal urethra into the bladder. Finally, the presence of a post-void residual can be determined.

Ambulatory urodynamic monitoring

Ambulatory urodynamic monitoring (AUM) is of particular use in the investigation of detrusor overactivity, where standard laboratory urodynamics have failed to replicate the symptoms that are experienced by the patient in her normal environment. Although laboratory urodynamics forms the standard method of objectively investigating bladder and urethral function, it is by design unphysiological. This is because relatively fast retrograde filling of the bladder is employed rather than slower filling from the kidneys via the ureters. In addition, the environment in which the test is performed and the focus of attention directed towards the subject are far removed from her everyday activities. In an attempt to study bladder function in circumstances that more closely approximate those in which the subject normally finds herself, ambulatory urodynamics has been developed.

AUM uses natural anterograde bladder filling and allows the patient to reproduce her normal daily activities, including those that commonly provoke symptoms e.g. exercise.

Technique

Ambulatory systems have three main components:

- 1 Pressure transducers are placed in the bladder and rectum as in laboratory urodynamics.
- 2 A portable recording system allows several channels of data to be recorded simultaneously. This should include

an event marker, to enable the patient to mark particular activities on the trace, and a method quantifying urine leakage, such as an electronic pad.

- 3 An analysing system is needed to retrieve and process the data. All traces are interpreted with the patient present so that more information can be obtained about particular events.

The ICS has standardised the terminology and methodology of AUM,⁹ allowing the comparison of results from different centres.

The investigation is usually carried out over a 4-hour time period. Once the transducers have been inserted into the bladder and rectum and the system has been calibrated, the patient is encouraged to drink normally and perform normal activities. During the investigation, the patient is asked to keep a careful record of symptoms and events, and the position of the catheters is checked periodically. At the conclusion of the test, provocative manoeuvres are carried out with a full bladder prior to removing the transducers and analysing the results. Significantly more detrusor overactivity is diagnosed using AUM than with conventional laboratory urodynamics. However, it is uncertain whether this is due to a higher sensitivity or whether AUM simply has a high false-positive rate for diagnosing detrusor overactivity. Ambulatory urodynamics is subject to significant artefact, but this can be greatly reduced by rigorous methodology.

Urethral pressure profilometry

The relationship between intravesical pressure and urethral pressure is the key to maintaining continence. Normally, urethral pressure exceeds intravesical pressure at all times, except during voluntary relaxation of the bladder neck leading to micturition. UPP can assess this ability of the urethra to exert a positive closure pressure in order to prevent leakage. This is done by simultaneously measuring the intravesical and urethral pressures using a catheter with two pressure transducers set 6 cm apart.

Technique

The pressure catheter is inserted into the bladder with the distal pressure transducer inside the bladder and the proximal transducer near the bladder neck. It is then withdrawn at a standard speed by a mechanical retractor, allowing pressure measurements to be made along the functional length of the urethra to give a graph of pressure over distance travelled along the urethra. The ICS has also standardised the terminology and methodology of urethral pressure measurement.¹⁰ Two types of UPP may be measured:

- 1 resting UPP, with the patient at rest in a supine position;
- 2 stress UPP, with the patient coughing throughout the test to see if the intravesical pressure exceeds the urethral pressure during increases in intra-abdominal pressure – this would result in a negative closure pressure and leakage of urine *per urethram*.

Although the closure pressures in women with urodynamic stress incontinence are generally less than in their dry

counterparts, this test is not sufficiently discriminatory to be used in the diagnosis of urodynamic stress incontinence. However, it is often useful in understanding the pathophysiology of urodynamic stress incontinence and in planning the most appropriate intervention, especially in women who have had previous failed surgery for incontinence. A low maximum urethral closure pressure correlates with a poor outcome for incontinence surgery. The other group of patients in whom UPP can be useful is women with voiding difficulties. An increased maximum urethral closure pressure indicates outflow obstruction, sometimes as the result of previous surgery or a stricture. In these women, urethral dilatation or urethrotomy may be appropriate.

NEUROPHYSIOLOGICAL INVESTIGATION

The normal coordinated functions of the bladder and urethra are controlled by a complex set of central and peripheral neurological reflexes. In an effort to understand these mechanisms better and to evaluate patients with lower urinary tract dysfunction, a whole range of neurophysiological tests have evolved. These techniques stimulate and record activity at different levels of the neurological pathways that control bladder and urethral function. The most commonly employed techniques in clinical neurophysiological testing are electromyography (EMG), in which recordings of bioelectrical potentials in muscles are studied, and nerve conduction studies. The latter examine the capacity of a nerve to transmit a test electrical stimulus along its length.

Electromyography

Electromyography is the study of bioelectrical potentials generated by the depolarisation of muscle fibres. It is predominantly used to study striated muscle, in particular the urethral sphincter and the pelvic floor muscles. The functional unit studied is called a motor unit and consists of the muscle fibres innervated by branches from the motor neuron of a single anterior horn cell. The potential it generates during contraction is called the motor nerve unit potential (MUP). This can be measured by means of surface electrodes or various types of needle electrode. By measuring the amplitude, duration and number of phases of the action potential, the extent of neurological denervation and subsequent re-innervation in the target muscle can be inferred. This is a highly specialist investigation and a skilled investigator is required to interpret the results. While EMG studies have greatly improved our understanding of pelvic floor, lower urinary tract and bowel function in health and disease, the results to date have had little effect on clinical management. The main clinical indication for EMG studies is as an adjunct to videourodynamics to distinguish between striated and smooth muscle in neuropathic urethral obstruction.

Nerve conduction studies

A number of different techniques have been employed to study the conduction of central and peripheral nerve pathways to the bladder and urethra. These examine the capacity of a nerve to transmit a test electrical signal along its length. If the pathway being tested is damaged, there will be a delay in conduction time and thus a prolonged latency between the stimulus and the muscular response. In addition, the amplitude of the muscle response will be reduced. A wide range of neurological pathways have been investigated using variations of this technique, including the sacral reflex arc, pudendal terminal motor latencies, transcutaneous spinal stimulation and cortical evoked responses. As with EMG studies, these investigations have improved our understanding of the neurophysiological control of the normal and dysfunctional bladder, but are of limited use in the clinical investigation of most patients.

RADIOLOGICAL IMAGING

Radiological imaging of the urinary tract is not justified as a routine investigation in all women presenting with urinary symptoms, but instead should be targeted at specific indications. The diagnostic procedures available include plain abdominal films, intravenous urography and various contrast studies of the lower urinary tracts.

Plain X-ray

A plain abdominal film may be a useful screening investigation for a variety of conditions that affect lower urinary tract function. Foreign bodies and bladder calculi causing outflow obstruction can be diagnosed. Bladder wall calcification is rare in the UK but is seen more frequently worldwide as a result of tuberculosis and schistosomiasis. Probably the most useful indication for plain radiographic films is to investigate spinal abnormalities, such as spina bifida or sacral agenesis, as a cause of neuropathic bladder disorder.

Intravenous urography

This is not a routine investigation of lower urinary tract dysfunction. It provides anatomical and some functional information on the kidneys, ureters and bladder. IVU is indicated in women with neuropathic bladders, suspected congenital or acquired abnormalities (such as uterovaginal fistulae), haematuria and suspected ureteric compromise secondary to the effects of a pelvic mass (e.g. large fibroids or a procidentia) or trauma. A CT urogram or MR urinary tract can often give the same information and discussion with the local radiologist regarding the preferred examination method is advised.

Micturating cystourethrography

This investigation requires instillation of radio-opaque contrast medium into the bladder and then screening with fluoroscopy as the patient voids. It is similar to the X-ray screening performed as part of a videocystometrogram, but without any pressure–flow information. Its main value is to demonstrate bladder and urethral fistulae, vesico-ureteric reflux and anatomical abnormalities of the lower tracts, such as urethral diverticulae.

ULTRASONOGRAPHY

Ultrasound provides a relatively non-invasive method of imaging the urinary tract in real time, without exposing the patient to ionising radiation. There is an ever-increasing range of applications for ultrasound imaging in the investigation of urinary tract dysfunction. As well as the lack of radiation exposure, ultrasound has the advantage of having significantly lower operating costs than comparable radiological investigation. The main disadvantage is that ultrasound waves do not penetrate as far and so the probe has to be held close to the target. The field of view is more limited than X-rays, so that only one part of the urinary tract can be viewed at a time. Ultrasound imaging depends on the different echogenicity of tissues to form a picture. It is especially well suited for visualizing fluid-filled and air-filled cystic structures.

Post-micturition residual volume

Ultrasonography is widely used to estimate residual urine volumes. This obviates the need for urethral catheterisation, with its concomitant risk of infection. This is particularly useful in the assessment of women with voiding difficulties. It can also be used following post-operative catheter removal or in women in labour as an alternative to repeated catheterisation to ensure that the bladder is not allowed to overdistend. There are many methods of estimating bladder volume from real-time scanning; however, most portable bladder scanners presently available automatically calculate the volume of urine in the bladder.

Assessing lower urinary tract structure

Ultrasound offers an inexpensive, non-invasive method of assessing the structure of the lower urinary tract and is advocated as an alternative to cystourethroscopy for many indications. The arguments in favour of each technique are similar to those proposed for the use of transvaginal ultrasonography and hysteroscopy for the assessment of the reproductive organs. The sensitivity of ultrasonography and endoscopy in different disorders varies, largely according to the experience of the operator and the quality of the equipment used. The majority of bladder tumours are exophytic and papillary in

Fig. 94.8 Rigid cystometry with multiple bladder biopsies being performed under general anaesthesia in a patient with a history of recurrent UTIs

shape and are well visualised by ultrasound. Similarly, bladder diverticulae and calculi are easily detected.

Transabdominal ultrasound does not provide satisfactory imaging of the bladder neck and urethra, owing to their position behind the symphysis pubis. These are visualised better with the use of a transvaginal, transrectal or perineal probe. Ultrasonography is a very sensitive method of detecting urethral diverticulae and their relation to the urethral sphincter. Differentiation from para-urethral cysts may be difficult if a connection cannot be visualised. Three dimensional ultrasound has been used as a research tool to determine urethral sphincter volumes as part of the assessment of women presenting with incontinence.

Another technique is the measurement of bladder wall thickness. This is performed using the transvaginal approach when the bladder is empty and offers a reproducible, sensitive method of screening for detrusor overactivity.⁸

IMAGING

CT and MRI can provide confirmation of alternative pelvic pathology, by means of cross-sectional imaging e.g. urethral diverticulae. It can be used to characterise the extent and anatomical contents of a pelvic organ prolapse, especially in the standing position with MRI.¹¹

CYSTOURETHROSCOPY

Cystourethroscopy enables the inside of the bladder and urethra to be visualised (Fig. 94.8). It is an invasive but relatively low-risk procedure that can be undertaken for women of any age as a day case. The choice between a rigid or flexible cystoscopy and the anaesthetic used will depend on the individual

case and the preferences of the operator. Modern cystoscopes consist of at least three elements.

- 1 An optical system for transmitting the image to a video monitor with maximum clarity and resolution. In a rigid endoscope this is performed by a rod–lens system, and in a flexible endoscope by a bundle of optical fibres.
- 2 Another system of optical fibres is needed to transmit light into the bladder.
- 3 An irrigating channel is needed to flush away blood and debris, and dilate the bladder under direct vision.

Most operating cystoscopes also have an outflow channel to carry debris away. Cystourethroscopy is an invaluable tool in investigating the lower urinary tract, as it provides detailed anatomical information. It is not usually performed as part of the routine investigation of women with incontinence, but there are many indications for which direct visual inspection and targeted biopsies of the bladder and urethra are important in establishing a diagnosis.

Indications

Cystourethroscopy is indicated:

- to investigate haematuria not related to UTI;
- when a reduced bladder capacity or painful filling is found at cystometry;
- to exclude bladder tumours and stones as a cause of recurrent or persistent UTI;
- if a lower urinary tract fistula is suspected;
- if interstitial cystitis is suspected;
- following failed incontinence surgery when the patient complains of voiding difficulty, overactive symptoms or persistent incontinence;
- to provide certain treatments e.g. intradetrusor injections of botulinum toxin A.

Technique

The majority of cystourethroscopies undertaken by gynaecologists are performed under a general anaesthetic with a rigid scope. The advantage of a rigid cystoscope is that biopsies and other manipulative procedures are relatively easily carried out through the large instrument channel. Flexible cystoscopes offer the advantage of use in the outpatient setting, with topical anaesthetic only, and the view is often better than that of a

KEY POINTS

- Investigations of lower urinary tract dysfunction vary from simple tests that can easily be performed in an office setting to complex investigations available in tertiary centres.
- As the correlation between lower urinary tract symptoms and underlying diagnosis is poor, early investigation is desirable so that a firm diagnosis can be established and rational treatment instigated.

- Thorough assessment, including urodynamics, is mandatory prior to considering surgical treatment.
- The choice of investigations performed should be individualised according to the patient's presenting symptoms and past medical history.

rigid scope. However, the instrumentation that can be used is slightly more limited. This and the fact that only a topical anaesthetic is used can make it difficult to take histologically valid biopsy specimens.

Rigid cystoscopes are available with several viewing angles, including 0° (straight), 12°, 30° and 70°. Angled telescopes have a field marker, which appears as a notch at the edge of the field of view and helps to maintain orientation. The choice of telescope depends on the procedure being performed and the operator's preference. The cystoscope is placed into the urethral meatus and advanced towards the bladder under direct vision with the irrigation fluid running. Sterile saline is usually used as the irrigating fluid unless diathermy is planned, in which case a non-ionic solution, such as glycine, is required. Once the bladder is sufficiently distended to allow inspection of the folds of mucosa (200–400 mL), the irrigation can be switched off. The careful inspection of the urethra is a vital part of the investigation and should not be neglected. This is most commonly done while withdrawing the instrument at the end of the procedure. The trigone and the position of the ureteric orifices should be noted. Next, the mucosa is examined for colour, vascularity, trabeculation and abnormal lesions. Orientation is easily established by identifying the air bubble at the dome of the bladder. This serves as a landmark during inspection of the bladder mucosa, which is conventionally performed by going around clockwise in a series of 12 sweeps, coming back to the bubble after each one. Visualisation of the bladder base can be difficult if a large cystocele is present. This is made easier by inserting a finger in the vagina to correct the prolapse.

NATIONAL POLICIES AND GUIDANCE

In 2013 NICE published guidelines on the management of urinary incontinence in women.⁶ It provided recommendations and practice algorithms on assessment and investigations of LUTS. The Fifth International Consultation on Incontinence (Paris 2013) has recently published recommendations and guidance on the assessment of urinary incontinence.¹²

ACKNOWLEDGEMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of James Balmforth to the chapter on this topic in the previous editions of the book.

Chapter 95 Urinary Incontinence

Dudley Robinson and Linda Cardozo

MRCOG standards

The established standards relevant for this topic are:

Theoretical skills

- Have good knowledge of normal pelvic anatomy, physiology and pathophysiology in relation to the functions of the pelvic floor.
- Understand the principles of all types of non-surgical and surgical interventions.

Practical skills

- Be proficient in history taking, general and pelvic examination.
- Be able to perform the more common and basic pelvic floor surgical procedures.
- Be able to undertake non-surgical management of bladder problems, including voiding disorder and urgency.
- Be able to undertake surgery for stress incontinence under supervision.

INTRODUCTION

Urinary incontinence is defined by the International Continence Society as ‘the complaint of any involuntary leakage of urine’.¹ Whilst not life threatening it is known to be a cause of considerable morbidity and has a considerable impact on quality of life.²

PREVALENCE

Urinary incontinence is known to be a prevalent and often under-reported condition. A large epidemiological study of urinary incontinence has been reported in 27,936 women from Norway.³ Overall 25 per cent of women reported urinary incontinence of whom 7 per cent felt it to be significant

and the prevalence of incontinence was found to increase with age. When considering the type of incontinence 50 per cent of women complained of stress, 11 per cent urge and 36 per cent mixed incontinence. Further analysis has also investigated the effect of age and parity. The prevalence of urinary incontinence among nulliparous women ranged from 8 per cent to 32 per cent and increased with age. In general parity was associated with incontinence and the first delivery was the most significant. When considering stress incontinence in the age group 20–34 years the relative risk was 2.7 (95% CI 2.0–3.5) for primiparous women and 4.0 (95% CI 2.5–6.4) for multiparous women. There was a similar association for mixed incontinence although not for urge incontinence.⁴

Evidence would suggest that incontinence is often under-reported. In a large study of patients assessed after tertiary referral 60 per cent of women were found to have delayed seeking treatment for more than one year from the time their symptoms became severe. Of these women 50 per cent claimed that this was because they were too embarrassed to discuss the problem with their doctor, and 17 per cent said that they thought the problem was normal for their age.⁵

EPIDEMIOLOGY

Age

The incidence of urinary incontinence increases with increasing age. Elderly women have been found to have a reduced flow rate, increased urinary residuals, higher filling pressures, reduced bladder capacity and lower maximum voiding pressures. In a large study of 842 women aged 17–64 years the prevalence rates of urinary incontinence increased progressively over seven birth cohorts (1900–1940) from 12 per cent to 25 per cent. These findings agree with those of a large telephone survey in the USA which reported a prevalence of urge incontinence of 5 per cent in the 18–44 age group rising to 19 per cent in women over 65 years of age.⁶ Conversely, as mobility and physical exercise decrease with advancing age so does the prevalence of stress urinary incontinence.

Race

Several studies have been performed examining the impact of racial differences on the prevalence of urinary incontinence in women. In general there is evidence that there is a lower incidence of both urinary incontinence and urogenital prolapse in black women and North American studies have found a larger proportion of white than African-American women reported symptoms of stress incontinence (31 per cent vs 7 per cent) and a larger proportion were found to have demonstrable stress incontinence on objective assessment (61 per cent vs 27 per cent). Overall white women had a prevalence of urodynamic stress incontinence 2.3 times higher than African-American women.⁷ Whilst most studies confirm these findings there is little evidence regarding the prevalence of urge incontinence or mixed incontinence.

Pregnancy

Pregnancy is responsible for marked changes in the urinary tract and consequently lower urinary tract symptoms are more common and many are simply a reflection of normal physiological change. Urine production increases in pregnancy due to increasing cardiac output and a 25 per cent increase in renal perfusion and glomerular filtration rate.

Frequency of micturition is one of the earliest symptoms of pregnancy affecting approximately 60 per cent in the first trimester and middle trimester and 81 per cent in the final trimester. Nocturia is also a common symptom although it was only thought to be a nuisance in 4 per cent of cases. Overall frequency occurs in over 90 per cent of women in pregnancy.

Urgency and urge incontinence have also been shown to increase in pregnancy. Urge incontinence has been shown to have a peak incidence of 19 per cent in multiparous women whilst other authors have reported a rate of urge incontinence of 10 per cent and urgency of 60 per cent. The incidence of detrusor overactivity and low compliance in pregnancy has been reported as 24 per cent and 31 per cent respectively. The cause of the former may be high progesterone levels whilst the latter is probably a consequence of pressure from the gravid uterus.

Stress incontinence has also been reported to be more common in pregnancy, with 28 per cent of women complaining of symptoms although only 12 per cent remained symptomatic following delivery. The long-term prognosis for this group of women remains guarded. Continent women delivered vaginally have been compared to those who had a caesarean section. Whilst there was initially a difference in favour of CS this effect was insignificant by three months following delivery.⁸

Childbirth

Childbirth may result in damage to the pelvic floor musculature as well as injury to the pudendal and pelvic nerves. The association between increasing parity and urinary incontinence has been reported in several studies. Some authorities

have found this relationship to be linear whilst others have demonstrated a threshold at the first delivery and some have shown that increasing age at first delivery is significant. A large Australian study has demonstrated a strong relationship between urinary incontinence and parity in young women (18–23 years) although in middle age (45–50 years) there was only a modest association and this was lost in older women (70–75 years).⁹

Obstetric factors themselves may also have a direct effect on continence following delivery. The risk of incontinence increases 5.7-fold in women who have had a previous vaginal delivery although a previous CS did not increase the risk.¹⁰ In addition an increased risk of urinary incontinence has been associated with increased exposure to oxytocic drugs, vacuum extraction, forceps delivery and fetal macrosomia.

Mode of delivery has also been investigated in a large population-based cohort study of 5236 primiparous women in Sweden followed up over 20 years after a single delivery. Overall the prevalence of stress incontinence, urgency incontinence and mixed incontinence was 15.3 per cent, 6.1 per cent and 14.4 per cent respectively and was higher in all types of incontinence following vaginal delivery when compared to CS. Moderate to severe incontinence was more prevalent after vaginal delivery than after CS (21.3 per cent vs 13.5 per cent; OR 1.68, 95% CI 1.40–2.03). In addition the prevalence of bothersome urinary incontinence was also greater after vaginal delivery (11.2 per cent vs 16.3 per cent; OR 1.85, 95% CI 1.42–2.39).¹¹

Menopause

The urogenital tract and lower urinary tract are sensitive to the effects of oestrogen and progesterone throughout adult life. Epidemiological studies have implicated oestrogen deficiency in the aetiology of lower urinary tract symptoms occurring following the menopause with 70 per cent of women relating the onset of urinary incontinence to their final menstrual period.¹² LUTS have been shown to be common in post-menopausal women attending a menopause clinic with 20 per cent complaining of severe urgency and almost 50 per cent complaining of stress incontinence.¹³ Urge incontinence in particular is more prevalent following the menopause and the prevalence would appear to rise with increasing years of oestrogen deficiency. Some studies have shown a peak incidence in perimenopausal women whilst other evidence suggests that many women develop incontinence at least 10 years prior to the cessation of menstruation with significantly more pre-menopausal women than post-menopausal women being affected.

THE CAUSES OF URINARY INCONTINENCE

- 1 Urodynamic stress incontinence (USI);
- 2 Detrusor overactivity;

Table 95.1 Symptoms and definitions

Definition	Symptoms
Daytime frequency	Complaint by the patient who considers that she voids too often by day
Urgency	Sudden and compelling desire to pass urine, which is difficult to defer
Nocturnal enuresis	Complaint of loss of urine occurring during sleep
Continuous urinary incontinence	Complaint of continuous leakage
Stress urinary incontinence	Complaint of involuntary leakage on effort or exertion, or on sneezing or coughing
Urgency Incontinence	Complaint of involuntary leakage accompanied by or immediately preceded by urgency
Mixed Incontinence	Complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing or coughing

- 3 Overflow incontinence;
- 4 Fistulae (vesicovaginal, ureterovaginal, urethrovaginal);
- 5 Congenital (e.g. ectopic ureter);
- 6 Urethral diverticulum;
- 7 Other (e.g. UTI, faecal impaction, medication);
- 8 Functional (e.g. immobility).

Urinary symptoms can be broadly divided. Detrusor over-activity is classically associated with frequency, urgency, urge incontinence, nocturia and nocturnal enuresis. Urodynamic stress incontinence is classically associated with involuntary leakage on effort or on exertion or on coughing or sneezing (Table 95.1).

Continuous incontinence and/or post-micturition dribbling are more likely to be associated with neurological disorders, overflow, urethral diverticulae or a fistula. However, there are problems with making a presumptive diagnosis on the basis of symptoms alone. Many women complain of a mixture of symptoms. For instance those women who are found to have USI often complain of frequency, as they are going to the toilet more often in order to avoid leaking. One study found that even an experienced clinician made the correct diagnosis only 65 per cent of the time when relying on symptoms only.¹⁴

URODYNAMIC STRESS INCONTINENCE

Definition

Urodynamic Stress Incontinence (USI) is noted during filling cystometry and is defined as ‘the involuntary leakage of urine during increased abdominal pressure, in the absence of a detrusor contraction’.

Incidence

Urodynamic stress incontinence is the commonest cause of incontinence in women. It is difficult to assess the true incidence, as many women suffer in silence and consider it an inevitable consequence of childbirth and ageing. However,

conservative estimates are that 1 in 10 women will suffer from USI at some point in their lives.

Aetiology

There are various factors that are thought to predispose to the development of USI.

- 1 Increased intra-abdominal pressure:
 - pregnancy
 - chronic cough
 - abdominal, pelvic mass
 - constipation
 - ascites.
- 2 Damage to the pelvic floor:
 - childbirth
 - radical pelvic surgery.
- 3 Fixed, scarred urethra:
 - previous surgery
 - radiotherapy.

Pathophysiology

The exact pathophysiology is unclear, but several hypotheses have been put forward.

- 1 Failure of the supporting structures such as the pubo-urethral and pubovesical ligaments.
- 2 Failure of the intrinsic sphincter mechanism as a result of damage to the rhabdosphincter, poor collagen or reduced urethral vascularity (intrinsic sphincter deficiency – ISD).
- 3 Failure of the extrinsic sphincter mechanism as a result of weakness or damage to the pelvic floor musculature. This allows displacement of the bladder neck from within the intra-abdominal pressure zone.

More recently the ‘integral theory’ has been described by Petros and Ulmsten.¹⁵ This hypothesises that the distal and mid urethra have an important role in the continence mechanism¹⁶ and that maximal urethral closure pressure is controlled at the mid-urethral point.¹⁷ The theory also proposes that damage to the pubo-urethral ligaments, which support the urethra, impaired support of the anterior vaginal wall to

KEY POINTS

1. USI is the most common cause of incontinence in women.
2. The diagnosis is based on urodynamic assessment.
3. Increased abdominal pressure, pelvic floor damage and urethral scarring all predispose to the development of USI.

the mid urethra, and weakened function of part of the pubococcygeal muscles, which insert adjacent to the urethra, are responsible for causing stress incontinence.

MANAGEMENT OF USI

Conservative management

USI interferes with a woman's quality of life but it is not a life-threatening condition and therefore conservative measures should be tried in every woman prior to resorting to surgical treatment.

Conservative treatment is effective, has few complications and does not compromise further surgical procedures.¹⁸ It is particularly useful in those women who are medically unfit for surgery and those who have not completed their family, are breastfeeding or are less than six months postpartum.

Conservative measures include:

- 1 pelvic floor exercises;
- 2 biofeedback;
- 3 electrical stimulation;
- 4 vaginal cones;
- 5 urethral devices.

In order to maximise the benefits that can be obtained using these techniques, it is vital to ensure that the treatment is tailored to the individual and that it is properly taught.

Pelvic floor muscle training

Pelvic floor muscle training (PFMT) and pelvic floor physiotherapy have been the first-line conservative measure since their introduction in 1948.¹⁹ PFMT appears to work in a number of different ways:

- women learn to consciously pre-contraction the pelvic floor muscles before and during increases in abdominal pressure to prevent leakage ('the knack');
- strength training builds up long-lasting muscle volume and thus provides structural support;
- abdominal muscle training indirectly strengthens the pelvic floor muscles.²⁰

In addition during a contraction the urethra may also be pressed against the posterior aspect of the symphysis pubis producing a mechanical rise in urethral pressure.²¹ Since up to 30 per cent of women with stress incontinence are unable to contract their pelvic floor correctly at presentation,²² some patients may simply need to be re-taught the 'knack' of squeezing the appropriate muscles at the correct time.²³

PFMT remains integral to the management of women with stress urinary incontinence with level 1, grade A evidence from five prospective RCTs with short-term cure rates between 35 per cent and 80 per cent.²⁴ Supervised training is generally felt to be more effective than unsupervised training²⁵ although benefits of biofeedback and electrical stimulation are less clear.²⁶ Consequently the International Consultation on Incontinence (ICI)²⁷ recommends that PFMT should be considered as first-line treatment in all women with stress urinary incontinence. In addition there is no evidence to suggest that age is a factor when determining outcome of PFMT.

There is also good evidence to support the use of PFMT for the prevention of urinary incontinence in antenatal and postnatal women in a systematic review of 15 studies including 6181 women.²⁸ Pregnant women without prior urinary incontinence who were randomised to antenatal PFMT were less likely than those who had no PFMT to report urinary incontinence in late pregnancy (RR 0.44, 95% CI 0.30–0.65) and immediately postpartum (RR 0.71, 95% CI 0.52–0.97). In addition postnatal women who had received PFMT with persistent urinary incontinence three months after delivery were less likely to report urinary incontinence at 12 months (RR 0.79, 95% CI 0.70–0.90). Consequently the evidence would suggest that PFMT in women during pregnancy may be useful in the prevention of incontinence.

Biofeedback

Biofeedback is used to augment the effect of pelvic floor exercises. It can range in complexity from the very simple, such as a vaginal examination measuring the strength of the squeeze, which the woman can perform herself at home, to the much more sophisticated electromyography, which is usually used in a clinic. Biofeedback has not been shown to be superior to pelvic floor exercises alone.

Electrical Stimulation

Electrical stimulation uses an electrical pulse to augment the ability to produce a voluntary contraction. A probe is put into the vagina near the muscles of the pelvic floor and a pulse of electricity is passed. The pulse frequency is debated, but it is usually in the 35–40 Hz range. This method cannot be used in pregnancy or in those with an IUCD *in situ*. It is not suitable for most women as it is excessively time consuming.

Vaginal cones and urethral devices

Vaginal cones or weights are now used infrequently, as the results are no better than those of pelvic floor exercises alone.

Many women find a tampon or an intravaginal device very helpful. These devices elevate the bladder neck and in some cases partially obstruct the flow of urine. They are particularly suitable for women who find they are incontinent only at specific times, for instance during aerobics or playing tennis. Several urethral support devices are available such as Conveen or Contrelle, although these are now very rarely used.

Pharmacological management

Whilst various agents such as α_1 -adrenoceptor agonists, oestrogens and tricyclic antidepressants have all been used anecdotally in the past for the treatment of stress incontinence, duloxetine is the first drug to be specifically developed and licensed for this indication.

Duloxetine is a potent and balanced serotonin (5-hydroxytryptamine) and noradrenaline re-uptake inhibitor (SNRI) which enhances urethral striated sphincter activity via a centrally mediated pathway.²⁹ The efficacy and safety of duloxetine has been evaluated in a double-blind randomised parallel group placebo-controlled phase II dose-finding study in the US involving 553 women with stress incontinence.³⁰ Duloxetine was associated with significant and dose-dependent decrease in incontinence episode frequency whilst the most frequently reported adverse event was nausea.

A further global phase III study of 458 women has also recently been reported.³¹ There was a significant decrease in incontinence episode frequency and improvement in quality of life with duloxetine compared to placebo. Once again nausea was the most frequently reported adverse event, occurring in 25.1 per cent of women receiving duloxetine compared to a rate of 3.9 per cent in those taking placebo.

Duloxetine may also be useful in those women awaiting continence surgery. In a further double-blind, placebo-controlled study of 109 women awaiting surgery for stress incontinence³² there was a significant improvement in incontinence episode frequency and quality of life when compared to placebo. Furthermore, 20 per cent of women who were awaiting continence surgery changed their mind whilst taking duloxetine.

In addition the role of synergistic therapy with PFMT and duloxetine has been examined in a prospective study of 201 women with stress incontinence. Women were randomised to one of four treatments: duloxetine, PFMT, combination therapy or placebo. Overall duloxetine, with or without PFMT, was found to be superior to placebo or PFMT alone whilst pad test results and QoL analysis favoured combination therapy to single treatment.³³

Surgical procedures

More than 200 operative procedures for the treatment of USI have been described. Many of these are modifications of similar procedures, but there is not one definitive operation. The first operative procedure offers the best chance of cure and therefore it is very important to select the appropriate procedure for each patient.

Historically colposuspension, originally described by Burch in 1961,³⁴ has been regarded as the operation of choice in cases of primary stress incontinence. However, with the description of the 'mid-urethral theory' or 'integral theory' by Petros and Ulmsten the rationale behind surgery for stress incontinence has changed and has led directly to the development of both the

retropubic and trans-obturator mid-urethral tape procedures and these new, minimally invasive procedures have now largely replaced retropubic suspensions and sling procedures.

For those women who may not be suitable for a mid-urethral tape procedure, urethral bulking agents may also be considered and many of these may now be performed under local anaesthesia in the ambulatory setting.

Colposuspension

The patient is placed in the modified lithotomy position using Lloyd–Davies stirrups. A Foley catheter is inserted into the bladder and allowed to drain freely. A low transverse incision is made just above the symphysis pubis (i.e. lower than a Pfannenstiel). The retropubic space is dissected until the white paravaginal tissue lateral to the bladder neck is exposed. Two to four polydioxanone (PDS), Ethibond or polyglycolic acid sutures are inserted into the paravaginal fascia. Each suture is tied and the needle is then re-inserted into the ipsilateral iliopectineal ligament. The first suture is placed at the level of the bladder neck and the subsequent sutures are placed 1 cm laterally and 1 cm cranially (Fig. 95.1). When all the sutures have been inserted, an assistant elevates the lateral fornix on each side to allow the sutures to be tied without tension (Fig. 95.2).

Fig. 95.1 Colposuspension: the bladder neck is mobilised medially and the first suture placed in the white paravaginal tissue

Fig. 95.2 Colposuspension: four sutures are placed on each side to elevate the paravaginal tissue to the ipsilateral pectineal ligament

A suction drain is left in the retropubic space, a suprapubic catheter is inserted and the urethral catheter is removed.

The suprapubic catheter is left on free drainage for at least two days and then a clamping regimen is initiated. This usually entails clamping the catheter at a set time and allowing the patient to void normally. Initially, the residual is checked after each void or, if the patient experiences discomfort, the clamp is released and the residual measured. If the patient is passing good volumes of urine with small residuals, the time between unclamping can be extended to 12 hours and then 24 hours. When the residuals are persistently under 100 mL, the suprapubic catheter can be removed.

Post-operative complications

Voiding difficulties are the main complication following a colposuspension. Overall the incidence of voiding difficulties lasting over one month is reported as 5 per cent (CI 3–5)³⁵ although other series have reported rates as high as 21 per cent.³⁶

These women are initially managed by allowing them to go home with their suprapubic catheter *in situ*, leaving it on free drainage. Two weeks later they are re-admitted and a further trial of clamping is attempted. The majority of women will be able to void spontaneously at this stage. About 2 per cent will continue to complain of voiding difficulties, and these women are usually taught clean intermittent self-catheterisation.

Detrusor overactivity arises *de novo* in between 12 per cent and 18.5 per cent of women who have undergone a colposuspension.³⁷ It seems to occur more commonly after previous continence surgery. It may be that a number of cases reflect pre-existing detrusor overactivity that went undetected at pre-operative cystometry. Alternatively, the autonomic nerve supply may be damaged when the bladder is medially displaced at the time of surgery.³⁸

A longer-term complication is the development of prolapse. Enterocoele and rectocoele formation is thought to occur as a result of elevation of the anterior vaginal wall creating a posterior defect and causing intra-abdominal pressure to be transmitted directly to the posterior vaginal wall. The incidence is estimated to be between 7 per cent and 17 per cent.³⁹ It is unclear whether these represent new defects or merely a pre-existing defect becoming symptomatic once the support of the anterior vaginal wall has been rectified.

Outcome

Historically there have been many prospective case series and cohort studies assessing the efficacy of colposuspension with some studies providing long-term follow-up data for up to 20 years and cure rates of 80⁴⁰–94⁴¹ per cent.

In addition there have also been three reported meta-analyses. The first of these was reported by Jarvis in 1994⁴² who reviewed 1726 women with follow-up of at least one year and a mean objective success rate of 84.3 per cent. Very similar results were reported from a meta-analysis of 2196 women reported by the American Urological Association

in 1997. Overall mean objective cure rates were 84 per cent at 48 months (CI 79–88%) with follow-up to at least four years. More recently the Cochrane group has published a meta-analysis of 39 RCTs involving 2403 women with a mean follow-up of one year. Objective cure rates were found to be 85–90 per cent and there was a slow decline in cure rates to 70 per cent over five years.⁴³

Laparoscopic colposuspension

Minimally invasive surgery is attractive and this trend has extended to surgery for stress incontinence. Although many authors have reported excellent short-term subjective results from laparoscopic colposuspension, early studies have shown inferior results to the open procedure.

Two large prospective RCTs have been reported from Australia and the UK comparing laparoscopic and open colposuspension. In the Australian study 200 women with USI were randomised to either laparoscopic or open colposuspension.⁴⁴ Overall there were no significant differences in objective and subjective measures of cure or in patient satisfaction at 6 months, 24 months or 3–5 years. Whilst the laparoscopic approach took longer it was associated with less blood loss and a quicker return to normal activities.

These findings are supported by the UK multicentre RCT of 291 women with USI comparing laparoscopic to open colposuspension.⁴⁵ At 24 months intention to treat analysis showed no significant difference in cure rates between the procedures. Objective cure rates for open and laparoscopic colposuspension were 70.1 per cent and 79.7 per cent respectively whilst subjective cure rates were 54.6 per cent and 54.9 per cent respectively.

These studies have confirmed that the clinical effectiveness of the two operations is comparable although the cost effectiveness of laparoscopic colposuspension remains unproven. A cost analysis comparing laparoscopic to open colposuspension was also performed alongside the UK study.⁴⁶ Healthcare resource use over the first six-month follow-up period translated into costs of £1805 for the laparoscopic group versus £1433 for the open group.

Post-operative complications

The incidence of urinary tract injury has been found to be higher during laparoscopic colposuspension than during the open operation. A 1–10 per cent rate of bladder injury has been reported, and although the rate of ureteric injury or kinking is less than 0.1 per cent, this is significantly higher than at the open procedure. Operative morbidity has also been extensively studied, with intra-operative blood loss, febrile morbidity and length of hospital stay all higher in the open colposuspension group.⁴⁷

Pubovaginal sling

Sling procedures are often performed as secondary operations where there is scarring and narrowing of the vagina.

The sling material can either be organic (rectus fascia, porcine dermis) or inorganic (Prolene, Mersilene, Marlex or Silastic). The sling may be inserted either abdominally, vaginally or by a combination of both. Normally the sling is used to elevate and support the bladder neck and proximal urethra, but not intentionally to obstruct it.

Sling procedures may be associated with a high incidence of side effects and complications. It is often difficult to decide how tight to make the sling. If it is too loose, incontinence will persist and if it is too tight, voiding difficulties may be permanent. Women who are going to undergo insertion of a sling must be prepared to perform clean intermittent self-catheterisation post-operatively. In addition, there is a risk of infection, especially if inorganic material is used. The sling may erode into the urethra, bladder or vagina, in which case it must be removed and this can be exceedingly difficult.

Mid-urethral tape procedures

Retropubic approach: tension-free vaginal tape

The tension-free vaginal tape (TVT, Gynaecare), first described by Ulmsten in 1996,⁴⁸ is now the most commonly performed procedure for stress urinary incontinence in the UK and more than two million procedures have been performed worldwide.

A knitted 11 mm × 40 cm polypropylene mesh tape is inserted transvaginally at the level of the mid urethra, using two 5 mm trochars (Fig. 95.3). The procedure may be performed under local, spinal or general anaesthesia.

Technique

The procedure may be performed under local or general anaesthesia. The patient is placed in the dorsal lithotomy position and having prepared the vagina and suprapubic area an indwelling 18 Fr Foley catheter is inserted into the bladder. Once the bladder has been emptied a rigid catheter guide is then inserted down the catheter in order to deflect the bladder away from the passage of the needle introducers. The use of local anaesthesia (20 mL bupivacaine 0.5% with 1 in 200,000 adrenaline – diluted in 100 mL normal saline) allows effective hydrodissection and vasoconstriction whilst at the same

Fig. 95.3 TVT: tension-free vaginal tape

time providing effective intra-operative and post-operative analgesia. 20 mL of dilute local anaesthetic is injected on each side retropubically immediately behind the pubic tubercle. In addition a further 20 mL is injected para-urethrally on each side up to the level of the urogenital diaphragm and 5 mL sub-urethrally.

A 2 cm midline sub-urethral vaginal incision is made and para-urethral dissection performed using sharp dissection with McIndoe scissors between the vaginal mucosa and pubo-cervical fascia to the level of the inferior pubic ramus and the urogenital diaphragm. Two small 0.5 cm suprapubic incisions at the upper border of the pubic tubercle 2 cm lateral to the midline may be made to facilitate needle passage through the skin.

The TVT needle is then placed in the starting position within the dissected para-urethral tunnel with the tip of the needle between the index finger (in the vagina) and the lower border of the pubic ramus. Prior to the passage of the needle the bladder is pushed away from the track of the needle using the rigid catheter guide. In a controlled movement the needle is then pushed through the urogenital diaphragm, the retropubic space and the rectus fascia keeping in close contact to the dorsal aspect of the pubic bone. The procedure is then repeated on the contralateral side.

With the needles still in position a cystoscopy using a 70° cystoscope is performed to check that there is no bladder injury (Fig. 95.4). Should a bladder perforation be noted the needle is withdrawn, replaced, passed once again and the cystoscopy repeated. Once the integrity of the bladder is confirmed the bladder is again emptied completely and the tape pulled through.

In those centres which continue to use the cough stress test the bladder is then refilled with 300 mL normal saline and the patient asked to cough vigorously. The tape may then be adjusted to a point where there is only a drop of leakage from the urethral meatus. After this final adjustment the

Fig. 95.4 TVT trochars inserted and check cystoscopy to exclude bladder perforation

Fig. 95.5 TVT: adjusting the tension of the tape

tape is held in position beneath the urethra using a pair of McIndoe scissors whilst the plastic sheaths are removed on each side (Fig. 95.5).

In those centres where a cough stress test is no longer used the tape is positioned loosely below the mid-urethra without tension. Finally the vaginal incision is closed using an absorbable suture and the suprapubic incisions are closed with steri-strips. Whilst an indwelling catheter is not required in all cases a urethral catheter should be left on free drainage for 48 hours following a bladder injury.

Outcome

The initial multicentre study carried out in six centres in Sweden reported a 90 per cent cure rate at one year in women undergoing their first operation for USI, without any major complications.⁴⁹ Long-term results would confirm durability of the technique with success rates of 86 per cent at 3 years,⁵⁰ 84.7 per cent at 5 years,⁵¹ 81.3 per cent at 7 years,⁵² 90 per cent at 11 years⁵³ and 90 per cent at 17 years.⁵⁴

The TVT has also been compared to open colposuspension in a multicentre prospective randomised trial of 344 women with USI.⁵⁵ Overall there was no significant difference in terms of objective cure; 66 per cent in the TVT group and 57 per cent in the colposuspension group. However, operation time, post-operative stay and return to normal activity were all longer in the colposuspension arm. Analysis of the long-term results at 24 months using a pad test, QoL assessment and symptom questionnaires showed an objective cure rate of 63 per cent in the TVT arm and 51 per cent in the colposuspension arm.⁵⁶ At five years there were no differences in subjective cure (63 per cent in the TVT group and 70 per cent in the colposuspension group), patient satisfaction and QoL assessment. However, whilst there was a significant reduction in cystocele in both groups there was a higher incidence of enterocele,

rectocele and apical prolapse in the colposuspension group.⁵⁷ Furthermore, cost utility analysis has also shown that at six months follow-up TVT resulted in a mean cost saving of £243 when compared to colposuspension.⁵⁸

A smaller randomised study has also compared TVT to laparoscopic colposuspension in 72 women with USI. At a mean follow-up of 20 months objective cure rates were higher in the TVT group when compared to the laparoscopic colposuspension group: 96.8 per cent vs 71.2 per cent respectively.⁵⁹

Post-operative complications

Following the procedure most women can go home the same day, although some do require catheterisation for short-term voiding difficulties (2.5–19.7 per cent). Other complications include bladder perforation (2.7–5.8 per cent), de-novo urgency (0.2–15 per cent) and bleeding (0.9–2.3 per cent).⁶⁰

SPARC: mid-urethral sling suspension system

The SPARC sling system (American Medical Systems) is a minimally invasive sling procedure using a knitted 10 mm-wide polypropylene mesh which is placed at the level of the mid urethra by passing the needle via a suprapubic to vaginal approach.⁶¹ The procedure may be performed under local, regional or general anaesthetic. A prospective multicentre study of 104 women with USI has been reported from France.⁶² At a mean follow-up of 11.9 months the objective cure rate was 90.4 per cent and subjective cure 72 per cent. There was a 10.5 per cent incidence of bladder perforation and 11.5 per cent of women complained of de-novo urgency following the procedure. More recently SPARC has been compared to TVT in a prospective randomised trial of 301 women.⁶³ At short-term follow-up there were no significant differences in cure rates, bladder perforation rates and de-novo urgency. There was, however, a higher incidence of voiding difficulties and vaginal erosions in the SPARC group.

Trans-obturator sling procedures

The trans-obturator route for the placement of synthetic mid-urethral slings was first described in 2001.⁶⁴ As with the retropubic sling procedures trans-obturator tapes may be performed under local, regional or general anaesthetic and have the theoretical advantage of eliminating some of the complications associated with the retropubic route such as bladder and urethral perforation.

The trans-obturator approach may be used as an ‘inside-out’ (TVT-O, GynaeCare) or alternatively an ‘outside-in’ (Monarc, American Medical Systems) technique. To date there have been several studies documenting the short-term efficacy of trans-obturator procedures.

Trans-obturator ‘inside-out’

The TVT-O device consists of an 11 mm × 40 cm tape of polypropylene mesh, both ends of which are attached to a plastic sheath which threads over the helical needle introducer. A winged needle guide is also provided to facilitate passage of the needle through the obturator membrane (Fig. 95.6).

Fig. 95.6 TVT-O: tension-free vaginal tape – obturator

The procedure may be performed under local or general anaesthesia. The patient is placed in the dorsal lithotomy position in 120° hyperflexion. The vagina and thighs are then prepared and an indwelling 12 Fr Foley catheter is inserted into the bladder. Next two 0.5 cm incisions are made 2 cm superior to a horizontal line level with the urethra and 2 cm lateral to the thigh folds. This marks the exit point for the helical needle introducer.

The use of local anaesthesia (20 mL bupivacaine 0.5% with 1 in 200,000 adrenaline – diluted in 100 mL normal saline) allows effective hydrodissection and vasoconstriction whilst at the same time providing effective intra-operative and post-operative analgesia. 20 mL of dilute local anaesthetic is injected para-urethrally on each side in the direction of the inferior pubic ramus.

A midline sub-urethral incision is then made at the level of the mid urethra prior to para-urethral sharp dissection between the vaginal epithelium and peri-urethral fascia using McIndoe scissors. Dissection is continued laterally to the inferior border of the pubic ramus at the level of the mid-urethra and the medial aspect of the obturator membrane is perforated.

The winged needle guide is then passed at 45° relative to the sagittal plane of the urethra until reaching the posterior aspect of the inferior pubic ramus and perforating the obturator membrane. Having mounted the tape onto the helical introducer the tip is then placed along the guide channel in the winged guide to pass through the obturator membrane and is then rotated so as to exit through the inner thigh incision. The tip of the tubing is then clamped and the helical introducer withdrawn. The procedure is then repeated on the contralateral side (Fig. 95.7). Once both needles have been passed and the tape inserted a cystoscopy may be performed to exclude bladder or urethral injury.

The tape is then held loosely in position beneath the urethra using a pair of McIndoe scissors whilst the protective plastic sheaths are removed ensuring that there is no tension on the urethra and the tape is lying flat (Fig. 95.8). The vaginal incision is then closed using an absorbable suture and steristrips are used to close the two small incisions on the thighs. Whilst an indwelling catheter is not required in all cases a urethral

Fig. 95.7 TVT-O: insertion of TVT-O using the winged guide

Fig. 95.8 TVT-O: adjusting the tension of the tape

catheter should be left on free drainage for 48 hours following a bladder injury.

Trans-obturator ‘outside-in’

The procedure may be performed under local or general anaesthesia. The patient is placed in the dorsal lithotomy position in 120° hyperflexion. The vagina and thighs are then prepared and an indwelling 12 Fr Foley catheter is inserted into the bladder. The use of local anaesthesia (20 mL bupivacaine 0.5% with 1 in 200,000 adrenaline – diluted in 100 mL normal saline) allows effective hydrodissection and vasoconstriction whilst at the same time providing effective intra-operative and post-operative analgesia. 20 mL of dilute local anaesthetic is injected para-urethrally on each side in the direction of the inferior pubic ramus.

A midline sub-urethral incision is then made at the level of the mid urethra prior to para-urethral sharp dissection between the vaginal epithelium and peri-urethral fascia using McIndoe scissors. Dissection is continued laterally to

the inferior border of the pubic ramus at the level of the mid urethra and the medial aspect of the obturator membrane is perforated. Next a small incision is made 1.5 cm lateral to the ischiopubic ramus on each side at the level of the clitoris. The helical needle introducer is then passed 'outside-in' through the incision to perforate the medial aspect of the obturator membrane. With the index finger in the vaginal incision palpating the ischiopubic ramus and obturator internus muscle the tip of the helical needle may then be guided through to the vaginal incision. Care should be taken to avoid perforating the lateral vaginal fornix and the urethra is guarded by the operator's finger. Once the tip of the needle has been passed through the vaginal incision the tape may then be attached to the needle and pulled through to exit through the thigh incision. The procedure is then repeated on the contralateral side.

The tape is then held loosely in position beneath the urethra using a pair of McIndoe scissors whilst the protective plastic sheaths are removed ensuring that there is no tension on the urethra and the tape is lying flat. The vaginal incision is then closed using an absorbable suture and steristrips are used to close the two small incisions on the thighs. Whilst an indwelling catheter is not required in all cases a urethral catheter should be left on free drainage for 48 hours following a bladder injury.

Outcome

Initial studies have reported cure and improved rates of 80.5 per cent and 7.5 per cent respectively at 7 months⁶⁵ and 90.6 per cent and 9.4 per cent respectively at 17 months.⁶⁶

More recently the trans-obturator approach (TVT-O) has been compared to the retropubic approach (TVT) in an Italian prospective multicentre randomised study of 231 women with urodynamic stress incontinence.³⁵ At a mean of nine months subjectively 92 per cent of women in the TVT group were cured compared to 87 per cent in the TVT-O group. Objectively, on pad test, cure rates were 92 per cent and 89 per cent respectively. There were no differences in voiding difficulties and length of stay although there were more bladder perforations in the TVT group; 4 per cent vs none in the TVT-O group. A further multicentre prospective randomised trial comparing TVT and TVT-O has also recently been reported from Finland in 267 women complaining of stress urinary incontinence.⁶⁸ Objective cure rates at nine weeks were 98.5 per cent in the TVT group and 95.4 per cent in the TVT-O group. Whilst complication rates were low and similar in both arms of the study there was a higher incidence of groin pain in the TVT-O group.

These data are supported by a recent meta-analysis of the five randomised trials comparing TVT-O with TVT and six randomised trials comparing TOT with TVT.⁶⁹ Overall subjective cure rates were identical with the retropubic and trans-obturator routes. However, adverse events such as bladder injuries (OR 0.12, 95% CI 0.05–0.33) and voiding difficulties (OR 0.55, 95% CI 0.31–0.98) were less common, whereas groin pain (OR 8.28, 95% CI 2.7–25.4) and vaginal erosions (OR 1.96, 95% CI 0.87–4.39) were more common after the trans-obturator approach.

Long-term data would also seem to support the durability and efficacy of the trans-obturator approach. A three-year follow-up study of a prospective observational study evaluating the use of TVT-O has been reported (Waltregny *et al.* 2008).⁷⁰ Of the 102 patients recruited 91 (89.2 per cent) were available for follow-up at a minimum of three years. The objective cure rate was 88.4 per cent with an improvement in 9.3 per cent of cases and there was no statistical difference in outcome as compared to the results reported at one year.

Post-operative complications

Whilst the trans-obturator route may be associated with a lower risk of bladder injury there is a risk of damage to the obturator nerve and vessels. In an anatomical dissection model the tape passes 3.4–4.8 cm from the anterior and posterior branches of the obturator nerve respectively and 1.1 cm from the most medial branch of the obturator vessels.⁷¹ Consequently nerve and vessel injury in addition to buttock pain, bladder injury and vaginal erosion remain potential complications of the procedure.

Urethral bulking agents

Urethral bulking agents are a minimally invasive surgical procedure for the treatment of USI and may be useful in the elderly and those women who have undergone previous operations and have a fixed, scarred, fibrosed urethra.

Although the actual substance which is injected may differ the principle is the same. It is injected either peri-urethrally or transurethrally on either side of the bladder neck under cystoscopic control and is intended to 'bulk' the bladder neck, in order to stop premature bladder neck opening, without causing outflow obstruction. The procedure may be performed under local, regional or general anaesthesia. There are now several different products available (Table 95.2). The use of minimally invasive implantation systems has also allowed some of these procedures to be performed in the office setting without the need for cystoscopy (Fig. 95.9).

Outcome

In the first reported series 81 per cent of 68 women were dry following two injections of collagen.⁷² There have been longer-term follow-up studies, most of which give a less than 50 per cent objective cure rate at two years but a subjective improvement rate of about 70 per cent.^{73,74,75} Macroplastique has been compared to Contigen in a recent North American study of 248 women with USI. Outcome was assessed objectively using pad tests and subjectively at 12 months. Overall objective cure and improvement rates favoured Macroplastique over Contigen (74 per cent vs 65 per cent; $p = 0.13$). Whilst this difference was not significant subjective cure rates were higher in the Macroplastique group (41 per cent vs 29 per cent; $p = 0.07$).⁷⁶

The role of Bulkamid in the management of women with USI has been investigated in an open-label multicentre European study of 135 women.⁷⁷ At 12 months the subjective

Table 95.2 Urethral bulking agents

Urethral bulking agent	Application technique
Glutaraldehyde crosslinked bovine collagen (Contigen)	Cystoscopic
Polydimethylsiloxane (Macroplastique)	Cystoscopic (MIS implantation system)
Pyrolytic carbon-coated zirconium oxide beads in β -glucan gel (Durasphere)	Cystoscopic
Calcium hydroxylapatite in carboxymethylcellulose gel (Coaptite)	Cystoscopic
Polyacrylamide hydrogel (Bulkamid)	Cystoscopic

**Fig. 95.9** Macroplastique: use of the Macroplastique implantation system under local anaesthesia

response rate was 66 per cent and there was a significant reduction in incontinence episodes (from 3.0 to 0.7 episodes per day) and pad test loss (from 29 g to 4 g). In addition the procedures were well tolerated and there was a corresponding improvement in QoL. The re-injection rate was 35 per cent. More recently a two-year follow-up has been reported documenting a subjective responder rate of 64 per cent and no deterioration in terms of objective outcomes. Reassuringly there were no reported safety concerns.⁷⁸

Whilst success rates with urethral bulking agents are generally lower than those with conventional continence surgery they are minimally invasive and have lower complication rates meaning that they remain a useful alternative in selected older women or those with significant co-morbidities.

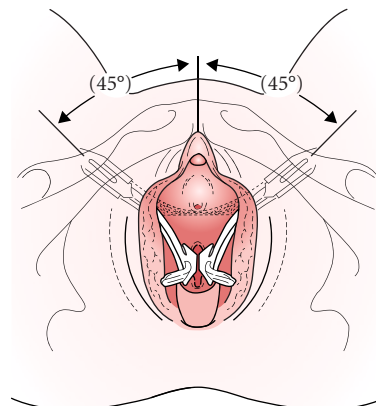

Single-incision mid-urethral tape procedures

Whilst the development of mid-urethral retropubic and trans-obturator tapes has transformed the surgical approach to stress urinary incontinence by offering a minimally invasive day-case procedure, there has recently been interest in

developing a new type of 'mini sling' which may offer a truly office-based approach. A number of single-incision tapes have been developed including the TVT Secur (Gynaecare) Fig. 95.10, MiniArc (American Medical Systems) and Ophira (Promedon) although the former has now been withdrawn.

Whilst there is an increasing evidence base to support their use at present there is a paucity of long-term efficacy data. A systematic review and meta-analysis has compared single-incision tapes with mid-urethral tapes in nine RCTs in 758 women.⁷⁹ Overall the single-incision tapes were associated with significantly lower patient-reported and objective cure rates (RR 0.83, 95% CI 0.70–0.99 and RR 0.85, 95% CI 0.74–0.97 respectively) although there was no difference in QoL improvement.

Consequently, whilst the single-incision mini tapes may offer a minimally invasive alternative to standard mid-urethral tapes, current evidence would suggest that efficacy may be inferior and further long-term studies are required.

**Fig. 95.10** Single incision tape (TVT Secur)

KEY POINTS

- Conservative measures should be offered prior to surgical intervention.
- Duloxetine may be used in conjunction with conservative measures.
- Mid-urethral tape procedures have largely replaced colposuspension as the operation of choice in primary continence surgery.
- Laparoscopic colposuspension has a comparable outcome to open colposuspension and TVT.
- Retropubic mid-urethral tape procedures and transobturator mid-urethral tape procedures have similar success rates.
- Urethral bulking agents offer an alternative minimally invasive approach to continence surgery.
- The role of single-incision mini tapes remains under investigation.

Nice guidelines

The management of stress urinary incontinence has recently been reviewed by NICE.⁸⁰

- A trial of supervised PFMT of at least three months' duration should be offered as first-line treatment to all women with stress or mixed urinary incontinence.
- Retropubic mid-urethral tape procedures using a 'bottom-up' approach with macroporous (type 1) polypropylene meshes are recommended as treatment options for stress urinary incontinence where conservative management has failed.
- Open colposuspension and autologous rectus fascial sling procedures are recommended alternatives where clinically appropriate.
- Laparoscopic colposuspension should only be performed by experienced laparoscopic surgeons.
- Single-incision mini slings (SIMS) should only be used within the setting of a clinical trial.
- Intramural bulking agents (silicone, carbon-coated zirconium beads, hyaluronic acid/dextran copolymer) should be considered for the management of stress urinary incontinence if conservative management has failed although women should be made aware that repeat injections may be required, the efficacy diminishes with time and it is inferior to that of a retropubic suspension or mid-urethral tape.
- Anterior colporrhaphy, needle suspension procedures, paravaginal defect repair and the Marshall–Marchetti–Krantz procedure are not recommended.

OVERACTIVE BLADDER

Overactive bladder is the term used to describe the symptom complex of urgency with or without urge incontinence, usually with frequency and nocturia, in the absence of UTI or any other obvious cause.¹

The symptoms of OAB are due to involuntary contractions of the detrusor muscle during the filling phase of the micturition cycle. These involuntary contractions are termed detrusor overactivity¹ and are mediated by acetylcholine-induced stimulation of bladder muscarinic receptors.⁸¹ It has been estimated that 64 per cent of patients with OAB have urodynamically proven detrusor overactivity and that 83 per cent of patients with detrusor overactivity have symptoms suggestive of OAB.⁸²

Detrusor overactivity

Detrusor overactivity is defined as 'a urodynamic observation characterised by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked' (Fig. 95.11). The detrusor is shown objectively to contract (either spontaneously or with provocation) during bladder filling whilst the subject is attempting to inhibit micturition.¹ Detrusor overactivity is a urodynamic diagnosis and usually presents with symptoms of frequency, urgency, urge incontinence, nocturia, nocturnal enuresis and sometimes incontinence at orgasm.

Fig. 95.11 Urodynamic trace showing detrusor overactivity

Prevalence

Epidemiological studies have reported the overall prevalence of OAB in women to be 16.9 per cent, suggesting that there could be 17.5 million women in the US who suffer from the condition. The prevalence increases with age, from 4.8 per cent in women under 25 years to 30.9 per cent in those over the age of 65 years.⁸³ This is supported by recent prevalence data from Europe in which 16,776 interviews were conducted in a population-based survey.⁸⁴ The overall prevalence of overactive bladder in individuals 40 years and above was 16.6 per cent and increased with age. Frequency was the most commonly reported symptom (85 per cent) whilst 54 per cent complained of urgency and 36 per cent urge incontinence. When considering management 60 per cent had consulted a doctor although only 27 per cent were currently receiving treatment.

More recently a further population-based survey of lower urinary tract symptoms in Canada, Germany, Italy, Sweden and the UK has reported on 19,165 men and women over the age of 18 years.⁸⁵ Overall 11.8 per cent were found to complain of symptoms suggestive of OAB and 64.3 per cent reported at least one urinary symptom. Nocturia was the most prevalent lower urinary tract symptom being reported by 48.6 per cent of men and 54.5 per cent of women.

Muscarinic receptors

Molecular cloning studies have revealed five distinct genes for muscarinic acetylcholine receptors in rats and humans and it has been shown that there are five receptor sub-types (M_1 – M_5). In the human bladder there are M_2 and M_3 receptors and the latter is thought to cause a direct smooth muscle contraction. Whilst the role of the M_2 receptor has not yet been clarified it may oppose sympathetically mediated smooth muscle relaxation. In general it is thought that the M_3 receptor is responsible for the normal micturition contraction although in certain disease states, such as neurogenic bladder dysfunction, the M_2 receptors may become more important in mediating detrusor contractions.

Pathophysiology

A detrusor contraction is initiated in the rostral pons. Efferent pathways emerge from the sacral spinal cord as the pelvic parasympathetic nerves (S2, S3, S4) and run forwards to the bladder. Whilst preganglionic neurotransmission is predominantly mediated by acetylcholine acting on nicotinic receptors transmission may also be modulated by adrenergic, muscarinic, purinergic and peptidergic presynaptic receptors.

Acetylcholine is released by the post-ganglionic nerves at the neuromuscular junction and results in a coordinated detrusor contraction mediated through muscarinic receptors. However ATP also has a role,⁸⁶ mediated through non-adrenergic, non-cholinergic (NANC) receptors.

Conversely sympathetic innervation is from the hypogastric and pelvic nerves acting on β -adrenoreceptors causing

relaxation of the detrusor muscle. Thus a balance between sympathetic and parasympathetic stimulation is required for normal detrusor function.

Detrusor overactivity a: outflow obstruction hypothesis

The association of detrusor overactivity with outflow obstruction has been recognised for some time⁸⁷ although it is more important in men than in women.

Outflow obstruction may lead to partial denervation and morphological studies have demonstrated a reduction in acetylcholine esterase staining nerves in obstructed human bladder.⁸⁸ In addition pharmacological studies have shown that muscle strips from patients with detrusor overactivity exhibit supersensitivity to acetylcholine.⁸⁹

In addition outflow obstruction may alter the contraction properties of the detrusor muscle⁹⁰ leading to changes in cell-to-cell propagation of electrical activity and this in turn may lead to a higher incidence of instability of membrane potential.⁹¹ These findings suggest that individual cells are more irritable when synchronous activation is damaged.

Outflow obstruction has also been shown to lead to the facilitation of the spinal reflex⁹² mediated by C-fibres with increased expression of nerve growth factor (NGF) and tachykinins.⁹³ The latter have been shown to have an effect on spinal and supraspinal control of the bladder via neurokinin receptors.⁹⁴

Detrusor overactivity b: neurogenic hypothesis

The pathophysiology of detrusor overactivity remains unclear. In-vitro studies have shown that the detrusor muscle in cases of idiopathic detrusor overactivity contracts more than normal detrusor muscle. These detrusor contractions are not nerve mediated and can be inhibited by the neuropeptide vasoactive intestinal polypeptide.⁹⁵ Other studies have shown that increased α -adrenergic activity causes increased detrusor contractility.⁹⁶

There is evidence to suggest that the pathophysiology of idiopathic and obstructive overactive bladder is different. From animal and human studies on obstructive overactivity, it would seem that the detrusor develops postjunctional supersensitivity, possibly due to partial denervation,⁹⁷ with reduced sensitivity to electrical stimulation of its nerve supply but a greater sensitivity to stimulation with acetylcholine.⁹⁸ If outflow obstruction is relieved the detrusor can return to normal behaviour and re-innervation may occur.⁹⁹

Detrusor overactivity c: urethral reflex

Relaxation of the urethra is known to precede contraction of the detrusor in a proportion of women with detrusor

overactivity.¹⁰⁰ This may represent primary pathology in the urethra which triggers a detrusor contraction or may merely be part of a complex sequence of events which originate elsewhere. It has been postulated that incompetence of the bladder neck, allowing passage of urine into the proximal urethra, may result in an uninhibited contraction of the detrusor. However, Sutherst and Brown¹⁰¹ were unable to provoke a detrusor contraction in 50 women by rapidly infusing saline into the posterior urethra using modified urodynamic equipment.

Detrusor overactivity d: myogenic hypothesis

Brading and Turner¹⁰² have suggested that the common feature in all cases of detrusor overactivity is partial denervation of the detrusor which may be responsible for altering the properties of the smooth muscle, leading to increased excitability and increased ability of activity to spread between cells, resulting in coordinated myogenic contractions of the whole detrusor.¹⁰³ They dispute the concept of neurogenic detrusor overactivity, that is, increased motor activity to the detrusor, as the underlying mechanism in detrusor overactivity, proposing that there is a fundamental abnormality at the level of the bladder wall with evidence of altered spontaneous contractile activity consistent with increased electrical coupling of cells, a patchy denervation of the detrusor and a supersensitivity to potassium.¹⁰⁴ Charlton *et al.*¹⁰⁵ suggest that the primary defect in the idiopathic and neuropathic bladders is a loss of nerves accompanied by hypertrophy of the cells and an increased production of elastin and collagen within the muscle fascicles.

Detrusor overactivity e: urothelial afferent hypothesis

More recently the role of afferent activation in the urothelium and sub-urothelial myofibroblasts has been investigated as a factor in the pathophysiology of detrusor overactivity. C-fibre afferents are known to have nerve endings in the sub-urothelial layer of the bladder wall as well as in the urothelium. Studies have revealed that ATP is released from the urothelium by bladder distension¹⁰⁶ and this may lead to activation of purinergic receptors on afferent nerve terminals which in turn evokes a neuronal discharge leading to bladder contraction.

In addition prostanoids¹⁰⁷ and nitric oxide¹⁰⁸ are synthesised locally in the urothelium and are also released by bladder distension. It is probable that a cascade of stimulatory (ATP, prostanoids, tachykinins) and inhibitory (nitric oxide) mediators are involved in the activation of sensory pathways during bladder filling.¹⁰⁹ The role of C-fibres in the pathophysiology of detrusor contractions is also supported by the use of intravesical vanilloids (capsaicin and resiniferatoxin) in patients with idiopathic detrusor overactivity and hypersensitivity disorders.¹¹⁰

Management of detrusor overactivity

The treatment options for detrusor overactivity can be divided into conservative, pharmacological, neuromodulation and surgical options.

Conservative management

Conservative measures include advice regarding fluid intake. It may be that simply cutting down on the volume of fluid consumed throughout the day or altering the times at which drinks are taken will be enough to reduce the symptoms and improve QoL. Women should be advised to consume between 1 L and 1.5 L in any 24-hour period. It is not advisable to restrict fluid intake severely, as a low urine output together with frequent voiding can lead to a reduction in the bladder's functional capacity. Caffeine and alcohol are known to irritate the bladder, and women should be advised to try to avoid caffeine-based drinks or substitute them with decaffeinated drinks.

Bladder retraining

The principles of bladder retraining are based on the ability to suppress urinary urge and to extend the intervals between voiding. The regimen is generally initiated at set voiding intervals and the patient is not allowed to void between these predetermined times, even if she is incontinent. When she remains dry, the time interval is lengthened. This continues until a suitable time span is achieved, usually around 3–4 hours. Cure rates using bladder retraining alone and no pharmacological agents have been reported between 44 and 90 per cent.¹¹¹ Many professionals advise the combined use of pelvic floor exercises with bladder retraining, as this can help suppress the symptom of urinary urgency.

Pharmacology

Drug therapy has an important role in the management of women with urinary symptoms caused by OAB although there are none which specifically act on the bladder and urethra which do not have systemic effects. The large number of drugs available is indicative of the fact that none is ideal and it is often their systemic adverse effects which limit their use in terms of efficacy and compliance. The pharmacology of drugs and recommendations for usage has recently been reviewed by the 5th ICI¹¹² (Table 95.3).

Antimuscarinic drugs

The detrusor is innervated by the parasympathetic nervous system (pelvic nerve), the sympathetic nervous system (hypogastric nerve) and by NANC neurones. The motor supply arises from S2, 3 and 4 and is conveyed by the pelvic nerve. The neurotransmitter at the neuromuscular junction is acetylcholine, which acts upon muscarinic receptors. Antimuscarinic drugs should therefore be of use in the treatment of detrusor overactivity. Atropine is the classic

Table 95.3 Drugs used in the treatment of overactive bladder

	Level of evidence	Grade of recommendation
Antimuscarinic drugs		
Tolterodine	1	A
Trospium	1	A
Solifenacin	1	A
Darifenacin	1	A
Fesoterodine	1	A
Propantheline	2	B
Atropine, hyoscamine	3	C
Drugs acting on membrane channels		
Calcium channel antagonists	2	D
Potassium channel openers	2	D
Drugs with mixed actions		
Oxybutynin	1	A
Propiverine	1	A
Flavoxate	2	D
Alpha-antagonists		
Alfuzosin	3	C
Doxazosin	3	C
Prazosin	3	C
Terazosin	3	C
Tamsulosin	3	C
Beta-agonists		
Mirabegron	1	B
Terbutaline	3	C
Salbutamol	3	C
Antidepressants		
Imipramine	3	C
Duloxetine	2	C
Prostaglandin synthesis inhibitors		
Indomethacin	2	C
Flurbiprofen	2	C
Vasopressin analogues		
Desmopressin	1	A
Other drugs		
Baclofen	3	C (intrathecal)
Capsaicin	2	C (intravesical)
Resiniferatoxin	2	C (intravesical)
Botulinum toxin (idiopathic)	3	B (intravesical)
Botulinum toxin (neurogenic)	2	A (intravesical)

non-selective anticholinergic drug with antimuscarinic activity; however, its non-specific mode of action makes it unacceptable for clinical use because of the high incidence of side effects. All antimuscarinic agents produce competitive blockade of acetylcholine receptors at postganglionic parasympathetic receptor sites. They all, to a greater or lesser extent, have the typical side effects of dry mouth, blurred vision, tachycardia, drowsiness and constipation. Unfortunately, virtually all the drugs which are truly beneficial in the management of OAB produce these unwanted systemic side effects.

Tolterodine

Tolterodine is a competitive muscarinic receptor antagonist with relative functional selectivity for bladder muscarinic receptors. Whilst it shows no specificity for receptor subtypes it does target the bladder muscarinic receptors rather than those in the salivary glands. Several randomised, double-blind, placebo-controlled trials have demonstrated a significant reduction in incontinent episodes and micturition frequency¹¹³ whilst the incidence of adverse effects has been shown to be no different to placebo. When compared to oxybutynin in a randomised double-blind placebo-controlled parallel group study, it was found to be equally efficacious and to have a lower incidence of side effects, notably dry mouth.¹¹⁴

Tolterodine has also been developed as an extended-release once-daily preparation. A double-blind multicentre trial of 1235 women has compared extended-release tolterodine to immediate-release tolterodine and placebo. Whilst both formulations were found to reduce the mean number of urge incontinence episodes per week the extended-release preparation was found to be significantly more effective.¹¹⁵

Extended release (ER) oxybutynin and ER tolterodine have also been compared. In the OPERA (Overactive bladder: Performance of Extended Release Agents) study, which involved 71 centres in the US, improvements in episodes of urge incontinence were similar for the two drugs although oxybutynin ER was significantly more effective than tolterodine ER in reducing frequency of micturition.¹¹⁶

In summary, the available evidence would suggest that tolterodine is as effective as oxybutynin although since it has fewer adverse effects patient tolerability and compliance are improved.

Trospium chloride

Trospium chloride is a quaternary ammonium compound which is non-selective for muscarinic receptor subtypes and shows low biological availability. It crosses the blood-brain barrier to a limited extent and hence would appear to have few cognitive effects.¹¹⁷ A placebo-controlled, randomised, double-blind multicentre trial has shown trospium to increase cystometric capacity and bladder volume at first unstable contraction, leading to significant clinical improvement without an increase in adverse effects over placebo.¹¹⁸ When compared to oxybutynin it was found to have comparable efficacy although was associated with a lower incidence of dry mouth and patient withdrawal.¹¹⁹ At present trospium chloride

would appear to be as effective as oxybutynin although it may be associated with fewer adverse effects.

Solifenacin

Solifenacin is a potent M₃ receptor antagonist that has selectivity for the M₃ receptors over M₂ receptors and has much higher potency against M₃ receptors in smooth muscle than it does against M₃ receptors in salivary glands.

The clinical efficacy of solifenacin has been assessed in a multicentre, randomised, double-blind, parallel-group placebo-controlled study of solifenacin 5 mg and 10 mg once daily in patients with OAB.¹²⁰ The primary efficacy analysis showed a statistically significant reduction of the micturition frequency following treatment with both 5 mg and 10 mg doses when compared with placebo, although the largest effect was with the higher dose. The most frequently reported adverse events leading to discontinuation were dry mouth and constipation. These were also found to be dose related.

In order to assess the long-term safety and efficacy of solifenacin a multicentre open-label long-term follow-up study has been reported. This was essentially an extension of two previous double-blind placebo-controlled studies in 1637 patients.¹²¹ Overall the efficacy of solifenacin was maintained in the extension study with a sustained improvement in symptoms of urgency, urge incontinence, frequency and nocturia over the 12-month study period. The most commonly reported adverse events were dry mouth (20.5 per cent), constipation (9.2 per cent) and blurred vision (6.6 per cent) and these were the primary reasons for discontinuation in 4.7 per cent of patients.

Solifenacin has also been compared with tolterodine ER in the Solifenacin (flexible dosing) od and Tolterodine ER as an Active comparator in a Randomised trial (STAR).¹²² This was a prospective double-blind, double-dummy, two-arm, parallel-group, 12-week study of 1200 patients with the primary aim of demonstrating non-inferiority of solifenacin to tolterodine ER. Solifenacin was non-inferior to tolterodine ER with respect to change from baseline in the mean number of micturitions per 24 hours. In addition solifenacin resulted in a statistically significant improvement in urgency, urge incontinence and overall incontinence when compared with tolterodine ER. The most commonly reported adverse events were dry mouth, constipation and blurred vision and they were mostly mild to moderate in severity. The number of patients discontinuing medication was similar in both treatment arms (3.5 per cent in the solifenacin arm vs 3.0 per cent in the tolterodine arm).

Darifenacin

Darifenacin is a tertiary amine with moderate lipophilicity and is a highly selective M₃ receptor antagonist which has been found to have a 5-fold higher affinity for the human M₃ receptor relative to the M₁ receptor.

A review of the pooled darifenacin data from the three phase III, multicentre, double-blind clinical trials in patients with OAB has been reported in 1059 patients.¹²³ Darifenacin

resulted in a dose-related significant reduction in median number of incontinence episodes per week. Significant decreases in the frequency and severity of urgency, micturition frequency and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations. The incidence of CNS and cardiovascular adverse events was comparable to placebo.

Fesoterodine

Fesoterodine is a novel derivative of 3,3-diphenylpropyl-amine which is a potent antimuscarinic agent that has more recently been developed for the management of OAB. A phase II dose-finding study was conducted in 728 patients in Europe and South Africa.¹²⁴ Fesoterodine 4 mg, 8 mg and 12 mg were all found to show significantly greater decreases in micturition frequency than placebo. The most commonly reported side effect was dry mouth with an incidence of 25 per cent in the 4 mg group, rising to 34 per cent in the 12 mg group. Discontinuation rates were 6 per cent and 12 per cent respectively. Subsequently a phase III randomised placebo-controlled trial has been reported comparing fesoterodine 4 mg and 8 mg with tolterodine ER 4 mg in patients complaining of OAB in 1135 patients at 150 sites throughout Australia, New Zealand, South Africa and Europe.¹²⁵ Both doses of fesoterodine demonstrated significant improvements over placebo in reduction of daytime frequency and number of urge incontinence episodes per day and were found to be superior to tolterodine. The current evidence from two large phase IV studies would support these findings and suggest that fesoterodine may offer some advantages over tolterodine in terms of efficacy and flexible dosing regimens.^{126,127}

Drugs that have a mixed action

Oxybutynin

Oxybutynin is a tertiary amine that undergoes extensive first-pass metabolism to an active metabolite, N-desmethyl oxybutynin, which occurs in high concentrations and is thought to be responsible for a significant part of the action of the parent drug. It has a mixed action consisting of both an antimuscarinic and a direct muscle relaxant effect in addition to local anaesthetic properties. Oxybutynin has been shown to have a high affinity for muscarinic receptors in the bladder and has a higher affinity for M₁ and M₃ receptors over M₂.

The effectiveness of oxybutynin in the management of patients with detrusor overactivity is well documented. A double-blind placebo-controlled trial found oxybutynin to be significantly better than placebo in improving LUTS although 80 per cent of patients complained of significant adverse effects, principally dry mouth or dry skin.¹²⁸

The antimuscarinic adverse effects of oxybutynin are well documented and are often dose limiting, with 10–23 per cent of women discontinuing medication.¹²⁹ Using an intravesical

route of administration higher local levels of oxybutynin can be achieved whilst limiting the systemic adverse effects. Intravesical administration of oxybutynin is an effective and useful alternative for patients with neurogenic detrusor overactivity who need to self-catheterise or who suffer from 'bypassing' an indwelling catheter.

In order to improve tolerability a controlled-release oxybutynin preparation using an osmotic system (OROS) has been developed which has been shown to have comparable efficacy when compared with immediate-release oxybutynin but is associated with fewer adverse effects.¹³⁰ In order to maximise efficacy and minimise adverse effects alternative delivery systems are currently under evaluation. An oxybutynin transdermal delivery system has recently been developed and compared with extended-release tolterodine in 361 patients with mixed urinary incontinence. Both agents significantly reduced incontinence episodes, increased volume voided and led to an improvement in QoL when compared to placebo. The most common adverse event in the oxybutynin patch arm was application site pruritus in 14 per cent although the incidence of dry mouth was reduced to 4.1 per cent compared to 7.3 per cent in the tolterodine arm.¹³¹

More recently a large prospective multicentre, randomised, double-blind placebo-controlled study has been reported investigating the use of oxybutynin gel in the management of OAB in 704 patients.¹³² Overall there was a significant reduction in urge incontinence episodes in the gel arm compared to placebo, a significant reduction in daytime frequency and an increase in volume voided. When considering adverse events dry mouth was more common in the treatment arm when compared to placebo (6.9 per cent vs 2.8 per cent) and skin site reactions were infrequent in both arms – 5.4 per cent and 1.0 per cent respectively. Consequently oxybutynin gel may represent an important development over the oxybutynin patch in terms of patient acceptability.

In summary, the efficacy of oxybutynin is well documented although very often its clinical usefulness is limited by adverse effects. Alternative routes and methods of administration may produce better patient acceptability and compliance.

Propiverine

Propiverine has both antimuscarinic and calcium channel-blocking actions. Open studies have demonstrated a beneficial effect in patients with overactive bladder¹³³ and neurogenic detrusor overactivity.¹³⁴ Dry mouth was experienced by 37 per cent in the treatment group as opposed to 8 per cent in those taking placebo, with dropout rates being 7 per cent and 4.5 per cent respectively. Overall propiverine was found to have comparable efficacy to oxybutynin but was better tolerated in terms of adverse effects.

More recently propiverine extended release has been introduced and been shown to be as effective as the immediate-release preparation in the management of overactive bladder.¹³⁵

β_3 Adrenoceptor agonists

β_3 Adrenoceptor agonists have been shown to be effective in the management of OAB and mirabegron¹³⁶ has been recently launched in the UK. β_3 adrenoceptor agonists induce bladder relaxation by the activation of adenylyl cyclase with the subsequent formation of cyclic adenylyl monophosphate (cAMP) and have been shown to increase bladder capacity with no change in micturition pressure and residual urine volumes.¹³⁷ β_3 adrenoceptor agonists may offer an alternative to antimuscarinic therapy whilst at the same time offering a better side-effect profile.¹³⁸ In addition the introduction of a new class of drug may offer the possibility of combination therapy which may minimise adverse events whilst maximising efficacy.

Tricyclic antidepressants

These drugs have a complex pharmacological action. Imipramine has antimuscarinic, antihistamine and local anaesthetic properties. It may increase outlet resistance by peripheral blockage of noradrenaline uptake and it also acts as a sedative. The side effects are antimuscarinic, together with tremor and fatigue. Imipramine is particularly useful for the treatment of nocturia and nocturnal enuresis. In light of relatively poor evidence and the serious adverse effects associated with tricyclic antidepressants their role in detrusor overactivity remains of uncertain benefit although they are often useful in patients complaining of nocturia or bladder pain.

Anti-diuretic agents

Desmopressin

Desmopressin (1-desamino-8-D-arginine vasopressin; DDAVP) a synthetic analogue of vasopressin has been shown to reduce nocturnal urine production by up to 50 per cent. It can be used for children or adults with nocturia or nocturnal enuresis,¹³⁹ but must be avoided in patients with hypertension, ischaemic heart disease or congestive cardiac failure. There is good evidence to show that it is safe to use in the long term and it may be given orally or as a buccal preparation. Desmopressin has also been used as a 'designer drug' for daytime incontinence¹⁴⁰ and also in the treatment of OAB.¹⁴¹

Desmopressin is safe for long-term use, however the drug should be used with care in the elderly due to the risk of hyponatraemia and the current recommendations are that serum sodium should be checked in the first week following the start of treatment.

Oestrogens in the management of overactive bladder

Whilst the effect of oestrogens on lower urinary tract function remains controversial there is evidence to show that oestrogen deficiency may increase the risk of developing OAB following the menopause. Animal data would suggest that oestrogen might inhibit the function of Rho-kinase in bladder smooth

muscle, and hence effect smooth muscle contraction, whilst having no effect on its expression. Consequently oestrogen deprivation following the menopause may lead to the development of OAB symptoms.¹⁴² In vitro work has demonstrated that ovariectomised rats showed a significant decrease in voided volume and an increase in 24 hour frequency with an increase in basal and stretch-induced acetylcholine release. Conversely there was a reduction in acetylcholine release from nerve fibres. This may explain why there is a decrease in detrusor contractility following the menopause with a corresponding increase in the development of OAB symptoms. Interestingly oestrogen replacement therapy reversed these changes.¹⁴³

Based on these findings oestrogen replacement following the menopause may lead to an improvement in physiological voiding function whilst at the same time reducing the risk of developing symptoms of OAB. Given the concerns regarding the use of systemic oestrogen replacement therapy the vaginal route of administration may offer a better treatment approach.

Oestrogens have been used in the treatment of urinary urgency and urgency incontinence for many years although there have been few controlled trials to confirm their efficacy. A double-blind placebo-controlled crossover study using oral oestrin in 34 post-menopausal women produced subjective improvement in symptoms,¹⁴⁴ although a double-blind multicentre study of the use of oestrin in post-menopausal women complaining of urgency has failed to confirm these findings.¹⁴⁵

There is some evidence to show that vaginal 17 β -oestradiol tablets (Vagifem) therapy may be useful in managing the symptoms of OAB and in particular improving the symptom of urgency.¹⁴⁶ A further double-blind, randomised, placebo-controlled trial has shown LUTS of frequency, urge, urgency and stress incontinence to be significantly improved although there was no objective urodynamic assessment performed.¹⁴⁷ However, some of the subjective improvement in these symptoms may simply represent local oestrogenic effects reversing urogenital atrophy rather than a direct effect on lower urinary tract function.

In a review of 10 randomised placebo-controlled trials oestrogen was found to be superior to placebo when considering symptoms of urgency incontinence, frequency and nocturia although vaginal oestrogen administration was found to be superior to placebo for the symptom of urgency.¹⁴⁸ Consequently the implications of these findings are that exogenous oestrogen therapy, particularly using the vaginal route of administration, may be useful in the management of OAB.

Intravesical therapy

Capsaicin

This is the pungent ingredient found in red chillies and is a neurotoxin of substance P-containing (C) nerve fibres. Patients with neurogenic detrusor overactivity secondary to multiple

sclerosis appear to have abnormal C-fibre sensory innervation of the detrusor, which leads to premature activation of the holding reflex arc during bladder filling. Intravesical application of capsaicin dissolved in 30 per cent alcohol solution can be effective for up to six months. The effects are variable (Chandiramani *et al* 1994) and the long-term safety of this treatment has not yet been evaluated.

Resiniferatoxin

This is a phorbol-related diterpene isolated from cactus and is a potent analogue of capsaicin that appears to have similar efficacy but with fewer side effects of pain and burning during intravesical instillation. It is 1000 times more potent than capsaicin at stimulating bladder activity. As with capsaicin, the currently available evidence does not support the routine clinical use of the agents although they may prove to have a role as an intravesical preparation in neurological patients with neurogenic detrusor overactivity.

Botulinum toxin

The use of intravesical botulinum toxin type A (onobotulinumtoxin) was first described in the management of patients with neurogenic detrusor overactivity¹⁴⁹ although there is now considerable evidence to support its usage in patients with idiopathic detrusor overactivity as well.

A randomised double-blind placebo-controlled trial of onobotulinumtoxin 200 IU has demonstrated a significantly greater improvement in urgency episodes, incontinence episodes and urinary frequency with onobotulinumtoxin when compared to placebo. The commonest side effects were UTI in 31 per cent of patients and voiding dysfunction necessitating self-catheterisation in 16 per cent of cases.¹⁵⁰

These results are supported by a large phase III randomised double-blind placebo-controlled trial of onobotulinumtoxin 100 IU in 557 patients with idiopathic OAB. There was a significantly greater decrease in incontinence episodes with onobotulinumtoxin when compared to placebo (-2.65 vs -0.87 , $p < 0.001$) and incontinence resolved in 22.9 per cent vs 6.5 per cent of patients respectively. Once again UTI was the most commonly reported adverse event although the rate of urinary retention was found to be reduced to 5.4 per cent with the lower dose of onobotulinumtoxin.¹⁵¹

The efficacy of onobotulinumtoxin 100 IU has also been compared to antimuscarinic therapy (solifenacin 5 mg escalating to 10 mg and trospium chloride 60 mg) in a randomised double-blind placebo-controlled trial in 249 women. There was no difference between groups in the mean reduction of urgency incontinence episodes between the antimuscarinic arm and the onobotulinumtoxin arm (3.4 vs 3.3; $p = 0.81$) and resolution of incontinence was reported by 13 per cent and 27 per cent of the women, respectively ($p = 0.003$). Whilst QoL improved in both groups, the antimuscarinic group had a higher rate of dry mouth (46 per cent

vs 31 per cent, $p = 0.02$) but lower rates of self-catheterisation at two months (0 per cent vs 5 per cent, $p = 0.01$) and UTIs (13 per cent vs 33 per cent, $p < 0.001$).¹⁵²

Consequently onobotulinumtoxin may be effective in managing women with refractory OAB symptoms and may be administered either under general anaesthetic with a rigid cystoscope or under local anaesthetic with a flexible cystoscope. Whilst botulinum toxin type A (Botox®) is currently licensed in the UK for the treatment of neurogenic detrusor overactivity it is not currently licensed for the management of idiopathic OAB.

Neuromodulation

Sacral neuromodulation

Stimulation of the dorsal sacral nerve root using a permanent implantable device in the S3 sacral foramen has been developed for use in patients with OAB and neurogenic detrusor overactivity. The sacral nerves contain nerve fibres of the parasympathetic and sympathetic systems providing innervation to the bladder as well as somatic fibres providing innervation to the muscles of the pelvic floor. The latter are larger in diameter and hence have a lower threshold of activation, meaning that the pelvic floor may be stimulated selectively without causing bladder activity.

Prior to implantation temporary cutaneous sacral nerve stimulation is performed to check for a response and if successful, a permanent implant is inserted under general anaesthesia. Initial studies in patients with OAB refractory to medical and behavioural therapy have demonstrated that after three years, 59 per cent of 41 urinary urge incontinent patients showed greater than 50 per cent reduction in incontinence episodes, with 46 per cent of patients being completely dry.¹⁵³

Whilst neuromodulation remains an invasive and expensive procedure, it does offer a useful alternative to medical and surgical therapies in patients with severe, intractable OAB prior to considering reconstructive surgery although technical failure may often necessitate surgical revisions.

Peripheral neuromodulation

Stimulation of the posterior tibial nerve in patients with urge incontinence was first reported in 1983¹⁵⁴ and has also been proposed for pelvic floor dysfunction.¹⁵⁵ The tibial nerve is a mixed nerve containing L4–S3 fibres and originates from the same spinal cord segments as the innervation to the bladder and pelvic floor. Consequently peripheral neural modulation may have a role in the management of urinary symptoms.

Posterior tibial nerve stimulation (PTNS) is performed by the insertion of a needle in the lower leg posterior to the tibia and two finger widths above the medial malleolus. Treatment is performed in the outpatient setting weekly for the first 12 weeks and then monthly maintenance therapy with each session lasting 30 minutes.

In a prospective multicentre study 35 patients with urge incontinence underwent 12 weekly sessions of PTNS with 70 per cent of patients reporting a greater than 50 per cent reduction in urinary symptoms and 46 per cent being completely cured.¹⁵⁶ In addition a randomised trial of PTNS vs sham stimulation has demonstrated improvement in 54.5 per cent of the active arm compared to 20.9 per cent in the sham arm.¹⁵⁷

More recently a prospective randomised multicentre North American study has been reported comparing PTNS with tolterodine 4 mg ER in 100 patients. Overall there was an improvement in 75 per cent of patients with PTNS compared to 55.8 per cent with tolterodine ER and there was a significant improvement in QoL in both groups.¹⁵⁸ Furthermore a recent systematic review and meta-analysis has reported a subjective success rate of 61.4 per cent (95% CI 57.5–71.8) and objective success rate of 60.6 per cent (95% CI 49.2–74.7) and also demonstrated similar efficacy to antimuscarinic therapy.¹⁵⁹

Consequently peripheral neuromodulation may offer an alternative therapeutic option for those patients with intractable OAB who have failed to respond to medical therapy.

Surgery

Approximately 10 per cent of women with OAB remain refractory to medical and behavioural therapy and may be considered for surgery. Various different surgical techniques have been developed although currently augmentation is the most commonly performed technique using a clam cystoplasty or auto-augmentation using detrusor myectomy.

Clam cystoplasty

In the clam cystoplasty¹⁶⁰ the bladder is bisected almost completely and a patch of gut (usually ileum) equal in length to the circumference of the bisected bladder (about 25 cm) is sewn in place. This often cures the symptoms of overactive bladder by converting a high-pressure system into a low-pressure system although inefficient voiding may result. Patients have to learn to strain to void or may have to resort to clean intermittent self-catheterisation, sometimes permanently. In addition, mucus retention in the bladder may be a problem and chronic exposure of the ileal mucosa to urine may lead to malignant change.

Detrusor myectomy

Detrusor myectomy offers an alternative to clam cystoplasty by increasing functional bladder capacity without the complications of bowel interposition. In this procedure the whole thickness of the detrusor muscle is excised from the dome of the bladder, thereby creating a large bladder diverticulum with no intrinsic contractility.¹⁶¹ Whilst there is a reduction in episodes of incontinence there is little improvement in functional capacity and thus frequency remains problematic.¹⁶²

Urinary diversion

As a last resort, for those women with severe overactive bladder or neurogenic detrusor overactivity who cannot manage clean intermittent catheterisation, it may be more appropriate to perform a urinary diversion. Usually this will utilise an ileal conduit to create an incontinent abdominal stoma for urinary diversion. An alternative is to form a continent diversion using the appendix (Mitrofanoff) or ileum (Koch pouch) which may then be drained using self-catheterisation.

KEY POINTS

- Bladder retraining should be considered as first-line therapy although it has high recurrence rates.
- There is a marked placebo effect associated with all pharmacological interventions.
- Oxybutinin is effective, although it may have significant adverse side effects.
- More specific antimuscarinic agents may have similar efficacy to oxybutinin but with fewer side effects.
- The beta 3 agonists are a new class of drug for treating OAB and have been shown to have similar efficacy with fewer adverse effects.
- Oestrogens are frequently prescribed, although there is little objective evidence to support their use.
- Botulinum toxin may offer a useful therapeutic option in patients with intractable detrusor overactivity.
- Neuromodulation may be an alternative to reconstructive surgery.
- Surgical interventions such as diversion are reserved for cases for which no other treatment has succeeded and quality of life is poor.

Nice guidelines

The medical management of OAB has recently been reviewed by NICE.⁸⁰

- Patients should be counselled regarding caffeine and fluid intake.
- Those who are overweight (BMI >30) should be encouraged to lose weight.
- PFMT lasting for a minimum of three months should be offered to all women with mixed incontinence.
- Bladder retraining lasting for a minimum of six weeks should be offered to all women with mixed or urge incontinence.
- In those women who do not achieve satisfactory benefit from bladder retraining alone the combination of an antimuscarinic agent, in addition to bladder retraining, should be considered.

Fig. 95.12 Genitourinary fistulae. (a) Mid-vaginal fistula. (b) Urethral fistula. (c) Post-hysterectomy vesicovaginal fistula.

- Immediate-release non-proprietary oxybutynin, tolterodine or darifenacin should be offered to women with OAB or mixed urinary incontinence as first-line drug treatment if bladder retraining has been ineffective.
- If first-line therapy is not well tolerated the drug with the lowest acquisition cost should be used as second-line therapy. Transdermal oxybutynin and mirabegron may also be used in patients who have had significant adverse effects with antimuscarinics. In addition women should be counselled regarding the adverse effects of antimuscarinic drugs.
- A medication review should be performed at four weeks. If there is clinical improvement then treatment should continue. If there is lack of efficacy or troublesome side effects then an alternative drug should be prescribed.
- Patients on medication should be followed up at 12 months. Those over the age of 75 years should be followed up at six months.
- Referral to secondary care should be considered if symptoms do not improve with primary or secondary therapy.
- Systemic HRT should not be recommended although intravaginal oestrogens are recommended for the treatment of OAB in postmenopausal women with urogenital atrophy.
- Patients referred to secondary care should be investigated with urodynamic investigations and their medical management discussed at a multidisciplinary team meeting.
- Patients who are happy to self-catheterise, have been taught how to do so, and have a diagnosis of detrusor overactivity, should be offered botulinum toxin.

- Sacral neuromodulation may be offered to patients who are unable to self-catheterise or who have failed on botulinum toxin.
- PTNS should be considered in women when botulinum toxin or sacral neuromodulation are not appropriate.
- If conservative measures fail those patients who are able to self-catheterise should be offered augmentation cystoplasty. Those who are unable to self-catheterise should be offered a urinary diversion.

URINARY FISTULAE

The development of a genitourinary fistula has profound effects on both the physical and psychological health of a woman. The most common simple genitourinary fistulae are (Fig. 95.12):

- vesicovaginal (42 per cent);
- ureterovaginal (34 per cent);
- urethrovaginal (11 per cent);
- vesicocervical (3 per cent).

The development of a fistula following surgery has considerable legal implications. Whilst most gynaecologists accept that the development of a fistula is deeply regrettable, it was generally thought that this was, on occasion, unavoidable. However, more recent legal cases involving ureteric injury would seem to refute that. There is a body of opinion that holds the view that ureteric damage can always be avoided and that not to do so constitutes negligence.

Vesicovaginal fistulae

Aetiology

The most common cause of vesicovaginal fistulae in the developed world is gynaecological surgery. The procedure with the highest incidence of post-operative fistula formation is a hysterectomy, either abdominal or vaginal. This accounts for about 75 per cent of cases. Particular risk factors include distorted anatomy, for example previous surgery, fibroids or endometriosis. Other procedures associated with fistula formation include anterior colporrhaphy, laparoscopic pelvic surgery and urological surgery. Fistula formation has also been associated with pelvic malignancy, pelvic trauma and radiotherapy.

In the developing world, the most common cause remains obstetric trauma. It is estimated that the incidence is 1–3/1000 deliveries in West Africa.

Presentation

The majority of women with a vesicovaginal fistula present with continuous leakage of urine, both day and night. This leads to discomfort and excoriation in the genital region as the urine irritates the skin of the vulva and thighs. However, if the fistula is relatively small, a woman may just complain of increased vaginal discharge. The timing of presentation is variable, although the most common time to present is 5–10 days following surgery.

Diagnosis

A large fistula is usually obvious, and may easily be seen by examining the woman in the left lateral position using a Simms' speculum. Urine may be seen pooling in the vagina. If no fistula can be seen, useful diagnostic tests include the introduction of methylene blue into the bladder, via a urethral catheter. The blue dye may then be seen draining into the vagina. Alternatively, Bonney's 'three swab test', in which three swabs are placed in the vagina prior to instilling the dye, may help to locate the site of the fistula, which is indicated by the swab that emerges with the most dye. However, this may mask the presence of multiple fistulae. Intravenous urogram is not usually helpful in the diagnosis of a vesicovaginal fistula, but it is mandatory to rule out a ureterovaginal fistula or ureteric obstruction, which is seen concurrently in as many as 12 per cent of cases and is obviously very important when planning future treatment. If an IVU has failed to elucidate the ureteric anatomy, retrograde ureteropyelography should be undertaken at the same time as a cystoscopy and examination under general anaesthesia.

When the woman is anaesthetised, it is often possible to palpate the vaginal opening of the fistula tract. The vesical opening may be seen at cystoscopy, usually on the posterior wall or at the bladder base. If the fistula is not related to recent gynaecological surgery for a benign condition, both the vaginal and the vesical openings should be biopsied to exclude the possibility of malignancy.

Treatment

Treatment options range from simple conservative measures to more complex surgical procedures using either an abdominal or vaginal approach. In addition it is important to give general advice regarding the management of symptoms experienced as a result of the fistula. Barrier creams may help prevent the skin becoming sore and excoriated. Advice about incontinence pads, the increased risk of UTI and the need in some cases for prophylactic antibiotics may be required.

Urethrovaginal fistulae

In the developed world, these occur most commonly following an anterior repair with or without a vaginal hysterectomy. However, they may develop as a result of a urethral diverticulum or its repair or following bladder neck suspension procedures. In the developing world, the overwhelming majority are again caused by childbirth.

Symptoms vary depending on the site of the fistula. With a fistula higher up in the urethra there may be continuous incontinence; a fistula nearer the bladder neck may present with stress incontinence and recurrent UTIs; and one lower down may cause symptoms of spraying of urine at micturition or post-micturition dribble.

Women should initially be managed using a conservative approach with a urethral catheter, although almost all patients will need surgical repair. Due to the complex nature of such procedures this should be performed in a specialist centre.

KEY POINTS

- In the developed world, gynaecological surgery is the most common cause, with 75 per cent being attributable to hysterectomy.
- Obstetric trauma is the most common cause in the developing world.
- Most present between 5 and 10 days post surgery.
- Presentation varies from a mild discharge with small fistulae to continuous urine loss with larger fistulae.
- IVU is mandatory as part of the assessment because of high ureteric co-morbidity.

OVERFLOW INCONTINENCE AND VOIDING DYSFUNCTION

Symptoms

These may be a result of the voiding difficulty, such as:

- poor stream;
- prolonged voiding time;
- double void;
- incomplete emptying;

- hesitancy;
- frequency;
- nocturia;
- urgency;
- pain;
- abdominal distension;

or may reflect the underlying disease:

- abdominal distension, due to a mass such as fibroids or an ovarian cyst;
- pregnancy;
- peri-anal pain;
- peripheral paraesthesia;
- herpetic rash;

or a consequence of the voiding difficulties:

- recurrent urinary tract infections.

Aetiology

Neurological

The aetiology depends on the underlying neurological condition and the level at which the anatomy is affected. CNS conditions that commonly cause voiding difficulties include multiple sclerosis, spinal injuries, cerebrovascular accidents and brain tumours. Peripheral lesions include lesions at the sacral outflow, for instance a prolapsed intervertebral disc, cauda equina syndrome or herpes zoster.

Myogenic

This usually results from ischaemia due to acute retention, for example after an epidural block or spinal shock.

Iatrogenic

Post-operative retention is relatively common and may be associated with long operation times, epidural anaesthesia, patient-controlled analgesia, high doses of opiates and large volumes of intravenous fluids. It may also be associated with obstructive outflow procedures such as continence procedures.

Obstructive

This may be extrinsic, for example pregnancy or a large fibroid uterus, or intrinsic, such as a urethral stricture or foreign body. Alternatively, it may be as a result of kinking of the urethra, as can occur with a large prolapse.

Inflammatory

Any lesion may be sufficiently painful to inhibit the voiding reflex. This is seen, for instance, with vulval abscess or acute herpetic infections.

Diagnosis

Voiding difficulties should be suspected if a pelvic mass that is dull to percussion is palpable on clinical examination. The

diagnosis can be confirmed using ultrasound. The patient is asked to empty her bladder and then an abdominal ultrasound scan can easily be performed to assess the residual urine. Alternatively, a urethral catheter can be inserted to assess the residual urine. In either case, it is very important that the residual volume is measured and accurately recorded.

Management

It is vital that all clinicians are aware of the complications associated with an episode of acute retention and that all possible steps are taken to avoid it happening. If it does occur, catheterisation should be undertaken as soon as possible and the catheter should be left in for at least two days, after which it is reasonable to undertake a trial without catheter, but only under strict supervision. If there is a further episode of retention, this should be managed with a suprapubic catheter and the bladder allowed to rest for a period of 2–6 weeks.

Medical therapy

Bethanechol 25 mg twice daily has been shown to enhance bladder emptying providing there is no evidence of outflow obstruction, although it is seldom useful clinically.

Surgery

If the voiding difficulties are a result of extrinsic compression, this is usually best treated by removing the underlying cause, for example a hysterectomy or myomectomy in the case of fibroids. However, in the case of pregnancy causing obstruction, supportive measures are usually used in the form of a urethral catheter until the uterus has grown a little more and the obstruction relieves itself.

If the obstruction is intrinsic, this may be treated by the removal of a foreign body or offending material. Alternatively, if a urethral stricture is suspected, a cystoscopy and an Otis urethrotomy may be required, in which case the patient would need to be counselled about having a urethral catheter on free drainage for two weeks on discharge from hospital and the possibility of post-operative urinary incontinence.

In the long term, intractable voiding difficulties may need to be treated with clean intermittent self-catheterisation. The patient needs to be able to perform the technique, and this usually requires a degree of manual dexterity in addition to willingness to undertake it.

CONCLUSION

Urinary incontinence is common and, whilst not life threatening, is known to have a significant effect on quality of life. Appropriate investigation and management allows an accurate diagnosis and avoids inappropriate treatment. Whilst many forms of conservative therapy may be initiated in primary care, continence surgery and the investigation of more

complex and recurrent cases of incontinence should be performed in specialist secondary and tertiary referral units. Ultimately, an integrated pathway utilising a multidisciplinary team approach including specialist nurses, continence advisors, physiotherapists, urologists and colorectal surgeons will ensure the best possible outcomes in terms of 'cure' and patient satisfaction.

Chapter 96 Other lower urinary tract disorders

Ganesh Thiagamoorthy and Sushma Srikrishna

INTRODUCTION

This chapter includes some disorders of the lower urinary tract which are seen less often. These are not necessarily well understood and there may be little evidence-based information regarding diagnosis or management. The established management is based largely on non-randomised, observational data and expert opinion.

BLADDER PAIN SYNDROME

Bladder pain syndrome (BPS), previously referred to as interstitial cystitis (IC), is defined as chronic pelvic pain, pressure or discomfort of greater than six months' duration, perceived to be related to the urinary bladder. This is usually accompanied by at least one other urinary symptom, such as persistent urge to void or urinary frequency.¹ BPS has a strong relationship with other pain syndromes, such as irritable bowel syndrome, fibromyalgia and chronic fatigue syndrome. Therefore, other diseases which may cause symptoms which are similar to those of BPS must be excluded (see Table 96.1). Based on this, a comprehensive article has been published by the European Society for the Study of Bladder Pain Syndrome/Interstitial Cystitis (ESSIC).²

The presence of other cognitive, behavioural, emotional and sexual symptoms should also be addressed. The diagnosis may change after findings at cystoscopy or bladder biopsies.

Historically, IC has been seen as a chronic severe inflammatory disease of the bladder that is difficult to diagnose and treat. It has been agreed by the members of the ICI that the term 'bladder pain syndrome' complies with the current knowledge and understanding of this syndrome.³ However, BPS and IC are being used in parallel for the time being, as IC is a well-known term and omitting the name 'Interstitial cystitis' might cause reimbursement problems in different health systems.

PREVALENCE

The prevalence of chronic bladder pain in the general population due to benign conditions is at least 19 per cent.⁴ The lack of a clear definition and valid diagnostic criteria have been deterrents to epidemiological studies of BPS. There is also an overlap of lower urinary tract symptoms such as frequency and urgency in conditions like overactive bladder and BPS.⁵ In one study, 15 per cent of BPS patients also demonstrated detrusor overactivity at urodynamics.⁶ This makes it difficult to estimate the true incidence. OAB however is not usually associated with pain, unlike BPS. The prevalence of painful bladder syndrome symptoms is 2.7–6.5 per cent in women depending on the sensitivity and specificity of the definition used.⁷ Painful bladder symptoms are more common than suggested by coded physician diagnoses and show a female preponderance of 5:1 or more.⁸ The presence of BPS is associated with a significant adverse impact on quality of life. There is a higher incidence of co-morbidities like anxiety, depression and overall mental health problems in BPS sufferers. Consequently, there is a six-fold increase in absenteeism from work due to sickness, over the general population.⁹

AETIOLOGY

Due to the lack of consensus relating to the definition and classification of BPS, the aetiology still remains obscure. However, there are several hypotheses with little evidence to support them. Inflammation and mast cell activation have been put forward as factors in ulcerative BPS. A defect in the glycosaminoglycan (GAG) layer has been proposed by some¹⁰ and bladder epithelial dysfunction by others.¹¹ Although certain histopathological characteristics present in BPS patients are similar to autoimmune diseases, only a portion of BPS patients have auto-antibodies. Infection, autonomic nerve changes, disorders of nitric oxide metabolism, toxic agents, hypoxia and genetic susceptibility are other factors that are considered as possible aetiologies. Numerous propositions without solid evidence show that the aetiology of BPS is more complex than previously believed.

MANAGEMENT

History

Patients presenting with frequency and urgency need to be carefully questioned about other urinary symptoms. Associated urgency incontinence, dysuria or suprapubic pain may be relevant. If haematuria is reported, this must be investigated further. The presence of a UTI, bladder carcinoma, calculus or a lesion of the upper urinary tracts needs to be excluded. A thorough history should be undertaken with special emphasis on previous pelvic surgery, UTIs and urological diseases. Characteristics of pain including onset, correlation with events, description, location and relation to bladder filling and emptying must be sought. History of previous pelvic radiation treatment, chemotherapy and autoimmune diseases is also important.

Examination

Examination should be undertaken in the standing position for kyphosis, scars and hernia and in the supine position to assess abduction/adduction of the hips and hyperaesthetic areas. A neurological assessment is important to exclude an upper motor neuron lesion. The S2, S3, S4 nerve roots innervate the bladder and particular regard should be paid to these dermatomes. An abdominal examination will rule out a mass or large distended bladder. Vaginal examination should be performed with pain mapping of the vulvar region and vaginal palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor. Tenderness might be graded as mild, moderate or severe. Assessment of prolapse should also be carried out via vaginal examination in the supine and standing positions.

Investigation

Initial investigation should always include a midstream urine sample for culture and sensitivity. If the woman is over 40 years of age with microscopic haematuria, or of any age with macroscopic haematuria, urine should also be sent for cytology. Appropriate cultures for 'fastidious organisms' (*Mycoplasma hominis*, *Ureaplasma urealyticum* and *Chlamydia trachomatis*), tuberculosis and schistosomiasis may be indicated.

A completed frequency–volume chart is an invaluable tool, providing useful information on fluid input and output, drinking habits, voided volumes and the episodes of urgency and incontinence. (Fig. 96.1 shows the frequency–volume chart used at King's College Hospital.) When the cause for the symptoms is not revealed by such assessment, more specialist investigations should be considered. Ultrasound scan can be used to assess residual bladder volumes accurately and to give more information on any masses detected on pelvic examination. Once a UTI has been ruled out, uroflowmetry, post-void residual urine volume and pressure–flow study may be performed.

In 1914, Hunner described the classic cystoscopic picture of a bladder ulcer with a corresponding appearance of patches of red epithelium exhibiting small vessels radiating to a central pale scar in patients with BPS.¹² Glomerulations, described as punctuate petechial haemorrhages observed after hydrodistension, have become the primary cystoscopic feature of BPS. However, these findings are not always present and do not correlate with the severity of the disease. There is also evidence that the cystoscopic appearance of the bladder wall after hydrodistension may not be constant over time and the absence of the initial findings of glomerulations or haematuria does not preclude further developments of these features on subsequent evaluation.¹³

There is also a considerable variation in the procedure of cystoscopy and hydrodistension. The ICI has recently recommended a standardised procedure using a rigid cystoscope to enable biopsies to be performed at the same time.³ The bladder is filled using a dripping chamber at 80 cm above the symphysis pubis and filling is stopped after fluid dribbling stops. Continuous inspection is necessary to view the epithelium for radiating vessels, hyperaemia, oedema, cracks, scars or any other changes. When maximum capacity is reached, the distension should be maintained for 3 minutes. The bladder is then emptied and the degree of bleeding, if any, is noted. The total volume drained is the measured maximum bladder capacity. The bladder is then refilled to a third or two thirds of the capacity to look for changes and perform biopsies. At least two biopsies including detrusor muscle should be taken and used for mast cell counting in addition to biopsies taken from abnormal areas. Only the biopsy with the highest number of mast cells/mm² should be reported and 27 mast cells/mm² is considered indicative of mastocytosis.¹⁴

Confusable diseases can be mistaken for BPS or BPS may coexist together with other disorders,¹⁵ such as chronic or remitting urinary infections or endometriosis. Endometriosis accounts for 70–90 per cent of pelvic pain in pre-menopausal women referred to a gynaecological pain unit and 93 per cent had some urinary symptoms as well.^{16,17} The diagnosis of BPS is usually made on the basis of exclusion of these disorders. If the main urinary symptoms are not explained by a single diagnosis, the presence of a second diagnosis should be considered. Table 96.1 lists some of these confusable diseases related to BPS and the diagnostic procedures to exclude them.

TREATMENT

Conservative treatment

In motivated patients, behavioural therapy has been noted to be efficacious in treating urinary frequency and urgency without any side effects. Behavioural therapy includes timed voiding, controlled fluid intake, pelvic floor muscle training and bladder training. Physical therapy for the pelvic floor is effective for genitourinary and anorectal disorders. Biofeedback and soft tissue massage may help in the relaxation of the pelvic

floor muscles. Stress reduction and dietary manipulation are other methods of conservative management which have been shown to be effective.¹⁸

Oral medications

Several groups of drugs have been used in the management of BPS. These include non-opioid analgesics e.g. paracetamol and NSAIDs, gabapentin and pregabalin. Opioid analgesics are used as a last resort and better administered in a pain clinic to reduce the incidence of addiction. Amitriptyline is a tricyclic antidepressant with the property of blocking H1-histaminergic receptors. It stabilises mast cells, inhibits painful nociception from the bladder and facilitates urine storage.

The most widely used antihistamine for BPS is hydroxyzine. It also inhibits bladder mast cell activation and has anticholinergic and anxiolytic properties.¹⁹ In addition, it has a good safety profile which makes it desirable. Sodium pentosanpolysulphate (PPS) is the most intensively studied treatment for BPS and is the only medication approved by the Food and Drug Administration for the pain of interstitial cystitis. A defective GAG layer is hypothesised to be one of the important causes of BPS and PPS may replenish it.²⁰

Intravesical medications

Intravesical therapies are the next line of treatment in patients in whom oral medications have failed. DMSO (dimethyl sulphoxide) has been used as a therapy for BPS for a long time. It is believed to reduce inflammation, degranulate mast cells, relax muscles and eliminate pain.²¹ The exact mechanism of action, however, is not known. The instillation is performed weekly for 6–8 weeks and treatment is suspended after an initial course until symptoms recur. A further 6-week course with monthly maintenance can be initiated if the results are good. Heparin, hyaluronic acid, chondroitin sulphate, PPS, capsaicin, resiniferatoxin, BCG, oxybutynin and lidocaine are other agents used.

Cystoscopic hydrodistension has been shown to have variable benefit but this is short lived and bladder rupture and voiding dysfunction are possible risks.²² Fulguration of Hunner's ulcers has been shown to improve symptoms in patients with repeat treatments required within 11–23 months.²³ Intravesical botulinum toxin type A injections have been shown to improve symptoms of BPS but patients must be monitored due to significant risk of urinary retention and UTIs.²⁴

Surgical treatment

Although BPS is a chronic and debilitating disease, surgical management should only be considered when other conservative and medical therapies have been unsuccessful. Bladder

augmentation cystoplasty has been used for refractory BPS for 50 years.²⁵ Urinary diversion with or without total cystectomy and urethrectomy is the ultimate, final and most invasive option. It should be used as a last therapeutic resort in selected patients. Urinary diversion with formation of an ileal conduit is the most common surgical treatment for BPS/IC. Initially, diversion can be performed without cystectomy, and only when bladder pain is persistent, cystectomy may be considered. To avoid further bowel resection, a bowel segment used for cystoplasty can often be converted to a conduit.

KEY POINTS

- BPS is defined as chronic pelvic pain, pressure or discomfort, related to the urinary bladder accompanied by urgency and/or urinary frequency.
- 'Confusable diseases' as the cause of the symptoms must be excluded.
- The initial assessment should consist of a frequency–volume chart, focused physical examination, urinalysis and urine culture.
- Urine cytology and cystoscopy are recommended.
- Patient education, dietary manipulation and pelvic floor relaxation techniques comprise the initial treatment of BPS.
- When conservative therapy fails oral medication, intravesical treatment should be offered.
- If medical therapy fails, further evaluation should include urodynamics, pelvic imaging and cystoscopy with distension, and biopsy under anaesthesia.
- Urinary diversion with or without cystectomy may be the ultimate option for refractory patients.

URETHRAL CARUNCLES

Urethral caruncles are found only in women, typically in post-menopausal women and pre-pubertal girls. They usually represent ectropion of the urethral wall secondary to hypo-oestrogenic regression of the vaginal epithelium. Urethral prolapse may be mistakenly diagnosed as a caruncle in a child. On physical examination, a urethral caruncle is seen as a solitary red polypoid lesion protruding from one segment of the urethral meatus, usually the posterior aspect. Most caruncles measure only a few millimetres in diameter. The caruncle consists of well-vascularised transitional epithelium and is sometimes uncomfortable during voiding, but more often does not give rise to any urinary symptoms. The patient may alternatively present with post-menopausal 'spotting'. Initial treatment is with topical oestrogen therapy. If the lesion does not respond to oestrogen, it is important to biopsy it to exclude more serious pathology. Once malignancy is ruled out, it can be treated by either excision or cauterisation. There is a high rate of recurrence.

URETHRAL PROBLEMS

The female urethra is a complex muscular tube, approximately 4 cm in length. It is composed of several layers of muscle, the richly vascular submucosa and the urothelium. There is considerable debate regarding the relative roles of different components of the muscles, both within the wall of the urethra and surrounding it, in maintaining continence. A number of changes occur to the urethra with age. The strength and the amount of urethral connective tissue fall as a result of oestrogen deficiency. This causes the support of the urethrovesical junction to weaken. In addition, urethral vascular pulsations in the submucosal plexus gradually decrease with age.

Urethritis

Urethritis is inflammation of the urethra leading to symptoms of frequency, urgency, dysuria and localised urethral pain. It is caused either by an infectious pathogen or by chemical irritation. Evidence of the use of causative chemical agents, such as bubble baths, vaginal deodorants and perfumed cosmetics, should be sought as part of the medical history in women with such symptoms. Responsible infectious agents include many of the microorganisms associated with sexually transmitted infections, such as herpes simplex virus, *Neisseria gonorrhoeae* and *Chlamydia*. The group of organisms that typically cause acute bacterial cystitis, such as *Escherichia coli*, may also cause urethritis. Where urethritis is suspected, appropriate cultures should be taken from the urethra and vagina, as well as a mid-stream urine culture. Urine microscopy typically shows evidence of pyuria and bacteria.

Acute urinary retention can occur secondary to urethritis and needs to be considered. Prompt treatment with an indwelling catheter until symptoms have resolved is important in order to prevent overdistension of the bladder. The initiation of treatment with the appropriate antibiotic usually results in a rapid recovery, but scarring of the urethra can result in strictures and subsequent voiding difficulties. Referral to a genito-urinary medicine clinic for contact tracing and treatment of partners is important if sexually transmitted organisms are responsible. Cessation of the use of the offending chemical agent results in fairly rapid resolution of symptoms without the need for further treatment.

Urethral diverticulum

A urethral diverticulum is usually found on the anterior vaginal wall along the distal two thirds of the urethra, bulging into the vagina. They are occasionally found congenitally, but thought to arise more often from repeated inflammation of the para-urethral glands. Urethral diverticula are formed as a consequence of infected peri-urethral glands or cysts rupturing into the urethral lumen.²⁶ Common organisms include *Escherichia coli*, *Gonococcus* and *Chlamydia*. The presenting symptoms vary, but usually include frequency, dysuria, dyspareunia, voiding difficulties and recurrent UTIs. The classical

symptom associated with this condition is post-micturition dribble, caused by the delay in the diverticulum draining after voiding.

On vaginal examination, it is sometimes possible to palpate a sub-urethral mass or even a calculus that has formed in the diverticulum. An infected urethral diverticulum is tender on examination and clear urine or purulent material can be expressed from the urethral meatus on compression. Alternatively, there may be no physical signs. However, Neitlich *et al.* demonstrated that high-resolution, fast-spin echo MRI has a higher sensitivity for detecting diverticula and has a higher negative predictive rate than double-balloon urethrography.²⁷

Sometimes, a urethral diverticulum may be found incidentally as part of X-ray screening during videourodynamics (Fig. 96.2). Similarly, they may be seen on transvaginal ultrasound examination. Urethral pressure profilometry shows a characteristic 'saddle-shaped dip' in urethral closure pressure and gives useful information about the position of the opening of the diverticulum relative to the urethral sphincter and bladder neck. If a patient has symptoms suggestive of a diverticulum and a diagnosis is required, a voiding cystourethrogram or a positive-pressure double-balloon urethrography using a Trattner catheter will give useful information about the size and position of the defect prior to surgery. These lesions are not always easy to see on cystourethroscopy unless the opening into the diverticulum is large.

Surgical repair is usually undertaken if the patient has related symptoms, such as suffering from recurrent urinary infections. Endoscopic incision has been described, but transvaginal excision is the preferred treatment.²⁸ The techniques described include marsupialisation and vaginal diverticulectomy. There are no good long-term studies to guide clinicians as

Fig. 96.2 A urethral diverticulum is clearly seen during the voiding phase of videourodynamic assessment

to the best surgical techniques for treating urethral diverticula. Recurrence is fairly common, especially if there has been failure to remove the whole sac. If the diverticulum is small and not causing any problems, it is better left alone.

Iatrogenic urinary tract injury

Damage to the urinary tract at the time of pelvic surgery is an important consideration for all gynaecological surgeons. It is estimated to occur in 0.5–2.5 per cent of routine pelvic operations and in as many as 30 per cent of radical pelvic procedures for malignancy.²⁹ Common types of iatrogenic ureteric injuries, in descending order of frequency, are ligation, kinking by suture, transection/avulsion, partial transection, crush and devascularisation.³⁰ Although relatively uncommon, when ureteric injury does occur, it presents a difficult challenge both to identify the injury and then to repair the damage. A good understanding of female pelvic anatomy and how this may be altered as the result of previous surgery or pelvic pathology is essential in order to minimise the risk of inadvertently damaging the urinary tract. Prompt recognition of the injury and the early involvement of an experienced urologist are important in ensuring a good outcome.

Aetiology

There are three common sites of ureteric injury during gynaecological surgery:

- 1 at the point where the ureters cross over the pelvic brim and enter the pelvis in close proximity to the ovarian vessels;
- 2 as the ureters course medially in the base of the broad ligament with the uterine artery crossing directly over the top of them; this is the site at which the ureters may be crushed by a clamp or divided while taking the uterine pedicle at hysterectomy;
- 3 at the ureterovesical junction as the ureters sweep medially to enter the bladder.

Any disease process that alters the normal anatomical course of the ureters or that makes their intraoperative identification more difficult increases the risk of injury. Malignant disease, advanced-stage endometriosis and previous abdominal surgery or radiotherapy all make it more difficult to predict the path of the ureters. Similarly, the normal anatomical relations of the bladder are often distorted in these circumstances. It is often wise to consider the use of a pre-operative intravenous urogram or the placement of ureteric stents at cystoscopy before proceeding to complex pelvic surgery. The path of the ureters should always be identified prior to any extensive pelvic dissection.

Management

A keen awareness of the proximity of the lower urinary tract during gynaecological surgery is the key to preventing these injuries. Such damage is largely preventable and forms an ever-increasing source of medical litigation. The success of

managing these problems once they occur is largely dependent on whether the injury was detected at the time of operation and on close liaison with urological colleagues. Most bladder injuries are relatively straightforward to repair, provided they are identified intraoperatively.

Methylene blue dye instilled into the bladder via a urethral catheter can aid in the identification of bladder injuries. If damage is found, associated ureteric injury should also be borne in mind. The bladder can be satisfactorily repaired with two layers of absorbable suture and left to drain freely with an indwelling catheter for 10–14 days. The bladder heals well and the prognosis for such repairs is extremely good.

If ureteric injury is suspected intra-operatively, the advice of a urologist should be sought. The course of the ureter above and below the area of concern needs to be demonstrated. Indigo carmine dye can be given intravenously to aid in checking the integrity of the ureters. The most appropriate method of repairing damage to the ureter depends largely on the site of the injury and should only ever be undertaken by an experienced surgeon with appropriate urological training. It is not appropriate for a gynaecologist who has not received such training to embark on these procedures. The most commonly employed techniques for repair of injuries to the mid-ureter are summarised in Box 96.1.

In those cases in which injury to the lower urinary tract goes unnoticed at the time of operation, the patient is likely to develop symptoms and signs within a few days postoperatively. These may include fever, abdominal or flank pain, abdominal distension, sepsis, decreased urine output and rising serum creatinine and leukocytosis. These result from the extravasation of urine into the peritoneal cavity or from ureteric obstruction. However, the presentation may be delayed and the patient subsequently complains of persistent discharge from a fistula or abdominal wound. Anuria may occur if there is bilateral ureteric injury. Sometimes, ureteric obstruction is only discovered many years later as an incidental finding.

If damage to the bladder or ureters is suspected post-operatively, an intravenous urogram is the diagnostic study of choice.³¹ Repair of the damaged bladder is dependent upon the extent of urinary leakage. Extraperitoneal injuries and small leaks in women who are still voiding spontaneously can be managed with a trial of catheter drainage for 10–14 days

Box 96.1 Possible methods of repair

- Mid-ureteric injuries
 - Boari flap
 - Primary ureteric anastomosis (uretero-ureterostomy)
 - Ureteric anastomosis to the contralateral ureter (transuretero-ureterostomy)
- Lower ureter (distal 4 cm of the ureter)
 - Primary ureteric anastomosis (uretero-ureterostomy)
 - Psoas hitch
 - Ureteric reimplantation into the bladder

in order to rest the bladder. In patients with more extensive bladder damage, intraperitoneal injuries with physical signs and in those in whom conservative management has failed, surgical exploration and repair of the defect are required. In cases where ureteric injury is recognised post-operatively, it is important to identify the site of damage in order to plan the most appropriate course of action. A retrograde urogram can give more information regarding the precise location of the injury. If the patient is septic or not well enough to undergo immediate surgical re-exploration, a nephrostomy tube can be inserted to improve renal function to the point at which surgery is a more realistic alternative. In a small minority of cases where ureteric obstruction is caused by suture entrapment, nephrostomy drainage alone may resolve the damage. More often, surgical intervention is required. The techniques available are the same as those discussed previously for performing an intra-operative repair at the time of the initial injury.

KEY POINTS

- The ureters and bladder should always be respected by gynaecologists operating in the pelvis.
- A thorough knowledge of their anatomical relationships and of how these may be modified by pathological processes is important in order to minimise the risk of inadvertently damaging the lower urinary tract.
- The possibility of such an injury should always be borne in mind, both at the time of surgery and in the post-operative period.

ACKNOWLEDGEMENT

This chapter has been revised and updated. The author and editors acknowledge the contribution of James Balmforth and Arasee Renganathan to the chapter on this topic in previous editions of this book.

Chapter 97 Lower urinary tract infections

Ilias Giarenis and Dudley Robinson

MRCOG standards

- Have comprehensive knowledge of lower urinary tract infections affecting pregnant and non-pregnant women.
- Appreciate the pathogenesis of lower UTI.
- Identify those at risk of developing UTI and those at risk of recurrence.
- Collect appropriate specimens, use the laboratory appropriately and order additional investigations when necessary.
- Make accurate diagnoses and appreciate definition of different terms.
- Successfully manage uncomplicated and complicated UTI and its recurrence.
- Make recommendations for follow-up care.

INTRODUCTION

‘Urinary tract infection’ is a term that is used to describe various infections involving the urinary tract. The spectrum ranges from asymptomatic bacteriuria to severe pyelonephritis.

There are different classifications for UTI and these can be divided into lower UTI, i.e. infection involving the urethra and bladder, or upper UTI, mainly involving the kidneys. UTI may also be classified as uncomplicated, when the infection happens without underlying structural or functional abnormalities, or complicated, when several anatomical abnormalities predispose to UTI. The classification system is important in patient management as it provides a guide to investigation, treatment and prophylaxis.

DEFINITIONS

Bacteriuria

This is used to describe the presence of small numbers of bacteria in the urine. In a clean-catch freshly voided sample, this represents 10,000 colony-forming units (CFU)/mL.

Significant bacteriuria

This term is used to describe the presence of at least 100,000 CFU/mL of urine in a voided midstream clean-catch specimen, or at least 100 CFU/mL of urine from a catheterised specimen.¹ While 20–40 per cent of women with symptomatic UTIs may present with bacterial counts of 100,000 CFU/mL,² bacterial counts of 100–10,000 CFU/mL have also been associated with symptoms of cystitis. This may represent the early stages of infection.

Asymptomatic bacteriuria

This is used to describe the presence of bacteria in the urine of an asymptomatic woman. Asymptomatic bacteriuria is common; the prevalence depends on age, sex, sexual activity and the presence of urological abnormalities. In women it is only diagnosed if the same organism is present in quantities of at least 100,000 CFU/mL of urine in at least two consecutive voided specimens.

Whilst the organisms causing asymptomatic bacteriuria and symptomatic UTI are the same, it is not fully understood why patients with asymptomatic bacteriuria do not develop symptoms. This is probably related to organism virulence, where organisms with decreased virulence may only colonise the urine, without causing symptoms.

Complicated lower UTI

This term is used to describe UTIs that may be related to other pathology (Table 97.1). One of the most common forms of complicated UTI is related to the use of urinary catheters. The incidence of bacteriuria associated with an indwelling urinary catheter is 3–10 per cent per day, and the duration of catheterisation is the most important risk factor for developing UTI. They represent a huge reservoir of resistant bacteria in the hospital environment.

Recurrent lower UTI

This is defined as three or more episodes of UTI during a 12-month period,³ or two infections in a six-month period. Recurrent UTI with the same organism following adequate therapy is termed a relapse. Reinfection is a recurrent UTI caused by bacteria previously isolated after treatment and a

Table 97.1 Conditions associated with complicated lower UTI

Type	Condition
Structural	Urolithiasis
	Malignancy
	Ureteric stricture
	Urethral stricture
	Bladder diverticula
	Renal cysts
	Fistulae
	Urinary diversions
Functional	Neurogenic bladder
	Vesico-ureteric reflux
	Voiding difficulties (incomplete bladder emptying)
Foreign bodies	Indwelling catheter
	Ureteric stent
	Nephrostomy tube
	Mid-urethral tapes for incontinence surgery
Other	Diabetes mellitus
	Pregnancy
	Renal failure
	Renal transplant
	Immunosuppression
	Multidrug resistance
	Hospital-acquired (nosocomial) infection

negative intervening urine culture or a recurrent UTI caused by a second isolate.⁴ In a study involving college students with their first UTI, Foxman *et al.*⁵ have shown that 27 per cent had at least one culture-confirmed recurrence within the six months following the initial infection, and 2.7 per cent had a second recurrence over the same period of time. The risk of recurrence of UTI is age related. In a study of women with age range between 17 and 82 years with *E. coli* cystitis, 44 per cent had a recurrence within one year, and recurrence is more common in older than younger women.⁶

EPIDEMIOLOGY

UTIs are common medical conditions. In the US, they account for 7–8 million clinic visits and more than 100,000 hospital admissions, mainly due to pyelonephritis.⁷ They are more common in females than males with a female-to-male ratio of 14:1. The reasons are probably related to anatomical and functional differences; the female urethra is shorter with the distal third contaminated by bacteria from the vagina and rectum. In addition, during intercourse, bacteria are introduced into the urethra and bladder, and also female bladder emptying may be incomplete compared with males.

The woman's lifetime risk of at least one UTI is around 20 per cent, with a prevalence that is age related, and increases by 1 per cent per decade of life.

RISK FACTORS FOR LOWER UTI

Risk factors for UTI seem to vary according to age. Data regarding recurrent UTIs are scarce. Tables 97.2 and 97.3 summarise congenital and acquired risk factors for urinary tract infection.

Table 97.2 Congenital risk factors for urinary tract infection

Location	Risk factor
Urethra	Hypospadias
	Epispadias
Bladder	Vesico-ureteric reflux
	Ectopic ureters
	Obstructive mega-ureter
Pelvis	Pelvic-ureteric junction obstruction
Central nervous system	Meningomyelocele
	Tethered cord syndrome

Table 97.3 Acquired causes of urinary tract infection

Type	Cause
Traumatic	Surgery (urinary diversion, clam cystoplasty)
	Sexual intercourse
	Sexual abuse
	Foreign bodies (catheters, stents)
	Contraceptive diaphragm
Inflammatory	Vulvo-urethritis
	Chronic inflammation (tuberculosis, syphilis, schistosomiasis)
	Interstitial cystitis
	Radiotherapy
	Fistulae
Metabolic	Calculi
	Diabetes mellitus
Drugs	Cyclophosphamide
	Tiopropenic acid
Anatomical	Cystocele
	Urethral diverticula
Functional	Detrusor hypotonia
	Detrusor dyssynergia
	Constipation
Malignancy	Bladder tumours
	Other pelvic tumours (cervix, uterus, ovary)

Pre-menopausal women

Behavioural factors are thought to increase the risk of UTI. In a large case–control study of women with and without a history of recurrent UTI, the strongest risk factor for recurrent UTI was the frequency of sexual intercourse. Other risk factors include spermicidal use during the past year, having a new sexual partner during the past year, having a first UTI at or before 15 years of age, and having a mother with a history of UTIs.⁸

Post-menopausal women

Anatomical and functional factors are thought to increase the risk of UTI. Raz *et al.*⁹ have shown that in healthy post-menopausal women with a history of recurrent UTI, when compared with a control group, three factors were found to be strongly associated with recurrent UTI; namely urinary incontinence, cystocele and post-void residual urine.

PATHOGENESIS

UTIs are the result of a complex interaction between several factors related to both the host and the uropathogens.

Host factors

The main route of bacterial entry into the urethra and bladder is ascending from the bowel to the vaginal vestibule, and then to the urethra and bladder. In support of that, it has been shown that the vaginal vestibule of women with recurrent UTI had higher enterobacterial colonisation than women with no recurrent UTI. Changes in the vaginal microflora are important in the aetiology. These changes may be caused by the use of spermicides, antibiotics and lack of oestrogen.

Host defence

There are several protective mechanisms against UTI; the main function is to prevent colonisation with uropathogens.¹⁰ These mechanisms include:

- Urinary hydrodynamics: urine production and micturition provide a washout mechanism to prevent uropathogens from colonising the urinary tract; if this mechanism is impaired, a significant post-void residual urine may result in increased risk of UTI.
- Urine biochemical characteristics; namely, high osmolality and low pH prevent bacterial multiplication.
- Urinary tract epithelium has bactericidal activities.
- Inhibitors of bacterial adherence: several protective mechanisms work to prevent bacterial adherence to the urinary tract epithelium which is a prerequisite for infection. The factors that prevent bacterial adherence include

Tamm–Horsfall protein, bladder mucopolysaccharides and oligosaccharides and lactoferrin.

- Inflammatory response will take effect when bacteria adhere to epithelium. The inflammatory response includes polymorphonuclear leukocytes and cytokines.
- Both humoral and cell-mediated arms of the immune system play an important part in the resistance against bacterial infection of the urinary tract.

Virulence factor

Microorganisms have the ability to survive and multiply in the bladder and are able to adhere to the bladder epithelium.¹¹ *E. coli* is responsible for 80 per cent of UTIs and this is why most virulence studies have focused on it. The virulence factors that are thought to play a role in the pathogenesis of UTI include:

- *Adherence factors*: The two most important fimbriae thought to play a role in the *E. coli* UTI are type P and type 1. These fimbriae will bind to specific receptors on the urinary tract epithelium, and eventually provoke an inflammatory reaction. It seems that they are site specific, where type 1 is present in the majority of *E. coli* causing lower UTI, and type P is mostly found in *E. coli* causing pyelonephritis.
- *Invasion factors*: Uropathogens produce substances that aid in the direct invasion of the urinary tract mucosa with subsequent systemic dissemination. The most important bacterial toxins are lipopolysaccharides and haemolysins.
- *Bacterial resistance*: This represents a microorganism defence mechanism against antimicrobials.

ORGANISMS OF LOWER URINARY TRACT INFECTION

The organisms responsible for UTI are well-established and consistent. *Escherichia coli* is responsible for almost 80 per cent of acute community-acquired uncomplicated infections. *Klebsiella*, *Proteus* and enterococci are infrequent causes of uncomplicated UTI. The commonly occurring organisms in community practice differ when compared to those found within the hospital environment (Table 97.4).¹²

Table 97.4 Common uropathogens in general practice and hospital

Organism	Community (%)	Hospital (%)
<i>Escherichia coli</i>	77.3	56.3
<i>Proteus mirabilis</i>	4.3	6.3
<i>Enterococcus faecalis</i>	3.8	8.4
<i>Klebsiella pneumoniae</i>	3.5	6.9
<i>Pseudomonas aeruginosa</i>	1.8	3.8

Viral UTIs

Lower UTIs are most often caused by bacteria; however, in the immunocompromised host, viruses are being increasingly recognised as a cause, especially in haemorrhagic cystitis. Predominant viruses include the BK virus (a type of polyomavirus that infects most people, but generally causes no symptoms), adenovirus and cytomegalovirus. The diagnosis is based on molecular techniques. Cidofovir is becoming a drug of choice in viral UTIs.¹³

MANAGEMENT

The management of lower urinary tract infection is aimed at treating the current infection and preventing further recurrences. The aims of treatment may be summarised as follows:

- symptomatic relief;
- microbiological cure;
- detection of predisposing factors;
- prevention of upper urinary tract involvement;
- management of recurrence.

DIAGNOSIS

Symptoms and signs

Women with lower UTIs typically complain of symptoms of cystitis i.e. dysuria, suprapubic discomfort, frequency, urgency and nocturia. While the diagnostic accuracy of clinical assessment of UTI is uncertain, the presence of both dysuria and frequency increases the probability of UTI by 90 per cent. Of these women, approximately 30 per cent will also have an upper UTI, which may present as loin pain and tenderness. Whilst young children may present with general malaise and pyrexia, in the elderly, UTIs may present with atypical symptoms, such as confusion and falls. History is also important in the differentiation between uncomplicated and complicated UTI.

Physical examination is usually unremarkable; however, suprapubic or loin tenderness may be the only physical signs.

INVESTIGATIONS

In the majority of women with simple acute lower UTI, there is no need for further investigation. However, some cases do warrant further investigation in order to exclude an underlying cause.

Indications for investigation include:

- children;
- proven recurrent UTI;
- adults with a childhood history of UTI;
- persistent haematuria;

- atypical organism such as *Proteus*, *Pseudomonas*, *Enterobacter* and *Klebsiella*;
- persistent infection despite appropriate antibiotic therapy.

Basic investigations

- Urine appearance. Whilst urine turbidity has been shown to have a specificity of 66.4 per cent and sensitivity of 90.4 per cent for predicting symptomatic UTI, it is prone to observer error.¹⁴
- Urine microscopy has a sensitivity of 60–100 per cent and specificity of 49–100 per cent for predicting significant bacteriuria in women.¹⁵
- Urine dipstick for nitrites and leukocytes. If the test is positive for both, then the probability of UTI is higher than each alone; however if both are negative, the likelihood of UTI is less than 20 per cent.¹⁶
- Urine culture will isolate the causative organism and provide antibiotic sensitivities that should guide antimicrobial treatment.

Other investigations

- In women who have recurrent or complicated urinary infections, renal function should be assessed with serum creatinine, urea and electrolytes.
- For persistent or recurrent infections, urine should be sent for culture of fastidious organisms (*Mycoplasma hominis*, *Ureaplasma urealyticum*, *Chlamydia trachomatis*) to rule out less common causes of infection.
- Ultrasound of the upper urinary tract will exclude renal causes, such as hydronephrosis or calculi, and a postmicturition bladder scan will rule out a significant urinary residual.
- An alternative is radiological imaging using an intravenous urogram or CT urogram. These involve exposure to ionising radiation and influence treatment in limited cases.
- A transvaginal ultrasound can exclude the possibility of a pelvic mass.
- Cystourethroscopy will exclude an intravesical lesion, such as a bladder tumour, and anomalies, such as diverticula and calculi, and also synthetic tapes eroding through the bladder wall or the urethra. A bladder biopsy may show evidence of chronic follicular or interstitial cystitis.

TREATMENT

General measures

Patients with cystitis should be encouraged to increase their fluid intake in order to achieve a short voiding interval and a high flow rate, which will help to dilute and flush out the

infecting organism. Using potassium citrate preparations may provide symptomatic relief; it is thought to act by reducing urinary pH.

Antimicrobials

When treating UTI, an antimicrobial should be selected that has the appropriate sensitivity and is also able to achieve a high concentration within the urinary tract. Drugs should be safe, efficacious and have few side effects. Ideally, the drugs should be rapidly absorbed and not induce bacterial resistance. Some antimicrobials are particularly useful when treating urinary infections. Nitrofurantoin is specific to the urinary tract and therefore has little effect on bowel and vaginal flora. It is bactericidal to most common uropathogens, but it is contraindicated in cases of renal failure. Trimethoprim, primarily bacteriostatic, is also useful in the treatment of urinary tract infection.

Antimicrobial therapy should ideally be based upon culture and sensitivity results from a midstream specimen of urine, although initially empirical treatment often needs to be on a 'best guess' basis. The choice of empirical treatment should be based on local guidelines considering the frequency and resistance of different uropathogens. In the lack of local guidance, international clinical practice guidelines could be followed (Table 97.5).^{17,18}

Duration

Compliance with therapy may be improved by using shorter courses of antimicrobial therapy which also have the advantage of reducing the effect on faecal and vaginal flora and may help in reducing the emergence of resistant organisms. Several studies have documented the dosing and effectiveness of antimicrobial regimens for uncomplicated UTI. A Cochrane review concluded that three days of antibiotic therapy is similar to 5–10 days in achieving symptomatic cure during uncomplicated UTI treatment,

while the longer treatment is more effective in obtaining bacteriological cure.¹⁹

PREVENTION OF RECURRENT URINARY TRACT INFECTION

Women with recurrent UTI, who use spermicides mainly in conjunction with contraceptive diaphragms, should be advised about their association with recurrent UTI, and hence a reduction in use or elimination would be expected to reduce recurrence. Early post-coital voiding and increased fluid intake might be helpful.

Methenamine hippurate may be effective for preventing UTI in patients without renal tract abnormalities, particularly when used for short-term prophylaxis. It does not appear to work in patients with a neuropathic bladder or in patients who have renal tract abnormalities.²⁰

Cranberry juice has been used for many years for the prevention and treatment of UTIs. It is thought to act by preventing bacterial adherence to bladder epithelium. A recent Cochrane review showed that cranberry juice is less effective than previously indicated by small studies.²¹ For patients interested in taking cranberry prophylaxis, cranberry tablets have been shown to be more cost effective than cranberry juice.

The use of probiotics, especially lactobacilli, can be beneficial for preventing recurrent UTI in women; they also have a good safety profile.²² Vitamin C is often recommended as a supplement that can prevent recurrent UTI. In-vitro data suggest that it can have a bacteriostatic effect in the urine, but there is a lack of strong clinical evidence.²³

In post-menopausal women, the prevalence rate for having one episode of UTI in a given year varies from 8 to 10 per cent. This increased risk is associated with a decrease in oestrogen levels. Vaginal oestrogens, but not oral oestrogens, have been shown to reduce the number of UTIs in post-menopausal women with recurrent UTI.²⁴ Local preparations, such as vaginal oestriol cream 0.1%, vaginal oestradiol tablets or oestradiol-releasing vaginal ring, should be considered in post-menopausal women with signs of urogenital atrophy.

When compared to placebo, continuous antibiotic prophylaxis for 6–12 months reduces the rate of UTI; however, there was no difference in the UTI incidence upon discontinuation of therapy.³ In women with recurrent UTI related to intercourse, post-coital prophylaxis is as effective as continuous daily therapy in preventing UTI with fewer side effects. Another alternative option is self-start therapy which involves providing patients with instructions and materials (urine reagent strips and antibiotics) that allow them to both diagnose and treat their UTI at the onset of symptoms. This strategy should be restricted to women who are motivated, compliant and have a good relationship with a doctor. Regimens for antibiotic prophylaxis are presented in Table 97.6.²⁵

Table 97.5 Recommended treatment for acute uncomplicated cystitis

1 st choice	Nitrofurantoin 50 mg every 6 hours for 7 days
2 nd choice	Trimethoprim 200 mg twice daily for 5 days (if local <i>E. coli</i> resistance is <20%)
3 rd choice	Ciprofloxacin 250 mg twice daily for 3 days OR Norfloxacin* 400 mg twice daily for 3 days
4 th choice	Co-amoxiclav 500/125 mg every 8 hours for 3 days OR Cefaclor 500 mg every 8 hours for 3 days

*Unavailable in the UK at time of print

Table 97.6 Prophylaxis regimens for women with recurrent UTI

Continuous prophylaxis	Cefaclor 250 mg daily Cephalexin 125–250 mg daily Ciprofloxacin 125 mg daily Nitrofurantoin 50–100 mg daily Norfloxacin* 200 mg daily Trimethoprim 100 mg daily
Post-coital prophylaxis (single dose)	Cephalexin 125–250 mg Ciprofloxacin 125 mg Nitrofurantoin 50–100 mg Norfloxacin* 200 mg Trimethoprim 100 mg
Self-start treatment	Ciprofloxacin 250 mg twice daily for 3 days Norfloxacin* 200 mg twice daily for 3 days Trimethoprim 200 mg twice daily for 3 days

*Unavailable in the UK at time of print

URINARY TRACT INFECTION IN PREGNANCY

UTIs are the most common medical complication of pregnancy.

The incidence of asymptomatic bacteriuria in pregnancy is 2–5 per cent.²⁶ If not treated, up to 20 per cent will develop lower UTI. The overall incidence of UTI in pregnancy is 8 per cent and the incidence of acute pyelonephritis is 2 per cent.

Aetiology

The increased susceptibility in pregnancy is due to a number of physiological changes that make asymptomatic bacteriuria progress to symptomatic UTI. These include changes in bladder volume, decreased bladder tone and ureteric dilatation secondary to an increased level of progesterone. This will lead to urinary stasis and chronic residual urine with subsequent UTI.

A review of randomised, controlled studies has found good evidence that urine culture and dipstick testing for leukocytes and nitrites reduced the risk of pyelonephritis and was cost effective, thus offering a rationale for screening.²⁷

Uropathogens responsible for UTI in pregnancy are similar to those in non-pregnant women, with *E. coli* responsible for over 80 per cent of the cases.

Maternal/fetal complication

UTIs in pregnancy have been associated with increased risks of chorioamnionitis and endometritis. With regard to the fetus,

it has been shown that UTI is associated with fetal growth restriction, stillbirth, preterm labour and delivery, increased perinatal mortality, mental retardation and developmental delay.²⁸

Treatment

Asymptomatic bacteriuria

Treatment of asymptomatic bacteriuria reduces the risk of pyelonephritis and, consequently, the risks of preterm delivery and low birthweight.

Symptomatic UTI

Treatment is directed by urine culture and sensitivity. Although antibiotic treatment is effective for the cure of UTIs, there are insufficient data to recommend any specific drug regimen for treatment of symptomatic UTIs during pregnancy.²⁹ An antibiotic course for 7 days would be appropriate, although in an attempt to increase patient compliance and reduce side effects shorter courses could be considered. It is of paramount importance to repeat urine culture after treatment to confirm bacteriological cure.

Penicillins and cephalosporins have been shown to be safe in the first and second trimesters. As it is a folate antagonist, trimethoprim should be avoided in the first trimester, although it may be used safely in late pregnancy. Conversely, nitrofurantoin and sulphonamides are safe in early pregnancy, although they should be avoided in the third trimester when the former may cause a haemolytic anaemia and the latter hyperbilirubinaemia and kernicterus. Tetracyclines should be avoided because of their chelating action, which will lead to hypoplasia and staining of the teeth. While in general erythromycin is considered safe, the estolate salt may be associated with cholestatic jaundice. Finally, fluoroquinolones may affect fetal cartilage formation, and chloramphenicol may be associated with neonatal cardiovascular collapse.

Recurrent UTI in pregnancy

The risk of recurrence in pregnancy is 4–5 per cent. While the exact aetiology of recurrence is uncertain, it is believed that the causes of the first infection are likely to cause recurrence. Postpartum urological investigation to exclude urinary anomalies should be considered. Long-term, low-dose antimicrobial cover and single-dose antimicrobial in intercourse-related UTI are suggested as prophylactic measures.³⁰

KEY POINTS

- Lower UTIs are a common cause of morbidity.
- Risks of lower UTI are related to behavioural, anatomical and functional factors.
- Community-acquired infections may be caused by different organisms from those acquired in hospital.

- In the majority of women with uncomplicated cystitis, there is no indication for further investigation.
- Antimicrobial therapy should be based upon culture and sensitivity results, although often initial treatment is on a 'best guess' basis.
- Short- and low-dose antibiotics may be used as prophylaxis and reduce infection rates by 95 per cent, compared with placebo.
- UTI in pregnancy may be associated with pyelonephritis, preterm delivery and low birthweight.

Chapter 98 Urogenital prolapse

Sushma Srikrishna and Dudley Robinson

MRCOG standards

Theoretical skills

- Have comprehensive knowledge of the functional pelvic anatomy as applied to gynaecological surgery.
- Understand the aetiology of urogenital prolapse.
- Understand preventative measures.

Practical skills

- Know how to clinically assess women presenting with urogenital prolapse.
- Be able to undertake conservative management of prolapse.
- Be able to undertake surgical management of urogenital prolapse.

STRAT OG: Learning objectives

To achieve a better understanding of:

- the incidence and epidemiology of urogenital prolapse;
- the classification and grading scales to indicate the severity of the prolapse;
- means of preventing urogenital prolapse;
- management procedures;
- non-surgical;
- surgical.

INTRODUCTION

Urogenital prolapse occurs when there is a weakness in the supporting structures of the pelvic floor allowing the pelvic viscera to descend and ultimately fall through the anatomical defect.

While usually not life threatening, prolapse is often symptomatic and is associated with a deterioration in quality of life and may be the cause of bladder and bowel dysfunction.

Increased life expectancy and an expanding elderly population mean that prolapse remains an important condition, especially since the majority of women may now spend a third of their lives in the post-menopausal state. Surgery for urogenital prolapse accounts for approximately 20 per cent of elective major gynaecological surgery and this increases to 59 per cent in elderly women. The lifetime risk of having surgery for prolapse is 11 per cent; a third of these procedures are operations for recurrent prolapse.

The economic cost of urogenital prolapse is considerable, with figures from the US revealing a total expenditure of \$1012 million in 1997: vaginal hysterectomy accounted for 49 per cent, pelvic floor repairs for 28 per cent and abdominal hysterectomy for 13 per cent of costs.¹

EPIDEMIOLOGY

Age

The incidence of urogenital prolapse increases with increasing age, with approximately 60 per cent of elderly women having some degree of prolapse and up to half of all women over the age of 50 years complaining of symptomatic prolapse. In a study of women with severe vaginal vault prolapse following hysterectomy, 60 per cent were over the age of 60 years.

Parity

Urogenital prolapse is more common following childbirth, although it may be asymptomatic. Studies have estimated that 50 per cent of parous women have some degree of urogenital prolapse and, of these, 10–20 per cent are symptomatic. Only 2 per cent of nulliparous women are reported to have prolapse.

Race

Prolapse is generally thought to be more common in Caucasian women and less common in women of Afro-Caribbean origin. However, a study examining racial differences in North America has shown that this may not be the case, as there was little racial variation noted, although this may simply reflect cultural differences in reporting.

CLASSIFICATION

Urogenital prolapse is classified anatomically depending on the site of the defect and the pelvic viscera that are involved.

- **Urethrocele:** prolapse of the lower anterior vaginal wall involving the urethra only.
- **Cystocele:** prolapse of the upper anterior vaginal wall involving the bladder. Generally, there is also associated prolapse of the urethra and hence the term cystourethrocele is used.
- **Uterovaginal prolapse:** this term is used to describe prolapse of the uterus, cervix and upper vagina.
- **Enterocoele:** prolapse of the upper posterior wall of the vagina, usually containing loops of small bowel. A traction enterocoele is secondary to uterovaginal prolapse, a pulsion enterocoele is secondary to chronically raised intra-abdominal pressure, and an iatrogenic enterocoele is caused by previous pelvic surgery. An anterior enterocoele may be used to describe prolapse of the upper anterior vaginal wall following hysterectomy.
- **Rectocele:** prolapse of the lower posterior wall of the vagina involving the anterior wall of the rectum.

GRADING OF UROGENITAL PROLAPSE

- **First degree:** The lowest part of the prolapse descends half-way down the vaginal axis to the introitus.
- **Second degree:** The lowest part of the prolapse extends to the level of the introitus and through the introitus on straining.
- **Third degree:** The lowest part of the prolapse extends through the introitus and lies outside the vagina. Procidentia describes a third-degree uterine prolapse.

PROLAPSE SCORING SYSTEM

Recently, the International Continence Society produced a standardisation document in order to assess urogenital prolapse more objectively.² The ICS Prolapse Scoring System (POPQ) allows the measurement of fixed points on the anterior and posterior vaginal walls, cervix and perineal body against a fixed reference point, the genital hiatus (Fig. 98.1). Measurements are performed in the left lateral position at rest and at maximal valsalva, thus providing an accurate and reproducible method of quantifying urogenital prolapse.

ANATOMY OF THE PELVIC FLOOR

The pelvic floor provides support to the pelvic viscera and consists of the levator ani muscles, urogenital diaphragm, endopelvic fascia and perineal body. The levator

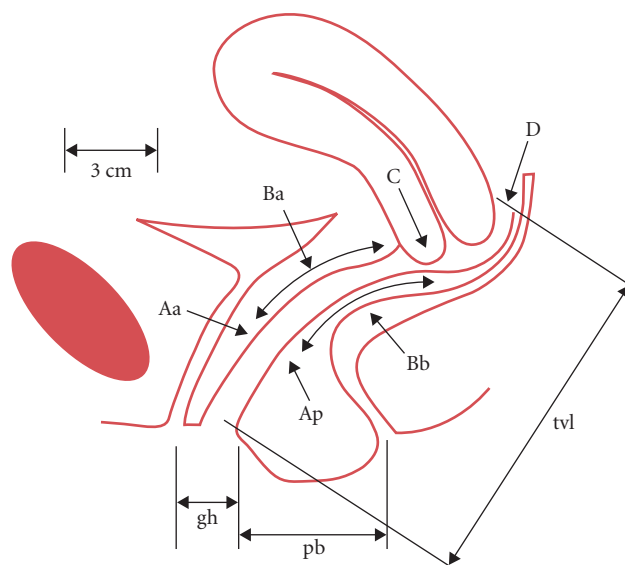

Fig. 98.1 ICS Prolapse Scoring System (POPQ)

ani, when considered with its associated fascia, is termed the 'pelvic diaphragm'.

The muscle fibres of the pelvic diaphragm are arranged to form a broad U-shaped layer of muscle with a defect anteriorly. This physiological defect is the urogenital hiatus and allows the passage of the urethra, vagina and rectum through the pelvic floor.

Pelvic floor musculature

The muscles of the pelvic floor are composed of the levator ani and coccygeus, which form a cradle within the bony pelvis supporting the pelvic organs. The levator ani originate on each side from the pelvic sidewall, arising anteriorly just above the arcus tendineus fasciae pelvis (the white line) and inserting posteriorly into the arcus tendineus levator ani. The arcus tendineus fasciae pelvis and arcus tendineus levator ani fuse near the ischial spine; the levator ani unite in the midline to form the anococcygeal raphe (Fig. 98.2).

The levator ani has three divisions: the pubococcygeus, iliococcygeus and puborectalis muscles (Fig. 98.3). The iliococcygeus and pubococcygeus arise from the arcus tendineus levator ani fascia overlying the obturator internus and insert into the midline anococcygeal raphe and the coccyx, while the latter forms the inner fibres of the pelvic floor musculature inserting into the rectum and perineal body. Posteriorly, the coccygeus arises from the ischial spine and sacrospinous ligament and inserts into the coccyx and sacrum.

The striated muscle of the pelvic floor is composed of both slow- and fast-twitch muscle fibres. The slow-twitch fibres provide muscle tone over a long period of time, thus supporting the pelvic viscera, while the fast-twitch fibres react to sudden increases in intra-abdominal pressure.

Fig. 98.2 Anatomy of the pelvic floor

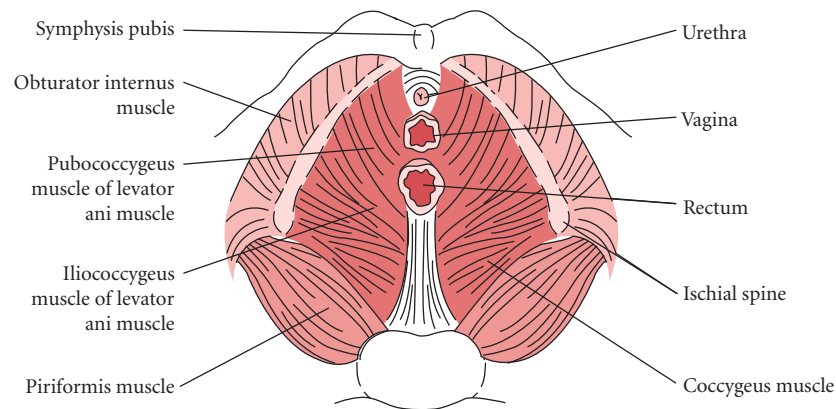

Fig. 98.3 Anatomy of the pelvic floor showing the divisions of levator ani

Urogenital diaphragm

The urogenital diaphragm (perineal membrane) is a triangular sheet of dense fibrous tissue spanning the anterior half of the pelvic outlet, which is pierced by the vagina and urethra. It arises from the inferior ischiopubic rami and attaches medially to the urethra, vagina and perineal body, thus supporting the pelvic floor.

Perineal body

The perineal body lies between the vagina and the rectum and provides a point of insertion for the muscles of the pelvic floor. It is attached to the inferior pubic rami and ischial tuberosities through the urogenital diaphragm and superficial transverse perineal muscles. Laterally, it is attached to the fibres of the pelvic diaphragm; posteriorly, it inserts into the external anal sphincter and coccyx.

Pelvic fascia

The endopelvic fascia is a meshwork of collagen and elastin that represents the fused adventitial layers of the visceral structures and pelvic wall musculature. Condensations of the pelvic fascia are termed 'ligaments' and these have an important part in the supportive role of the pelvic floor.

Uterine support

The parametrium, composed of the uterosacral and cardinal ligaments, attaches the cervix and upper vagina to the pelvic sidewall. The uterosacral ligament forms the medial margin bordering the pouch of Douglas; the cardinal ligaments attach the lateral aspects of the cervix and vagina to the pelvic sidewall over the sacrum. The former is composed mostly of smooth muscle, whereas the cardinal ligaments contain mostly connective tissue and the pelvic blood vessels. The round

ligaments are not thought to have a role in supporting the uterus, although they may help to maintain anteversion and anteflexion; the broad ligaments are simply folds of peritoneum and provide no support.

Vaginal support

Support to the upper third of the vagina is provided principally by the downward extension of the cardinal ligaments; the middle third is supported by lateral attachments to the arcus tendineus fasciae pelvis, a condensation of the obturator and levator fasciae. These supports suspend the anterior vaginal wall across the pelvis, the layer of fascia anterior to the vagina being called the 'pubocervical fascia'. Posterolaterally, the vagina is attached to the endopelvic fascia over the pelvic diaphragm and sacrum by the rectovaginal septum (fascia of Denonvilliers), which extends caudally into the perineal body and cranially into the peritoneum of the pouch of Douglas. The lower third is attached anteriorly to the pubic arch by the perineal membrane, posteriorly to the perineal body and laterally to the medial aspect of levator ani.

Urethral support

The proximal urethra is supported by a sling of endopelvic fascia and the anterior vaginal wall, which is stabilised by lateral attachments to the arcus tendineus fasciae pelvis, and medial border of the levator ani. Contraction and relaxation of the levator muscles allows elevation or descent of the urethra, respectively, which is important in the control of voiding. In addition, an increase in intra-abdominal pressure causes compression of the urethra against the fixed anterior vaginal wall, thus maintaining continence. Bladder neck mobility and the stress continence mechanism are thus dependent on fascial integrity and connective tissue elasticity.

AETIOLOGY

Pregnancy and childbirth

The increased incidence of prolapse in multiparous women would suggest that pregnancy and childbirth have an important impact on the supporting function of the pelvic floor. Damage to the muscular and fascial supports of the pelvic floor and changes in innervation contribute to the development of prolapse.

The pelvic floor may be damaged during childbirth, causing the axis of the levator muscles to become more oblique and creating a funnel that allows the uterus, vagina and rectum to fall through the urogenital hiatus. In addition, the proportion of fascia to muscle within the pelvic floor tends to increase with increasing age, and thus once damaged by childbirth, muscle may never regain its full strength. This is supported by studies showing decreased cellularity and increased collagen content in 70 per cent of women with urogenital prolapse, compared to 20 per cent of normal controls.

Mechanical changes within the pelvic fascia have also been implicated in the causation of urogenital prolapse. During pregnancy, the fascia becomes more elastic and thus more likely to fail. This may explain the increased incidence of stress incontinence observed in pregnancy and the increased incidence of prolapse with multiparity.

Denervation of the pelvic musculature has been shown to occur following childbirth, although gradual denervation has also been demonstrated in nulliparous women with increasing age. However, the effects were greatest in those women who had documented stress incontinence or prolapse.³ Furthermore, histological studies have revealed changes in muscle fibre type and distribution, suggesting denervation injury associated with ageing and also following childbirth. In conclusion, it would appear that partial denervation of the pelvic floor is part of the normal ageing process, although pregnancy and childbirth accelerate these changes.

The biochemical properties of connective tissue may also play an important role in the development of prolapse. Changes in collagen content have been identified, the hydroxyproline content in connective tissue from women with stress incontinence being 40 per cent lower than in continent controls. In addition, changes in collagen metabolism may be associated with the development of urogenital prolapse, increased levels of collagenases being associated with weakened pelvic support and stress incontinence.

Hormonal factors

The effects of ageing and those of oestrogen withdrawal at the time of the menopause are often difficult to separate. Rectus muscle fascia has been shown to become less elastic with increasing age, and less energy is required to produce irreversible damage. Furthermore, there is also a reduction in skin collagen content following the menopause. Both of these factors lead to a reduction in the strength of the pelvic connective tissue.

More recently, oestrogen receptors, alpha and beta, have been demonstrated in the vaginal walls and the utero-sacral ligaments of pre-menopausal women, although the beta receptor was absent from the vaginal walls in post-menopausal women. However, a further study was unable to identify oestrogen receptors in biopsies from the levator ani muscles in urinary incontinent women participating in pelvic floor exercises. In conclusion, it would appear that oestrogens and oestrogen withdrawal have a role in the development of urogenital prolapse, although the precise mechanism has yet to be established.

Smoking

Chronic chest disease resulting in a chronic cough leads to an increase in the intra-abdominal pressure and thus exposes the pelvic floor to greater strain. Over a period of time this will exacerbate any defects in the pelvic floor musculature and fascia, leading to prolapse.

Constipation

Chronically increased intra-abdominal pressure caused by repetitive straining will exacerbate any potential weaknesses in the pelvic floor and is also associated with an increased risk of prolapse.

Obesity

Although obesity has been linked to urogenital prolapse due to a potential increase in intra-abdominal pressure, there has been no good evidence to support this theory.

Exercise

Increased stress placed on the musculature of the pelvic floor will exacerbate pelvic floor defects and weakness, thus increasing the incidence of prolapse. Consequently, heavy lifting and exercise, as well as sports such as weight lifting, high-impact aerobics and long-distance running, increase the risk of urogenital prolapse.

Surgery

Pelvic surgery may also have an effect on the occurrence of urogenital prolapse. Continence procedures, while elevating the bladder neck, may lead to defects in other pelvic compartments. At Burch colposuspension, the fixing of the lateral vaginal fornices to the ipsilateral ileopectineal ligaments leaves a potential defect in the posterior vaginal wall that predisposes to rectocele and enterocele formation. In a five-year follow-up study of women, 36 per cent had cystoceles, 66 per cent rectocele, 32 per cent enterocele and 38 per cent uterine prolapse. A further study of 109 women with vaginal vault prolapse reported that 43 per cent had previously undergone Burch colposuspension. Overall, 25 per cent of the women who had had Burch colposuspension required further surgery for prolapse.

Needle suspension procedures, such as the Pereyra or Stamey endoscopically guided bladder neck suspension, are also associated with an increased incidence of recurrent cystocele, although this is not the case following sling procedures. In addition, there is an increased incidence of posterior compartment defects, such as enterocele and rectocele, after Manchester repair, caused by the anterior plication of the uterosacral and cardinal ligaments, which leaves a large posterior hiatus.

The association between prolapse and prior hysterectomy is not as clear. One large study reporting on this followed up 184 women over a median of 11.3 years. Less than 3% had stage-3 prolapse. No significant difference was found in the presence of stage-2 or higher stage prolapse between the two hysterectomy groups (39% in subtotal hysterectomy versus 37% in Total Hysterectomy; OR 1.28, 95% CI 0.59–2.80). There was also no significant difference in the quality-of-life measurement between the two groups.⁴ However, other factors, such as the ageing process and oestrogen withdrawal following the

menopause, may also have an important role. Prolapse of the vaginal vault may present following either vaginal or abdominal hysterectomy, although the incidence is low, with only 0.5 per cent of women who have had a hysterectomy requiring further surgical intervention for vaginal vault prolapse.

CLINICAL SYMPTOMS

Most women complain of a feeling of discomfort or heaviness within the pelvis in addition to a 'lump coming down'. Symptoms tend to become worse with prolonged standing and towards the end of the day. Women may also complain of dyspareunia, difficulty in inserting tampons and chronic lower backache. In cases of third-degree prolapse, there may be mucosal ulceration and lichenification, which results in a symptomatic vaginal discharge or bleeding.

A cystocele may be associated with LUTS of urgency and frequency of micturition in addition to a sensation of incomplete emptying, which may be relieved by digitally reducing the prolapse. Recurrent UTIs may also be associated with a chronic urinary residual. While less than 2 per cent of mild cystoceles are associated with ureteric obstruction, severe prolapse may lead to hydronephrosis and chronic renal damage. Between 33 and 92 per cent of cases of complete procidentia are associated with some degree of ureteric obstruction.

A rectocele may be associated with difficulty in opening the bowels, some women complaining of tenesmus and having to digitate to defaecate.

CLINICAL SIGNS

Women are generally examined in the left lateral position using a Simms' speculum, although digital examination when standing allows more accurate assessment of the degree of urogenital prolapse and, in particular, vaginal vault support. An abdominal examination should also be performed to exclude the presence of an abdominal or pelvic tumour that may be responsible for the vaginal findings.

Differential diagnosis includes:

- vaginal cysts;
- pedunculated fibroid polyp;
- urethral diverticulum;
- chronic uterine inversion.

INVESTIGATION

In women who also complain of concomitant LUTS, urodynamic studies or a post-micturition bladder ultrasound should be performed in order to exclude a chronic residual due to associated voiding difficulties. In such cases, a mid-stream specimen of urine should be sent for culture and sensitivity.

Subtracted cystometry, with or without videocystourethrography, will allow the identification of underlying detrusor overactivity, which is important to exclude prior to surgical repair. In cases of significant cystocele, stress testing should be carried out by asking the patient to cough while standing. Since occult urodynamic stress incontinence may be unmasked by straightening the urethra following anterior colporrhaphy, this should be simulated by the insertion of a ring pessary or tampon to reduce the cystocele. If stress incontinence is demonstrated, a continence procedure such as colposuspension or insertion of tension-free vaginal tape may be a more appropriate procedure.

In cases of severe prolapse in which there may be a degree of ureteric obstruction, it is important to evaluate the upper urinary tract with either a renal tract ultrasound or an intravenous urogram.

Although a cystocele itself may be responsible for irritative urinary symptoms, if these are unusually severe cystoscopy should be performed to exclude a chronic follicular or interstitial cystitis.

MANAGEMENT

Prevention

In general, any factor that leads to chronic increases in intra-abdominal pressure should be avoided. Consequently, care should be taken to avoid constipation, which has been implicated as a major contributing factor to urogenital prolapse in Western society. In addition, the risk of prolapse in patients with chronic chest pathology, such as obstructive airways disease and asthma, should be reduced by effective management of these conditions. Hormone replacement therapy may also decrease the incidence of prolapse, although to date there are no studies that have tested this effect.

Maintaining an ideal BMI during pregnancy, smaller family size and improvements in antenatal and intrapartum care have also been implicated in the primary prevention of urogenital prolapse. A large national cohort study investigating the prevalence and risk factors for symptomatic pelvic organ prolapse women 20 years after one vaginal delivery or one caesarean delivery found that the prevalence of symptomatic prolapse was doubled after vaginal delivery compared with caesarean section, two decades after one birth. Infant birthweight and current BMI were implicated as risk factors for prolapse after vaginal delivery.⁵ The role of caesarean section may also be important, although studies examining the outcome in terms of incontinence and symptomatic prolapse have had mixed results. Equally, antenatal and postnatal pelvic floor exercises have not yet been shown conclusively to reduce the incidence of prolapse, although they may be protective.

Physiotherapy

Pelvic floor exercises may have a role in the treatment of women with symptomatic prolapse, although there are no objective evidence-based studies to support this. Education about pelvic floor exercises may be supplemented with the use of a perineometer and biofeedback, allowing quantification of pelvic floor contractions. In addition, vaginal cones and electrical stimulation may also be used, although again, while they have been shown to be effective in the treatment of urodynamic stress incontinence, there are no data to support their use in the management of urogenital prolapse.

In summary, physiotherapy probably has a role in cases of mild prolapse in younger women who find an intravaginal device unacceptable and are not yet willing to consider definitive surgical treatment, especially if they have not yet completed their family.

Intravaginal devices

The use of intravaginal devices offers a further conservative line of therapy for those women who are not candidates for surgery. Consequently, they may be used in younger women who have not yet completed their family, during pregnancy and the puerperium, and also for those women who may be unfit for surgery. Clearly, this last group of women may include the elderly, although age alone should not be seen as a contraindication to surgery. In addition, a pessary may offer symptomatic relief while awaiting surgery.

Ring pessaries made of silicone or polythene are currently most frequently used. They are available in a number of different sizes (52–120 mm) and are designed to lie horizontally in the pelvis with one side in the posterior fornix and the other just behind the pubis, hence providing support to the uterus and upper vagina. Pessaries should be changed every six months; long-term use may be complicated by vaginal ulceration and therefore a low-dose topical oestrogen may be helpful in post-menopausal women.

Ring pessaries may be useful in the management of minor degrees of urogenital prolapse, although in severe cases, and for vaginal vault prolapse, a shelf pessary may be more appropriate. These may be difficult to insert and remove and their use is becoming less common, especially as they preclude coitus.

SURGERY

Surgery offers definitive treatment of urogenital prolapse. As in other forms of pelvic surgery, patients should receive prophylactic antibiotics to cover both Gram-negative and Gram-positive organisms, as well as thromboembolic prophylaxis in the form of low-dose heparin, and thromboembolic deterrent (TED) stockings.

All patients should also have a urethral catheter inserted at the time of the procedure unless there is a particular history

of voiding dysfunction, in which case a suprapubic catheter may be more appropriate. This allows the residual urine volume to be checked following a void without the need for recatheterisation.

Patients having pelvic surgery are positioned in lithotomy with the hips abducted and flexed. To minimise blood loss, local infiltration of the vaginal epithelium is performed using 0.5 per cent xylocaine and 1/200,000 adrenaline, although care should be taken in patients with coexistent cardiac disease. A vaginal pack may be inserted at the end of the procedure, and removed on the first postoperative day.

Anterior compartment defects

Anterior colporrhaphy

Indication

Anterior colporrhaphy is indicated for the correction of cystourethrocele.

Procedure

A midline incision is made in the vaginal epithelium from 1 cm below the urethral meatus to the cervix or vaginal vault. The cystocele is dissected off the overlying epithelium using sharp and blunt dissection and is secured using two poly-glycolic (Vicryl, Ethicon) or polydioxanone (PDS, Ethicon) purse-string sutures. The redundant skin edges are then trimmed and the epithelium and fascia closed using interrupted polyglycolic (Vicryl, Ethicon) sutures.

In patients who have mild concurrent stress incontinence, a 'Kelly' mattress suture⁶ may be placed under the urethrovesical junction, although colposuspension is preferable in cases of severe stress incontinence and will also cure a mild to moderate cystocele.

Lower urinary tract injury is uncommon. However, should a bladder or urethral injury occur, the defect can be repaired in layers using absorbable sutures and the bladder left on free drainage for ten days.

Paravaginal repair

Indication

Paravaginal repair is indicated for correction of cystourethrocele.

Procedure

First described in 1909, this offers an abdominal approach to correct an anterior compartment defect. The retropubic space (cave of Retzius) is opened through a Pfannenstiel incision and the bladder swept medially, exposing the pelvic sidewall. The lateral sulcus of the vagina is elevated with the overlying pubocervical fascia and reattached to the pelvic sidewall using interrupted polydioxanone (PDS, Ethicon) sutures from the pubis to just anterior to the ischial spine. Long-term follow up in a series of 800 patients reported a cure rate of more than 95 per cent.⁷

Posterior compartment defects

Posterior colporrhaphy

Indication

Posterior colporrhaphy is indicated for the correction of rectocele and deficient perineum.

Procedure

Two Allis forceps are first placed on the perineum at the level of the hymenal remnants, allowing the calibre of the introitus to be estimated. Following infiltration, the perineal scarring is excised and the posterior vaginal wall opened using a longitudinal incision. The rectocele is mobilised from the vaginal epithelium by blunt and sharp dissection and secured using two or more polyglycolic (Vicryl, Ethicon) or polydioxanone (PDS, Ethicon) purse-string sutures. The redundant skin edges are then trimmed, taking care not to remove too much tissue and thus narrow the vagina. The pararectal and rectovaginal fasciae from each side are approximated using interrupted polyglycolic (Vicryl, Ethicon) sutures incorporating the vaginal epithelium, and the posterior wall is closed with a continuous polyglycolic (Vicryl, Ethicon) suture. Care should be taken not to create a constriction ring in the vagina, which will result in dyspareunia. Finally, a perineoplasty is performed by placing deeper absorbable sutures into the perineal muscles and fascia, thus building up the perineal body to provide additional support to the posterior vaginal wall and lengthening the vagina.

Injury to the rectum is unusual, but should be identified at the time of the procedure so that the defect can be closed in layers using an absorbable suture and the patient managed with prophylactic antibiotics, low-residue diet and faecal softening agents to avoid constipation.

Pelvic floor surgery may also have an adverse effect on sexual function. Following pelvic floor repairs with or without vaginal hysterectomy, 50 per cent of women reported sexual dysfunction, nearly half of the cases being due to shortening of the vagina, dyspareunia or fear of injury.⁸

These findings have been confirmed more recently in a follow-up study of women undergoing posterior repair.⁹ This series reported an increase in sexual dysfunction from 11 per cent pre-operatively to 27 per cent following surgery. In addition, 22 per cent of women complained of vaginal pain, 11 per cent had incontinence of faeces and 33 per cent had constipation.

Enterocele repair

Indication

Enterocele repair is indicated for the correction of enterocele.

Procedure

An enterocele repair is normally performed using a vaginal approach similar to that of posterior colporrhaphy. The vaginal epithelium is dissected off the enterocele sac, which is then secured using two or more polyglycolic (Vicryl, Ethicon) or polydioxanone (PDS, Ethicon) purse-string sutures. It is not

essential to open the enterocele sac, although care should be taken not to damage any loops of small bowel that it may contain. The posterior vaginal wall is then closed as described for posterior colporrhaphy.

An abdominal approach may also be used, although this is much less common. The Moschowitz procedure¹⁰ is performed by inserting concentric purse-string sutures around the peritoneum in the pouch of Douglas, thus preventing enterocele formation.

Uterovaginal prolapse

Vaginal hysterectomy

Indication

Vaginal hysterectomy is indicated for uterovaginal prolapse. This procedure may be combined with anterior and posterior colporrhaphy.

Contraindications (relative)

- Uterine size >14 weeks' gestation, although morcellation¹¹ or uterine bisection may be used;
- Two or more caesarean sections;
- Endometriosis;
- PID;
- Suspected malignancy (uterine or ovarian).

Procedure

A cervical incision is performed and the uterovesical fold and pouch of Douglas opened. The uterosacral and cardinal ligaments are divided and ligated first, followed by the uterine pedicles and finally the tubo-ovarian and round ligament pedicles. In cases of procidentia, care should be taken to avoid kinking of the ureters, which are often dragged into a lower position than normal. After closure of the pelvic peritoneum, the upper pedicles are tied in the midline to provide support for the vaginal vault, while the uterosacral ligaments are tied posteriorly to obliterate the potential enterocele space. In addition, a McCall suture¹² may be performed, bringing the two uterosacral ligaments together in the midline as a further precaution against enterocele formation. Inclusion of the upper posterior vaginal wall also provides additional vault support. The vaginal epithelium is then closed with interrupted sutures.

Uterine preserving surgery

Uterine prolapse can also be treated with 'uterus sparing' procedures where an attempt is made to suspend the uterus rather than remove it through a hysterectomy. The evidence base for such procedures is very limited and largely anecdotal. The indications to preserve the uterus may be as follows:

- preservation of fertility;
- role of uterus in orgasm and female sexuality;
- influence on female sexual identity;
- lack of uterine pathology.

Routes

- Abdominal: Sacrospinous hysteropexy, Shirodkar's sling, pectineal ligament suspension;
- Vaginal: Manchester repair, sacrospinous hysteropexy and uterosacral ligament plication have been described;
- Laparoscopic: Round ligament plication, sacrohysteropexy, uterosacral plication.

Manchester repair (Fothergill repair)

Procedure

This procedure is only rarely performed nowadays. Cervical amputation is followed by approximating and shortening the cardinal ligaments anterior to the cervical stump and elevating the uterus. This is combined with an anterior and posterior colporrhaphy. The operation has fallen from favour, as the long-term complications include fertility problems in addition to recurrent uterovaginal prolapse and enterocele formation.

Vaginal vault prolapse

Vaginal vault prolapse occurs equally commonly following vaginal or abdominal hysterectomy, with an incidence of approximately 5 per cent, although only 0.5 per cent of women require further surgery.

Sacrospinous ligament fixation

Indication

Sacrospinous ligament fixation is indicated for vaginal vault prolapse.

Procedure

A longitudinal posterior vaginal wall incision is performed to expose the rectovaginal space. The right ischial spine is then identified and exposed using sharp and blunt dissection. The sacrospinous ligament may then be palpated running from the ischial spine to the lower aspect of the sacrum. An absorbable braided polyglycolic suture (Dexon, Davies + Geck) is passed through the ligament using a Miya hook ligature carrier and then through the vaginal vault. Care must be taken to avoid the sacral plexus and sciatic nerve, which are superior, and the pudendal vessels and nerve, which are lateral to the ischial spine. Once the enterocele has been secured using two purse-string sutures, the upper third of the vagina is closed as previously described. The sacrospinous sutures are then tied to support the vaginal vault from the sacrospinous ligament, following which a perineorrhaphy is performed.

Success rates of 98 per cent have been reported,¹³ although posterior fixation of the posterior vaginal wall increases the incidence of anterior compartment defects. For this reason, it should not be performed routinely at vaginal hysterectomy. As the vaginal axis is changed by the procedure, there is a risk of post-operative dyspareunia and development of stress incontinence.

Abdominal sacrocolpopexy

Indication

Abdominal sacrocolpopexy is indicated for vaginal vault prolapse.

Procedure

This procedure may be performed through a lower midline or Pfannenstiel incision after packing the vagina. The apex of the vagina and sacral promontory are identified and a retroperitoneal tunnel is created between the two just to the right of the midline and medial to the right ureter. A strip of Mersilene tape is then passed through the peritoneal tunnel and sutured to the vaginal vault and posterior vaginal wall using interrupted, non-absorbable ethylene sutures (Ethibond, Ethicon). Once the other end of the tape has been secured to the periosteum overlying the sacral promontory, the sutures are tied, allowing gentle elevation of the vaginal vault towards the sacrum, but without tension. The peritoneum is then closed over the vaginal vault and sacral promontory. Complications include bleeding from the presacral venous plexus and sacral artery and damage to the right ureter and sigmoid colon.

A 93 per cent success rate has been reported,¹⁴ although associated cystocele or rectocele may still require a vaginal colporrhaphy. In addition, since the vaginal axis is changed, there is also the risk of developing dyspareunia and stress incontinence following the procedure. Mesh erosion into the vagina, and rarely into the bladder or bowel, is a possible late complication.

A recent Cochrane review into surgical management of prolapse showed that abdominal sacrocolpopexy is associated with a lower rate of recurrent vault prolapse and dyspareunia than the vaginal sacrospinous colpopexy. These benefits must be balanced against a longer operating time, longer time to return to activities of daily living and increased cost of the abdominal approach.¹⁵

Posterior intravaginal slingplasty

Indication

Posterior intravaginal slingplasty (IVS) is indicated for vaginal vault prolapse.

Procedure

Posterior IVS using an 8-mm polypropylene tape has been described as a minimally invasive procedure for the treatment of vaginal vault prolapse. Under tension, a 5-cm transverse full-thickness incision is made in the posterior vaginal wall 1.5 cm below the scar line at the vaginal vault. Adjacent rectocele and enterocele are then dissected out so as to avoid accidental damage while passing the IVS tunneller (Tyco Healthcare, Mansfield, MA, USA) needle. Bilateral 1-cm perineal skin incisions are then made 2 cm lateral and below the external anal sphincter at the 4 and 8 o'clock positions.

Next, the IVS tunneller is advanced 4 cm into the ischioanal fossa before being turned inwards and guided using a finger through the rectovaginal fascia so as to exit through the

transverse vaginal incision. The procedure is then repeated on the contralateral side and a rectal examination performed to exclude bowel injury. The tape is then secured to the vaginal vault using polydioxanone (PDS, Ethicon) and the vagina closed with interrupted polyglycolic (Vicryl, Ethicon) sutures. A posterior colpoperineorrhaphy is then performed as previously described. Finally, the polypropylene tape is pulled posteriorly through the bilateral buttock incisions pulling the vaginal vault in a postero-superior direction. The tape is then cut flush with the skin and incisions closed using interrupted sutures.

To date, only one retrospective series of posterior IVS has been reported¹⁶ with symptomatic cure rates of 91 per cent. However, there were five cases of tape rejection, one rectal tape erosion and one rectal perforation. Consequently, while early data would appear to be encouraging, more studies are required to determine its role in the management of vaginal vault prolapse.

Recurrent urogenital prolapse

Approximately one third of operations for urogenital prolapse are for recurrent defects. Recurrent prolapse may occur following both abdominal and vaginal hysterectomy, previous vaginal repairs and continence surgery. In addition, women with intrinsically weak connective tissue, such as patients with Ehlers Danlos syndrome, are at increased risk.

In such cases, the vaginal epithelium may be scarred and atrophic, making surgical correction technically more difficult and increasing the risk of damage to the bladder and bowel. The risk of post-operative complications, such as dyspareunia secondary to vaginal shortening and stenosis, is also increased. In those women who have had a previous continence operation, such as colposuspension, there is an increased risk of recurrent incontinence that may require further surgical correction.

Mesh repair

The use of synthetic mesh is becoming increasingly common in patients with prolapse, and may offer further support in cases in which the endopelvic fascia and vaginal epithelium are felt to be deficient. The ideal mesh should be strong and flexible, allowing ease of use. In addition, woven meshes should have an adequate pore size to allow the ingrowth of fibroblasts so as to minimise the risks of erosion and rejection.

Vaginal mesh kits are being used to surgically treat apical vaginal prolapse; however, their safety and efficacy are currently unknown. Several companies now market these 'mesh kits' despite lack of robust evidence regarding their safety and efficacy. A recent systematic review of these kits suggests that although they are associated with high objective cure rates between 87 and 95 per cent, they have a high risk of mesh

erosion (4.6–10.7 per cent) and re-operation rates of up to 6 per cent.¹⁷

Recent guidelines by NICE and the MHRA suggest more stringent regulation on the use of mesh for prolapse surgery. The guidelines advise that mesh should only be considered for recurrent prolapse, and that all patients being considered for such surgery need to be discussed at the multidisciplinary team meeting, and only operated on by a surgeon with a special interest in surgery for pelvic organ prolapse.^{18,19}

Dyspareunia is a common complication associated with the use of synthetic mesh and may be associated with erosion into the vagina, lower urinary tract and rectum. Although the use of mesh is becoming more common, it should be reserved for those patients with recurrent defects in specialist pelvic floor reconstructive surgery units.

CONCLUSION

Although not life threatening, urogenital prolapse is responsible for a significant degree of morbidity and impairment of quality of life. With approximately half of elective gynaecological operations being performed for correction of urogenital prolapse, the economic considerations are also considerable. In common with continence procedures, the initial procedure offers the greatest probability of success, and therefore patients should be carefully assessed with regard to their symptoms and investigations prior to surgery.

KEY POINTS

- Urogenital prolapse is a common condition associated with a high degree of morbidity.
- Incidence increases with increasing age and parity.
- Lifetime risk of surgery for urogenital prolapse is 11 per cent.
- Urogenital prolapse may be associated with concomitant urinary and faecal incontinence.
- Conservative management involves pelvic floor exercises and the use of vaginal pessaries.
- Surgery should be tailored to the needs of the individual patient.
- The use of synthetic mesh should be reserved for repeat procedures only.
- There is a high risk of recurrence following surgery, with a third of women requiring a further procedure.
- Complicated or recurrent cases are best managed using a multidisciplinary approach

Although conservative measures may be useful in the management of mild symptomatic prolapse, surgery offers the definitive treatment. The number of surgical procedures described is indicative of the fact that there is no perfect

solution, and this is reflected in the number of patients who complain of recurrent prolapse. Such women should be managed in tertiary units by surgeons with a specialist interest in pelvic floor reconstructive surgery.

Chapter 99 Infection and sexual health

Melanie Mann

MRCOG standards

Theoretical competencies

- Know the evidence for diagnosing, treating and following up pelvic inflammatory disease.
- Know which infections of the genital tract are transmitted sexually.
- Understand the pathological course of sexually transmitted infections.
- Understand how to investigate and manage STIs when encountered in the gynaecological setting.
- Know the law related to STIs.
- Recognise the sexual healthcare needs of vulnerable groups: young people, commercial sex workers, asylum seekers, drug users and prisoners.
- Understand the National Chlamydia Screening programme and local implementation.
- Understand local care pathways for multi-agency working and cross-referrals for individuals with sexual health needs.

Clinical competencies

- Take a history in relation to sexual health needs: counsel women (and their partners) sensitively, display tact, empathy and concern.
- Respect confidentiality.
- Explain clearly and openly treatments, complications and adverse effects of drug treatment.
- Demonstrate effective liaison with colleagues in other disciplines, such as genito-urinary medicine, counsellors.
- Respect cultural and sexual diversity.
- Recognise and manage common clinical presentations of STIs in the female patient e.g. dysuria, discharge, genital ulceration (including performing appropriate investigations, treating and arranging follow-up, according to local protocols).
- Revise the causes of pelvic pain.

- Recognise presentations of complications of common STIs e.g. acute PID.
- Recognise and manage clinical presentations of non-STI genital infections e.g. bacterial vaginosis.
- Explain the principles of partner notification and epidemiological treatment for sexual contacts.
- Perform an HIV risk assessment and discuss HIV transmission with women, including pre-test discussion and appropriate management of results, both positive and negative.
- Give appropriate advice to an HIV-positive woman about available interventions to prevent vertical transmission in pregnancy.
- Assess risk for hepatitis A/B/C infections and arrange appropriate vaccination for at-risk groups according to local protocol.
- Understand the psychological and psychosocial aspects of living with HIV/AIDS and STIs.
- Demonstrate the ability to promote healthy lifestyles, including safer sex.

PELVIC INFLAMMATORY DISEASE

This section covers the diagnosis, treatment and follow-up of PID. PID is important because it can have serious long-term sequelae such as pelvic pain, ectopic pregnancy and infertility. It is the result of post-infection scarring that is normally associated with healing. The virulence of the infection and the host-immune factors both determine the extent of the damage caused. There may be complete tubal closure, extensive peritubal adhesions, intratubal adhesions and mucosal and ciliary damage, all of which can cause ectopic pregnancy and infertility (including interference with ovum transport and sperm migration). In a large, multicentre WHO study of more than 8000 couples in 25 countries investigated for infertility, approximately 32 per cent of diagnoses were tubal factor infertility in the female.

Incidence

The incidence of PID is unknown, as many cases go unnoticed until investigations for infertility are performed. There is no record of cases of PID held nationally apart from diagnosed records of all attendances at genito-urinary (GUM) clinics. Approximately 1 in 60 consultations in general practice is for women less than 45 years for suspected PID.

Aetiology

Neisseria gonorrhoeae and *Chlamydia trachomatis* are the most important organisms (but only account for a quarter of cases in the UK), although *Gardnerella vaginalis*, anaerobes and other organisms, such as mycoplasmas commonly found in the vagina, may also be implicated. Other factors associated with PID include:

- young age (<25 years);
- multiple sexual partners;
- past history of STI (in the patient or her partners);
- termination of pregnancy;
- insertion of an IUD in the previous six weeks;
- hysterosalpingography;
- IVF procedure;
- postpartum endometritis;
- bacterial vaginosis;
- a new sexual partner (within the previous three months).

Diagnosis

PID can be symptomatic or asymptomatic. Even in symptomatic patients, clinical symptoms and signs lack sensitivity and specificity. The positive predictive value of a clinical diagnosis is 65–90 per cent compared to laparoscopic diagnosis in experienced hands. The symptoms suggestive of PID include:

- lower abdominal pain;
- fever >38°C;
- dyspareunia;
- unscheduled vaginal bleeding;
- abnormal vaginal discharge.

The signs associated with PID are usually also non-specific. Pyrexia may be present, but not exclusively. Lower abdominal and adnexal tenderness on bimanual examination, as well as cervical excitation (cervical motion tenderness) on bimanual examination, are indicative of acute inflammation affecting the pelvic peritoneum. However, they are not specific for PID. Other conditions that should be considered when assessing lower abdominal pain in a young woman include:

- ectopic pregnancy;
- acute appendicitis;
- urinary tract infection;
- endometriosis;
- complications of an ovarian cyst (torsion or rupture);
- constipation;
- functional pain (pain of unknown origin).

Investigation of suspected PID

Testing for gonorrhoea and chlamydia in the lower genital tract is recommended, as positive results support a diagnosis (see p. 796–797 for details on testing for gonorrhoea and chlamydia). However, the absence of infection at this site does not exclude PID. Absence of cultured organisms may be due to poor sampling technique, inadequate storage and/or transportation of swabs or the presence of organisms that cannot easily be cultured in the laboratory, such as mycoplasmas. An elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) can support the diagnosis. Laparoscopy may strongly support the diagnosis of PID, but is not justified routinely on the basis of cost and invasiveness. Furthermore, even laparoscopy lacks the sensitivity to identify mild intratubal inflammation or endometritis reliably. Endometrial biopsy and ultrasound scanning may also be helpful when there is diagnostic difficulty, but there is insufficient evidence to support their routine use at present.

Management

It is likely that delay in treatment increases the risk of the development of long-term sequelae of PID, such as ectopic pregnancy, pelvic pain and infertility. Owing to this, and to the lack of definitive diagnostic criteria, it is recommended that clinicians have a low threshold for treating empirically. It is also important that women are not labelled with the wrong diagnosis just because they appear to be in a high-risk group for having PID. Effort must be made to confirm the correct diagnosis, particularly in difficult or recurrent episodes of lower abdominal pain. It is also important in the gynaecological setting not to forget to investigate and treat the sexual partner(s), in order to prevent reinfection.

General measures

- Rest is advised for severe disease (preferably as an in-patient for observation to check that there is resolution of symptoms and signs) [C].
- A pregnancy test should be performed [C].
- Appropriate analgesia is advised [C].
- Parenteral therapy as an inpatient is advised for those with severe disease [C].
- Patients should avoid sexual intercourse until they and their partners have been fully treated and contact traced [C].

A full explanation should be given to the patient regarding the short- and long-term issues associated with PID. Leaflets to clarify and back up verbal explanation should be given to the client and her partner, if present. All patients should be offered full STI screening and HIV testing at some point in the management [C]. Good links with local GUM clinics are essential.

Antibiotic treatment

Broad-spectrum antibiotics are needed that will cover gonorrhoea and chlamydia. This treatment should be commenced as soon as possible. Information on recent and current medications should be obtained and appropriate advice given regarding any interactions. Latest evidence is that antibiotics (unless liver enzyme inducing e.g. rifampicin) do not affect the efficacy of hormonal contraception. There is a lack of evidence regarding antibiotic use and the prevention of long-term complications and fewer data on oral than parenteral regimens. There are important factors to be considered when choosing a regimen:

- local antimicrobial sensitivities (especially gonorrhoea);
- local epidemiology of infections (knowing where there are high-prevalence areas for gonorrhoea);
- cost;
- patient preference and likelihood of compliance;
- severity of disease.

When considering selection for inpatient treatment, the uncertainty of the diagnosis and severity of the disease will usually be sufficient to identify those who require inpatient observation. Other cases for which inpatient supervision is advised include women who have failed to respond to orally administered outpatient therapy, those who are suspected of having a tubo-ovarian mass and those who are unable to tolerate oral therapy. Two special subgroups might also be considered for inpatient treatment: those known to have an immunodeficiency problem (where a much more severe disease situation can develop quickly) and those who are pregnant – PID can occur up to about 12 weeks of pregnancy.

Recommended regimens

The following are evidence based. Intravenous therapy should be continued until 24 hours after clinical improvement and then switched to oral treatment [B].

Outpatient regimens

- Oral ofloxacin 400 mg twice daily plus oral metronidazole 400 mg twice daily for 14 days [A].
- Intramuscular ceftriaxone 500 mg single dose followed by oral doxycycline 100 mg daily plus metronidazole 400 mg twice daily for 14 days [A].
- Ofloxacin should be avoided in women at high risk of gonococcal PID due to increased quinolone resistance in the UK.

There is no evidence of one antibiotic regime listed above being superior to the others.

Inpatient regimens

Inpatient antibiotic treatment should be based on intravenous therapy which should be continued until 24 hours after clinical improvement and followed by oral therapy. Recommended regimens are:

- ceftriaxone 2 g by intravenous infusion daily plus intravenous doxycycline 100 mg twice daily, followed by oral doxycycline 100 mg twice daily plus oral metronidazole 400 mg twice daily for a total of 14 days;

- oral doxycycline may be used, if tolerated, while on intravenous ceftriaxone;
or
- intravenous clindamycin 900 mg three times daily plus intravenous gentamicin, followed by either – oral clindamycin 450 mg four times daily to complete 14 days or – oral doxycycline 100 mg twice daily plus oral metronidazole 400 mg twice daily to complete 14 days.
- Gentamicin should be given as a 2 mg/kg loading dose followed by 1.5 mg/kg three times daily (or a single daily dose of 7 mg/kg may be substituted).
- Intravenous ofloxacin 400 mg twice daily plus intravenous metronidazole 500 mg three times daily for 14 days.

The clinical trial data support the use of cefoxitin for the treatment of PID, but this agent is not easily available in the UK so ceftriaxone, which has a similar spectrum of activity, is recommended. An alternative third-generation cephalosporin would also be acceptable. If parenteral gentamicin is used, then serum drug levels and renal function should be monitored. The choice of an appropriate treatment regimen will be influenced by robust evidence on local antimicrobial sensitivity patterns, robust evidence on the local epidemiology of specific infections, cost, the woman's preference and compliance, and severity of disease. Evidence of the efficacy of antibiotic therapy in preventing the long-term complications of PID is currently limited. Metronidazole may be discontinued in those women with mild or moderate PID who are unable to tolerate it, since its addition provides uncertain additional efficacy in this patient group.

Other important situations

Women with PID who are also infected with HIV should be treated with the same antibiotic regimens as women who are HIV-negative. Hospital admission and parenteral treatment is only required for those with clinically severe disease. Potential interactions between antibiotics and antiretroviral drugs should be considered.

The risk of giving any of the recommended antibiotic regimens in very early pregnancy (before a positive pregnancy test) is low, since significant drug toxicity results in failed implantation.

Pregnant women should ideally receive IV therapy, as PID is associated with higher maternal and fetal morbidity. (However, PID in pregnancy is rare except for septic abortion.) None of the regimens above is of proven safety in this group. There is insufficient evidence in pregnant women to suggest one treatment over another as long as the appropriate organisms are covered for 14 days' treatment and this is parenteral, if possible.

Consideration should be given to removing an IUD in women presenting with PID, if symptoms have not resolved within 72 hours [A] of starting antibiotics. The RCT evidence for whether an IUD should be left in place or removed in women presenting with PID is limited. Removal of the IUD should be considered and may be associated with better short-term clinical outcomes, but the decision to remove it needs to

be balanced against the risk of pregnancy in those who have had unprotected intercourse in the preceding seven days. Emergency hormonal contraception may be appropriate for some women in this situation.

Fitz–Hugh–Curtis syndrome comprises right upper quadrant pain associated with perihepatitis, which occurs in up to 10–20 per cent of women with PID and may be the most obvious symptom. There is insufficient evidence to recommend laparoscopic adhesiolysis in this situation.

Management of partners should be by testing and treatment, ideally in a GUM clinic. Empirical treatment should be given. Broad-spectrum antibiotic treatment should be offered to male partners e.g. azithromycin 1 g single dose [C]. Contact tracing of all partners in the previous six months is recommended. Partners should avoid sexual intercourse until they and the index patient have completed the treatment course [C].

Follow-up

All patients should be followed up at three days to check improvement and exclude the need for parenteral or surgical treatment. Further review at four weeks is recommended to check resolution of symptoms, pregnancy test where appropriate and to discuss long-term issues. It is also an ideal time to check up on partner notification and treatment.

Management of vaginal discharge in women of reproductive years

The commonest cause of vaginal discharge is bacterial vaginosis (BV), which is not an STI. Candidiasis is the next commonest but is overdiagnosed by both women and their healthcare professionals. It is not an STI either. *Trichomonas vaginalis* (TV) is sexually transmitted and, if diagnosed, contact tracing needs to be done. Other causes of abnormal vaginal discharge can be infective (chlamydia or gonorrhoea) or non-infective such as foreign bodies, malignancies, fistulae, cervical ectopy or physiological (a diagnosis of exclusion).

Taking a good history is vital including a sexual history to pick up those at higher risk of an STI (under 25 years, previous STI, recent change in sexual partner or more than one partner in the previous year). Questions need to be asked regarding whether there has been unscheduled bleeding, upper reproductive tract symptoms (such as pelvic pain/deep dyspareunia), pregnancy/recent termination of pregnancy/recent instrumentation and whether these are recurrent symptoms and treatment has failed. In these situations, a full STI screen and examination should be carried out and referral to GUM may be necessary. It is useful to ask about medication already/recently used such as antibiotics.

The most important questions about the discharge then need to be asked: is there associated itch (candida) or malodour (BV or TV)? Is the discharge lumpy (? candida) or thin

(BV) or frothy (TV)? Does anything make the symptoms worse (e.g. sex/menses/bathing make BV worse)? Has any treatment been tried (e.g. antifungals) and does it help?

If a woman is at low risk of STI and has no other concerning symptoms/history it is reasonable to examine and also test the vaginal pH. If the pH is >4.5 and the symptoms fit with BV, then she can be treated as such. If the symptoms are of candida and the clinical picture fits, then she can be treated with oral or topical antifungals. A high vaginal swab is not necessary unless there are recurrent or worrying symptoms or failure of therapy.

SEXUALLY TRANSMITTED INFECTIONS

This section focuses generally on the management of women, but one should not forget to consider partners and to think about them when talking about this aspect of gynaecology. Talking about these very personal aspects of a woman's life is very important and all gynaecologists need to be able to talk about sex sensitively and non-judgementally in order to do the best for the patient. It is therefore important that clinicians practise taking a sexual history to achieve this (Box 99.1). Clinician communication skills are very important.

Sexually transmitted infections are an important part of the everyday work of a gynaecologist and these conditions can have long-term sequelae for the patient if not managed promptly and thoroughly. The majority of large towns and cities in the UK have a department of GUM with at least one

Box 99.1 Taking a sexual history to assess the risk of STI

Preface by warning the patient that you need to ask some personal questions to do with her relationships with partners:

I need to ask you some personal questions now. Are you in a sexual relationship?

You need to find out if this is a heterosexual or homosexual relationship. This is one of the most difficult questions. You can ask the first name of the partner and then clarify whether male or female if the first name is equivocal e.g. Nicky or Chris. Or you can say:

Can I just check, is your partner male or female? How long have you been with your partner?

Avoid the term 'steady' or 'long term' as these have different meanings for different people.

Do you or your partner have any other partners, as far as you are aware?

In some situations, it is important to ask about different sexual practices, such as oral or anal sex. Sometimes patients may volunteer the information that sex in a particular position causes discomfort, so it is important to be able to discuss this openly. Consideration should be given to asking about intimate partner violence and alcohol and recreational drug history.

specialist employed. It is good practice to develop strong links with this local department to improve the overall management of STIs within each gynaecology unit. This will ensure that patients receive optimum evidence-based treatment and that contact tracing and partner notification are performed according to approved guidelines.

Basic tenets of GUM

- The patient's confidentiality is paramount and patient details are not given to other patients or other healthcare professionals without the patient's informed consent (see below). Sexual history taking should take place in a private environment.
- If a patient has an STI, at least one other person is also carrying it and needs to be sought, treated and contact traced.
- If a patient has one STI, she must be at risk of all other STIs. She should therefore be offered screening for all other infections. This may be carried out in a GUM clinic.
- When swabs for STI are taken, it is important to obtain informed consent about the nature of the tests and explain what the follow-up procedure will be if the test is positive for an STI.
- Patients diagnosed with an STI should be advised not to have sexual intercourse until they and their partners have completed treatment and follow-up. This is to minimise further spread or reinfection.
- Patients should be given a detailed account of their condition, with particular emphasis on the long-term implications for themselves and their partner(s). This should be reinforced with clear and accurate written information.

Law relating to STIs

All NHS employees are required to adhere to the Caldicott principles for confidentiality and there is also explicit guidance from the General Medical Council to emphasise the importance. Confidentiality is a common-law duty and is absolute except in special circumstances such as when breaking confidentiality would be in the patient's or the public's best interests e.g. child protection cases.

The Venereal Diseases Act 1917 applies to GUM clinics and makes the rules of confidentiality even stricter: patient records are locked away and are not accessible to other clinicians outside the department, including the GP, without the express consent of the patient.

Terms used in GUM clinics

Partner notification

Contact slips, with a nationally agreed code for each STI, are given to patients to pass on to their sexual contacts. Contacts can then present the slip at any GUM clinic in the UK, where the infection will be managed appropriately. This is because there is communication between GUM clinics regarding partner notification.

Contact tracing

This involves finding the sexual contacts of the index patient carrying an infection and managing them appropriately, including ongoing partner notification if possible.

Health advisors

These are specially trained professionals whose job is to educate patients in the GUM clinics about STIs. They are also responsible for most partner notification and contact tracing.

Gonorrhoea

Gonorrhoea is an STI caused by the Gram-negative diplococcus *N. gonorrhoeae*. The primary sites of infection are the mucous membranes of the urethra, endocervix, rectum, pharynx and conjunctiva. Transmission occurs as a result of direct inoculation of secretions from one mucous membrane to another. Vertical transmission from mother to fetus may also occur during labour.

Clinical features

Up to 50 per cent of women are asymptomatic. In those who do have symptoms, the most common are an increased or altered vaginal discharge (up to 50 per cent) and lower abdominal pain (up to 25 per cent). Urethral infection may cause dysuria (12 per cent), but not usually frequency. Gonorrhoea is a rare cause of intermenstrual bleeding or menorrhagia and this is due to infection of the endometrium (endometritis). Infection in the pharynx is usually asymptomatic. Coexistent pathogens may be responsible for symptoms e.g. candida or trichomonas.

In men, the infection may also be asymptomatic (10 per cent), but generally causes urethral discharge (80 per cent) or dysuria (50 per cent).

Clinical signs

Less than 50 per cent of women will present with mucopurulent endocervical discharge and easily induced endocervical bleeding, and less than 5 per cent will present with pelvic or lower abdominal tenderness. Commonly, no abnormal findings are present on clinical examination. In men, there is usually a purulent urethral discharge present. Epididymal tenderness or balanitis, although reported, is rare. Gonorrhoea is also transmitted vertically to the fetus. It can cause severe conjunctivitis (ophthalmia neonatorum) and this is a notifiable disease in the UK. Neonatal infections can be severe and should be managed systemically by a paediatrician/ophthalmologist.

Complications

Transluminal spread of *N. gonorrhoeae* may occur, causing PID (<10 per cent) and epididymo-orchitis (<1 per cent) in men. Haematogenous dissemination can also occur, causing skin lesions, arthralgia, arthritis and tenosynovitis. Disseminated gonococcal infection is rare (<1 per cent).

Diagnosis

Detection of *N.gonorrhoeae* can be achieved by nucleic acid amplification tests (NAATs) or culture. NAATs are generally more sensitive than culture and offer testing on a wider range of specimen types. NAATs show a higher sensitivity (>96 per cent) in both symptomatic and asymptomatic infection; they are therefore the test of choice for asymptomatic individuals. Positive NAATs from low-prevalence populations need confirmation by supplementary testing that uses a different nucleic acid target. There is equal sensitivity of the test whether a vaginal swab or an endocervical swab is used. The sensitivity of urine NAATs in women is significantly lower and it is not the optimal specimen in women [B]. In men there is equal sensitivity in testing both urine and urethral swabs.

Positive NAATs should be confirmed by culture on selective medium which has been impregnated with antibiotics to prevent overgrowth of unwanted organisms. Gonorrhoea, under different circumstances, may not be cultured easily and so refrigeration of swabs prior to transport to the laboratory is recommended and sensitivities to antibiotics checked. Culture requires an endocervical and urethral swab specimen for maximal sensitivity. The collection of rectal and pharyngeal swab specimens should be directed by sexual history and symptoms and considered in women who are sexual contacts of gonorrhoea. Rectal gonorrhoea in women can be caused by tracking of discharge posteriorly. It is important to follow local guidance and liaise with the laboratory.

Management

All patients should be treated if they have a positive test result (NAAT or culture, if NAAT positive then culture too to confirm infection especially in low-prevalence areas and to check antibiotic sensitivities) or if a recent partner has confirmed gonococcal disease and testing of the patient is not possible. Consider treating epidemiologically after sexual assault. Referral to GUM is highly recommended [B]. There have been clinical reports of treatment failures using many recommended treatments and there is increasing concern about reduced sensitivity of *N. Gonorrhoeae* to third-generation cephalosporins.

Recommended treatments

Uncomplicated anogenital infection in adults:

- Ceftriaxone 500 mg IM as a single dose plus azithromycin 1 g oral as a single dose (Grade C recommendation). This is first-line treatment due to concerns around drug resistance and drug failures. Azithromycin is always recommended as a co-treatment to epidemiologically treat chlamydia, but even if chlamydia negative there is evidence that it might delay the widespread onset of cephalosporin resistance.
- Cefixime 400 mg oral as a single dose. Only if there are contraindications to an IM injection or refused (Grade A recommendation)
or
- Spectinomycin 2 g IM as a single dose (Grade A recommendation).

Surveillance data for 2009 show significant levels of *N. gonorrhoeae* resistance to penicillin (22 per cent), tetracyclines (68 per cent) and ciprofloxacin (35 per cent) in the UK. Most resistant infections are acquired in the UK.

Antimicrobial therapy should take account of local patterns of antimicrobial sensitivity to *N. gonorrhoeae*. The chosen regimen should eliminate infection in at least 95 per cent of those presenting in the local community. This issue of local resistance patterns is another reason why all cases should be referred to GUM in the UK.

Treatment of gonorrhoea when pregnant or breastfeeding

Pregnant women should not be treated with quinolone or tetracycline antibiotics. Azithromycin: manufacturer advises use only if adequate alternatives are not available.

Recommended regimes

- Ceftriaxone 500 mg IM as a single dose with azithromycin 1 g orally as a single dose [C]
or
- Spectinomycin 2 mg IM as a single dose with azithromycin 1 g stat orally [A].

In the case of allergy, the above regimes can be used.

Co-infection with *C. trachomatis* is common (up to 41 per cent of women) and therefore screening and, if positive, treatment should always be performed. In many departments, epidemiological treatment for chlamydia is given at the same time as gonococcal disease is treated.

Partner notification using national recommendations and contact tracing should be performed as described previously [B].

Follow-up and test of cure

At least one follow-up visit is recommended to confirm compliance with therapy, resolution of symptoms and partner notification. A test of cure is now recommended because of the concerns around antibiotic resistance. Test of cure should be done by NAAT ideally 2 weeks after treatment is completed. Infection identified at this point may be due to reinfection. All cases of gonorrhoea should be seen by a trained person (ideally a GUM health advisor) for partner notification and contact tracing.

Chlamydia trachomatis

National Chlamydia Screening Programme

The National Chlamydia Screening Programme (NCSP) is a control-and-prevention programme in the UK, targeted at sexually active young people under 25 years of age. Chlamydia is the most common bacterial STI in the UK, affecting both men and women, with sexually active young people at highest risk, with equal frequency in men and women. Most people with chlamydia have no symptoms but left untreated, chlamydia in women can lead to tubal factor infertility, ectopic pregnancy and chronic pelvic pain. In men, it may cause urethritis and epididymitis. In both sexes, it can cause arthritis.

The Chief Medical Officer's Expert Advisory Group on *Chlamydia trachomatis* (1998) considered the evidence base associated with screening for genital chlamydial infection. This group concluded that chlamydia screening met the criteria for a screening programme and recommended that one be established. Since then, the evidence base for chlamydial screening has continued to develop. Self-collected first-void urine specimens and vulvovaginal swabs have been found suitable samples for testing with NAATs. RCTs have demonstrated reductions in PID among women screened for chlamydia. There is considerable uncertainty and scientific debate about the mathematical models of screening effectiveness. The studies have predicted more moderate reductions in prevalence following the introduction of chlamydia screening than before screening. The NCSP facilitates the provision of screening in core sexual health services (community contraceptive services, general practice, abortion services and community pharmacies). Tests are also available via internet request and samples can be sent to the test provider in the mail.

It is recommended that young people are tested annually or when they change partner. If a young person has a positive test it is recommended that they are retested at three months as there is evidence that this group are at higher risk of being reinfecting with higher risk of longer-term sequelae.

Screening for chlamydia should be promoted in young people, especially those who are pregnant (antenatal and those seeking abortion) and those attending GUM clinics, where the incidence varies between 5 and 16 per cent. Infection is sustained by unrecognised and untreated, symptomless chlamydial infection. It is now thought that overall the complications of this infection cost at least £50 million annually in the UK.

Clinical features

Eighty per cent of infected women are asymptomatic. When symptoms are present, they include post-coital or intermenstrual bleeding, lower abdominal pain, purulent vaginal discharge, mucopurulent cervicitis and/or contact bleeding. Fifty per cent of men are asymptomatic, with urethral discharge and dysuria being the most common symptoms. The risk factors associated with chlamydial infection include young age (<25 years), new sexual partner or more than one sexual partner in recent years. There is also an association with contraceptive practice, with infection being less common in barrier contraception users and more common in those using combined oral contraception. Women undergoing termination of pregnancy also appear to have a higher association with chlamydial infection. Prophylactic antibiotic use and screening for infection reduce the risk of post-abortion infection [B].

Complications

One of the immediate complications is developing PID. In chlamydial PID, perihepatitis can also occur; this is known as Fitz-Hugh-Curtis syndrome. As with other types of PID, the long-term sequelae include tubal damage resulting in an increased risk of infertility and ectopic pregnancy and

chronic pelvic pain. Less common outcomes include adult conjunctivitis and sexually acquired reactive arthritis or Reiter's syndrome. This is more common in men who have chronic chlamydial infection.

Chlamydia can be transmitted to the neonate at the time of delivery, causing neonatal conjunctivitis (ophthalmia neonatorum) and pneumonitis. The risk of transmission is about 20–50 per cent for eye infections and 10–20 per cent for lung infections. The mother may also be at increased risk of infection of the uterus.

Specimen collection and laboratory tests for chlamydia

With the advent of NAATs reliable specimens are both self-taken vulvovaginal swabs (first choice) and also first-catch urine samples. Endocervical tests can also be taken, if a speculum examination is being done anyway. There are also assays which test for chlamydia and gonorrhoea detection in the same assay. It is recommended that patients are tested for chlamydia (using a NAAT) when they first present but that they are made aware of the two-week 'window period' and are advised to return for a repeat NAAT two weeks after the last exposure.

The current standard is to use NAAT testing which is highly sensitive for all cases including medico-legal cases. Enzyme immunoassay is now not recommended and culture is now not available.

In general, NAATs are 90–95 per cent sensitive with the majority of studies indicating that as either the number of sites sampled increases, or the number of different NAAT used increases, the greater the detection of *C. trachomatis* in any given population. Both first-catch urine (65–100 per cent sensitivity) and self-taken vulvovaginal swabs (90–95 per cent sensitivity) are suitable for testing and for screening. However, first-catch urine samples may be less sensitive than vulvovaginal or cervical samples for detecting infection with *C. trachomatis*.

General management

Women should be advised to take the treatment (see below under Treatment) and avoid sexual intercourse (including oral sex) for the duration of the treatment, or for one week after taking the stat dose of azithromycin. Men and women with a positive chlamydia test should be offered a full STI screen and this may require a visit to the local GUM department. All contacts of positive chlamydia tests should be tested and treated epidemiologically and also offered a full STI screen. Uncomplicated chlamydia is not an indication to remove an IUD or IUS. All patients with a positive test for chlamydia should be given written information regarding the infection.

Treatment

The recommended treatment of uncomplicated chlamydial infection is with azithromycin 1 g stat as a single dose or doxycycline 100 mg twice a day for seven days. Alternative

regimens include erythromycin 500 mg four times a day for seven days or erythromycin 500 mg twice a day for 14 days. However, erythromycin has a significant side-effect profile and is less than 95 per cent effective. Ofloxacin 400 mg once a day for one week can also be used. The majority of studies are flawed in design, small and give no details regarding the treatment of sexual partners. Doxycycline and azithromycin have been the most rigorously tested. Women using combined hormonal contraception should be advised there is no interaction between these antibiotics and their contraception and they should use as normal. Follow-up of chlamydial infection is recommended to check partner notification, reinforce health education, assess treatment efficacy and exclude reinfection [B].

Treating *Chlamydia trachomatis* in pregnancy: Quinolones and tetracyclines should not be used in pregnancy.

Amoxicillin appears to be an acceptable alternative to erythromycin in achieving microbiological cure (amoxicillin 500 mg three times a day for seven days) and is better tolerated. Clindamycin and azithromycin may be considered. Azithromycin is recommended for treatment by WHO, but is not licensed in the UK for use in pregnancy. The British National Formulary (BNF) says it can be used if no other alternative is available. However, Scottish guidelines recommend azithromycin as first-line treatment in pregnancy [A] (1 g as a single oral dose).

Test of cure

A test of cure is not routinely recommended but should be performed in pregnancy or if non-compliance or re-exposure is suspected. It should be deferred for five weeks (six weeks if azithromycin has been given) after treatment is completed.

Trichomonal infection

The causative organism is *Trichomonas vaginalis*. This is a flagellated protozoon which is found in the vagina, urethra and para-urethral glands. Transmission is almost exclusively sexual in adults. It can be acquired perinatally and occurs in 5 per cent of babies born to infected mothers. If infection is found after the first year, sexual contact is implied, although other modes of transmission are postulated.

Clinical features

Between 10 and 50 per cent of women are asymptomatic [B]; among the remainder, the most common symptoms are vaginal discharge, vulval itching, dysuria and offensive odour. Occasionally, lower abdominal pain may be present. Seventy per cent of infected women have a vaginal discharge, which can vary in consistency from thin and scanty to profuse and thick. The classical frothy yellow discharge occurs in 10–30 per cent. Vulvitis, vaginitis and cervicitis are associated with trichomonal infection. A 'strawberry cervix' appearance is visible to the naked eye in approximately 2 per cent of cases

and in more women on colposcopy. No abnormalities are found in 10–15 per cent of women.

Complications

There is increasing evidence that trichomonal infection can have a detrimental effect on pregnancy and is associated with preterm delivery and low-birthweight infants [B].

Diagnosis

Direct observation of a wet smear from the posterior fornix will diagnose 40–80 per cent of cases, whereas culture of the organism will correctly diagnose 95 per cent of infected women. Trichomonads are no longer reported by the national cervical screening programme which is now mainly using liquid-based cytology methods. There may be NAATs in future.

Treatment

Systemic chemotherapy is recommended, as urethral and para-urethral glands are frequently infected. Most strains of TV are highly sensitive to metronidazole and related drugs (approximately 95 per cent cure rate). There is a spontaneous cure rate in 20–25 per cent.

The recommended regimens for treating trichomonal infection include metronidazole 2 g orally in a single dose (avoid in pregnancy and breastfeeding) or metronidazole 400–500 mg twice daily for 5–7 days [A]. The single dose is cheaper with better compliance, but there is evidence that there may be a higher failure rate, especially if partners are not treated concurrently. Patients should be advised not to drink alcohol for the duration of, and for 48 hours after completion of, treatment due to the disulfiram-like effect (severe sickness).

Treatment failures should be referred to GUM to assess the possible reasons, such as poor compliance, re-infection, co-infection and/or resistance. There is no evidence that metronidazole is teratogenic in the first trimester of pregnancy [A], although the BNF warns against high-dose regimens. In breastfeeding women, metronidazole may change the taste of breast milk. High doses should be avoided.

Genital herpes

Genital herpes is acquired by sexually transmitted infection with either herpes simplex type 1 virus (HSV-1) – which is the usual cause of orolabial herpes – or herpes simplex type 2 virus (HSV-2). The infection may be primary or non-primary and disease episodes may be initial or recurrent and symptomatic or asymptomatic. Severe primary attacks of herpes constitute a genito-urinary emergency and patients should be dealt with quickly and referred to a department of GUM for ongoing support and partner notification. After childhood, symptomatic primary infection with HSV-1 is equally likely to be acquired in the genital or oral areas. After primary infection, the virus becomes latent in local sensory ganglia, periodically reactivating to cause symptomatic lesions or asymptomatic

but infectious viral shedding. This may be important in the acquisition of infection in long-term relationships where there has been primary infection with no history of a new partner. New diagnoses of genital herpes are equally likely to be caused by HSV-1 or HSV-2; however, HSV-2 is more likely to recur than HSV-1. Median recurrence rates per month after a first episode are 0.34 for HSV-2 (approximately 4 episodes a year) and 0.08 for HSV-1 (approximately 1 episode a year). Recurrence rates generally reduce over time.

Clinical features of genital herpes in women

The most common symptoms are those of vulval pain, which is usually associated with ulcers that are preceded by blisters (Table 99.1). In a primary infection, this can be quite severe and the whole vulva can become swollen, ulcerated and infected. This, in turn, can cause discharge and dysuria and in severe cases urinary retention. The cervix may also become ulcerated. Tender inguinal lymphadenopathy is also a feature of the primary infection, although this may be the result of secondary infection. More generalised features of a viral illness may also be present, particularly in primary infections. These include fever and myalgia. Herpetic infection can be asymptomatic; this is more likely in recurrent episodes.

Complications

Urinary retention can occur as a result of autonomic neuropathy, or because of the severe pain caused by the local reaction around the urethra and vulva. It has also been postulated that chronic vulval pain may also be a result of post-herpetic neuralgia.

Diagnosis

HSV confirmation and typing are important for diagnosis, prognosis and counselling [C]. Swabs must be taken from the base of a lesion, kept cold and transported directly to the laboratory in the viral culture medium. Serology is not commonly used to make the diagnosis. Given the implications of the diagnosis and potential for recurrent infections, it is vital that an accurate diagnosis be made at the outset. It cannot be assumed that vulval ulceration is herpetic until so proven by viral culture. HSV NAAT/PCR (polymerase chain reaction for HSV DNA) for herpes diagnosis has a higher sensitivity (71 per cent) than virus culture (11 per cent).

Table 99.1 Clinical features of acute herpes infections in women

Symptoms	Signs
Painful ulceration, dysuria, vaginal discharge	Blistering and ulceration of vulva ± cervix, preceded by vesicles
Fever, myalgia (flu-like symptoms) – more common in primary infections	Inguinal lymphadenopathy
May be asymptomatic	

Management

Primary genital herpes

General advice includes drinking large quantities of fluids to make the urine less concentrated and therefore reduce the pain on micturition, saline bathing and analgesia with a combination of NSAIDs and topical anaesthetic gels. Antiviral drugs are indicated if commenced within five days of the start of the episode and if lesions are still developing. Aciclovir (200 mg five times daily), valaciclovir (500 mg twice daily) and famciclovir (250 mg three times daily) all reduce the severity and duration of episodes [A], but they do not alter the natural history of the infection. Topical agents are less effective than oral agents, and intravenous therapy is only indicated when the patient cannot tolerate oral medication.

Management of complications

Hospitalisation may be required because of urinary retention, meningism and severe constitutional symptoms. If catheterisation is required, it is recommended that the suprapubic approach be used [C] to prevent the theoretical risk of ascending infection, reduce the painfulness of the procedure and allow normal micturition to take place without multiple attempts at recatheterisation.

Recurrent genital herpes

Recurrent attacks of genital herpes are generally less severe than primary attacks and are self-limiting. It is important to make management decisions together with the patient, and advice should be given with regard to sexual activity while potentially infective. However, not all patients will be aware of their potential infective state, particularly those who do not have symptoms or a prodrome (disordered local vulval sensations prior to the onset of a recurrent attack). Supportive and episodic antiviral therapy may be given [A], but if individuals suffer more than six attacks each year, suppressive therapy using antiviral agents and under the supervision of a genitourinary physician should be considered. Counselling may be required for those with problems adapting to the diagnosis.

Management in pregnancy

Referral of a woman with suspected herpes in pregnancy to a GUM physician is recommended. The main concern is the risk of neonatal HSV acquired during delivery from maternal viral shedding. This is most likely to occur with new maternal acquisition in the third trimester.

First-episode genital herpes

First- and second-trimester acquisition: Diagnosis in pregnancy is as described above. Serological testing of HSV-1 and -2 (IgG) has not been fully evaluated. First-trimester herpes has been associated with miscarriage, but there is no evidence of increased risk of fetal abnormality if the pregnancy continues. It is not an indication for termination of pregnancy.

Management should be as above, with oral or intravenous aciclovir in standard doses. Aciclovir is not licensed in pregnancy, but there is substantial clinical evidence

supporting its safety. Unless there are other complications, vaginal delivery can be anticipated. Continuous aciclovir in the last 4 weeks of pregnancy (aciclovir 400 mg tds) reduces the risk of both clinical recurrences at term and the need for caesarean section [A]. However, this point is contentious as other RCOG guidance quotes a study which did not demonstrate that aciclovir in the last 4 weeks of pregnancy gave any further protection.

Third trimester acquisition: Caesarean section should be considered for those developing symptoms after 34 weeks, as the risk of viral shedding during labour is very high, and thus also the risk of vertical transmission to the neonate (risk of neonatal herpes 41 per cent). If it is difficult to differentiate between a primary and a recurrent attack, it may be helpful to take viral swabs as well as serum (IgG) and if the HSV is the same type then CS may be avoided. If membranes have been ruptured for more than 4 hours, then CS may not prevent vertical transmission. The paediatricians should be informed. Neonatal herpes carries a mortality of 30 per cent for disseminated herpes infection and 17 per cent have long-term neurological sequelae. Caesarean section for the prevention of neonatal herpes has not been evaluated in RCTs and may not be completely protective against neonatal herpes. If CS does not take place, prolonged rupture of membranes and invasive monitoring should be avoided, intrapartum antivirals should be given and the baby treated postnatally.

Recurrent genital herpes

Sequential cultures in late pregnancy do not predict viral shedding at term. If there are no lesions at delivery, CS should not be performed, even if there has been a brief recurrence during the third trimester. Continuous aciclovir in the last four weeks of pregnancy may be cost effective compared with no therapy or CS. It may not reduce the risk of CS, as it does not eliminate viral shedding completely. There is no proven benefit in taking swabs for viral cultures at delivery to assess asymptomatic shedding.

Genital lesions (recurrent herpes) at delivery

The current British Association for Sexual Health and HIV (BASHH) consensus is that a caesarean section should be performed, despite lack of evidence for its effectiveness. The current RCOG consensus is that mode of delivery and pros and cons should be discussed with the mother, but that CS is not necessary as recurrent lesions are associated with a much lower risk of neonatal herpes (1–3 per cent). Therefore, the risks for the fetus at vaginal delivery may be small and need to be compared to the risks to the mother of caesarean section.

Prevention of acquisition of infection

All women should be asked about genital herpes in themselves or in their partners. The asymptomatic female partners of men known to have genital herpes should be advised to avoid sexual contact during recurrences [C]. Conscientious use of condoms during pregnancy may reduce the risk of acquisition, but this is unproven. Pregnant women should be advised about the risk of orogenital contact for acquiring HSV-1. The identification of susceptible women by means of type-specific

antibody testing has not been shown to be cost effective. All women, not just those with a history of genital herpes, should undergo careful inspection of the vulva at the onset of labour to look for clinical signs of herpes infection. Mothers, staff and other relatives and friends with active oral lesions should be advised about the risk of postnatal transmission.

Bacterial vaginosis

Bacterial vaginosis is not regarded as an STI and its aetiology is unknown. It is the most common cause of vaginal discharge in women of child-bearing age. The reported prevalence varies from 5 per cent in a group of asymptomatic college students to 50 per cent of women in Uganda. It has been reported in 12 per cent of pregnant women and in 30 per cent of women undergoing termination of pregnancy in the UK.

BV is characterised by an overgrowth of predominantly anaerobic organisms (*Gardnerella vaginalis*, *Prevotella* spp., *Mycoplasma hominis*, *Mobiluncus* spp.) in the vagina. This leads to replacement of lactobacilli and an increase in pH from a normal of 4.5 to 7. BV can arise and remit spontaneously in sexually active and non-sexually active women. It is more common in black than in white women, in those with an IUD and in those who smoke cigarettes.

Clinical features

In approximately 50 per cent of confirmed cases, there are no volunteered symptoms. Those with symptoms usually complain of an offensive, fishy-smelling vaginal discharge, not usually associated with vulvovaginitis. There is also a thin, white, homogeneous discharge coating the walls of the vagina and vestibule.

Complications

Although the incidence of BV is high in women with PID, there are no prospective studies investigating whether treating asymptomatic women for bacterial vaginosis reduces their risk of developing it subsequently. The condition is common in some populations of women undergoing elective termination of pregnancy and is associated with post-termination endometritis and PID [A]. In pregnancy, BV is associated with late miscarriage, preterm birth, preterm premature rupture of the membranes and postpartum endometritis [A]. It has been associated with an increased incidence of vaginal cuff cellulitis and abscess formation following transvaginal hysterectomy [B]. It is unclear how important this is in the UK, where antibiotic prophylaxis is routine practice. There are no studies investigating the role of BV in the development of PID following IUD insertion.

Diagnosis

Amsel's criteria for diagnosing bacterial vaginosis

At least three out of these four should be present for the diagnosis to be confirmed:

- thin, white, homogeneous discharge;
- clue cells on microscopy;

- pH of vaginal fluid >4.5;
- release of a fishy odour on adding alkali (10 per cent potassium hydroxide). (This test is rarely performed these days.)

Routine use of a high vaginal swab may not be useful, as culture of *G. vaginalis* can be possible in more than 50 per cent of normal women [B]. However, criteria can be used to judge whether a vaginal smear that has been Gram-stained shows features consistent with a diagnosis of BV. Realistically, if a woman has typical symptoms, history and signs together with a raised pH (>4.5), a presumptive diagnosis can be made and the woman treated.

Management

Initially, simple advice should be offered; this includes advice against the practice of vaginal douching, use of shower gels and antiseptic bath agents [C].

Antibiotic treatment is recommended for symptomatic women [A], women undergoing surgical procedures [A] and some pregnant women [A]. Studies support screening and treating BV with either metronidazole or clindamycin cream, to reduce the incidence of endometritis and PID post abortion. Using the oral route of administration, recommended regimens for treating BV include metronidazole 400–500 mg twice daily for 5–7 days [A] or metronidazole 2 g as a single dose [A]. An alternative approach is to use the vaginal route, with intravaginal metronidazole gel (0.75 per cent) once daily for five days [A] or intravaginal clindamycin cream (2 per cent) once daily for seven days [A]. All these treatments have been shown to achieve cure rates of 70–80 per cent after four weeks in controlled trials using placebo or comparing with oral metronidazole.

No reduction in relapse rates has been reported in studies in which the male partners were treated, and therefore there is no indication to treat the male partners of women with BV.

Follow-up is only required if symptoms recur, although a more cautious approach should be employed in pregnancy where recurrent infection may be associated with adverse outcomes.

The optimal management of those who have recurrent episodes of bacterial vaginosis remains unresolved.

EBM: Pregnancy and bacterial vaginosis

- Meta-analyses have concluded that there is no evidence for teratogenicity from the use of metronidazole in pregnancy [A].
- The results of clinical trials investigating the value of screening for and treating BV in pregnancy are conflicting, and it is therefore difficult to make firm recommendations.

In summary, symptomatic pregnant women should be treated in the normal way and there is insufficient evidence to treat asymptomatic women. Breastfeeding women might be better treated intravaginally as metronidazole affects the taste of the milk.

Anogenital warts

Aetiology

Warts are benign epithelial skin tumours that are caused by the human papillomavirus (HPV), of which there are more than 100 genotypes. The mode of transmission is most often sexual, but it may be transmitted perinatally and also from digital lesions (more commonly in children). Although the majority are benign and caused by HPV sub-types 6 and 11, others may contain oncogenic subtypes that are associated with genital tract dysplasia and cancer. Warts are just one manifestation of HPV infection of the genital tract, as there may also be subclinical and latent infection. Men and women with warts are best treated in a GUM department and also screened for other STIs.

Clinical features

Anogenital warts may cause irritation, but generally present as ‘lumps’ which may be found disfiguring and psychologically distressing. They can occur at any site in the genital area including perianally, which does not imply anal intercourse. Lesions can be flat or raised, single or multiple, soft or keratotic, small or ‘cauliflower like’, flesh-coloured or pigmented.

Occult lesions may also occur in the vagina and cervix. Extra-genital lesions may occur on the oral mucosa, larynx, conjunctiva and nasal cavity. Warts may be exophytic, single or multiple, keratinised and non-keratinised, broad based or pedunculated, and some are pigmented.

Diagnosis is mainly by naked-eye examination, although any doubt about the diagnosis should prompt biopsy under local anaesthetic. Speculum examination should be performed to look for cervical and vaginal lesions.

Management

General advice

Condom usage with regular partners has not been shown to affect the treatment outcome of anogenital warts. However, using condoms may result in both partners feeling more comfortable and may prevent the transmission of HPV to uninfected partners and therefore should be encouraged.

Treatment (see Box 99.2)

Treatment is generally uncomfortable and can be painful, and patients should be made aware that all treatments have

Box 99.2 HPV vaccination for genital wart protection

In the UK, young women at the age of 12 and 13 are offered Gardasil (from September 2012), a quadrivalent vaccine, meaning it protects against four strains of HPV. Gardasil protects against HPV-16, HPV-18 (high-risk HPV strains that are responsible for 70 per cent of cervical cancers in Europe) and HPV-6 and HPV-11, the strains responsible for 99 per cent of genital warts in young women. It is likely that genital warts will become far less frequent. In France the quadrivalent vaccine accounted for between 37 and 56 per cent cost savings in terms of genital wart protection.

significant failure and relapse rates. Warts may regress and disappear spontaneously; one third of all visible warts will disappear by six months. The choice of treatment depends on the morphology, number and distribution of the warts. First- and second-line treatments are not based upon robust evidence.

Soft, poorly keratinised warts respond well to podophyllin, podophyllotoxin (an antimetabolic agent) and trichloroacetic acid, whereas keratinised lesions are better treated with physical ablative therapies, such as cryotherapy (causes cytolysis at dermal/epidermal junction), excision and electrocautery. Imiquimod, an immune modulating agent, may be suitable for both types. Podophyllotoxin is usually administered over a four week cycle and imiquimod for up to 16 weeks, and both are suitable for self-application at home after appropriate instruction and screening for other sexually transmitted infections. This is best supervised from a GUM clinic, as are most anogenital wart treatments. Adequate contraception must be ensured prior to the use of podophyllin-type chemicals because of the known teratogenic effect in animals.

Cervical warts can be removed by a variety of methods. Colposcopy is recommended if there is any doubt as to the diagnosis, but otherwise warts on the cervix are not an indication for colposcopy in themselves.

Anogenital warts in pregnancy

Podophyllin and podophyllotoxin should be avoided because of their possible teratogenic effects, and currently imiquimod does not have approval for use in pregnancy. The objectives of treatment in pregnancy are to minimise the number of lesions present at delivery and to reduce neonatal exposure to the virus. Potential problems in the neonate are the development of laryngeal papillomatosis and anogenital warts. Very rarely, a caesarean section is indicated due to blockage of the vaginal outlet.

Cervical cytology

The National Health Service Cervical Screening Programme (NHSCSP) recommends no changes to screening intervals for women with anogenital warts. Furthermore, developing anogenital warts prior to the age when screening would normally start is not an indication to commence cervical screening.

Immunosuppressed women

This category includes women with impaired cell-mediated immunity (renal transplant patients and those infected with HIV), who are likely to have poor treatment responses, increased relapse rates and dysplasia. Careful follow-up is required.

Syphilis

Aetiology

Treponema pallidum, the spirochaete responsible for sexually acquired syphilis, causes one type of treponemal disease.

The pathological strains also cause non-sexually transmitted tropical diseases, such as yaws, endemic syphilis, bejel and pinta. These organisms are serologically and morphologically similar and cannot be grown on artificial media. Occasionally, saprophytic strains, found in the mouth in dental sepsis, can cause diagnostic confusion.

Syphilis is transmitted sexually, via blood products and vertically in pregnancy; therefore, the condition can be acquired and congenital. Syphilis is a treatable but complicated infection, best managed by GUM.

Epidemiology

Syphilis first became widespread and epidemic at the end of the fifteenth century in Europe. Syphilis and gonorrhoea were recognised as STIs in the eighteenth century, but were thought to be the same disease, until they were finally shown to be separate infections in the mid-nineteenth century. Until recently, syphilis was in a steady decline in the West, but over the last 20 years the incidence has begun to increase together with HIV infection.

Classification

Acquired syphilis can be divided into early and late infections. Early syphilis is further subdivided into primary, secondary and early latent (less than two years of infection). The subdivisions of late infection include late latent (greater than two years of infection) and tertiary, which includes gummatous, cardiovascular and neurological involvement. Cardiovascular and neurological involvement is sometimes classified as quaternary syphilis.

Congenital syphilis is divided into early (first two years) and late, which includes the classical stigmata of congenital syphilis.

Clinical features

Primary syphilis is characterised by an ulcer (the chancre) and regional lymphadenopathy. The chancre is classically a single, painless and indurated ulcer with a clean base discharging clear serum and is usually found in the anogenital region. However, it may also be atypical, multiple, painful, purulent and destructive and occur at extra-genital sites. The ulcer(s) of primary syphilis should not be confused with other genital ulcerative disorders (Box 99.3).

Box 99.3 Aetiology of anogenital ulceration

- Herpes simplex
- Syphilis
- Chancroid
- Lymphogranuloma venereum
- Donovanosis
- Candidiasis (severe)
- Behçet's disease
- Scabies-excoriated

Secondary syphilis is characterised by multisystem involvement occurring within the first two years of infection. The features include a generalised polymorphic rash, often affecting the palms and soles, condylomata lata (moist warty lesions at sites of skin friction such as vulva, under breasts, axillae) mucocutaneous lesions, generalised lymphadenopathy and other rare multisystem manifestations. Early latent syphilis is characterised by positive serological tests for syphilis with no clinical evidence of treponemal infection, again within the first two years of infection. In cases testing positive serologically for treponemal infection in the absence of clinical signs, it is important to exclude other infections such as yaws, particularly in people of Caribbean origin. All women with positive treponemal serology should be investigated and treated in a GUM department.

Diagnosis

The diagnosis can be made by direct demonstration of *Treponema pallidum* from lesions or infected lymph nodes in early syphilis by dark-field microscopy, direct fluorescent antibody testing and tests based upon the PCR.

Serological tests include:

- cardiolipin (reagin) tests: Venereal Disease Research Laboratory;
- carbon antigen test/rapid plasma reagin (RPR) test;
- specific tests: treponemal enzyme immunoassay (EIA) to detect IgG, IgG and IgM; *T. pallidum* haemagglutination assay (TPHA) and others.

Treatment

All treatment should be managed in a GUM clinic.

The mainstay of treatment is parenteral penicillin as it is given under supervision, therefore ensuring compliance, and has bioavailability guaranteed.

Early syphilis is treated with benzathine penicillin G with a single dose, which is unlicensed in the UK. Azithromycin single dose can be used as second line.

Late syphilis is treated with benzathine penicillin G at three-weekly doses, except for neurosyphilis where procaine penicillin G with concomitant oral probenicid is used as first line. All patients should be offered screening for other STIs, including HIV.

Approximately 40 per cent of those treated will have a reaction to the penicillin treatment called the Jarisch–Herxheimer reaction. In pregnancy this also occurs in the same frequency and in addition to the fever the pregnant woman may experience uterine contractions, which resolve in 24 hours. Fetal heart rate decelerations may also occur. As described below these cases should be managed with obstetric and paediatric colleagues.

Pregnancy

All pregnant women should be screened for syphilis at the initial antenatal visit. Syphilis may be transmitted transplacentally at any stage of pregnancy and may lead to

polyhydramnios, miscarriage, preterm labour, stillbirth, hydrops and congenital syphilis.

Sixty to ninety per cent of the infants of pregnant women with untreated primary or secondary syphilis will be infected and one third will be stillborn. Mother-to-child transmission is lower (40 per cent) in early latent and decreases to less than 10 per cent in late latent syphilis.

Patients should be jointly managed with GUM physicians and treated as above, but in the third trimester be given a second dose of benzathine penicillin G one week after the first dose. Ceftriaxone 500 mg IM for 10 days should be added to alternatives. When pregnant women are treated for syphilis after 26 weeks, the fetus should be investigated for infection and distress during treatment in a department of fetal medicine. All neonates should be treated at birth.

Congenital syphilis

Babies of mothers with positive serology for syphilis and treated antenatally should be managed jointly by a GUM physician and a paediatrician. Laboratory blood tests should be performed on the infant's (not cord) blood. In view of the highly treatable nature of the disease and the high perinatal morbidity and mortality of congenital syphilis, it is extremely important to continue with antenatal testing.

Human immunodeficiency virus

There are two strains of HIV, types 1 and 2, of which HIV-1 is responsible for most HIV infections. HIV carries its genetic code as RNA; this is translated by an enzyme present in the virus (reverse transcriptase) into DNA, which then integrates into the host's target cells, including CD4 T-lymphocytes, and other cells of the immune system. This results in a decline in CD4 cells and progression to AIDS. HIV infection can cause a decline in CD4 counts from a normal level of about 1000/ μ L to <200/ μ L. The infected person then becomes susceptible to the opportunistic infections and malignancies characteristic of AIDS.

HIV disease is an extremely important, fatal disease worldwide. It is currently estimated that approximately 40 million people are infected. HIV infection increases the susceptibility to other infectious diseases, such as tuberculosis, with a huge impact on morbidity and mortality. HIV is most prevalent in economically deprived areas in the developing world where people are less likely to be able to afford the expensive antiretroviral drugs that can limit disease progression and spread. HIV is transmitted sexually, in blood products and to the fetus vertically and through breastfeeding. In developed countries such as the UK, infected people have access to the latest evidence-based treatments and are managed by GUM physicians.

With the currently available antiretroviral agents, eradication of HIV infection is not likely to be possible. The aims of treatment are to prolong life and improve quality of life by maintaining suppression of virus replication for as long as possible. Antiretroviral therapy is monitored by measurements of

viral load together with CD4 counts. The aim of therapy is to decrease the viral load to less than 50 copies per mL within four to six months of commencing therapy. Treatment is recommended for patients with primary HIV infection, asymptomatic HIV infection and symptomatic HIV infection or AIDS. However, treatment should be commenced in patients when their CD4 count is <350 cells/mL. There is overwhelming evidence from cohort studies to show that the dramatic fall in AIDS-related mortality seen in the developed world coincided with the introduction of anti-retroviral therapy (ART). ART regimens should be individualised to achieve the best potency, minimise toxicity and avoid drug interactions. Prior to commencing therapy, individuals should have full tests for HIV drug resistance, and be screened for hepatitis B and C infections.

The primary aim of ART is the prevention of morbidity and mortality associated with chronic HIV infection at low cost of drug toxicity. The effectiveness and tolerability of ART has improved over the last 15 years and the majority of patients attending HIV services in the UK and receiving ART experience long-term virological suppression and good treatment outcomes, which compare with other developed countries. Recent life-expectancy data have been still about 13 years less than that of the UK population as a whole. Other aims of ART are to reduce sexual transmission of HIV and also to prevent mother-to-child transmission.

ART consists of three drugs which can be from a variety of types: protease inhibitors, non-nucleoside reverse transcriptase inhibitors, or nucleoside reverse transcriptase inhibitors. Issues to be considered during therapy are adherence, toxicity, resistance, long-term safety, clinical trial data and stage of disease. Change of therapy is advocated for virological failure diagnosed by viral load testing. Up-to-date guidance should be sought on which drugs are suitable for which group of people based on evidence.

Therapy-naïve patients should start ART containing two nucleoside reverse transcriptase inhibitors (NRTIs) plus one of the following: a ritonavir-boosted protease inhibitor (PI/r), an NNRTI or an integrase inhibitor (INI) [A]. It is recommended that patients are given the opportunity to be involved in making decisions about their treatment.

HIV testing

A significant number of people are unaware of their HIV infection and they are at risk from HIV-related infections leading to an increase in morbidity and mortality. They are also at risk of transmitting the infection both sexually and vertically (to a fetus). HIV testing should be encouraged in a variety of settings and healthcare professionals should obtain consent for testing in the same way as for any other investigation. Lengthy pre-test counselling is not necessary, simply discussion of the benefits of early diagnosis and how the results will be given. Concerns about insurance applications should be discussed; insurance companies are not allowed to ask if an individual has been tested for HIV.

However, applicants should declare HIV positivity in the same way as any other medical condition.

Fourth-generation assays test for HIV antibodies and p24 antigen simultaneously and they will detect the vast majority of individuals who have been infected with HIV at four weeks after specific exposure. An additional HIV test should be offered at 12 weeks to definitively exclude HIV infection and this test alone is sufficient for people at lower risk to avoid the need for HIV testing twice.

Post-exposure prophylaxis for HIV following sexual exposure (PEPSE)

There is evidence that HIV infection can be aborted after sexual exposure if antiretrovirals are given as soon as possible after exposure. Delays in commencing PEP can adversely affect its efficacy and certainly after 72 hours PEP may be ineffective and is not recommended. Ideally it should be started as soon as possible, ideally within 1 hour. This works by inhibiting viral replication once the virus has crossed the mucosal barrier. It then takes five days before HIV can be detected in the blood. PEPSE drugs need to be given as soon as possible and only up to 72 hours after initial exposure. The risk of acquisition needs to be assessed depending on the HIV risk or status of the contact and the type of sexual contact that has taken place. For example, receptive vaginal intercourse from a known HIV-positive individual carries a median risk of 0.1 per cent and receptive oral sex of 0.02 per cent. It is recommended that PEPSE is indicated if the risk is 1 in 1000 or greater. There is evidence of greater risk of HIV acquisition if the source has a known or high risk of other STIs. Clinicians may consider PEPSE more readily in cases of sexual assault as it is believed that there is a higher risk of HIV transmission where sex is aggravated. Informed consent must be taken following full discussion including the possible side effects (mainly gastrointestinal) and the need for blood tests at the time, and at three and six months after the event. Hepatitis B screening, immunoglobulin and accelerated vaccination should also be considered. Twenty-four hour access to starter packs for treatment (in Accident and Emergency and GUM departments) should be available, following GUM advice and arrangement for at least four weeks of ongoing treatment.

Risk assessment for HIV testing/other blood-borne viruses (for women)

Several questions can be asked which enable some assessment of the risks of HIV/other blood-borne viruses, and these questions are asked routinely in GUM:

- Have you or any of your partners ever injected (recreational) drugs (injecting drug user, IDU)?
- Have you ever had any partners who come from another country? If yes, ask where and assess whether this may pose an extra risk e.g. sub-Saharan Africa.
- Have any of your partners also had sex with men?

- Do you have any tattoos which were done in unlicensed premises without adequate precautions for sterility?
- Have you ever been paid for sex?

HIV and sexual and reproductive health

There can be huge psychosocial issues for women with HIV, especially around conception and pregnancy. All women with HIV should be offered an annual sexual health check to include screening for STIs and contraceptive advice, where appropriate. The majority of STIs can be treated in the same way as in the non-HIV-positive woman. If considering conception, pre-conception counselling should be given especially carefully and if possible should include written consent in non sero-same couples, regarding the small risk of HIV transmission. This guidance should be led by an HIV expert.

Women with HIV on ART have a decreased risk of HIV sexual transmission. Those whose viral loads are very low for long periods of time may have almost negligible risks of transmission, especially in the absence of any STIs. Counselling and advice to continue to use condoms should take place. In those who wish to have unprotected sex, detailed counselling by experts should be offered.

HIV and contraception

It is important that HIV-positive women are open about their infection so that they receive the best advice. Safer sex is to be encouraged, with the concomitant use of condoms, as well as a reliable hormonal method to prevent pregnancy. For HIV-positive women not on ART, all methods of contraception can be used.

Methods of contraception adversely affected by ART are combined hormonal contraception and progestogen-only pills, if on PI/rs. Antiretroviral drugs have the potential to either decrease or increase the bioavailability of steroid hormones in hormonal contraceptives. However, DMPA, the LNG-IUS and IUDs can all be used by HIV-positive women on ART without increased failure rates.

Where emergency contraception is required for a woman on ART or other liver enzyme-inducing drugs, then an emergency IUD is preferable. If progesterone-only emergency contraception is requested, then a 3 mg (double stat dose) is recommended. Ulipristal acetate cannot be used by women using liver enzyme-inducing drugs.

HIV and cervical screening, colposcopy and cervical cancer

Cervical cancer is an AIDS-defining illness. Women with HIV need to have regular cervical cytology and all women with cervical cancer should be offered an HIV test. The current NHSCSP guidelines on screening suggest that HIV-positive women should have an annual smear. Any cytological abnormality, however minor, should be taken as an indication for colposcopy. As there is a higher incidence of inflammatory vaginocervical disorders in HIV-positive women, the accuracy of both cytology and colposcopy is less than in non-HIV-infected women.

Women with proven cervical intraepithelial neoplasia (CIN) require treatment, although the results of treatment of CIN are significantly worse than in non-HIV women. Data also suggest that HIV-positive women with normal CD4 counts have better outcomes than those who have low CD4 counts. This observation supports the concept that the host cell-mediated immune system is implicated in the eradication of CIN following local treatments.

HIV infection and pregnancy

The prevalence of HIV in pregnancy varies over the UK. For example, in 2009, a large survey of over 400,000 livebirths estimated HIV prevalence as 1 in 449, about 1 in 250 in London, about 1 in 700 elsewhere. The majority of these women are from sub-Saharan Africa. The risk of transmission is related to maternal health, obstetric factors and infant prematurity. There appears to be a linear correlation between maternal viral load and risk of transmission. Antenatal testing is carried out in all units in the UK, and there is a recommendation to repeat test women at increased risk of acquisition during the pregnancy. Near-patient testing is also recommended in untested women in labour. Checking documentation of HIV testing is important, as well as communicating results to labour ward staff. Uptake of antenatal screening for HIV was >80 per cent in over two thirds of maternity units, in 2003. There is a greater diversity of clinical situations for women with HIV and each scenario may need individual clinical guidance.

Viral load is important in terms of transmission and should be measured every three months, at 36 weeks or two weeks after changing therapy, and at delivery. Any opportunistic infections suspected should be investigated and managed as in non-pregnant women. Pregnant women with HIV should be managed jointly by obstetric and HIV specialists according to British HIV Association (BHIVA) guidelines to optimise up-to-date treatment.

Fetal ultrasound scanning should be performed as per national guidelines regardless of maternal HIV status [D]. Invasive prenatal diagnostic testing should not be performed until the HIV status of the woman is known and should be deferred until the viral load is adequately suppressed, if HIV positive.

Obstetric factors in untested women that consistently show an association with risk of transmission are mode of delivery and duration of membrane rupture. It is suggested that invasive monitoring of babies and artificial rupture of membranes is avoided in HIV-positive women. Delivery should be expedited for term pre-labour rupture of membranes. If maternal viral load is >1000 RNA copies per mL, then immediate CS is recommended. Delivery before 34 weeks has been shown to be associated with an increased risk of transmission. There is an untreated vertical transmission risk of 25 per cent. The findings of the first RCT in 1994 showed that the use of zidovudine (AZT) could reduce transmission from 25 to 8 per cent. This has since been confirmed by multiple smaller observational studies. Vaginal delivery is recommended for women on ART with a very low

viral load (<50) at 36 weeks. Neonatal PEP should be given in untreated HIV-positive mothers. Exclusive formula feeding is still recommended in all HIV-positive women in the UK. Elsewhere in the world, where formula feeding poses extra risks to the infant because of unsafe water, breastfeeding is recommended. Highly active ART (HAART) started before pregnancy can be continued throughout pregnancy. There is no evidence for teratogenicity of any retroviral drugs, but there is an increased risk of preterm delivery. Zidovudine monotherapy should commence by 28 weeks and remains a valid option in women who do not wish to use HAART in pregnancy, or do not need to.

There should be clear local referral pathways for HIV-positive pregnant women, including specialist nurses and social workers where available. Information for the woman concerning follow-up for the baby needs to be given. Use of ART in pregnant women with HIV is both to prevent mother-to-child transmission and also for the welfare of the mother herself. Pregnant women with HIV should be screened for all STIs, including syphilis (and again in the third trimester or if clinically indicated) and hepatitis B. Genital tract infections should be treated according to BASHH guidelines [B]. There should be social assessment of all women with HIV in pregnancy by the multidisciplinary team.

Preconception and fertility management in men and women with HIV

There are three groups to consider:

- 1 HIV-positive men and negative female partners;
- 2 HIV-positive women and negative male partners;
- 3 HIV-positive couples.

All three groups may have fertility problems, but for the first two groups there is also the risk of HIV transmission.

Positive man, negative woman

The risk of transmission to the woman is approximately 1:500 per sexual encounter and until recently this was the only way couples could conceive. Limiting exposure to the most fertile period only has been shown to reduce the risk of transmission. In one study, four of 103 women seroconverted using this method. In 1992, Semprini *et al.*² invented the technique of 'sperm washing' – a process whereby spermatozoa are removed from the surrounding seminal plasma. (HIV is found in the seminal plasma, but not bound to the spermatozoa themselves.) There have not so far been any seroconversions of women after they have been inseminated with washed sperm. The technique of sperm washing is only available in a few centres in the UK and is funded by the couple in more than 50 per cent of cases.

Positive woman, negative man

Couples are advised to use condoms and then to practise self-insemination around ovulation to minimise the risk of transmission to the man.

Positive couples

These couples are recommended to practise safer sex (condoms) in order to reduce the risk of transmission of viral variants. It is advisable that the couple are in the best possible health before embarking on a pregnancy and are under specialist care. The woman should have normal up-to-date cervical cytology before becoming pregnant. They are advised to have unprotected sex around ovulation. There has been considerable debate concerning HIV-infected couples and IVF; it is now ethically acceptable as the vertical transmission rate is less than 1 per cent and there is an increased life expectancy for parents on treatment.

HEPATITIS

Hepatitis A

Hepatitis A is caused by a picorna virus (RNA) and is common in areas of the world where there is poor sanitation and mainly affects children in those areas. There were only 367 cases in England and Wales in 2010 in all age groups. (Hepatitis A is a notifiable disease.) Transmission is by the faeco-oral route or close personal contact and there have been outbreaks in men who have sex with men (MSM), and in those who have multiple partners and group sex. There are also increased risks among IDUs and haemophiliacs (cases of contamination of factor VIII) and vaccination may be important in these groups. The incubation period is 15–45 days and people are most infectious two weeks before the jaundice when they are asymptomatic or not yet diagnosed. Many people have no symptoms at all, but the typical illness is characterised by a prodromal flu-like illness with possible right upper quadrant pain, followed by an icteric illness with jaundice (mixed hepatic and cholestatic, with symptoms of pale stools and dark urine) associated with nausea, anorexia and fatigue which can go on for 1–3 weeks or even longer. Hepatitis A is rarely complicated by acute liver failure (ALF, 0.4 per cent). This is more common in those with chronic other liver disease, including hepatitis B and C. Mortality rates are very low (0.1 per cent), except those complicated by ALF.

There is no evidence that hepatitis A is teratogenic, but there is an increased risk of miscarriage and premature labour.

There have been cases of possible vertical transmission. Breastfeeding can be continued and most children will have mild or asymptomatic infection. The diagnosis can be confirmed by positive serum hepatitis A-specific IgM and can remain positive for six months or more. If the hepatitis A was acquired sexually, then tests for other STIs should be undertaken.

General advice for women should include avoiding food handling and refraining from unprotected sex. Rest and fluids are advised together with advice to seek medical help if there is a deterioration in health. A full explanation including a patient information leaflet should be given.

Vaccination is recommended to travellers to developing countries, haemophiliacs and for people at risk in an outbreak.

Hepatitis B

Hepatitis B is a hepadna virus (DNA). It is endemic worldwide with high carriage rates of up to 20 per cent in high-risk areas, such as South and East Asia, Central and South America, Africa and Eastern Europe. In the UK, 0.01–0.04 per cent of blood donors have evidence of hepatitis B infection. In 2010, there were 5805 cases notified in England and Wales. Transmission is sexual, parenteral and vertical. The incubation is 40–160 days. It is mainly asymptomatic in children and in 10–50 per cent of adults and is especially likely in coexistent HIV infection. The prodrome and icteric phases are similar to hepatitis A. Fulminant hepatitis can occur in <1 per cent. Chronic infection (greater than six months) occurs in 5–10 per cent and is more likely in HIV patients. Chronic active hepatitis can proceed to cirrhosis and liver cancer. Concurrent infection with HIV or hepatitis C worsens the disease. It is important to screen for other STIs, to check liver function and to advise to avoid sexual intercourse.

In pregnancy, there is an increased risk of miscarriage and premature labour in acute infection and there is a risk of vertical transmission in >90 per cent. Infants born to infected mothers are vaccinated at birth, usually in conjunction with hep B-specific antigen, which decreases transmission by 90 per cent. Women can continue to breastfeed as there is no additional risk of transmission. Partner notification should take place and all children not vaccinated at birth should be screened.

Specific hepatitis B Ig (HBIg) can be administered to a non-immune contact after sexual exposure from a known infective contact. This needs to be done before 48 hours, but works for up to 7 days and should be followed up by an accelerated course of hep B vaccine (0, 7 and 21 days). Hep B vaccine should be given to MSM, sex workers, IDUs, victims of sexual assault and needle-stick injury and sex partners of high-risk patients.

All those with active infection should be referred to a hepatologist (HbsAg-positive). All should also have an HIV test, as well as a full STI screen. The screening test for hepatitis B is anti-HBc. Those who have been vaccinated will have anti-HBs detectable in the blood.

All hepatitis B patients should be considered for hepatitis D testing which can coincide and make patients worse. Hepatitis D occurs in IDUs and sex workers.

Hepatitis C

Hepatitis C is an RNA virus and is prevalent (1–4.5 per cent) in Europe, Africa, the Pacific and the Eastern Mediterranean. UK prevalence is 0.53 per cent in adults but is >40 in IDUs. There were 8147 cases in England in 2010. Transmission is parenteral via shared needles, transfusion pre-1990s and in renal dialysis. There are low rates of sexual transmission (<1 per cent per

year in relationships). There are also increased levels in MSM, female sex workers and tattoo recipients. Vertical transmission takes place in only 5 per cent, but is increased in HIV co-infection. Incubation is 7–140 days and serology may take three months to show.

More than 60 per cent will be asymptomatic with occasional icteric phase. There can also be chronic infections in hepatitis B. Acute fulminant hepatitis is rare. Of these, 50–85 per cent become chronic carriers and 30 per cent of these will develop severe liver disease after long periods of up to 30 years with an increased risk of liver cancer. Pregnant patients should be treated as for hepatitis A.

Screening of blood is by EIA then confirmed with PCR.

General advice would be to not donate blood, semen or organs.

KEY POINTS

- Pelvic inflammatory disease is most commonly caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*; the long-term sequelae include infertility, ectopic pregnancy and chronic pelvic pain.
- The symptoms and signs of PID can be non-specific and treatment may have to be initiated empirically.
- PID should be considered as a sexually transmitted infection and therefore contact tracing, treating partners and liaison with GUM departments are important features of management.
- Gynaecologists should take sexual histories where indicated and apply the basic tenets of GUM practice.
- Many patients will have concurrent sexually transmitted infections; therefore genito-urinary screening is recommended.
- For better patient care, it is recommended that each clinician should have a thorough understanding of the chlamydia test used in his/her clinical setting, and encourage women under 25 years to take part in the NCSP.
- Testing for chlamydial infection should be considered when undertaking any procedure that entails instrumentation of the upper genital tract, such as hysteroscopy and IUD insertion, because of the serious possible complications.
- The only way to assess the risk of infection is to take a sexual history, as outlined above.
- The vulva should be carefully examined in all women – not just those at high risk of genital herpes – at the onset of labour.
- The aetiology of bacterial vaginosis is unknown; it is not sexually transmitted.
- Anogenital warts are the most common STI in the UK; they do not indicate the need for cervical screening outwith the NHSCSP.
- All women with positive tests for syphilis should be referred to GUM departments to confirm or exclude neurological, cardiovascular and ophthalmic involvement.
- There has been a significant improvement in survival and quality of life for HIV-infected women treated with ART.

Refer all HCV positive patients to liver specialist. In both the acute and chronic phases, they may respond to interferon. Interferon is also used in some hepatitis B patients. All hepatitis C patients should be vaccinated against hepatitis A and B to decrease the chances of fulminant hepatitis co-infection. There is no firm evidence that breastfeeding increases the risk of transmission, except if the woman is very ill. Sexual contacts and children should be tested. There is no vaccine or immunoglobulin preparation that will prevent transmission. All IDUs, haemophiliacs and people receiving blood pre-1990 should be tested, as well as sex workers and tattoo recipients.

Chapter 100 Dyspareunia and other psychosexual problems

Melanie Mann

MRCOG standards

Theoretical skills

- Understand the classification and causes of dyspareunia.
- Be able to manage the individual causes of dyspareunia.
- Know the anatomy and physiology of the human sexual response.
- Understand the epidemiology, aetiology, pathogenesis, clinical features and prognosis of psychosexual and sexual problems and the links with gynaecological disease.

Practical skills

- Be able to take an appropriate sexual history with regard to dyspareunia and psychosexual problems.
- Be able to perform a clinical examination to diagnose the cause of dyspareunia.
- Be able to ask about sexual relationship problems related to the dyspareunia, either as a result of the dyspareunia or causing the dyspareunia i.e. be able to take a related psychosexual history.
- Be able to recognise, counsel and plan initial management of psychosexual problems.

DYSPAREUNIA

This is recurrent genital pain associated with sexual activity, usually penetration, although it can refer to any genital stimulation. Dyspareunia can be primary, where pain has always occurred, or secondary, where it occurs after a period of pain-free sexual activity. It is important to classify it further in terms of the site of pain: i.e. superficial or deep. Dyspareunia can itself lead to relationship difficulties due to the cycle of fear. Pain at intercourse can lead to problems of sexual arousal,

causing further sexual pain and then avoidance of sexual activity.

Talking to patients about the exact site, nature and other features of the pain is important. It is also important to be comfortable talking about aspects of the sexual act, especially as some dyspareunia may be position related. Remember that patients are usually more embarrassed mentioning these aspects to us and may expect us to bring up the subject. Most of these causes (see Box 100.1) are dealt with in more detail in other sections of this book.

It is important to confirm diagnoses as far as possible with diagnostic tests, such as pelvic ultrasonography, microbiological swabs, laparoscopy or vulval biopsy where appropriate. Some diagnoses or problems are best dealt with by general practitioners or other specialists, such as gastroenterologists.

If an organic cause for dyspareunia is found, it does not necessarily exclude emotional and/or psychological sequelae for the woman. The aetiology of dyspareunia should be viewed on a continuum from primarily physical to primarily psychological, with many women exhibiting components of both.

HUMAN SEXUAL RESPONSE

According to Masters and Johnson,¹ there are classically four phases in the human sexual response:

- 1 Excitement: This is the first part of arousal and is caused by physical stimulation, especially clitoral stimulation, thoughts of sex and emotions. It leads to vasodilatation in the genitals causing swelling of the labia and the tissues surrounding the vagina resulting in heightened labial colouring and increased vaginal lubrication. Excitement can be enhanced or inhibited by signals from the brain, which are in turn influenced by previous experience. Oestrogen affects vaginal lubrication by enhancing the vascular bed beneath the epithelium. The clitoris becomes swollen and erect, the skin flushed and the nipples erect.

Box 100.1 Causes of dyspareunia**Main causes of superficial dyspareunia (superficial vulval and vaginal pain at intercourse)**

Vulvitis and vulvovaginitis (infection, hypo-oestrogenic)

Vestibulodynia (provoked vulval pain)

Vulvodynia (unprovoked vulval pain)

Topical irritants/dermatitis

Urethral disorders and cystitis

Vaginismus

Lack of vaginal lubrication (arousal problems)

Obstetric perineal trauma, mainly episiotomy

Radiation vaginitis

Main causes of deep dyspareunia

Pelvic inflammatory disease

Endometriosis

Genital or pelvic masses e.g. ovarian cyst

Pelvic congestion syndrome

Urinary tract infection

Retroverted uterus in some women

Irritable bowel syndrome

Psychosexual issues

- 2 Plateau: There is intensification of the above changes with increased blood flow to the genitals accompanied by increases in heart rate, blood pressure and breathing rates. The vagina lengthens and balloons with engorgement.
- 3 Orgasm: This is a genital reflex controlled by spinal neural centres (spinal injuries to vertebrae T11 to L2 can lead to orgasmic problems). There is reflex contraction of pelvic muscles located around the vaginal introitus together with release of vaginal fluids. Orgasm is the highest point of pleasure. Orgasm can last longer in women and be multiple.
- 4 Resolution: There is a feeling of satisfaction and wellbeing together with a return to the pre-arousal state. Men experience a refractory phase during which they cannot have another orgasm, but women do not.

There is also another phase which is necessary before the classic phases described above and this is known as desire or libido. This varies from one person to another and during the life cycle. It is also subject to changes in oestrogen and testosterone. A newer model, 'the sexual response cycle', describes physical, emotional and cognitive feedback. A variety of biological, social and psychological factors can affect the cycle.²

Educating patients regarding the phases above is really important. The most important of these is giving sufficient time for foreplay and relaxation to be sufficiently aroused and lubricated prior to penetration, together with the importance of stimulating the clitoris to achieve orgasm. Women often

feel they are failing in some way if they cannot achieve orgasm with vaginal intercourse alone and may need to be reassured.

PSYCHOSEXUAL PROBLEMS

Physiological events, such as pregnancy, childbirth, menopause and ageing, as well as gynaecological conditions, such as infertility, prolapse, urinary incontinence and gynaecological cancers, can have an impact on sexual wellbeing. Sexual activity in later life remains taboo, but a large number of women remain sexually active beyond 70 years. It must also be remembered that intercourse is only one way for couples to be sexual and there are other ways that sexual intimacy can be maintained at different times of the life cycle.

Psychosexual problems may present to the gynaecologist as part of general history taking for a variety of presenting complaints, and it is sometimes difficult to disentangle how much of the gynaecological complaint is due to the psychosexual problem, or whether the gynaecological problem has caused the psychosexual issue. It is therefore extremely important that the clinician feels comfortable asking about sexual problems, especially in relation to gynaecological problems, for which there is a good chance of concomitant psychosexual issues, such as vulval disorders and dyspareunia. However, there may also be circumstances in which it is important to establish sexual habits and issues, for example prior to gynaecological surgery when any interference with sexual function can cause problems within a sexual relationship. It is also very important to have an open and non-judgemental attitude to people's sexual practices (as long as they are not causing or suffering harm) and this includes those in same sex relationships.

Psychosexual history taking

Each clinician needs to find his/her own words that feel comfortable to use when talking about sex with the patient. There is no substitute for practice, and the more you use the words and ask the difficult questions, the more comfortable you will feel. Open-ended questions are useful in order to encourage the patient to talk; for example: 'Tell me a little bit about ...'. The clinician's body language is also extremely influential to the way the patient will feel about opening up in this very intimate part of history taking. For example, sitting back in the chair, putting down your pen and not having a large expanse of desk between you and the patient will go a long way towards making her feel more comfortable.

Some drugs will also affect sexual function such as antidepressants, antipsychotics, antihypertensives, corticosteroids and hormones including contraception and HRT.

Typical questions for use in psychosexual history taking

Not all the questions need to be asked or are appropriate to ask every time.

- ‘Are you in a sexual relationship?’
- ‘Is sex comfortable for you?’
- ‘Are there any problems with sex?’
- ‘Do you get any pain with sex?’
- ‘Where exactly does it hurt during sex – on the outside or the inside?’
- ‘Is there anything that makes the pain worse; any position, for example?’
- ‘Are you able to have an orgasm during sex?’
- ‘Have you ever masturbated? Do you get an orgasm during masturbation?’
- ‘Tell me a little bit about your relationship with your partner.’
- ‘Tell me a little bit about what happens when you try to have sex with your partner.’

Most gynaecologists would refer a patient on to an expert in psychosexual medicine for further treatment. There will be local variation in availability and waiting time.

SEXUAL PAIN DISORDERS

Dyspareunia

Dyspareunia is recurrent or permanent genital pain associated with sexual intercourse. This is the only sexual disorder in which physical factors are thought to play a major aetiological role. However, the psychological and interpersonal factors are significant.³ The organic causes for this condition are discussed above. In addition to gynaecological treatment approaches, women may require an adjunctive course of cognitive-behavioural sex therapy to ensure good outcomes.⁴

Vaginismus

Vaginismus is the involuntary spasm of the pubococcygeal and associated muscles causing painful and difficult penetration of the vagina, during sex, tampon insertion or clinical examination. Primary vaginismus occurs when a woman has never experienced vaginal penetration; secondary vaginismus is diagnosed when the problem occurs after previous successful vaginal penetration.

Usually at the root of vaginismus is a combination of physical or non-physical triggers that cause the body to anticipate pain. The body reacts to this by automatically tightening the vaginal muscles, which makes sex more painful and this response becomes the ‘cycle of pain’.

The patient may present with a painful vulva at intercourse. The differential diagnosis is then of organic vulval disorders, such as vulval vestibulitis. However, there is likely to be some degree of vaginismus in all women with organic vulval disease. The skill is in trying to work out whether the vaginismus is the primary problem or is a result of organic disease. The ‘Q-tip’ test can be helpful to elucidate the exact site of pain and whether it is in the contracted muscles or in the tender

epithelium of the vestibule. (The ‘Q-tip’ test involves the use of a moistened cotton bud to elicit the exact site and degree of discomfort or vulval pain.) The other main form of presentation is admission of non-consummation of a relationship in the fertility clinic setting.

Aetiology

Vaginismus is a conditioned (learned) response that often results from associating sexual activity with pain and fear. It can occur together with a phobia of all sexual contact or as the only problem within an otherwise normal sexual relationship. Typical phrases used by the patient include: ‘There’s a block’; ‘He just can’t seem to get it (his penis) in’; ‘It’s as if it (her vaginal opening) is too small’.

Vaginal examination is important in diagnosing vaginismus but is not always straightforward. What happens at the point of vaginal examination might be significant in terms of what happens with the woman’s partner and sometimes reflecting feelings felt by the doctor or observations can help elucidate the psychosexual problem. Sometimes the doctor may be able to feed back to the patient that she appears to be disassociated from that area of her body, and further questioning often confirms that she does not touch that area much herself due to concerns with cleanliness, smell or religious beliefs.

Causes of vaginismus

- No cause found
- Sexual abuse
- Physical abuse
- Painful medical procedure in the perineal area
- Painful first intercourse
- Relationship problems/anger between couples (‘I won’t let him in’ – subconsciously)
- Fear of pregnancy/labour
- Religious orthodoxy
- Poor sexual education
- Sexual inhibition.

Treatment

There needs to be discussion around the main issues in the relationship and how the woman feels about touching her own genitalia. Behavioural therapy comprising systematic desensitisation, pubococcygeal muscle training and the use of vaginal trainers works well. The response to this therapy for this group is good, with complete resolution for most couples, especially if the origin is uncomplicated in nature.⁵ The phobia of penetration needs to be explored so that the woman reaches a situation in which she feels in control of her vagina and can enjoy sex when and how she wishes.

A Cochrane systematic review of the different interventions for vaginismus such as sex therapy and desensitisation could not rule out a clinically relevant effect of systematic desensitisation when compared to any control interventions. However the findings were very limited by the evidence available and so conclusions about the efficacy of interventions

for the treatment of vaginismus should be drawn cautiously. Further larger studies are needed.⁶

Treatment includes:

- discussion and education about sex and the condition;
- teaching the location and control of the vaginal (pubococcygeal) muscles;
- self-examination of the vulva and vagina when alone and relaxed e.g. in the bath (beginning of systematic desensitisation);
- insertion of her own finger, then fingers or plastic vaginal trainers;
- doing the above in a sexual situation with her partner present;
- the woman inserting her partner's finger, then penis, with her in control;
- insertion of the penis with her partner in control, but with the woman on top so that it is less threatening;
- sexual intercourse as the couple would wish.

EBM

There have been no RCTs on vaginismus. Observational studies indicate that treatment is generally very successful for women with vaginismus.

SEXUAL DESIRE DISORDERS

This is now often referred to as hypoactive sexual desire disorder (HSDD). This usually presents as loss of libido (loss of interest in sex). It should also be remembered that there is huge variability between individuals and within the normal range. Interest in sex declines in both sexes with increasing age, but this change is more pronounced in women. The prevalence of 'low sexual desire' is about 30 per cent but the personal distress is about 20 per cent from this problem and is highest in middle-aged women. Sometimes it is the disparity between partners that leads a woman or couple to seek help. Risk factors for female sexual dysfunction may be non-hormonal (e.g. conflict between partners, insomnia, inadequate stimulation, life stress, depression and other medical disorders such as hypothyroidism/diabetes) or hormonal (oestrogen and androgen deficiency). Testosterone deficiency can be considered among the underlying causes of desire disorders in post-menopausal women but no level of a single androgen is predictive of low sexual function in women. However, post-menopausal oestrogen deficiency does cause atrophic changes and lead to painful sex, which can in itself lead to a decrease in desire as well as any direct effect of oestrogen within the brain. Testosterone should only be replaced together with oestrogens.

Specific pathways for sexual arousal, desire, reward and inhibition exist in the brain and are altered by hormones and experience. Hypothalamic, limbic and dopamine systems are important for desire as are certain neuropeptic systems.⁶

There is also controversy about what comes first in women, arousal or desire.

The prognosis is variable, but is better when it is the female with the initial problem. One study examined 60 couples presenting with the female partner's loss of interest as the major problem. There was only modest success, with 56 per cent experiencing a relatively good outcome at the end of treatment.⁷

These problems are usually the symptom of a generally poor relationship overall, and the sexual disorder is only part of the whole problem. Sexual wellbeing is related to a woman's subjective happiness and wellbeing.

SEXUAL AROUSAL DISORDER

It is difficult to separate sexual arousal disorder from sexual desire disorder and female orgasm disorder due to the close relationship of the three conditions in women. Causes of lack of arousal are numerous. They can be psychological (distractions, childhood loss, low self-esteem), endocrine (lack of oestrogen), neurological (e.g. multiple sclerosis) or drug induced (e.g. antihistamines). Additionally, the widespread use of vaginal lubricants/vaginal oestrogens may mask or alleviate the disorder.

There have been cases of persistent sexual arousal syndrome, where women with no conscious desire for sexual expression are overwhelmed by continual sensations in the genitals. This is differentiated from hypersexuality, a syndrome which does involve a high level of desire for sexual activity. Little is known about these disorders, but psychological/cognitive-behavioural treatment does seem to confer some benefit.⁸

FEMALE ORGASMIC DISORDER (ANORGASMIA)

This is the term used for failure to achieve orgasm due to inhibition of the orgasmic reflex or poor sexual technique/ignorance.

Aetiology

There may be holding back and fear of losing control. It may be situational, in that the woman can achieve orgasm by masturbation or with the aid of sex toys, but not during sexual intercourse. Sometimes, realistic ideas and the discussion of what most women achieve are necessary. For example, many women do not experience orgasm by penetration alone and do need other clitoral stimulation at the same time. Education regarding sexual positions to enhance clitoral stimulation and education about the clitoris itself may be required. There may be unrealistic expectations on the part of the partner, who may equate the female orgasm with his own and will not be happy unless his female partner also has one during penetration.

This pressure on the female can lead to faking of orgasm to keep the partner happy and a premature end to the sexual act and frustration on the part of the female, who has not actually achieved orgasm. Drugs, such as antipsychotics, can also cause orgasm problems.⁹

Treatment of anorgasmia

- Encourage self-exploration and what is pleasurable when she is alone.
- Sensate focus – concentration on the sensual pleasure of touching her partner, but avoiding the genitals.
- Masturbation.
- Use of sex toys such as vibrators, if helpful; use of DVDs to help arousal and provide ideas (e.g. *The Lovers' Guide* series by Dr Andrew Stanway).
- Discussion and resolution of unconscious fears of orgasm, if present.
- Heightening sexual arousal so that the woman is close to orgasm before penetration.

Hysterectomy and sexual function

There has been debate in the literature about the role of hysterectomy in sexual function. This has become more important now that women are more involved in their own treatment choices and feel more able to demand a good outcome from surgery. It has also become more pertinent since there have been more non-surgical (e.g. the levonorgestrel intrauterine system) and less complicated (e.g. endometrial destruction methods) procedures to treat one of the most common reasons for hysterectomy, namely menorrhagia. There has been a steady rise in some countries in the number of supracervical hysterectomies performed for benign conditions. The ratio of subtotal to total hysterectomies in Scandinavia is high at 0.56 compared to the UK where in 2005 it was reported as 0.04.¹⁰ This may reflect the changing attitudes of surgeons and women towards a less invasive procedure, which was believed to have a reduced operative morbidity and reduced the risk of urinary and sexual dysfunction. Various mechanisms have been proposed to explain why cervical conservation may have a less detrimental effect on sexual function than total abdominal hysterectomy. Early pioneering work¹ described elevation of both the cervix and uterus during excitement and the plateau phase, followed by fundal uterine contractions progressively involving the lower uterine segment as orgasm developed. Cervical dilatation occurred immediately afterwards, implicating a role for the cervix in the female sexual response. Another theory postulates that the ability to achieve orgasm depends on the nerve endings of the uterovaginal (cervical) plexus of Frankenhauser.¹¹ This plexus is a matrix of nerve fibres intimately surrounding the cervix. Stimulation of the cervix may contribute to a pleasurable sensation ultimately experienced as orgasm. However, the most recent evidence does not support superiority of subtotal over

total hysterectomy and instead the most rigorous studies show that the majority of women experience no negative impact on sexual satisfaction, whatever the method and whether subtotal or not [A]. In a Cochrane review of total versus subtotal hysterectomy for benign gynaecological conditions, subtotal hysterectomy did not offer an improved outcome for sexual function.¹² Most of the studies demonstrate improvement in sexual function in general after hysterectomy, because there is relief from dyspareunia and menstrual bleeding.¹³

OESTROGEN REPLACEMENT THERAPY AND SEXUAL FUNCTION

Women often complain about changes in sexual function after a natural or iatrogenic menopause (bilateral salpingo-oophorectomy). Oestrogens appear to be an important part of the sexual response and loss of libido is a recognised symptom of the menopause.¹⁴ Systemic oestrogens (e.g. oral, transdermal, subcutaneous) can be used following full discussion of the pros and cons. Testosterone may also be used, but should always be used in conjunction with systemic oestrogens.

If the main problem with sex is due to vaginal dryness causing dyspareunia and diminishing sexual pleasure and desire, it may also be useful to use local oestrogens in the form of cream or pessaries (let the woman try both to see what suits her best). Even if a woman is using systemic oestrogens she may also require local therapy, especially if she has ongoing symptoms of hypo-oestrogenism (soreness, dryness, dyspareunia). Care with the type of vaginal oestrogens should be taken with longer-term use to prevent endometrial hyperplasia in the woman with an intact uterus (only use oestriol cream or oestradiol pessaries).

TESTOSTERONE THERAPY AND SEXUAL FUNCTION

Testosterone is produced in the ovaries and in the adrenal glands in women. Testosterone has been used in women with various sexual disorders and testosterone deficiency disorders since the 1930s. Despite this, the use of testosterone therapy is still controversial. Circulating testosterone declines in the late reproductive years so that healthy women in their forties have half the level compared to women in their twenties. A direct link between sexual dysfunction and endogenous testosterone levels has not been clearly found in pre-menopausal women. Research on testosterone levels is mainly confined to post-menopausal women so the place of testosterone therapy in pre-menopausal women with low libido is not currently known. The generalised use of testosterone by women has been advised against because of inadequate indications and long-term data.

Decreased levels of testosterone in post-menopausal women may lead to decreased levels of libido, sexual activity

and physical wellbeing. Bilateral salpingo-oophorectomy (BSO) causes a decrease in sex drive by 50 per cent, by removing ovarian contribution of testosterone. Many gynaecologists have used subcutaneous implants for testosterone replacement after BSO, for many years. There is also another form of hormone replacement therapy used in post-menopausal women which is licensed for libido problems, called tibolone. It has some androgen-like properties.

Transdermal patches and gels or creams are preferred over oral products because of first-pass hepatic effects documented with oral formulations. Monitoring should include assessments of sexual response as well as (usually reversible) side effects of hirsutism and acne. It is also good practice to measure fasting lipid and glucose levels after six months of therapy. More recently, transdermal testosterone therapy has been shown to increase sexual activity and satisfaction in at least 51 per cent of women in randomised double-blind trials compared to placebo. The patches are well tolerated with the main side effect being atopic site reactions. Testosterone therapy overdose can also cause acne, hirsutism and lowered voice.¹⁵

Psychosexual dysfunction in women treated for gynaecological cancer

There is no convincing evidence to support the use of any interventions for psychosexual dysfunction in women treated for gynaecological cancer. This is mainly due to the lack of studies of high methodological quality. However one trial did suggest short-term benefit from vaginal oestrogens after pelvic radiotherapy.¹⁶

PLACES TO REFER WOMEN/COUPLES WITH PSYCHOSEXUAL PROBLEMS

- Relate – provides counselling for all relationship and psychosexual problems (there may be a fee).
- Local contraceptive/reproductive healthcare services may have a psychosexual service (contact your local consultant).
- Local hospital-based psychosexual services – may be within urology, gynaecology, genito-urinary medicine or psychiatry departments.
- Private sex therapists (contact via the British Association for Sexual and Relationship Therapists or the British Association for Counselling).
- Doctors trained by the Institute of Psychosexual Medicine (contact the institute directly).

KEY POINTS

- It is important to classify further the site of pain: superficial or deep.

- Pain at intercourse can lead to problems of sexual arousal causing further sexual pain and then avoidance of sexual activity.
- If an organic cause for dyspareunia is found, it does not necessarily exclude emotional and/or psychological sequelae for the woman.
- In assessing gynaecological problems where there is a good chance of concomitant psychosexual issues, such as vulval disorders and dyspareunia, it is extremely important that the clinician feels comfortable to ask about sexual problems.
- Dyspareunia is the only sexual disorder in which physical factors are thought to play a major aetiological role. However, the psychological and interpersonal factors are significant.
- Observational studies indicate that treatment is generally very successful for women with vaginismus.¹⁷

Chapter 101 Child sexual abuse

Catherine White

MRCOG standards

Knowledge criteria

- The laws relating to child protection, consent and the Sexual Offences Act 2003.
- Female genital mutilation (FGM).
- Recognise the sexual health needs of vulnerable groups e.g. young people.
- Understand how victims of child sexual exploitation may present and what their management might entail.
- Understand safeguarding duties.
- Understand local care pathways for multiagency working for individuals with sexual health needs.
- Understand the long term sequelae of child sexual abuse and how it might present in adulthood.

Clinical competency

- Network with other providers in multidisciplinary team e.g. counsellors, social workers, police.
- See chapter on rape for information on injuries, forensic samples, etc.

INTRODUCTION

Child sexual abuse (CSA) can take on many forms. WHO defines child sexual abuse as:

The involvement of a child in sexual activity that he or she does not fully comprehend, is unable to give informed consent to, or for which the child is not developmentally prepared, or else that violate the laws or social taboos of society. Children can be sexually abused by adults or other children who are – by virtue of their age or stage of development – in a position of responsibility, trust, or power over the victim.

WHO, 2006.

Working Together to Safeguard Children, 2013¹ states that sexual abuse:

... involves forcing or enticing a child or young person to take part in sexual activities, not necessarily involving a high level of violence, whether or not the child is aware of what is happening. The activities may involve physical contact, including assault by penetration (for example, rape or oral sex) or non-penetrative acts such as masturbation, kissing, rubbing and touching outside of clothing. They may also include non-contact activities, such as involving children in looking at, or in the production of, sexual images, watching sexual activities, encouraging children to behave in sexually inappropriate ways, or grooming a child in preparation for abuse (including via the internet). Sexual abuse is not solely perpetrated by adult males. Women can also commit acts of sexual abuse, as can other children.

HM Government, 2013.

DEFINITION OF A CHILD

There is no single law that defines the age of a child across the UK. The UN Convention on the Rights of the Child, ratified by the UK government in 1991, states that a child 'means every human being below the age of eighteen years unless, under the law applicable to the child, majority is attained earlier' (Article 1, **Convention on the Rights of the Child**, 1989). That a healthcare worker may be dealing with a child that has reached the age of 16, may be living independently, etc. does not change his/her status or entitlements to services or protection.

THE LAW

The **Sexual Offences Act 2003**² states that the age of consent for sex is 16 years in England and Wales. In order to protect younger children, the law says that children aged under 13 years can never legally give consent. The Sexual Offences Act 2003 covers a variety of offences against children. These include offences such as:

- sexual activity with a child;
- causing or inciting a child to engage in sexual activity;
- meeting a child following sexual grooming.

In addition the Female Genital Mutilation Act 2003 covers FGM.

PREVALENCE OF CHILD SEXUAL ABUSE

According to WHO³ approximately 20 per cent of women and 5–10 per cent of men report being sexually abused as children, while 23 per cent of people report being physically abused as children.

Research done by the NSPCC⁴ in 2011 involved interviewing over 6000 young adults, adolescents and parents of younger children. Participants were asked whether anyone had tried to make them do anything sexual whilst they were under the age of 18 years. Parents of children aged under 11 years responded on their child's behalf. Older teenagers and young adults were also asked if they had done sexual things with an adult when they were still under 16 years or with an adult in a position of trust whilst they were still under 18 years. This research used a definition of sexual abuse that included any unwanted sexual activity, as well as criminal sexual activity with an adult, where physical contact took place. It excluded non-contact sexual abuse (such as flashing or saying sexual things) as well as 'consensual' sexual activity between adolescents. The figures below are all based on the reports from young people aged 11–17 years.

- One in 20 children (4.8 per cent) have experienced contact sexual abuse.
- Over 90 per cent of children who experienced sexual abuse were abused by someone they knew.
- More than one in three children (34 per cent) who experienced contact sexual abuse by an adult did not tell anyone else about it.
- Four out of five children (82.7 per cent) who experienced contact sexual abuse from a peer did not tell anyone else about it.

There have been many recent changes in the recognition of how children may be victims of sexual abuse. For example, there has been much publicity about historical disclosures of institutional CSA. In addition, the arrival of new technologies has seen the development of new practices such as online grooming and abuse, sexting, etc. Child sexual exploitation is something that will have been happening throughout the centuries and yet is only now beginning to be recognised. Recent inquiries have shown that these children were often failed by professionals, who had been judgemental in their assessment of the behaviour and circumstances of the children and had failed to pick up on the signs and symptoms of sexual abuse.

RISK FACTORS FOR CHILD SEXUAL ABUSE

Whilst all children may be a victim of sexual abuse, research shows that certain children are more at risk than others.

Girls seem to be more at risk than boys. Children with disabilities are particularly vulnerable. A 2012 WHO-funded systematic review⁵ indicated that children with disabilities are 3.7 times more likely than non-disabled children to be victims of any sort of violence, 3.6 times more likely to be victims of physical violence, and 2.9 times more likely to be victims of sexual violence. Children with mental or intellectual impairments appear to be among the most vulnerable, with 4.6 times the risk of sexual violence than their non-disabled peers. It may be that they have fewer people to tell, are less able to communicate what is happening to them or that when they do tell, they are less likely to receive adequate protection.

Sexual abuse is only one form of child abuse, the others being physical, emotional and neglect. Often a child will be subjected to more than one type of abuse, highlighting the need to undertake a holistic assessment of the child.

Whilst a common myth about CSA is that perpetrators are strangers, the reality is that most children will be abused by someone that they know. Therefore much of the risk for children will be determined by who their carers are and who has access to them. Educating children about such issues should help empower them. There have been a variety of campaigns with this in mind.⁶

MANAGEMENT

For the clinician, the management of CSA will vary case by case, dependent upon the age of the child, the nature of the abuse, the wishes of the child, etc. (See Table 102.1, Things to consider when someone discloses acute rape/sexual assault, in Chapter 102.)

Many children, particularly younger children, may not present with a direct disclosure. For example they may present with vaginal bleeding, genital soreness, STIs or behavioural changes. It is therefore incumbent upon the clinician to have a high level of suspicion of CSA when formulating a differential diagnosis. Where abuse is suspected it is important that there is an opportunity for the child to disclose what is happening, bearing in mind that the child may be reluctant to provide details within earshot of carers in attendance. In addition a child may have been manipulated or threatened by the abuser not to tell.

The assessment of a child where CSA is suspected should always be a holistic one, not merely a preoccupation with the genitalia. That said, knowledge of normal genital anatomy, including prepubertal genitalia, is a prerequisite for the clinician in order to be able to identify anything abnormal (Fig. 101.1).

Key messages for the generalist would be to have a high level of suspicion and to involve senior colleagues at an early stage. The Royal College of Paediatrics and Child Health (RCPCH) and the Faculty of Forensic and Legal Medicine (FFLM) have produced guidance⁷ on paediatric forensic examinations for CSA. Information regarding injury documentation and the

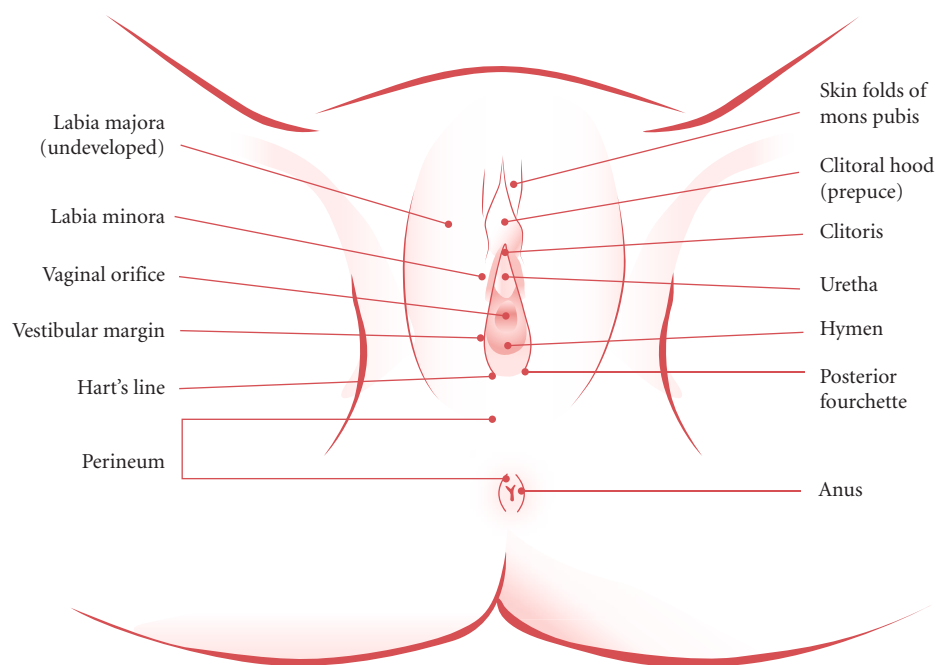

Fig. 101.1 Prepubertal female genitalia. Taken from *Sexual Assault, A Forensic Physician's Practice Guide*. Dr Catherine White. 2010. ISBN 978-0-9564737-0-7.

gathering of forensic samples is included in Chapter 102, Rape and sexual assault.

Any examination should be preceded by a careful discussion with the child and/or carer that covers issues around consent for the examination, the limitations of confidentiality, disclosure of information for safeguarding purposes, etc. as well as the nature of the examination. Given that sexual abuse is about the disregard of consent and the abuse of power, great care must be taken by healthcare workers not to repeat this process.

Careful consideration must be given by the doctor to balance what may sometimes seem to be competing pressures, such as the child requesting information regarding sexual activity not be shared, the need to protect a child from the risk of ongoing abuse and the need to protect other children from serial offenders. Readers are advised that they should be well versed on GMC guidance on these matters.⁸

ANOGENITAL INJURY RATES

The common misconception is that there would be a high injury rate for child victims of sexual abuse. Whilst this may sometimes be the case it is not the norm. Many forms of abuse will not result in any injury and even when anogenital injuries are sustained they tend to heal quickly and completely. It is important to appreciate that for many cases the absence of injury does not necessarily negate the allegation of

abuse. The RCPCH in collaboration with the FFLM has produced an evidence-based review of the physical signs of CSA.⁹

VIRGINITY TESTING

Many cultures place a very high value on virginity. There may be a great deal of pressure exerted on a clinician to say if a child is a virgin or not; indeed there may even be requests for certificates of virginity.

Doctors should not get involved in such practice. Apart from the myriad of associated ethical issues there is no evidence base to determine with accuracy if a person has been sexually active or not.

MEDICAL AFTERCARE

This should include consideration of the risk of STIs (including post-exposure prophylaxis and screening), emergency contraception, pregnancy testing as well as psychological care.

Where samples are taken for STI screening, it may be appropriate to do so employing chain of custody so that the results may be submitted as evidence in any subsequent court process.

Advice around HIV PEP and hepatitis B PEP is available from BASHH (www.BASHH.org) and also the Children's HIV Association (CHIVA, www.chiva.org.uk).

A risk assessment for safeguarding with the appropriate referrals should be made.

Psychological follow-up will vary from child to child. Not all children will need the services of mental health teams. Some units e.g. some Sexual Assault Referral Centres (SARCs) have dedicated staff specialising in the follow-up care of these children. Knowledge of what services are available in the local area is important to ensure timely smooth referrals and ensure seamless care for this very vulnerable group.

CHILD SEXUAL EXPLOITATION

There are various definitions of child sexual exploitation (CSE); the following is used by BASHH in its guidance:

CSE involves those under 18 in exploitative situations, contexts and relationships where young people (or a third person or persons) receive something (for example food, alcohol, cigarettes, affection, gifts) as a result of them and/or another or others engaging in sexual activities. It is an abuse of power by those exploiting by virtue of their age, gender, intellect and physical strength and/or economic or other resources.

CSE encompasses both gang-related and other sexual violence and exploitation.

A *pro forma*, *Spotting the Signs*,¹⁰ has been developed to help health professionals across the UK to identify young people attending sexual health services who may be at risk of or experiencing sexual exploitation.

As well as professionals being alert to the warning signs that a child is either a victim of exploitation or at risk of such, it is also crucial that the child or young person is not alienated by an interrogative style of history taking and any suggestion that they may to blame for what has happened to them by the decisions they have made.

SAFEGUARDING

The 2013 Working Together to Safeguard Children¹ guide sets out the legislative requirements and expectations on individual services to safeguard and promote the welfare of children. It states:

This guidance aims to help professionals understand what they need to do, and what they can expect of one another, to safeguard children. It focuses on core legal requirements and it makes clear what individuals and organisations should do to keep children safe. In doing so, it seeks

to emphasise that effective safeguarding systems are those where:

- *the child's needs are paramount, and the needs and wishes of each child, be they a baby or infant, or an older child, should be put first, so that every child receives the support they need before a problem escalates;*
- *all professionals who come into contact with children and families are alert to their needs and any risks of harm that individual abusers, or potential abusers, may pose to children;*
- *all professionals share appropriate information in a timely way and can discuss any concerns about an individual child with colleagues and local authority children's social care.*

Section 11 of the **Children Act 2004**¹¹ places duties on a range of professionals including healthcare workers. It is clear that health professionals are in a strong position to identify welfare needs or safeguarding concerns regarding individual children and, where appropriate, provide support. This includes understanding risk factors, communicating effectively with children and families, liaising with other agencies, assessing needs and capacity, responding to those needs and contributing to multi-agency assessments and reviews.

Clinicians should be familiar with the intercollegiate document, March 2014, *Safeguarding children and young people: roles and competences for health care staff*.¹²

EFFECTS OF CHILD SEXUAL ABUSE

As in all aspects of life where individuals respond to events, situations and stresses in their own way the same is true for CSA. The impact will depend upon many factors such as the nature of the abuse, who the abuser was, in terms of the abuse of power and trust, how long the abuse went on for, what other disadvantages a child was subject to, etc. Therefore victims will show a range of symptoms as a result of their abuse, with some seemingly having no long-term ill effects. Whilst much is often made of physical sequelae it is often the psychological effects that affect a victim the most.¹³ Some children will have been told that the abuse was their fault and this will have an impact on their psychological recovery. Some victims may suffer with low self-esteem, underperformance at school, self-harm or suicide. Feelings of shame and guilt are frequent and can have devastating effects on a victim's ability to go on to have healthy relationships later in life.

In addition to this some longer-term studies are revealing that child victims are at increased risk of physical illness including cardiovascular disease in adulthood.¹⁴

KEY POINTS

- Child abuse involving boys and girls is common although many victims do not disclose their abuse.
- Clinicians should have a high level of suspicion for CSA and must facilitate disclosure by empowering the child.
- Safeguarding is everyone's responsibility. Knowledge of local safeguarding procedures is vital.
- Absence of injury does not negate the possibility of abuse.
- Virginity testing has no basis in evidence-based medicine.
- The long-term health consequences of CSA can be massive. Prevention and early detection are key.
- SARCs can provide holistic, medical, forensic and psychological care for victims.

CONCLUSIONS

All doctors will be exposed to the consequences of CSA no matter what speciality they practice in. A society is judged by its treatment of its most vulnerable. Doctors must play a central role in this, acting as advocates for those without a voice, challenging myths and stereotypes, raising awareness of issues however unpalatable and seeking to eradicate the causes and perpetuation of the circumstances that allow such abuse to flourish.

Chapter 102 Rape and sexual assault

Catherine White

MRCOG standards

Core Module 15: Sexual and Reproductive Health

Knowledge criteria

- Mental Capacity Act 2005
- Sexual Offences Act 2003
- Recognise the sexual health needs of vulnerable groups.
- Emergency contraception: mode of action and efficacy, methods, indications, contraindications and complications.
- Recognise and manage the sexual healthcare needs of vulnerable groups e.g. young people, asylum seekers, commercial sex workers, drug users and prisoners.

Forensic Gynaecology (2011)

This ATSM is designed to create departmental and regional leaders who can structure a successful multiprofessional service to manage the victims of domestic violence and sexual assault.

Section 1 covers the law and the basic competencies for the initial contact, management, examination, evidence collection and subsequent follow-up.

Completion of the Diploma of the Faculty of Sexual and Reproductive Healthcare (DFSRH) prior to the ATSM is recommended but not mandatory.

Training to child protection level 3 is required. This may be undertaken either prior to or during the ATSM.

The ATSM must be undertaken under the supervision of an identified preceptor who must be in a position to directly supervise and assess competency. In order to ensure exposure to the required case mix the unit must be of a sufficient size to ensure completion of the training.

Once trained, individuals should:

- be clinically competent and confident in all aspects of domestic violence and forensic services;

- be competent to lead the provision of domestic violence and forensic services in a unit or region;
- work well as part of a multidisciplinary team;
- be clinically competent in understanding police processes and know how the Police Criminal Evidence Act 1984 might have an impact on the process of forensic medical examination;
- be competent and confident to write a statement which is an accurate account based on contemporaneous evidence;
- be able to define and identify different types of injury by undertaking full examination;
- be able to undertake and use clinical audit;
- be able to write protocols and evidence-based guidelines.

INTRODUCTION

The worldwide prevalence of sexual violence is high. Frequently it remains a hidden problem and yet the sequelae may have profound effects on the physical and psychological health of the victim, both in the short and long term. This in turn may have an impact on subsequent generations. Victims of sexual violence can be of any age, gender and sexuality. Those who are already vulnerable e.g. the elderly and those with learning disorders or physical disabilities are often targeted.

It is important for clinicians to have an awareness of the scale of the problem, how it may present and then how to manage the situation. They should be able to respond to a direct disclosure of rape or sexual violence and also, perhaps more importantly, they should be alert to the possibility of sexual violence as the root cause of other presentations e.g. chronic pelvic pain, STIs, requests for emergency contraception, unplanned pregnancy and mental health problems including depression, self-harm and substance misuse and be able to respond appropriately.

Interpersonal violence may also cause ethical dilemmas for the clinician. There may be a need to balance the competing requirements and demands of respecting the autonomy of a victim versus public interest issues. Therefore thorough knowledge and understanding of the relevant laws, for example the Mental Capacity Act 2005, professional guidelines (for example GMC guidelines), and ethical principles are vital.

This chapter will cover the immediate management of a patient who discloses rape/sexual assault and also cover some of the possible long-term consequences.

There are many *myths and stereotypes* held by professionals and public alike regarding sexual violence. For example:

- *Most victims will be raped by a stranger.*
- *Men cannot be raped.*
- *A rape victim would put up a struggle and try to fight off the assailant.*
- *A rape victim would report the assault immediately.*
- *A female who was raped, especially if she was a virgin, would always have genital injuries as a result.*

These can act as a barrier for victims to seek and subsequently receive the help that they require. The aim is to highlight and hopefully dispel some of these.

PREVALENCE (BOX 102.1)

Box 102.1 Statistics on the prevalence of sexual violence

Statistics on sexual violence from the UK

- 28% of women aged 16–59 have experienced abuse in their lifetime.¹
- 3.1 million women have been sexually assaulted since the age of 16.²
- 70% of women with mental health problems have experienced physical or sexual abuse.³
- 40–50% of women who have experienced domestic violence are raped within their physically abusive relationship.⁴
- Just under 50% of mental health service users have been subject to sexual abuse and around 50% to physical abuse in childhood, notwithstanding adult abuse which they may also be surviving.⁵
- 23% of women and 3% of men experience sexual assault as an adult.⁶
- Around 21% of girls and 11% of boys experience some form of childhood sexual abuse.⁷
- 2.5% of women aged 16–59 and 0.5% of men had experienced a sexual assault (including attempts) in 2010–2011.⁸

International key facts⁹

- Violence against women – particularly intimate partner violence and sexual violence against women – is a major public health problem and violation of women's human rights.
- Recent global prevalence figures indicate that 35% of women worldwide have experienced either intimate partner violence or non-partner sexual violence in their lifetime.
- On average, 30% of women who have been in a relationship report that they have experienced some form of physical or sexual violence by their partner.
- Globally, as many as 38% of murders of women are committed by an intimate partner.
- Violence can result in physical, mental, sexual, reproductive health and other health problems, and may increase vulnerability to HIV.
- Risk factors for being a perpetrator include low education, exposure to child maltreatment or witnessing violence in the family, harmful use of alcohol, attitudes accepting of violence and gender inequality.
- Risk factors for being a victim of intimate partner and sexual violence include low education, witnessing violence between parents, exposure to abuse during childhood and attitudes accepting violence and gender inequality.
- In high-income settings, school-based programmes to prevent relationship violence among young people (or dating violence) are supported by some evidence of effectiveness.
- In low-income settings, other primary prevention strategies, such as microfinance combined with gender equality training and community-based initiatives that address gender inequality and communication and relationship skills, hold promise.
- Situations of conflict, post-conflict and displacement may exacerbate existing violence and present new forms of violence against women.

THE LAW

The Sexual Offences Act (SOA) 2003 deals with offences that have taken place in England and Wales and applies to offences committed after 1 May 2004. Prior to that the Sexual Offences Act 1956 would apply.

Northern Ireland (The Sexual Offences (Northern Ireland) Order 2008) and Scotland are covered by similar legislation.

The SOA 2003 covers over 50 sexual offences. Box 102.2 sets out the definitions of two of the main sections.

Box 102.2 The Sexual Offences Act 2003

Sexual Offences Act 2003¹⁰

Section 1 (Statutory definition of rape)

1. A person (A) commits an offence if:
 - (a) he intentionally penetrates the vagina, anus or mouth of another person (B) with his penis.
 - (b) B does not consent to the penetration, and
 - (c) A does not reasonably believe that B consents.

2. Whether a belief is reasonable is to be determined having regard to all the circumstances, including any steps A has taken to ascertain whether B consents.

Section 5 (Statutory definition of rape of a child under 13 years)

1. A person commits an offence if:
 - (a) he intentionally penetrates the vagina, anus or mouth of another person with his penis, and
 - (b) the other person is under 13 years.

MANAGEMENT

Given the prevalence of sexual violence *all* obstetricians and gynaecologists will be seeing rape victims on a regular basis. Only the best doctors will have any inkling of how many they see.

The management of a complaint of rape or sexual violence will depend on several factors. One of the main issues is how a rape victim presents (see Fig. 102.1).

A key issue when dealing with any victim is to understand that sexual violence is fundamentally about power and control: the loss of it for the victim, and the exertion of it by the assailant. It is important not to replicate this. Wherever possible give back power and control to the patient. Know and then outline to them their options, given their particular circumstances, allow them to make choices and then respect their decisions (Table 102.1).

Up to date, comprehensive knowledge of local resources and referral pathways is necessary.

Ideally a rape victim would have the option of being seen in a Sexual Assault Referral Centre. SARCs offer medical, forensic, practical and emotional support to anyone who has been sexually assaulted or raped. They have specially trained doctors, support workers and counsellors to care for victims.

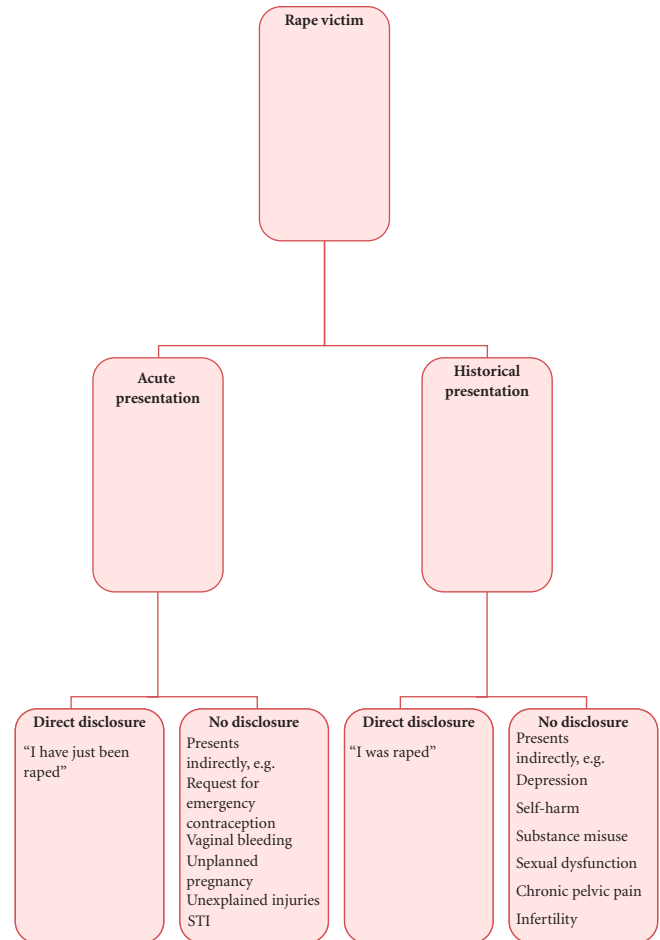

Fig. 102.1 Possible ways a rape victim may present

Many SARCs, as well as seeing victims who have made a report to the police, will offer the option of seeing victims as 'self-referrals' i.e. those who are not willing to report to the police.

In the UK contact details for SARCs can be found on the NHS Choices website <http://www.nhs.uk/Pages/HomePage.aspx>.

Table 102.1 Things to consider when someone discloses acute rape/sexual assault

Immediate safety	<p>Are they safe?</p> <p>Are there any third parties to consider e.g. children, other dependants?</p> <p>Are any safeguarding referrals required?</p> <p>Are you safe?</p>
Medical needs	<p>Injuries, assessment and treatment</p> <p>Emergency contraception</p> <p>HIV PEPSE</p> <p>Hepatitis B PEPSE</p> <p>Screening for STIs</p> <p>Pregnancy testing</p>

Forensic needs	<p>Preservation of evidence</p> <p>Documentation of injuries including photography where necessary</p> <p>Documentation of allegations</p> <p>All to be done in a manner that makes evidence admissible to court</p>
Psychological needs	<p>Of the complainant (including risk of self-harm, suicide)</p> <p>Of other witnesses</p> <p>Of you</p>

Safeguarding

Remember that safeguarding issues, for both children and vulnerable adults, are the responsibility of *every* healthcare worker, not the remit of only the specialists.¹¹ All clinicians must be alert to safeguarding issues and know how to respond when a concern arises, always considering both the patient in front of them and also any of their dependants.

In the O&G setting there are numerous situations where the doctor may be faced with safeguarding problems, for example:

- domestic violence during pregnancy;
- substance misuse in pregnancy;
- termination services;
- contraception and women with learning difficulties;
- female genital mutilation;
- 'honour'-based violence.

Consent

Consent is important in all patient–doctor interactions. For the reasons discussed already, it is especially important with victims of sexual violence. A thorough understanding of the Mental Capacity Act 2005 is needed.

Capacity and the Mental Capacity Act

The definition of, assessment of and responsibilities in relation to capacity (also known as mental capacity) in England and Wales are laid out in the Mental Capacity Act (MCA) 2005.

The MCA applies to all adults aged 16+.

The MCA defines capacity as the ability to make a decision. It relates to the *process* of making a decision and not to the *outcome* of the decision. It is not limited to medical decisions, but can apply to any decision-making process e.g. financial or social choices.

Capacity is task specific. A person may be capable of deciding one issue but not another.

Capacity is also time specific. A person's capacity may alter with time.

The MCA defines the lack of capacity thus: if, at the time the decision needs to be made, patients are unable to make the decision because of an 'impairment of, or a disturbance

in the functioning of, the mind or brain', they are deemed incapable.

The term 'capacity' was previously used interchangeably with the term 'competence'. Since the MCA 2005 'capacity' is the preferred term.

The MCA lays out five statutory principles:

- 1 A person must be assumed to have capacity unless it is established that s/he lacks capacity.
- 2 A person is not to be treated as unable to make a decision unless all practicable steps to help him or her to do so have been taken without success. (*This includes communicating in an appropriate way. In forensic practice the clinician may need to arrange for interpreters or signers to be present or to use visual aids.*)
- 3 A person is not to be treated as unable to make a decision merely because s/he makes an unwise decision.
- 4 An act done, or a decision made, under this Act for or on behalf of a person who lacks capacity must be done, or made, in his or her best interests.
- 5 Before the act is done, or the decision is made, regard must be had as to whether the purpose for which it is needed can be as effectively achieved in a way that is less restrictive of the person's rights and freedom of action.

Healthcare professionals are warned that a person cannot be judged to lack capacity simply because of age, appearance or behaviour.

Assessment of capacity

All adults are presumed to have capacity unless there is evidence to the contrary.

In order to assess someone's capacity to make a valid treatment decision, two criteria have to be considered:

- 1 Do they have an impairment of mind or brain (temporary or permanent)?
- 2 Does the impairment mean that the person is unable to make the decision in question, at the time it needs to be made?

Where the patient is less than 16 years old they are still able to make autonomous decisions independent of those with parental responsibility provided that they have the capacity to do so. The term 'Gillick competence' is often used here following on from a particular court case where Victoria Gillick had a legal challenge against the NHS providing contraceptive advice to girls under the age of 16 years.¹² The outcome was a judicial decision that, provided the child was competent to make the decisions in question, then they were able to do so without involving their parents, although medical best practice would be to encourage parental involvement where possible.

There has been some confusion over the years with the terminology, in particular with what became known as the Fraser Guidelines. These too were related to the Gillick case but deal specifically with prescribing contraception to this age group (as opposed to a general assessment of capacity where 'Gillick competency' is used).

History taking

Ideally this will be done by a forensic physician.

The information gathered and note keeping must be:

- 1 Comprehensive
- 2 Comprehensible
- 3 Correct
- 4 Contemporaneous

When making enquiries about the details of the assault, open rather than closed questions should be used. Sometimes direct questions may need to be employed but these should be recorded verbatim as should their answers. Accusations of 'contaminating' evidence may otherwise be levied.

Injuries

There are several key points regarding injuries as the result of sexual violence:

- The majority of victims will not have any injuries.
- Should any injuries be sustained they tend to be minor.
- Many of the usual injuries sustained in sexual violence will heal quickly and rarely will they leave any scars.
- Where possible they should be documented by a trained forensic physician specialising in sexual assault.
- Documentation must be accurate and may include photo documentation.

Although some rape victims may suffer extensive, possibly even fatal, injuries, many will have none. They should be reassured that lack of injuries is common and does not negate their allegations.

Any injuries that are found, however small, should be documented accurately to help aid subsequent interpretation (e.g. age of injury and possible causation). Objective findings must be distinguished from subjective descriptions or conclusions.

Injuries can be subdivided into:

- bruises;
- abrasions;
- lacerations;
- incisions;
- burns.

Bites are not unusual in sexual assault and may contain a mixture of injuries including bruises, abrasions and lacerations.

More information regarding the interpretation of injuries (or the lack of them) can be found elsewhere.¹³

Forensic samples

Dependent upon a number of factors including the nature of the assault and the time elapsed, there may be an opportunity for a forensic physician to gather forensic samples. The FFLM has produced *Recommendations for the Collection of Forensic*

Specimens from Complainants and Suspects. These are updated twice a year and available on their website¹⁴ along with numerous other guidelines, *pro formae* and body maps to aid the documentation of injuries. These give guidance regarding samples in terms of what to take, when to take, how to take and how to store.

When dealing with an acute rape victim, urgent medical considerations should always take precedence over the preservation of forensic evidence, but where possible both should be achieved. If in doubt seek advice. Where there may be a delay to a patient being seen by a forensic physician seek advice from them on the best way to minimise destruction of any forensic evidence and how to gather and store any possible evidence source (e.g. underwear) in a way that will be most useful and also admissible in any subsequent criminal investigation.

It must be remembered that forensic evidence is not restricted to forensic samples e.g. DNA evidence. It may be possible to collect forensic evidence such as documentation of injuries and scars long after any trace evidence has been lost. The concept of a 'forensic window' is sometimes referred to but should be avoided as it is often restricted to trace evidence and an opportunity to gather other types of evidence, offer support and reassurance is then lost.

Emergency contraception

Where the sexual assault is such that pregnancy is a possibility then a risk assessment for the need for emergency contraception should be done as soon as possible.

Given the nature of what has happened, possible injuries and risk of STIs, hormonal methods are often preferable to using a copper coil, but the pros and cons of the different methods should be evaluated on a case-by-case basis. Prophylactic use of antibiotics if inserting a coil is recommended.

For emergency contraception, see Chapter 72.

Pregnancy and paternity analysis

Where it is believed that a pregnancy has been the result of a rape paternity analysis can be carried out to establish the identity of the father. This may be done when a child is born or using the products of conception following a termination. Guidance has been produced to assist this process.¹⁵

HIV and hepatitis B post-exposure prophylaxis

A risk assessment should be undertaken to assess the need for PEP for blood-borne viruses e.g. HIV and hepatitis B. Risks will be dependent upon assailant factors and the nature of the assault. Detailed guidance on this has been developed.¹⁶

When it is required HIV PEP should be started as soon as possible and certainly within 72 hours. Specialist advice from GUM should be sought if one is not familiar with its use. Usually a SARC would prescribe a 5-day starter pack with follow-up by the GUM clinic.

Hepatitis B PEP can be started within 6 weeks although in some circumstances immunoglobulins may be required soon after the assault.

Suicide/self-harm risk

Mental health problems are not unusual in complainants of sexual violence. This may be as a consequence of the assault, or the case that having such problems makes them vulnerable and therefore a target for perpetrators. Often it can be a mixture of both.

The clinician must be able to undertake a preliminary screening of the mental health assessment including suicide risk of the victim and then manage the situation accordingly (Box 102.3).

Box 102.3 Suicide risk assessment¹⁷

High-risk indicators are in red print

1. Do you have thoughts about harming yourself?
2. **Are you thinking about suicide?**
3. **Do you have a specific plan to kill yourself?**
4. What methods have you considered?
5. **Do you have access to any of these methods?**
6. Do you have a date or place in mind?
7. **Have you ever self-harmed or attempted suicide in the past?**
8. Has anyone in your family died by suicide?
9. **Are you suffering from mental health problems?**
10. Have you suffered from mental health problems in the past?
11. Have you ever had contact with mental health services or seen your GP in relation to psychological or psychiatric problems?
12. Are you taking any medication for mental health problems?
13. Do you have a problem with drugs or alcohol?
14. Have you been drinking in the past few hours?
15. Are you experiencing particular difficulties in your life or struggling to deal with difficult past events (e.g. bereavement, divorce, running away from home)?
16. Do you have friends or family you can turn to for help?
17. **Do you feel that the future is hopeless and that things cannot improve?**

STI screening

Given the incubation times for most STIs, usual practice would be for the patient to be screened at 2 weeks post assault and then at 3 months for blood-borne viruses.

ISVAs

Independent Sexual Violence Advisors (ISVAs) are victim-focused advocates who help people who have experienced sexual violence to access the services they need. Most SARCs and some voluntary organisations will have access to them. Many will see victims even in cases where the police are not involved. They will be able to support the victim with practical issues and offer support through the criminal justice process. Should counselling be required they will be able to facilitate this.

LONG-TERM CONSEQUENCES OF SEXUAL VIOLENCE

In a national cross-sectional study of reported health outcomes and exposure to violence, Black *et al.* (2011)¹⁸ found a statistically significant ($p < 0.001$) higher prevalence of adverse physical and mental health outcomes for nine out of the ten measured health outcomes in women with a history of rape, stalking, or physical violence by an intimate partner in comparison with women with no reported exposure to these forms of gender-based violence. The health outcomes measured in the study were: asthma, irritable bowel syndrome, diabetes, high blood pressure, frequent headaches, chronic pain, difficulty sleeping, activity limitations, poor physical health and poor mental health; the only measured outcome with non-significant difference was high blood pressure.

Psychological sequelae of sexual violence

Sexual violence is likely to have an impact on a victim. The level of impact will depend upon a number of factors, including the baseline mental health, nature of the assault, chronicity of the violence and subsequent support and safety for the victim. Early intervention has been found to be protective in reducing the risk of longer-term psychological problems. There is no one 'uniform' response. Judgemental response by professionals when dealing with victims can be immensely damaging.

Many victims will suffer initial symptoms, both physical and mental. They should be reassured that this is a normal response to an abnormal event. Some will go on to develop more long-term problems.¹⁹ Rape victims are more at risk of developing PTSD than other victims of violence.

MALE RAPE

Male rape is a not uncommon problem. For the O&G specialist it may present as an issue in settings such as patients with psychosexual problems or investigations of fertility. There are many excellent resources for male victims and the clinician should have up-to-date local knowledge of such.²⁰

FEMALE GENITAL MUTILATION

FGM describes any deliberate, non-medical removal or cutting of female genitalia. Different regions and communities practise various forms of mutilation.

FGM includes procedures that intentionally alter or cause injury to the female genital organs for non-medical reasons.

A review by WHO in 2000²¹ and a more recent review in 2008 showed that FGM has significant health consequences for a woman's physical, mental, gynaecological and reproductive health.^{22,23}

HONOUR-BASED CRIMES

Honour-based violence (HBV) is a form of domestic abuse which is perpetrated in the name of so-called 'honour'. The honour code which it refers to is set at the discretion of a family or community. Those who do not abide by the 'rules' may be punished for bringing shame on the family. Infringements may include a girl or woman having a boyfriend; rejecting a forced marriage; pregnancy outside marriage; interfaith relationships; seeking divorce; inappropriate dress or make-up and even kissing in a public place.

Forced marriage is a component of honour-based crime. Women may present in a healthcare setting as a result. The clinician should be alert to possibility that this is a problem and be able to deal with it sensitively and safely. More information and resources can be found at Honour-Based Violence Awareness Network, <http://hbv-awareness.com>.

Advice regarding the law can be found at http://www.cps.gov.uk/legal/h_to_k/honour_based_violence_and_forced_marriage/#a02.

DOMESTIC VIOLENCE

- Domestic sexual violence is common and frequently is not disclosed.
- Patients may present in a healthcare setting with sexual violence-related problems.
- Domestic sexual violence can have an impact on the physical and mental health of victims, both in the immediate and long term.

- Deal with victims in a sensitive, non-judgemental manner.
- Have a thorough and up-to-date knowledge of local resources.

CONCLUSIONS

Sexual violence continues to be a worldwide problem of high prevalence. All ages can be victims.

The clinician must keep an open mind as to its possibility. The response of the clinician may be crucial in reducing the impact of an assault and indeed preventing further victimisation.

Chapter 103 Female genital mutilation

Ben Chisnall and Janice Rymer

MRCOG standards

- Core Curriculum 4 (Ethics and Legal Issues): Demonstrate the ability to discuss issues surrounding female genital mutilation with patients in a sensitive manner.
- Core Curriculum 8 (Antenatal Care): Counsel about defibulation in cases of female genital mutilation.
- Core Curriculum 11 (Delivery): Management of female genital mutilation.

Additional competencies

- Knowledge of the short-term and long-term physical and psychological consequences of FGM.
- Identification of girls who may be at high risk of FGM.
- Understanding of the legal context around FGM and the statutory duty of health professionals if FGM is encountered.

EBM

A 2013 Cochrane review found no suitable studies for inclusion in a meta-analysis of interventions to improve obstetric outcomes in women who have undergone FGM.

INTRODUCTION

Female genital mutilation (FGM) comprises all procedures involving partial or total removal of the external female genitalia or other injury to the female genital organs for non-medical reasons. FGM has been documented in at least 29 countries in Africa, where it is most prevalent, as well as in countries in Asia and the Middle East.¹

FGM is carried out for traditional and cultural reasons. There may be involvement of religious leaders in communities which practise FGM, even though FGM pre-dates Christianity, Islam and Judaism, and is not advocated in any religious scripture.²

DEFINITION

Normal female anatomy is illustrated in Fig. 103.1.

FGM is classified by the WHO into four types:

- Type 1: Clitoridectomy (Fig. 103.2a): Partial or total removal of the clitoris and/or prepuce;
- Type 2: Excision (Fig. 103.2b,c): partial or total removal of the clitoris and labia minora, +/- excision of the labia majora;
- Type 3: Infibulation (Fig. 103.2d): narrowing of the vaginal orifice with creation of a covering seal by cutting and opposing the labia majora and /or minora with/without excision of the clitoris;
- Type 4: Other: all other harmful procedures to the female genitalia for non-medical purposes, for example pricking, piercing, cutting. This is also called 'symbolic circumcision'.

Current estimates indicate that around 90 per cent of FGM includes Types 1, 2 or 4, and about 10 per cent are Type 3.¹

TERMINOLOGY

The term 'female genital mutilation' has been used by the WHO to describe the practice since 1991. The practice had previously been referred to as 'female circumcision', and the new terminology was chosen to differentiate FGM from male circumcision. UNICEF and the UN currently use the term 'female genital mutilation/cutting' (FGM/C) which they feel reflects the practice's violation of women's and girls' rights, but also allows respectful terminology to be used amongst practising communities. The 2011 Department of Health report on FGM includes a useful list of terms used for FGM in different languages.²

PREVALENCE

The WHO estimates that FGM affects around 140 million women worldwide, and that 3 million women in Africa are at risk of FGM each year.¹ Girls are most likely to be subjected to FGM between infancy and age 15, and although the average age at which FGM occurs differs between countries the most common age is thought to be between 5 and 8 years.³

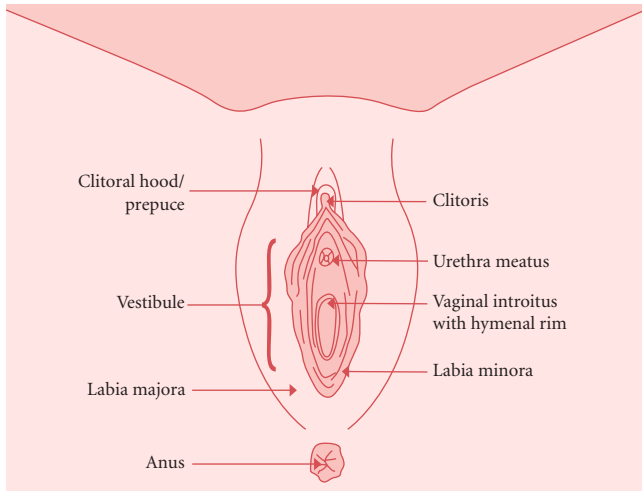

Fig. 103.1 Unaltered female genitalia. Simpson J, *et al.* Female genital mutilation: the role of health professionals in prevention, assessment, and management. *BMJ* 2012;344:e1361

Countries where the prevalence of FGM amongst women is estimated at over 90 per cent are Somalia, Guinea, Djibouti, Sierra Leone and Egypt, and over 80 per cent in Sudan, Eritrea and Mali.²

In England and Wales nearly 66,000 women are estimated to be living with the consequences of FGM, and over 20,000 girls under the age of 15 could be at risk of FGM each year.² As these figures are based on 2001 census data they may underestimate the scale of FGM in the UK, and a study began in October 2013 to establish figures based on the 2011 census. Women who come to Britain from high-prevalence countries are likely to have undergone FGM, and their daughters may be at risk of mutilation in future.

There are certain regions of the UK where FGM is more prevalent, due to large populations of communities from high-prevalence countries residing within these areas. These are London, Cardiff, Manchester, Sheffield, Northampton, Birmingham, Oxford, Crawley, Reading, Slough and Milton Keynes.²

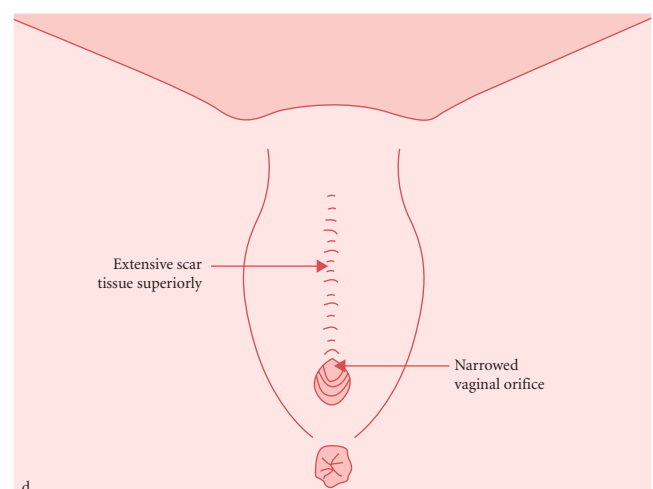

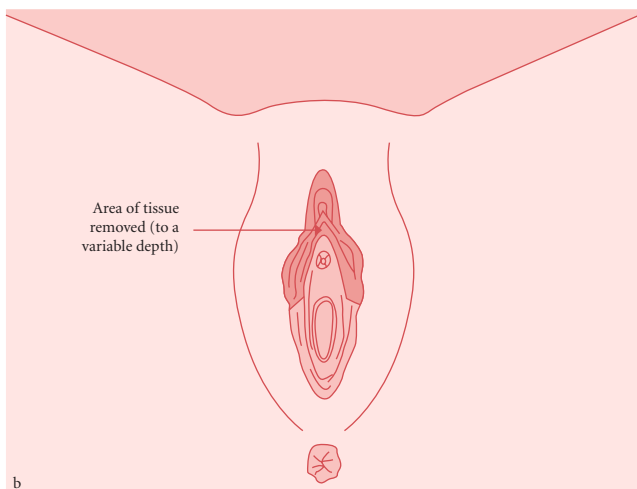

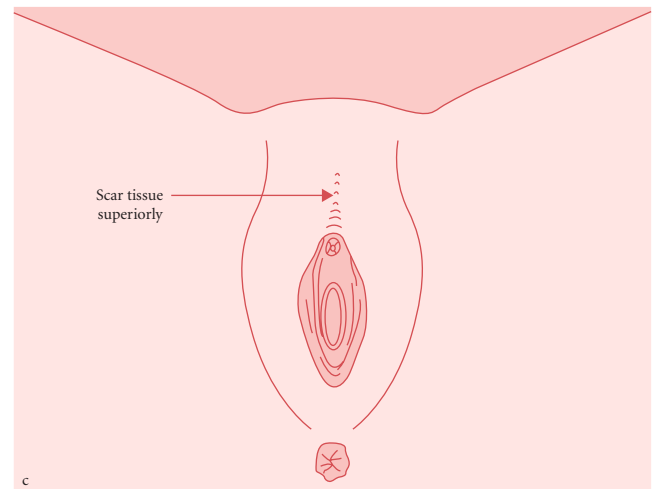

Fig. 103.2 Tissue removed in type 1 female genital mutilation (a); type 2 female genital mutilation (b,c); type 3 female genital mutilation (d). Simpson J, *et al.* Female genital mutilation: the role of health professionals in prevention, assessment, and management. *BMJ* 2012;344:e1361

CULTURAL AND TRADITIONAL BACKGROUND TO FGM

In some cultures it is believed that FGM will preserve a girl's virginity until marriage.⁵ Another view in practising communities is that mutilation makes girls 'clean' or beautiful by removing the 'masculine' parts of the female vulva (such as the clitoris), and that infibulation creates a 'smoothness' which is aesthetically pleasing.⁶

FGM is considered necessary to raise a girl properly and to prepare her for adulthood and marriage in practising cultures. It is performed to secure a girl's status in society, and although mothers may feel uncomfortable about hurting their daughters they perceive the social advantages for the girl to outweigh the risks of the practice.⁷ Girls may themselves desire to undergo FGM, due to family and community expectations, and the promise of rewards and gifts afterwards.

The position of men with regard to FGM is complex. A belief sometimes held by women is that FGM enhances men's sexual pleasure. Although some men in practising cultures express a preference for women who have undergone FGM, a study of Sudanese men found that many preferred sex with women who hadn't been mutilated, and experienced discomfort during sex with a woman with FGM [D].⁸ As FGM is largely performed and encouraged by women, men in these cultures may not be fully aware of the procedure and potential complications. A recent study amongst Gambian men showed that 77 per cent did not realise that FGM had a negative impact on women's health, and 60 per cent thought it was equivalent to male circumcision [D].⁹ Younger men, with more knowledge of FGM and its effects, are more receptive to banning it.⁵

Women are more likely to support the continuation of FGM if they are uneducated, married, living in a rural area, and lacking exposure to the media. A Nigerian study found that educating mothers and their daughters over a 10-year period reduced the prevalence of FGM [C].¹⁰ Recent data suggest that FGM is becoming less prevalent over time, with 36 per cent of girls aged 15–19 in practising countries having undergone FGM compared to 53 per cent of women aged 45–49 [C].³

HEALTH CONSEQUENCES OF FGM

Short term

The procedure of FGM is traumatic, often being performed by 'traditional circumcisers' in non-sterile conditions with no anaesthetic, and requiring girls to be physically restrained. As a result, there are a number of immediate complications including severe pain, haemorrhage, infection (including tetanus) and sepsis, transmission of blood-borne viruses including hepatitis B and C and HIV, urinary retention, damage

to adjacent tissues, and fracture or dislocation from being restrained.

If a woman is admitted acutely following mutilation, they should be assessed for signs of blood loss and sepsis, and offered analgesia and tetanus vaccination. Consideration should be given to prophylactic antibiotics in the absence of overt sepsis, and to urinary catheterisation.⁴

Long term

Obstetric complications

FGM causes scar tissue formation around the vulva and perineum, which is less elastic than normal perineal tissue and leads to obstetric complications. These include a greater risk of caesarean section, postpartum haemorrhage and extended hospital stay correlated with the severity of the mutilation [C].¹³ Additionally, type 3 FGM requires anterior episiotomy (defibulation) either antenatally or at the time of delivery, which carries risks of infection, bleeding and damage to the genital and urinary tracts.

Although FGM has been linked with obstructed labour in studies conducted in African countries, this does not seem to be the case in countries with more developed obstetric care and facilities.⁴ A case-control study carried out in Sweden in 2005 found that women requiring defibulation had shorter labours than Swedish controls who had not undergone FGM [C].¹¹ Perineal tears are more common in women with FGM, but evidence suggests that types 1 and 2 FGM are not independent risk factors for obstetric fistula formation [C].^{4,12}

Perinatal mortality

The 2006 WHO Study Group on FGM and Obstetric Outcome in six African countries found increased rates of perinatal mortality of around 1–2 per 100 deliveries amongst babies born to mothers who had undergone FGM [C].¹³ Death rates were 15 per cent higher for those whose mothers had type 1, 32 per cent higher for type 2 and 55 per cent higher for type 3 FGM. Babies born to mothers with FGM were also more likely to need resuscitation after delivery, but no association was found between neonatal birthweight and maternal FGM [C].

Urinary symptoms

FGM can alter the structure of the urinary tract, predisposing women to recurrent UTIs as well as urethral strictures and peri-urethral tears. This altered anatomy may impair women's ability to detect dysuria; a study from Khartoum showed that only 8 per cent of women and girls with FGM diagnosed with UTI on urine testing reported experiencing urinary symptoms [D].¹⁴ Although FGM can cause urinary retention and poor flow, and UTIs can predispose to urinary incontinence, FGM does not seem to be implicated as a direct causal factor of incontinence.

Genital and pelvic infections

An increased frequency of bacterial vaginosis, genital herpes and candidiasis has been found amongst women subjected to FGM, correlating with the extent of their mutilation and the amount of labia majora removed [C].¹ The prevalence of chronic pelvic disease is higher in women who have undergone FGM than in non-mutilated women, and women with FGM have higher rates of primary infertility associated with the extent of their FGM [C].¹⁵

HIV transmission

Although there is no epidemiological evidence linking FGM to HIV transmission, some studies have suggested possible associations between the two. These include the increased likelihood of coital bleeding in women who have undergone FGM; the increased need for blood products perinatally; the repeated use of FGM equipment between numerous girls; and the increased likelihood of anal intercourse occurring in infibulated women [E].¹⁶

Cyst formation

Epidermal inclusion cysts may occur in around 5 per cent of women who undergo type 2 FGM, and in around 0.6 per cent with type 3 [C].¹⁷ These are caused by excision of tissue and growth of epidermal elements in the dermal layer. Inclusion cysts grow slowly but become symptomatic when infected. Treatment requires excision and drainage of the cyst, with removal of the excess skin and re-approximation of the skin edges.

Chronic pain

Infibulated women may experience pelvic pain from haematocolpos, if the passage of menses is blocked, and dyspareunia, if the vaginal opening is not sufficient to allow intercourse. The mutilation itself can cause chronic neuropathic vulval pain from severed nerve endings, and women may also experience pain from chronic pelvic and urinary infections.

Psychological consequences

Women who have been subjected to FGM have significantly higher rates of PTSD and other psychiatric conditions than women who have not undergone mutilation [C].¹⁸ Women who have undergone FGM may experience lower rates of orgasm and reduced orgasmic functioning, with lower sexual quality of life scores the greater the extent of their FGM [C].¹⁹

IDENTIFYING GIRLS AT RISK

Risk factors for FGM include a low level of family integration into British society; a family history of FGM, including within the extended family; withdrawal from school; or withdrawal from Personal, Social and Health Education lessons at school.²

FGM may also be imminent if a female family elder is visiting the UK, or if a girl mentions that she is about to have a 'special procedure' or 'become a woman'.

If FGM has already taken place, the girl may show obvious signs of trauma such as difficulty walking, standing or sitting; urinary or menstrual difficulties; prolonged or repeated absences from school; noticeable behaviour changes, such as depression or withdrawal; or reluctance to undergo medical examinations.²

THE CONSULTATION

RCOG Guidelines on FGM state that any woman from a country which practises FGM – especially where prevalence is high – should be asked about her mutilation status.⁴ In antenatal care, this can be incorporated into the family origin questioning used for haemoglobinopathy screening. Alongside those from high-prevalence African countries, the possibility of FGM should be considered in women from Yemen and from Iraq, where prevalence is around 23 per cent and 8 per cent respectively [D].³

A female member of staff should be available, should the girl or woman prefer this. It is important to be sensitive; loaded terms such as 'mutilation' should be avoided, and instead questions like 'Have you been closed/cut?' should be used. It is equally important, however, to ascertain if she or any other female in her family has been subjected to or is at risk of FGM. Symptoms indicative of FGM such as dyspareunia, dysuria, voiding difficulties, pelvic pain, dysmenorrhoea or other menstrual symptoms, and obstetric difficulties, should be explored.

Explain that FGM is illegal, and that the law can be used to protect them and other family members from being mutilated. If the woman is worried about her immigration status, reassurance must be given that any treatment for FGM will not affect this.²⁰

In cases where a girl has already been subjected to or is at risk of FGM, a referral to children's services and to the police must be made.²¹ For women who have undergone FGM, an individual risk assessment should be made using an FGM safeguarding risk tool, and a referral to the police should be considered, with the woman's consent.² In both cases a detailed history should be taken and clearly documented, including the nature of their mutilation, where and when it was carried out and by whom, and any immediate complications. The woman should be asked about symptoms or complications resulting from FGM, as listed above. Blood and urine should be tested for infection, including a screen for blood-borne viruses.

If a child is at risk of FGM, her parents may be asked to sign a contract prohibiting FGM, and carry a 'health passport' which states the law around FGM and can be used to resist pressure to undergo FGM in their home country.²²

Examination, where required for girls, should be performed by a consultant paediatrician or gynaecologist with experience of dealing with FGM.² For adult women, the use

of a speculum should be determined by the size of the vaginal opening. A paediatric speculum is preferable, but if the woman is not able to tolerate this then a bimanual examination may be performed with one finger. The nature of the injuries should be documented, either as diagrams or clinical photographs, to reduce the need for repeat examinations.⁴ If necessary, vaginal swabs should be taken as the incidence of STIs is higher in women with FGM.¹

Women with FGM should be involved in planning their delivery; the RCOG suggests that FGM is not an absolute indication for caesarean section, unless their anatomy is severely distorted. A referral to a local African Well Woman clinic can be made, to advise on suitability for vaginal delivery. If a vaginal birth is planned, a low threshold for episiotomy should be maintained due to the risk of prolonged labour and perineal tears [D].⁴

The British Medical Association has published guidance for health professionals on the ethical considerations involved in managing women already subjected to, or at risk of, FGM.²³

DE-INFIBULATION

The WHO recommends that defibulation should be offered to women as soon as possible, as it may reduce some of the complications of FGM [D].¹ When a woman with FGM wishes to become pregnant, defibulation should be recommended before conception, especially if difficult surgery is anticipated. If the woman is already pregnant, defibulation should be performed before 20 weeks to allow adequate healing time [D].⁴ Caution should be exercised at later gestations as the gravid uterus may cause hypotension during the procedure. Guidance should be sought from an obstetrician or centre with experience of managing FGM. Urine should be screened for bacteria before surgery, and bloods should be sent for group and save because of the risk of bleeding. The procedure itself can be carried out in a suitable outpatients' room or operating theatre under local or general anaesthesia.⁴

The defibulation procedure requires the operator to identify the urethra, incise the vulval scar with cutting diathermy to reduce risk of bleeding, and to use fine absorbable sutures (e.g. Vicryl Rapide) to suture raw edges. Prophylactic antibiotics should be considered.⁴

If vaginal access is adequate then intrapartum defibulation may be performed, either in the first stage of labour by anterior midline episiotomy with epidural, or during the second stage at crowning of the baby's head. Defibulation can also be performed following a Caesarian section.

Re-infibulation, or re-closing a woman, is illegal and must not be performed after birth or at any other time. In the repair of birth trauma after FGM, the WHO recommends suturing any raw edges to prevent re-infibulation passively occurring through the healing process.²⁴

Women who have undergone FGM should be offered counselling after childbirth.² The woman should be told the

benefits of not being re-infibulated, which include better hygiene, less pelvic pain and dyspareunia, fewer obstetric complications and better fertility outcomes.² Where the mother has given birth to a girl, she should have the reasons for not having her daughter subjected to FGM explained to her.

THE LAW AND FGM

The Prohibition of Female Circumcision Act (1985) made FGM illegal in Britain. The Female Genital Mutilation Act (2003) made it illegal to take girls out of the UK to undergo FGM, or to assist someone with this. The maximum sentence for carrying out or assisting in FGM is 14 years in prison. Re-infibulation is also illegal in the UK and should never be performed by any health professional. To date, three doctors have been struck off the medical register by the GMC for serious professional misconduct relating to FGM, and in 2014 two individuals were charged and subsequently acquitted by the Crown Prosecution Service under the FGM Act 2003 for carrying out and aiding FGM.¹⁹

Under the Children Act of 1989, local authorities can apply to the courts to prevent a child being taken abroad for mutilation. Section 47 of the Act states the requirement of health professionals to inform social care or the police if they believe a child to be actually or potentially at risk. This also includes if the ill treatment of a child is seen or heard of, through the Adoption and Children Act 2002.

Other relevant legislation includes the Children Act 2004 (England and Wales), the Human Rights Act 1998, and the European Convention on Human Rights.

ELIMINATING FGM

FGM is already illegal in developed nations, and 26 countries in Africa and the Middle East have passed laws or constitutional decrees against FGM. This legislation ranges in scope, from the prohibition of health professionals carrying out FGM in Mauritania, to complete prohibition in Burkina Faso and Kenya, which includes fines for failing to report knowledge of others carrying out the procedure.

Internationally, efforts are being made to eliminate FGM. The WHO published *Eliminating Female Genital Mutilation: An Interagency Statement* in 2008 and *A Global Strategy to Stop Healthcare Providers from Performing Female Genital Mutilation* in 2010. In 2012 the UN General Assembly passed a resolution to ban FGM. The UK Department for International Development (DFID) has committed £35 million over 5 years to support African communities to eliminate FGM.

The 2013 report *Tackling FGM in the UK: Intercollegiate recommendations for identifying, recording and reporting* sets out a number of steps towards eliminating FGM in the UK. These include treating FGM as child abuse and integrating

its management into current safeguarding frameworks; multi-agency collaboration, documentation and data sharing; education of frontline staff; reporting cases of FGM; and education and empowerment of girls at risk of FGM. The report identifies a lack of knowledge amongst healthcare professionals and concerns about offending cultural groups as barriers to the detection of FGM. In May 2012 the Chief Medical Officer wrote to all clinical staff to request that they know about FGM, and what action is to be taken if it is discovered or suspected. Consequently, it is vital that all NHS staff have good knowledge of FGM, and understand the importance of asking women whether they have been subjected to mutilation. Partnerships between health organisations and community groups or educational institutions are crucial to raise awareness of FGM amongst girls who may be at risk, and to ensure that they are aware of the help available.

KEY POINTS

- FGM is conducted in at least 29 countries in Africa, as well as in Asia and the Middle East.
- 140 million women have been subjected to FGM, and 3 million are at risk each year, but its global prevalence may be decreasing.
- Many cultural, social and traditional factors lie behind FGM.
- It is illegal to perform or assist FGM in the UK, or to take a UK citizen abroad for the purposes of FGM.
- Short-term complications: pain, infection, haemorrhage, and damage to adjacent structures.
- Long-term complications: infertility, chronic pain, cyst formation, obstetric complications, neonatal mortality, recurrent UTIs, PID and psychosexual trauma.
- Defibulation may be required antenatally or during labour, but is most beneficial prior to conception and should be offered routinely.
- All women from high-prevalence countries should be asked about FGM.
- FGM should be addressed sensitively and findings should be clearly documented.
- If a girl is at risk of, or has already undergone, FGM, child protection services and the police must be informed.
- Indications that a girl is at risk are poor family integration, family history of FGM, and withdrawal from school or from certain lessons at school.
- A multi-agency approach is needed including education, information sharing, and community programmes to raise awareness of FGM.

Chapter 104 Benign vulval problems

Lubna Haque and Margaret Cruickshank

MRCOG standards

Theoretical skills

- Revise your knowledge of vulva anatomy and physiology.

Practical skills

- Take a vulvar history.
- Counsel patient on the use of topical steroids/emollients on the vulva.
- Interpret histopathological reports and ask a histopathologist if needed.
- Take a vulva biopsy under local anaesthetic.
- Be able to perform excision biopsy of a benign vulva lesion under local or general anaesthetic.

INTRODUCTION

Benign vulval skin disorders are common. Vulval itch, pain or skin changes are commonly experienced. Community-based surveys indicate that about 20 per cent of women have significant vulval symptoms. Of women who are referred on to a gynaecology clinic, the most common causes seen are dermatitis, lichen simplex, vulval candidiasis, lichen sclerosus and lichen planus. This chapter relates to the initial assessment and care of women with vulval disorders expected in the RCOG core curriculum by the general gynaecologist.

ANATOMY

The vulva consists of the external genital organs of the female (Fig. 104.1).

Major structures of the vulva are:

- the mons pubis;
- the labia, consisting of the labia majora and the labia minora;
- the external portion of the clitoris, consisting of the clitoral glans and the clitoral hood;

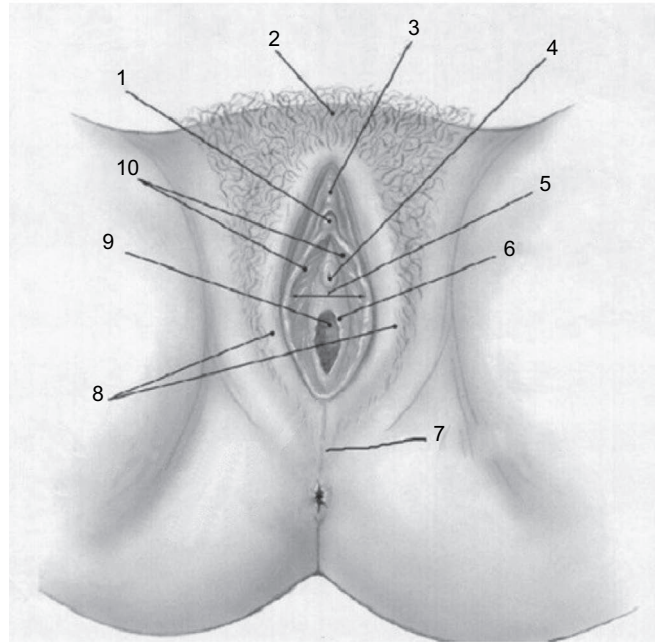

Fig. 104.1 Anatomical landmarks of the vulva: 1, clitoris; 2, mons pubis; 3, clitoral hood; 4, urethral meatus; 5, vestibule; 6, hymen (torn); 7, perineum; 8, labia majora; 9, vaginal opening; 10, labia minora

- the urinary meatus;
- the vaginal orifice;
- the hymen.

The mons pubis is the soft mound of the anterior vulva formed by fatty tissue covering the pubic bone. This separates into two folds known as the labia majora. Between the labia majora is the pudendal cleft and posteriorly between the pudendal cleft and the anus is the flat hairless area of the perineum. The labia minora are two folds of skin within the labia majora which originate with the covering of the clitoris, the clitoral hood. Between the labia minora is the vestibule which contains the urethral and vaginal openings. The opening of the vagina is known as the introitus. This may be partly covered by the hymen, a mucosal membrane or, more commonly, its remnants known as carunculae myrtiliformes which can be mistaken for skin tags or polyps. Posteriolateral on the left and right of the introitus are two

Bartholin glands and the ducts from these open into the lower, posterior vagina.

ASSESSMENT

A standard gynaecological history will not identify all relevant symptoms and potential causes of vulva skin disorders. In addition to factors that relate to the presenting vulval symptoms, the patient should be asked specifically about symptoms at other skin sites, other medical problems, and recent or current drug history and family history.

History

Non-specific symptoms such as pruritus and pain are the common presenting symptoms in vulval skin disorders but they are not diagnostic. The pattern of intensity and flare-up of symptoms should be explored during the day and over the menstrual cycle, and aggravating and relieving factors such as urinary or faecal incontinence. The use of self-medication or previous inadequate or inappropriate treatments may contribute to symptoms. It is not unusual for vulval skin to come into contact with potential allergens and irritants such as sanitary products, textile dyes, perfumes and preservatives.

Examination

It is important to examine the vulva with an adequate light source and a systematic approach. Colposcopy is not necessary as the use of a gynaecology couch allows visualisation of the whole anogenital region. It is important to ask the patient to identify the symptomatic area. If vulval intraepithelial neoplasia (VIN) is suspected, it is important to examine other lower genital tract sites including the vagina, cervix and perianal skin. Consider examination of other skin sites including the mouth for signs of lichen planus or ulcers and the scalp, elbows, knees and nails for psoriasis. Eczema can involve any site but is more commonly found on the scalp, neck, and elbow and knee flexor surfaces.

Investigations

Routine investigations in the initial assessment of women with vulval symptoms should only be performed if clinically indicated. These include thyroid function tests and random blood glucose,¹ a vulval skin swab for culture or an STI screen [D]. In addition, serum ferritin and skin patch testing should be considered in women with vulval dermatitis [D].² Specific allergic reactions are often identified in women with pruritus vulvae. The most common relevant allergens are cosmetics, medicaments and preservatives. Others include fragrances, preservatives in topical treatments, rubber and textile dyes. Washing powder, fabric conditioners, sanitary towels or panty liners and synthetic underwear may also be irritants and secondary sensitisation to multiple products is common.

Selectiveness in the use of skin biopsy is advised as a diagnosis can usually be made on clinical examination. Many vulval dermatoses can be recognised from history and classical features on examination. Biopsy is required if the woman fails to respond to treatment, there is diagnostic uncertainty of skin changes or there is clinical suspicion of VIN or cancer [E].

General measures

General measures are a key component of the management of vulval dermatoses in addition to condition-specific management. Emollients protect the skin and restore skin barrier function. General vulval care includes avoiding potential irritants that may worsen vulval symptoms, reducing symptoms and resolving contact dermatitis and lichen simplex. Avoiding soap and detergents and using soap substitutes instead can be soothing and protective to the skin. The combined use of emollients and soap substitutes helps maintain symptom relief³ and reduce use of topical steroids making this approach safe and inexpensive [C]. (See Box 104.1 on general measures.)

Box 104.1 General measures for vulval care

General measures which can help improve symptoms of vulval discomfort and irritation.

- Use a soap substitute to clean the vulva area. Water on its own tends to cause dry skin and lead to soreness.
- Shower rather than bathe and clean the vulval area only once a day. Overwashing can aggravate vulva symptoms.
- Wear loose-fitting natural fabric (silk/cotton) underwear.
- Sleep without underwear.
- Avoid fabric conditioners and biological washing powders.
- Avoid soaps, shower gel, scrubs, bubble baths, deodorants, baby wipes or douches in the vulval area.
- Some over-the-counter creams including baby or nappy creams, herbal creams (e.g. tea tree oil/aloe vera) and 'thrush' treatments may include possible irritants.
- Avoid wearing panty liners or sanitary towels on a regular basis.
- Avoid antiseptic (as a cream or added to bath water) in the vulval area.
- Wear white or light colours of underwear. Dark textile dyes (black, navy) may irritate sensitive skin.
- Use white or pastel toilet paper and avoid strong colours such as blue, green and peach.

DERMATOSES

The term 'dermatosis' covers any skin disorder and those most commonly seen in anogenital skin are covered below but the complete classification has been developed by the

Box 104.2 Summary of 2011 ISSVD clinical classification of vulvar dermatological disorders⁵

1. Skin-coloured lesions

A. Skin-coloured papules and nodules
e.g. Bartholin gland cyst, warts, skin tags

B. Skin-coloured plaques

1. Lichen simplex chronicus (LSC)
2. Vulvar intraepithelial neoplasia

2. Red lesions: patches and plaques

A. Eczematous and lichenified diseases

e.g. dermatitis, lichen simplex

B. Red patches and plaques

e.g. candidiasis, psoriasis, plasma cell (Zoon's) vulvitis, extramammary Paget's disease

3. Red lesions: papules and nodules

A. Red papules

e.g. hidradenitis suppurativa

B. Red nodules

e.g. urethral caruncle, Bartholin's abscess

4. White lesions

A. White papules and nodules

e.g. warts, scars

B. White patches and plaques

e.g. lichen sclerosis, lichen planus, VIN, vitiligo

5. Dark coloured lesions

A. Dark coloured patches

e.g. melanocytic naevus

B. Dark coloured papules and nodules

e.g. VIN, melanoma

6. Blisters

A. Vesicles and bullae

e.g. herpes simplex, pemphigoid

B. Pustules

e.g. candidiasis, folliculitis

7. Erosions and ulcers

A. Erosions

e.g. erosive lichen planus

B. Ulcers

e.g. chancre, Beçhet's

8. Oedema

A. Skin coloured oedema

e.g. Crohn's disease, post-radiation lymphatic obstruction

B. Pink or red oedema

e.g. cellulitis, Bartholin's abscess

International Society for the Study of Vulvovaginal Disease (ISSVD).⁵ The ISSVD terminology was designed to enable clinicians to describe skin features in a consistent and systematic way with the intention of aiding the diagnosis and care of women (Box 104.2).

Lichen sclerosis

Lichen sclerosis (LS) is a chronic inflammatory dermatosis that is commonly seen in post-menopausal women but can present at any age. Women complain bitterly of severe pruritus that often follows a fluctuating pattern of symptoms but may be worse at night. The vulval and perianal area is usually affected in a typical figure-of-eight distribution although occasionally it can be localised. Scratching causes skin trauma with symptoms of discomfort, pain and dyspareunia.

Pruritus is related to active inflammation with erythema and keratinisation of the skin. The skin is often atrophic and erythematous, classically demonstrating sub-epithelial haemorrhages (ecchymoses), and fissuring. Hyperkeratosis may be marked with thickened white skin. Continuing inflammation results in inflammatory adhesions. Lateral fusion of the labia minora starts with adherence to the outer mucosa and increasing agglutination can eventually result in complete reabsorption. The hood of the clitoris and its lateral margins may fuse, burying the clitoris. The accumulation of underlying skin debris and secretions can form a painful retention cyst often described as the sensation of 'walking on a pebble'. Midline fusion produces webbing at the fourchette and narrowing of the introitus, making intercourse painful and eventually penetration impossible. Occasionally the labia minora fuse together medially causing difficulty with micturition, dribbling incontinence and eventually acute urinary retention.

Aetiology

The aetiology of LS is unknown but it does not appear to be linked to female hormone changes, contraceptives, HRT or the menopause. Evidence suggests that it is an autoimmune condition with around 40 per cent of women with LS having or going on to develop another autoimmune condition.⁶

Prognosis

Prepubescent LS often improves at puberty but can recur in adulthood. It is a lifelong condition but good symptom control and prevention of tissue destruction can be achieved with ultrapotent topical steroids. LS is associated with a 4 per cent lifetime risk of squamous cell carcinoma (SCC) of the vulva⁷ and women need to know the signs or symptoms of malignant change to look out for.

Management

The treatment of LS should control symptoms, prevent further skin damage and reduce the risk of developing cancer. Ultrapotent corticosteroids are the cornerstone of treatment for most women with LS. Clobetasol propionate is the most

potent topical corticosteroid available and recommended as first-line treatment. Response rates are high with either complete or partial resolution of symptoms [A].⁸ Relapse of symptoms is common although improved response rates are seen with longer regular use on an ultrapotent steroid, usually on a reducing regime before returning to 'as required' use. Lower-potency steroids and topical testosterone are not advocated. The British Association of Dermatology has detailed guidelines based on the best available evidence for the management of LS (see Box 104.3 for summary points) [A].⁹ Women need clear information and directions on the use of their medications. Underuse of topical steroids is a more common problem than overuse. However there are no RCTS to support the frequency and duration of use of topical steroids. A widely used regime is daily clobetasol propionate for one month followed by a gradual reducing regime [E].⁴

Box 104.3 British Association of Dermatologists' guidelines for the management of lichen sclerosus 2010:⁹ Recommendations and conclusions

1. An ultrapotent topical corticosteroid is the first-line treatment for LS in either sex or age group, at any site, but there are no RCTS comparing steroid potency, frequency of application and duration of treatment.
2. Asymptomatic patients with evidence of clinically active LS (eczchymosis, hyperkeratosis and progressing atrophy) should be treated.
3. Anogenital LS is associated with SCC but the development of this complication is rare in clinical practice, <5%. It is not yet known whether treatment lessens the long-term risk of malignant change.
4. Long-term follow-up in a specialised clinic is unnecessary for uncomplicated disease that is well-controlled clinically using small amounts of a topical corticosteroid i.e. <60 g in 12 months.
5. Secondary care follow-up should be reserved for patients with complicated LS that is unresponsive to treatment and those patients who have persistent disease with a history of a previous SCC.
6. A dermatology opinion should be sought in any patient with atypical or poorly controlled LS.
7. Surgical intervention is only indicated in women for the complications of scarring, premalignant change or an invasive SCC.
8. If psychosexual issues arise, these should be addressed and, if appropriate, referral made to a practitioner experienced in this field.

Second-line treatment

Approximately 5–10 per cent of women with LS will have symptoms that do not improve with topical ultrapotent steroids (steroid-resistant disease). The recommended

second-line treatment is topical tacrolimus under the supervision of a specialist clinic.⁹ Tacrolimus and pimecrolimus belong to the class of immunosuppressant drugs known as calcineurin inhibitors. Their mode of action differs from corticosteroids, mainly reducing inflammation by suppressing the T-lymphocyte responses. Tacrolimus and pimecrolimus have both been shown to be effective in controlling the symptoms of LS⁸ although less effective in reversing changes in the skin appearance [A]. In a phase II study, maximal effects were seen after 10–24 weeks of treatment and 77 per cent of women had a full or partial response.¹⁰ Calcineurin inhibitors are well tolerated and avoid steroid side effects. However use in LS is off licence and should be monitored in a specialist clinic. Local side effects such as burning are usually short lived. They may also cause heat sensitivity and increase the risk of herpes. Tacrolimus cannot be used in pregnancy due to teratogenic effects. The long-term safety of topical calcineurin inhibitors is not established although based on reports from extensive use, this would appear to be low. Whilst long-term data are awaited, use for longer than two years is not recommended due to concerns about potential malignant transformation [E].

It is important to consider other factors which may contribute to failure to respond to first-line treatment: poor compliance with treatment; inability to comply e.g. due to poor eyesight or mobility problems; superimposed secondary condition such as infection; contact allergy to medications; urinary or faecal incontinence; development of vulvodinia secondary to tissue damage.⁹

Surgery

Surgery and CO₂ laser vaporisation do not relieve the symptoms of LS but have a role in restoring function impaired by agglutination and adhesion of vulva skin or mucosal surfaces. This can result in partial or complete urinary retention or narrowing of the vaginal introitus with altered body image or impaired sexual function. Prior to surgery, the skin should be pre-treated with daily clobetasol propionate to ensure that there is no active inflammation at the time of surgery. Simple procedures such as modified Fenton's procedure can be effective in releasing webbing to allow restoration of sexual function [D].¹¹

Follow-up

Women who achieve good symptom control on 'as required' regimes of topical ultrapotent steroids do not require follow-up at a gynaecology clinic. They should have information on suspicious symptoms and continue to use general measures to improve skin care. There are no clinical trials on self-examination or the frequency or duration of monitoring. However patient support groups and specialist societies do advocate self-examination to detect any suspicious areas.¹² Self-examination techniques are provided by these groups and may have a role in follow-up [E].

Lichen planus

Lichen planus (LP) is a common dermatosis which may affect the skin anywhere on the body. LP usually affects mucosal surfaces and is more commonly seen in oral mucosa. LP presents with polygonal purple plaques and papules with a fine white reticular pattern (Wickham's striae). However, in the vulva it is more likely to be erosive LP and associated with pain rather than pruritus. Erosive LP appears as a well demarcated, glazed erythema around the introitus. It can extend into the vagina as a painful desquamative vaginitis¹³ which can cause dyspareunia and apareunia from stenosis and even vaginal obliteration.

Aetiology

The aetiology of LP is unknown but it may be an autoimmune condition. It can affect all ages, although it is more common after the menopause, and is not linked to hormonal status.⁶

Prognosis

Like LS, LP is thought to have a small lifetime risk of SCC of the vulva, but the small number of reported cases makes the level of risk unclear. A UK-wide audit suggests a similar rate to LS of 2.3 per cent although this may be confounded by case collection from specialist centres.¹³

Management

High-potency topical corticosteroids are first-line therapy for all forms of LP although there have been no RCTs to support this widely accepted practice which include anogenital LP [A].¹⁵ It needs to be recognised that this is indirect evidence as this systematic review identified only RCTs of the management of LP in oral disease. In addition to clobetasol, topical tacrolimus appears to be an effective treatment for vulvovaginal LP. A number of different treatments are reported for women when LP does not respond to topical treatment, or symptoms are severe or widespread. The most common is oral steroids until disease remission is reached.¹⁴ Evidence is limited for vulval LP refractory to topical steroids but a multicentre UK CRS trial completed recruitment in July 2015 and is still to report. The hELP study (systemic therapy for vulval erosive lichen planus) compares methotrexate, hydroxychloroquine and mycophenolate mofetil¹⁶ along with general supportive measures and topical ultrapotent steroids and oral steroids if required. (Further information can be found at <http://public.ukcrn.org.uk/search/StudyDetail.aspx?StudyID=16788>)

Prognosis

LP may resolve spontaneously within one to two years, although recurrences are common. However, LP involving mucous membranes may be more persistent and resistant to treatment.

Lichen simplex

Women with sensitive skin, dermatitis or eczema can present with vulval symptoms of dermatitis which can result in lichen simplex, a common chronic inflammatory skin condition. This presents with severe intractable pruritus, especially at night. Non-specific inflammation often involves the labia majora but can extend to the mons pubis and inner thighs. There may be erythema and oedematous swelling with discrete areas of thickening and lichenification often secondary to scratching. This can be exacerbated by chemical or contact dermatitis and is sometimes linked to stress or low body iron stores.

Management

The mainstay of treatment is general care of the vulva avoiding potential irritants and use of emollients and soap substitutes. Antihistamines or other antipruritics may be helpful, especially if sleep is disturbed. However, moderate or ultrapotent topical steroids may be necessary to break the itch-scratch cycle.

Vulval candidiasis

Vulval candidiasis tends to present with irritation and soreness of the vulva and anus rather than discharge. Diabetes, obesity and antibiotic use may be contributory factors. Vulval candidiasis may become chronic. On examination, a leading edge of inflammation with satellite lesions may be seen extending out from the labia majora to the inner thighs or mons pubis. There may be oedema, fissuring and excoriation from inflammation and scratching.

Management

Prolonged topical antifungal therapy may be necessary to clear a skin infection with oral or topical preparations. A small prospective case series suggests that a combined approach with oral fluconazole and topical antifungal cream may increase clearance and reduce recurrence [D].¹⁷ In non-responsive cases, identification of the candida type and sensitivity may help to guide treatment.

Extramammary Paget's disease

Extramammary Paget's disease of the vulva is a rare condition seen in post-menopausal women. The main symptom is pruritus. On examination, discrete lesions usually affect hair-bearing skin and not the mucosa, and have a florid eczematous appearance with lichenification, erythema and excoriation. Extramammary Paget's disease can be associated with an underlying adenocarcinoma. Imaging is recommended for the GI and urinary tracts and breasts but there is insufficient evidence to advocate best practice.

Management

Surgical excision is recommended to exclude adenocarcinoma arising locally from a skin appendage and a case series of 76 cases pooled by BSSVD¹⁸⁻¹⁹ indicated that this is the treatment option of choice. Photodynamic therapy, radiotherapy and topical imiquimod have been used with some success in case reports [D]. Despite what appear to be obvious clinical features, surgical margins are difficult to achieve due to subclinical disease and recurrence is common. However the margin status and lesion size did not appear to correlate with progression-free interval in a retrospective cohort study from a single institution.¹⁹

Psoriasis

Psoriasis can involve the skin of the vulva but not vaginal mucosa. The appearance differs from the typical scale of non-genital sites. It often appears as smooth, non-scaly red or pink discrete lesions. Scratching may cause infection, dryness and skin thickening. Examination of other sites including nails and scalp may be helpful in making a diagnosis.

Management

Emollients, soap substitutes, topical steroids and calcipotriene are useful for symptom control but cold tar preparations should not be used in genital sites.

Plasma cell vulvitis (Zoon's vulvitis)

Zoon's vulvitis is a rare benign chronic inflammatory condition of the vulva which presents with symptoms of pruritus, burning, dyspareunia and dysuria. It usually presents in postmenopausal women and its appearance is similar to erosive LP with glazed erythema often involving the introitus and labia minora. Zoon's vulvitis is diagnosed histologically and is characterised by dermal infiltration with plasma cells, vessel dilatation and haemosiderin deposition. The aetiology of this condition is unknown; one theory is that it is an autoimmune disorder. There have been case reports favouring successful treatment with topical ultrapotent steroids and surgical excision.²⁰

Blistering and ulcerative conditions

Herpes

Genital herpes usually presents with acute vulva pain and asymptomatic episodes with genital blisters or ulcers are more likely to be seen with recurrence than primary infection. Swabs should be taken for confirmation and typing when herpes infection is suspected as it is essential to have an accurate diagnosis.

Beçhet's disease

Beçhet's disease is a chronic multisystem disease characterised by recurrent oral and genital ulcers. In women, ulcers can involve the cervix, vulva or vagina. These are usually recurrent, painful and can leave scarring. Treatment to control flare-ups and reduce symptoms is based on topical or systemic immunosuppressants.

Vulval Crohn's disease

Crohn's disease is a chronic inflammatory bowel disorder. It can involve the vulva by direct extension from involved bowel or 'metastatic' granulomas. Rarely it is seen without known bowel disease or preceding the presentation of bowel disease. The vulva is often swollen and oedematous with granulomas, abscesses, draining sinuses and ulceration. Surgery can result in sinus and fistula formation and tissue breakdown and therefore should be avoided. Treatments include metronidazole and oral immunomodulators and so care needs to involve liaison with medical and surgical gastrointestinal specialists.

Pemphigoid and pemphigus

Pemphigoid is a rare blistering disorder which usually occurs in later life, the average age of onset for vulval disease being over 70 years. Pemphigoid is classified as a connective tissue autoimmune disease. Prior to blister development or with atypical disease, there may be non-specific pruritic papules, eczematous or urticarial rash with marked itch. The blisters are large tense fluid-filled bullae.

Pemphigus vulgaris is a rare autoimmune disease that causes severe blistering of the skin and of the mucous membranes lining the mouth, nose, throat and genitals. The fragile blisters break down to painful ulcers and itching is unusual. Treatment is with topical or oral steroids. Vulval rather than vaginal involvement is more common and is almost always associated with mouth and skin lesions. The bullae are usually large and tense. Treatment is important because secondary infection can lead to sepsis. Pemphigus vulgaris is usually treated with oral corticosteroids.

If pemphigoid or pemphigus is suspected, the diagnosis can usually be made on the clinical appearance of the preceding rash or large fluid-filled bullae. Biopsies of the blister and adjacent normal skin should be taken for histological examination and a fresh sample in 0.9% saline for direct immunofluorescence. Dermatological opinion on atypical blistering rashes and the treatment is essential.

Vulva lumps and bumps

Lumps and bumps are common in the vulva area and normal anatomical features such as carunculae myrtiformes or papillomatosis may be mistaken by the patient (or their doctor) for pathology. Vulval cysts are usually benign and can be treated conservatively.

Sebaceous cyst

Sebaceous cysts are generally mobile masses that can consist of fibrous tissue filled with inspissated sebaceous material. They are more common in hair-bearing areas, are smooth in appearance and to the touch, and vary greatly in size. They can be multiple and widespread involving the labia majora. Infection is uncommon but can recur. Excision of a sebaceous cyst can be done under local anaesthetic. It is important to remove the central punctum to prevent recurrence. With multiple cysts, it is possible to treat by laser ablation to avoid scarring and extensive skin excision.²¹

Epithelial inclusion cyst

This benign cyst is usually found on the skin of the labia majora or minora. The appearance is similar to a sebaceous cyst. The cyst may be asymptomatic but can also become infected. The management is the same as for a sebaceous cyst.

Bartholin's cyst

A Bartholin's cyst is formed when the duct from the Bartholin's gland to the vaginal opening becomes blocked, causing a fluid-filled cyst to develop. Infection of the duct and/or gland results in a Bartholin's abscess. Bartholin's cysts are most likely to occur in women of child-bearing age and can grow from the size of a pea to the size of a golf ball. This is usually smooth and well localised but when infected, there may be surrounding oedema and induration. Marsupialisation is more effective than simple incision and drainage for cysts and abscesses as it allows the gland to drain and reduces the risk of recurrence. A cruciate incision is performed over the dome of the abscess, the cavity drained and the wound edges are sutured apart to ensure drainage. An alternative procedure is to insert a balloon catheter under local anaesthetic. The catheter stays in place using a saline-filled balloon, usually for up to 4 weeks. This is to allow epithelialisation of the tract, after which it is deflated and removed if it has not fallen out spontaneously. This procedure is recommended by a NICE review²² which identified from a small number of case series that insertion is almost always successful, most women find this procedure acceptable and the recurrence rate is 3–17 per cent [C] even if the catheter falls out in a shorter time [D].

Papillomatosis

Papillomatosis describes a benign epithelial tumour, growing exophytically with often finger-like fronds. Vulvar vestibular papillomatosis is considered an anatomical variant of the vulva, characterised by pink, asymptomatic, fine projections.⁹ Recognition of this condition is important to distinguish it from warts and therefore avoid unnecessary biopsy or treatment. Papillomatosis may be more pronounced with inflammation of the vulval mucosa.

Dermatofibroma

Dermatofibromas are classed as benign, often pigmented, skin lesions forming firm solitary papules. They can be elevated or

pedunculated. Dermatofibromas cause little or no discomfort. On the shin, they are thought to arise from reaction to previous injuries such as shaving but trauma is less often related to vulva lesions. They tend to recur and should be managed conservatively.

Lipoma

Vulvar lipomas are uncommon and benign consisting of lobulated fat enclosed by a thin fibrous capsule. They can occur anywhere and in the anogenital area they usually involve the labia majora or buttock. They tend to be slow growing and are usually asymptomatic. They are more commonly seen in the third and fourth decades of life. Treatment of vulval lipomas should be conservative as surgery can cause scarring and disfigurement from removing subcutaneous fat which can extend deeply.

Hidradenitis suppurativa

Hidradenitis suppurativa (HS) is a chronic skin disorder characterised by skin abscesses, fistulas and scarring, generally affecting the anogenital and axillary areas. It is a common disease with an estimated prevalence of 1 per cent.²³ The aetiology is unknown although it appears on histological examination to be a disease of hair follicles rather than apocrine sweat glands. Recurrent and multiple boils and scarring makes this condition embarrassing and distressing. Treatment options are limited. First-line treatment includes topical antibiotics (e.g. metronidazole gel) or systemic antibiotics (e.g. low-dose minocycline). Second-line treatment with retinoids and immunosuppressive drugs may have limited response and should involve collaboration with dermatology.

Hidradenoma

Hidradenoma papilliferum (HP) is a rare, benign, cystic, papillary tumour. It is a sharply circumscribed nodule of ectopic breast tissue usually found on the labia majora or interlabial folds. It is often confused clinically with carcinoma of the vulva as it often ulcerates. Histologically, it is identical to an intraductal papilloma of the breast.

EBM

The supporting evidence for the management of common vulva disorders is limited mostly to uncontrolled observational studies or case series.

Vulval varicosities

Vulval varicosities are rare outwith pregnancy. They may present with pain, dyspareunia or general discomfort, especially when standing or later in day. Varicose swellings are most likely to involve the labia majora. An MRI scan of the

pelvis may identify pelvic varicosities, local venous malformations of the vulva or vagina or arteriovenous malformations of the leg or ovarian vessels or other pelvic organs.²⁴ Isolated varicosities are managed conservatively in pregnancy but when symptomatic in non-pregnant women may be treated by incision and ligation or by sclerotherapy [D].

KEY POINTS

- Vulval itch is a very common complaint.
- The history required for vulva skin disorders differs from a standard gynaecological history to include information on other skin disorders and related factors.
- Examination requires good positioning of the patient with a good light source and a systematic approach to examining the whole ano-genital region.
- Skin biopsy is not always necessary unless you suspect malignant disease or the condition does not improve with first-line therapy.
- Advice on general care of vulva skin and avoiding irritants often benefits women with vulva skin disorders in addition to specific therapies.
- Lichen sclerosus is a lifelong condition but good symptom control and prevention of tissue destruction can be achieved with topical ultrapotent steroids.
- LS is associated with a 4 per cent risk of squamous cell cancer of the vulva and women should be aware of the signs or symptoms of malignant change.
- Surgery is rarely required for LS except to correct the effects of scarring such as apareunia or urinary retention.
- Lumps and bumps are common in the vulva area and can often be managed conservatively.

Chapter 105 Vulvodynia

Shuchi Dixit and David Nunns

MRCOG standards

The established standards relevant for this topic are:

Theoretical skills

- Understand and distinguish between the different subgroups of vulvodynia.

Practical skills

- Be able to clinically assess patients presenting with superficial dyspareunia and vulval pain.
- Be able to plan appropriate management and understand when to involve other disciplines.

INTRODUCTION

Vulvodynia has been defined by the ISSVD as vulval discomfort, most often described as a burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurological disorder.¹ Patients can be further classified by the anatomical site of the pain (e.g. generalised vulvodynia, hemivulvodynia, clitorodynia) and also by whether pain is provoked or unprovoked. Patients previously given a diagnosis of vestibulitis should now be diagnosed with vestibulodynia (localised provoked vulvodynia) (see Box 105.1). Some patients may have a combination of vulvodynia with another vulval problem e.g. herpes or thrush, and both conditions may require treatment.

Before a diagnosis of vulval pain syndrome can be made, infections and vulval dermatoses should be excluded.

PAIN PATHOPHYSIOLOGY

Clinical pain can either be inflammatory or neuropathic in origin. Inflammatory pain is associated with tissue damage or injury and clinically exhibits sensory hypersensitivity, which is characterised by hyperalgesia and allodynia. Hyperalgesia is the exaggerated response to noxious substances through a general increase in the responsiveness of tissues. Allodynia is

Box 105.1 ISSVD classification of vulval pain

Vulval pain related to a specific disorder

1. Infectious (e.g. candidiasis, herpes, etc.)
2. Inflammatory (e.g. lichen planus, lichen sclerosus, immunobullous disorders, etc.)
3. Neoplastic (e.g. Paget's disease, squamous cell carcinoma, etc.)
4. Neurologic (e.g. herpes neuralgia, spinal nerve compression, etc.)

Vulvodynia

1. Generalised
 - i. Provoked (sexual, non-sexual or both)
 - ii. Unprovoked
 - iii. Mixed (provoked and unprovoked)
2. Localised (vestibulodynia – previously known as vulval vestibulitis, clitorodynia, hemivulvodynia, etc.)
 - i. Provoked (sexual, non-sexual or both)
 - ii. Unprovoked
 - iii. Mixed (provoked and unprovoked)

the production of pain by stimuli that do not usually cause pain, by a reduction in the sensory threshold of neurons. Hence, inflammatory pain seen with vestibulodynia is associated with pain on light touch and is usually localised. Neuropathic pain is usually caused by damage to either the central or peripheral nervous system and produces a diffuse burning, aching pain with intermittent flare-ups. Hyperalgesia and allodynia may not necessarily be present.

ASSESSMENT

History

An accurate pain history is essential to differentiate between the different subtypes. In addition to the nature of the pain, one should record any aggravating and relieving factors, with particular reference to sexual intercourse. Any past treatments should also be recorded to avoid duplication.

A psychosexual history is essential, as many women have significant dysfunction and may require a psychosexual referral [II].²

Examination

Identifying sites of vulval tenderness and discomfort can help in making a diagnosis. Clinical examination should also exclude other vulval conditions that can produce similar symptoms. Inflammatory vulval diseases such as lichen sclerosus and seborrhoeic dermatitis can cause vulval pain and soreness through excoriation, splitting and fissuring of the vulval skin, as well as itching. Some conditions may not be manifest at the time of examination, such as a tight posterior fourchette and the vulval fissuring.³ Symptomatic dermatographism is a rare cause of vulval pain, but this may be suggested by dermatographism evident at other body sites.⁴ Other less common causes of vulval pain are worth considering, including aphthous ulceration, erosive lichen planus and genital herpes simplex. These conditions are less common but should be ruled out by adequate examination and investigation. Where diagnosis is unclear patients should be referred to a vulval service or clinic.

VESTIBULODYNIA (LOCALISED PROVOKED VULVODYNIA – FORMERLY VULVAL VESTIBULITIS)

Definition

Vestibulodynia is a cause of superficial dyspareunia and is characterised by vestibular tenderness on light touch.⁵ This hyperaesthesia can be generalised throughout the vestibule or can be more focal, involving the opening of the ducts of the major vestibular glands or the posterior fourchette.⁶

Clinical features

Affected women are usually Caucasian, aged between 20 and 40 years, and present with a history of provoked pain such as superficial dyspareunia, tampon intolerance and pain during gynaecological examinations.^{5,7} There is often a delay between the onset of symptoms and receiving a diagnosis, which varies from months to years. A 6-month period of time has been arbitrarily suggested from the onset of symptoms to making a diagnosis of vestibulodynia so as to exclude women recovering from acute vulval inflammation from other causes.⁶

As the condition is frequently chronic, a high level of psychological morbidity is common. Some patients are prone to stress and anxiety, which may play a role in developing symptoms [III].² Sexual dysfunction is common and frequently reported.⁸ Reduced sexual arousal, more negative sexual feelings and less spontaneous interest in sex (not

elicited by a partner) have all been described in vestibulodynia. These are all risk factors for significant psychosexual dysfunction such as vaginismus and anorgasmia, the management of which usually requires psychosexual input [III] (see Chapter xx).

Clinically, simply using a Q-tip applicator can identify vestibular tenderness. A defining feature of vestibulodynia is that the labial skin is non-tender. Vestibular erythema is a subjective finding that is often present on normal examination and is usually not helpful in making the diagnosis of vestibulodynia or in planning management.⁹ The application of diluted acetic acid to the vulva does not assist in making a diagnosis [II].

Incidence

The incidence within gynaecology clinics in the UK remains unknown. However, the prevalence of vestibulodynia was 1.3 per cent of women attending a Central London GUM clinic.¹⁰ Misdiagnosis is common.

Aetiology/risk factors

This remains unknown, but is likely to be multifactorial. It is often difficult to identify a cause, as symptoms usually develop insidiously. Recurrent attacks of vaginal candidiasis are frequently cited, but this may be due to initial misdiagnosis.

Prognosis

Up to 30 per cent of women with vestibulodynia may experience resolution of their symptoms without treatment and in 50 per cent of these, resolution can occur within 12 months [II].⁶

Management

The aims of management are to reduce vestibular tenderness and to identify the potential need for input from other disciplines, for example psychosexual counsellors.

General measures

Reassurance and an explanation of the condition are essential, and providing written information is helpful [II].¹¹ Strict vulval hygiene measures should be practised to reduce the chance of contact sensitivity [III].

Only one RCT addresses surgery, group therapy and bio-feedback.¹² Good evidence for effective treatment is lacking. Many studies are methodologically flawed, for example low study numbers and short follow-up times.

Topical agents and vaginal dilators

No RCTs have compared topical agents. Local anaesthetic gel/ointment prior to sex and emollients are worthy of mention

as first-line treatment [III]. Lidocaine gel together with the use of vaginal dilators can help desensitise the pelvic floor for patients who are fearful of sex and where secondary vaginismus may exist [II].¹³

Other topical agents include steroids and antifungal creams, which have been used with variable results, but no control arm existed in these studies.¹⁴ Long-term empirical prescribing of topical treatments should be discouraged, as it places the woman at unnecessary risk of developing irritant dermatitis and contact allergy. Irritant dermatitis is common on the vulva and in essence is a chemical irritation to a topical treatment. It usually resolves when the irritant is removed.

Pain management and psychosexual counselling

A cognitive-behavioural assessment has been suggested to complement the physical treatments [Ib].¹² Over a series of sessions, a clinical psychologist can teach patients coping mechanisms and pain management strategies such as the pain-gate theory, and can address the patient's expectations of treatment, which might not necessarily be a cure for pain, but rather the ability to have penetrative sex. Fig. 105.1 outlines a connection between the psychological and psychosexual aspects of vulval pain connecting thoughts, emotions, behaviours and symptoms. Hence there is an important role that psychological therapies play in the overall management of vulval pain. For many women with vestibulodynia, sexual rehabilitation may be required and this can be structured over several sessions with a psychosexual counsellor, preferably with the woman's partner. It is important to stress that a referral for therapy does not mean that the pain is all in the mind.²¹ Improving physical non-coital sexual contact, helping to overcome pelvic floor muscle hypertonia using sensate focus therapy, and addressing secondary psychosexual dysfunction such as low libido and anorgasmia will be of help to many.⁸

Surgery

The modified vestibulectomy is the procedure of choice, involving excision of a horseshoe-shaped area of the vestibule and inner labial fold followed by dissection of the posterior vaginal wall [II]. The vaginal tissue is then advanced to cover the skin defect. The complete response rate is around 60 per cent. Women who respond to lidocaine gel prior to sex have a more successful outcome.¹⁵ The response rate can be further improved with post-operative psychosexual counselling, which is likely to help overcome the fear of sex after surgery [II].¹³

In an RCT, 78 women with vestibulodynia were randomised to one of three arms: (1) group cognitive-behavioural therapy (12 weeks' duration), (2) pelvic floor biofeedback therapy (12 weeks' duration), and (3) vestibulectomy.¹² At follow-up at 6 months, all patients reported significant improvements in pain scoring. Sexual functioning with surgery had the highest success rates; however, one concern was the high number of participants randomised to surgery who declined to be included in the study. The study did support both non-surgical treatments for vestibulodynia and suggested that patients prefer a behavioural approach to treatment than a surgical one.

Other treatments

Biofeedback therapy using surface electromyographic (sEMG) signals from the pelvic floor has been used successfully to help overcome pelvic floor muscle dysfunction in women with vestibulodynia [II].¹⁶ Using portable home machines with a special vaginal skin sensor, 78 per cent of patients with apareunia had resumed penetrative sex and there was an objective improvement in the sEMG reading of the pelvic floor; however, many of these patients were also treated with amitriptyline. The system is not routinely available and experience in the UK is lacking. It is likely that patients may benefit from desensitising the vulval area using a variety of techniques; the optimal technique is not clear. Biofeedback or vaginal dilators may all work in a similar way.

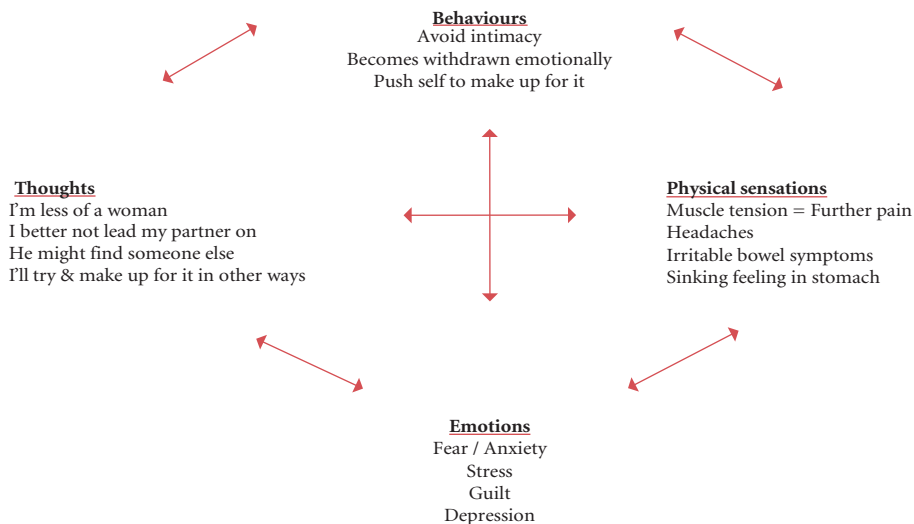

Fig. 105.1 Psychological and psychosexual therapy aspect of sexual pain

KEY POINTS

Vestibulodynia

- Topical agents are commonly used, but the evidence supporting a specific application is lacking.
- Surgery is of benefit in well-selected patients.
- One RCT showed a benefit of vestibulectomy above biofeedback therapy and group cognitive-behavioural therapy.
- Biofeedback is effective, but UK experience is limited and requires further evidence of benefit. Physiotherapy referral for pelvic floor assessment and treatment can be considered.

No evidence exists that dietary manipulations can improve outcome in vestibulodynia.

UNPROVOKED VULVODYNIA

Definition

Unprovoked vulvodynia is a cutaneous dysaesthesia causing non-localised vulval pain. Unlike with provoked pain, unprovoked vulvodynia gives more constant neuropathic-type pain in the vulva and occasionally the perianal area.¹⁷

Clinical features

The affected women are typically perimenopausal or post-menopausal and, like women with vestibulodynia, can present with a long history of multiple, inappropriate use of topical agents prior to a diagnosis.¹⁸ Superficial dyspareunia is not consistently reported, as many women are less sexually active.⁵ In addition, many experience rectal, perineal and urethral discomfort and there may be an overlap with other perineal pain syndromes.¹⁷ Psychological morbidity is likely to be high as a consequence of chronic pain.

Clinical examination of the vulva is normal.

Incidence

The incidence is unknown, but, as with vestibulodynia, misdiagnosis is likely.

Aetiology/risk factors

These remain unknown.

Prognosis

The prognosis also remains unknown.

Management

The aims of treatment are pain relief and identification of the potential need for input from other disciplines.

General measures

Reassurance and an explanation of the condition are essential, and providing written information is helpful.¹¹ Strict vulval hygiene measures should be practised to reduce the chance of contact sensitivity.

No RCTs have been carried out to assess the management of this group of patients, and only case-controlled studies exist, which frequently contain small numbers of women.

Tricyclic antidepressants and neuroleptics

Amitriptyline (a tricyclic antidepressant) is of benefit and addresses the central and peripheral components of neuropathic pain seen in unprovoked vulvodynia [II].¹⁶ A dose of 10 mg/day, increasing every week until the pain is controlled, has been suggested. The average dosage is 60 mg/day, although up to 150 mg/day can be used. Side effects may affect compliance. The duration of treatment is debatable, but 3–6 months has been suggested. Patients intolerant of the side effects can try dothiepin or nortriptyline. The neuroleptic gabapentin can be used as a second-line agent. In the only series to date of 17 patients with unprovoked vulvodynia, the complete response rate was 41 per cent for treatment with gabapentin with a follow-up period of 26 months [II].¹⁹

Surgery

Surgery is contraindicated in this group.

Other treatments

Acupuncture has shown limited promise in cases refractory to standard medical treatments. In one study comprising only 12 patients with unprovoked vulvodynia, two were completely cured [II].²⁰

KEY POINTS

Unprovoked vulvodynia

- Tricyclic antidepressants and gabapentin are of benefit.
- Surgery is contraindicated.

CONCLUSION

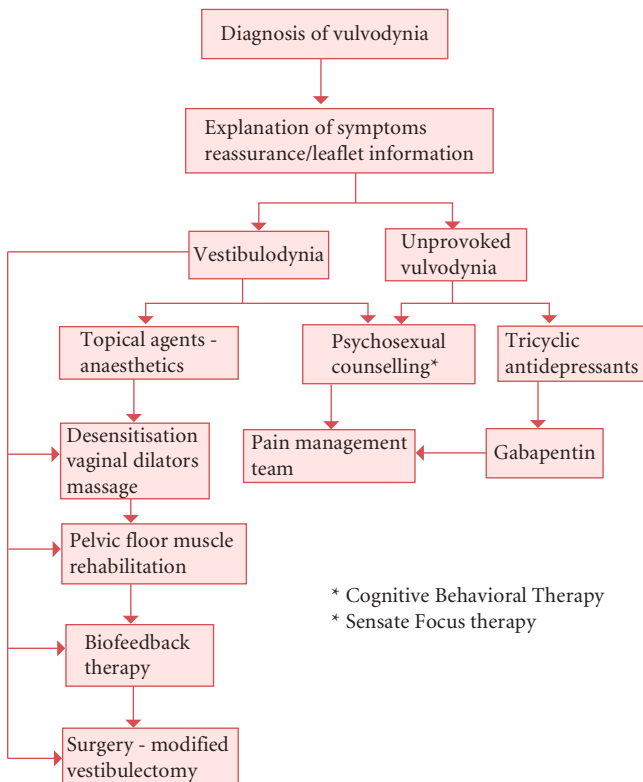

Women with vulvodynia form a heterogeneous group, with the clinical presentation reflecting physical, psychological and psychosexual factors. As with other chronic pain syndromes, a specific cause remains elusive and is probably multifactorial. A multidisciplinary approach to symptoms is likely to be of benefit to address the many complex issues surrounding vulval pain (Table 105.1). For some women who fail to respond to treatment, living and coping with pain become key issues in management. (Fig. 105.2.)

Table 105.1 The multidisciplinary approach to vulval pain syndromes

Health professional	Treatments offered
Clinician	Topical agents
	Tricyclic antidepressants/neuroleptics
	Modified vestibulectomy
Clinical psychologist	Cognitive-behavioural therapy
	Pain management
	Coping strategies
Psychosexual counsellors	Treatment of secondary sexual dysfunction
	Sensate focus therapy
	Increasing non-coital sexual activity
Physiotherapist	Biofeedback
	Pelvic floor muscle rehabilitation and desensitisation

The role of the general gynaecologist is assessment and then triage of the patient to the correct health professional depending on the needs of the patients. If the clinician is unsure of management or the patient does not respond to treatment then the patient should be referred to the local vulval service.

Algorithm for Managing Vulvodynia

**Fig. 105.2** Algorithm for managing Vulvodynia

KEY POINTS

- A good history and clinical examination are essential to distinguish between different vulvodynia subgroups.
- Surgery is only suitable for well-selected patients with vestibulodynia.
- Amitriptyline/gabapentin are treatments for unprovoked vulvodynia.
- A multidisciplinary approach can be helpful.
- Good evidence for effectiveness is lacking.
- It is important to escalate patients to senior colleagues for ongoing referral if 1) the patient has not responded to treatment, 2) the diagnosis is unclear, or 3) the symptoms are severe and there is a significant impact on function.

Chapter 106 Pre-invasive disease

Nirmala Rai and Gabrielle Downey

MRCOG standards

The established standards relevant for this topic are:

Theoretical skills

- Understand the central role of human papilloma-virus in the aetiology of cervical intraepithelial neoplasia.
- Understand the principles of organising population screening, the current NHS cervical screening programme and the implications of HPV positivity.
- Be confident about interpreting cervical cytology reports and counselling women accordingly.
- Be aware of the new changes to the cervical screening programme including HPV triage and 'test of cure'.
- Understand the principles and application of the national HPV vaccination programme.
- Be aware of the controversies in both screening and vaccination.

Practical skills

- Recognise pre-malignant conditions and cancer of cervix.
- Be able to counsel patients with abnormal cervical cytology/HPV tests.
- Understand indications and limitations of screening and investigative techniques of cytology, HPV testing and colposcopy.

INTRODUCTION

Worldwide, cervical cancer is the third most common cancer affecting women. Of the estimated 530,000 new cases in 2008, more than 85 per cent were in developing countries; in the same year 275,000 women died from it, about 88 per cent of whom were in the developing world. In developed nations, the figures for invasive cervical cancer are much lower. The disease has a relatively long natural history, and intervention

and treatment in the pre-malignant phase is highly effective. The accessibility of the cervix and the availability of a simple test for the presence of pre-malignancy make it suitable for mass screening. Other malignancies and pre-malignancies of the lower genital tract are much less common and therefore most of this chapter focuses on the cervix. A causal relationship has been established beyond reasonable doubt between cervical cancer and infection with human papillomavirus (HPV). The association has been seen in virtually all cases worldwide, paving the way for tests based on viral detection to be integrally linked with screening.

CERVICAL INTRAEPITHELIAL NEOPLASIA, ITS PATHOGENESIS AND THE ROLE OF HPV INFECTION

Definitions

Pre-cancer of the cervix was first described at the end of the nineteenth century. Histologically areas were described where neoplastic cells replaced the entire thickness of the epithelium without breaching the basement membrane. This was referred to as carcinoma *in situ* (CIS). Retrospective studies found CIS lesions in women who subsequently went on to develop cervical cancer, and so the precursor nature of CIS came to be established. Subsequent prospective studies have confirmed these findings.^{1,2} After exfoliative cytology was introduced, lesser degrees of change, not amounting to CIS, were recognised and termed 'dysplasia'. In order to rationalise the classification to encompass all degrees of change, the term cervical intraepithelial neoplasia (CIN) was introduced.³ Pre-invasive changes were divided into grades 1, 2 and 3. Grades 1 and 2 corresponded to mild and moderate dysplasia respectively, and grade 3 combined severe dysplasia and CIS into one category. The definition implied a continuum of change from CIN-1 through to CIN-3 and invasive cancer. As knowledge of the natural history of pre-malignancy has grown, the concept of a continuum of change has been challenged. For practical purposes, there is now a two-stage grading, with CIN-1 becoming low-grade CIN (in which there is a significant chance of

regression), and CIN-2 and CIN-3 being grouped together as high-grade CIN (Table 106.1). In North American and some European countries, this grouping has been formalised as the Bethesda Classification for cytological changes, consisting of low-grade squamous intraepithelial lesions (LSIL) and high-grade squamous intraepithelial lesions (HSIL).

Table 106.1 Glossary of terms

Term	Explanation
CIN	Cervical intraepithelial neoplasia, graded 1–3 depending on severity
VAIN	Vaginal intraepithelial neoplasia, graded 1–3 depending on severity
VIN	Vulval intraepithelial neoplasia, graded 1–3 depending on severity
AIS	Adenocarcinoma <i>in situ</i> , pre-invasive disease of glandular tissue
CIGN	Cervical intraepithelial glandular neoplasia, pre-invasive disease of glandular tissue graded low and high; high-grade CIGN = AIS
Pap smear	Cervical smear – cytological test described by Papanicolaou
ASCUS	Atypical squamous cells of uncertain significance – Bethesda system grade equating to borderline nuclear abnormalities
LSIL	Low-grade squamous intraepithelial lesion – Bethesda system grade equating to mild dyskaryosis/CIN-1
HSIL	High-grade squamous intraepithelial lesion – Bethesda system grade equating to moderate and severe dyskaryosis/CIN-2 and CIN-3
Dyskaryosis	A cytological term describing the nuclear abnormalities – not synonymous with dysplasia
Squamo-columnar junction (SCJ)	Where squamous and columnar tissue meet; this is not fixed, but is affected by metaplasia
Metaplasia	A physiological process whereby columnar epithelium is replaced by squamous tissue in response to the acid environment of the vagina
Transformation zone	That area on the cervix that has undergone metaplasia; it is bounded by the original SCJ and the present SCJ
Dysplasia	A histological term describing architectural abnormalities within tissue
LLETZ	Large loop excision of the transformation zone
LEEP	Loop electrosurgical excision procedure
DLE	Diathermy loop excision: taking a cone biopsy with an electrosurgical loop

Incidence

The UK has the second highest recorded incidence of CIN in the European Community. In 2010 in the UK there were 2900 new cases of invasive cervical cancer and 940 deaths, which equates to 8 women per day being diagnosed with cervical cancer and over 2 women per day dying of it.^{4,5} The majority of deaths are in women aged over 50. There has been an increase in incidence rates of 60 per cent for women aged 25–34 years of age since 2002, which previously had seen a fall until then. This is attributed perhaps to an increase in HPV infection because of the increased proportion of women initiating sexual activity before the age of 16. Changes in smoking behaviour in women born after the 1970s are also proposed to be a factor contributing to the raised incidence. Another contributory factor is an increasing number of migrants from other countries without a screening programme being diagnosed with cervical disease after arrival in UK. There was an increase in incidence in 2009 across the UK which was attributed to the raised awareness brought on by the high-profile death of a young reality TV star; incidence has subsequently dropped below the rates for 2008. There has also been a statistically significant increase in the age-standardised incidence by 17 per cent for all ages in the UK.⁴ Statistical modelling performed by the Imperial Cancer Research Fund (now a part of Cancer Research UK) has extrapolated that the current screening programme prevents around 3900–4500 deaths from cervical cancer per annum.^{6,7}

It is difficult to estimate the total number of cases of CIN, as cancer registries only record cases of CIN-3, but there were around 24,070 cases of CIN-3 in England, Scotland and Wales registered in 2010 with the peak incidence being between 25 and 29 years of age.⁸

Aetiology

HPV infection is the essential prerequisite for the development of cervical malignancy. The most recent data on Dutch archived cervical cancer specimens, using sensitive methods of detecting HPV DNA, call into question whether HPV-negative cervical cancers actually exist: the estimated prevalence of HPV in cervical cancers is 99.7 per cent.⁹ On the other hand, population-based studies have shown that genital HPV infection is extremely common with up to 80 per cent of sexually active women being HPV positive at some point during their lifetime. Using the incidence of genital warts as a marker the incidence appears to be rising five-fold in the female population and eight-fold in the male population, with approximately 15 per cent prevalence of the oncogenic HPV types 16 and 18.

While the likelihood of acquiring the infection is high, most infections are usually transient with 90 per cent of women clearing the infection within two years. Thus, the overwhelming majority of HPV infections will not lead to the development of cancer. Progression or regression depends on several factors that interfere with the host's ability to clear the virus.

The cell-mediated arm of the adaptive immune response is responsible for clearing HPV. If cell-mediated immunity is impaired, such as in transplant patients or in HIV-positive women, the virus will not be cleared and abnormalities may develop. How the virus results in cancer has now largely been defined. The virus lives in epithelial cells and is species specific. Genital infection with HPV can only be acquired through sexual contact. It is thought that the virus enters the epithelium through a breach in the skin integrity caused by microtrauma. The virus can remain and replicate within the cytoplasm (episomal) of the cell and is often cleared by the host immune system. Occasionally, the virus enters the cell's nucleus and this step towards oncogenesis is termed 'integration'. The cell no longer undergoes programmed cell death after 40–60 cycles but now becomes immortalised. The E6 and E7 oncoproteins are necessary for this, but vary in their ability to do so according to HPV type; E6 binds to the p53 cellular protein and E7 to the RB cellular protein, both of which are cell cycle regulators.^{10,11} Interfering with the cell cycle allows DNA damage to accumulate, which may result in genetic instability and transformation of the cell into a malignant cell line. This process may be accelerated by cofactors.

Why persistent infection happens in what appears to be a healthy individual is largely unknown. Smoking is a recognised cofactor for the development of disease: local immunity within the cervix appears to be suppressed in women who smoke. Women who smoke and have pre-invasive disease of the lower genital tract should be advised to stop smoking and offered smoking cessation support. The major histocompatibility complex is responsible for presenting viral antigen to the host's immune system and there is limited evidence to suggest that women with particular human leukocyte antigen (HLA) types may have increased susceptibility to disease. The majority of HPV infections result in CIN-1 and 60 per cent of these will regress without the need for treatment, while approximately 10 per cent will progress to high-grade lesions. However, it should be noted that women with mild dyskaryosis have a 16–47 times increased incidence of invasive disease compared with the general female population.^{12,13}

Cervical pre-cancer has a long natural history, which is one of the reasons why it is a suitable condition for screening. If a cancer is going to develop at all, it will take several years to do so, even from a CIN-3 lesion. It is unclear why some CIN-3 lesions become invasive, while others stay as intraepithelial disease, and it is not known how many CIN-3 lesions will become invasive, as prospective studies are unethical. However, the best prospective data suggest that at least 36 per cent of women with CIN-3 would develop invasive cancer if left untreated.²

Screening for cervical intraepithelial neoplasia

The test

The traditional Papanicolaou (Pap) smear test is used worldwide to screen for pre-cancerous cellular changes from

the cervix. Although the test has been a significant factor in the reduction of the incidence of cervical cancer by the detection of pre-malignant cells the drive to improve the screening test has led to the development of liquid-based cytology. Traditionally, the cytology sample from the cervix was spread on a glass slide at the time of collection. Each slide would therefore have only a proportion of the cells collected from the cervix (around 20 per cent). In October 2003 liquid-based cytology (LBC) was introduced following a recommendation from NICE. LBC collects the whole sample from the sampling device in a liquid medium that is sent to a laboratory for processing. Cells are transferred from the transport liquid to a slide as a monolayer for examination. This technique reduces the proportion of inadequate smears and increases the detection of true dyskaryosis and improved recall rates. This also resulted in improved efficiency by laboratories as it improved the quality of the sample and reduced the workload per lab. It also reduced anxiety in women by reducing recall and giving quicker results. LBC is now the standard test used for the NHS cervical screening programme. There are two main types in use, Surepath™ and Thinprep®. The evaluation of the sentinel sites for the transport medium suggested that both mediums were equally efficient for HPV testing. An additional advantage of the new transport media is that they also allow screening for sexually transmitted infections if required.

HPV testing for triage of low-grade abnormal cytology and 'test of cure' following treatment was incorporated in January 2011 into the NHS cervical screening programme following the evaluation of the pilot studies conducted in six sentinel sites in England. It was concluded that the introduction of HPV testing for triage and 'test of cure' is not only feasible but also acceptable and cost effective and it was rolled out in England in 2012.¹⁴

More than 90 per cent of cervical cancers develop within the transformation zone, the upper limit of which is the squamo-columnar junction. It is therefore important that this area is adequately sampled by direct visualisation of the cervix. In order to quality assure the screening programme, all cytology samplers have a unique identification code.

Test performance

Cervical cytology is not a perfect test: there are false-positive results (i.e. no disease is actually present) and false-negative results (i.e. genuine disease is missed). False-positive rates vary from 7 to 27 per cent (high specificity) and false-negative rates from 20 to 50 per cent (low sensitivity). HPV testing has higher sensitivity for detecting CIN-2 or worse compared to cytology. Therefore HPV triage was introduced along with cytology with intent to improve outcomes and screening efficiency. About 98 per cent of the smears taken are adequate for diagnosis, and just under 10 per cent of adequate smears are 'not normal'. Most smear abnormalities are at the minor end of the spectrum.

According to the NHS cervical screening programme (2011–2012) (comparable with new British Society for Cervical

Cytology classifications), cervical smear abnormalities can be broken down as in Table 106.2.

In general, the proportion of normal smears increases in older women, but so does the proportion of abnormalities representing invasive cancer. Borderline changes and mild dyskaryosis are very common in young women; the proportion of moderate dyskaryosis is highest for women aged 20–29 years; and the proportion of severe dyskaryosis is highest in women aged 25–34 years.¹³

Table 106.2 Breakdown of cervical smear abnormalities

Type (<i>new BSCC classification in brackets</i>)	Per cent
Borderline nuclear abnormalities (<i>borderline change, squamous, and borderline change in endocervical cells</i>)	3.4
Mild dyskaryosis (<i>low-grade dyskaryosis</i>)	1.8
Moderate dyskaryosis (<i>high-grade dyskaryosis – moderate</i>)	0.5
Severe dyskaryosis (<i>high-grade dyskaryosis – severe</i>)	0.6
? Invasive or glandular abnormalities (<i>? invasive or ? glandular neoplasia endocervical non-cervical</i>)	0.0

The programme

By definition, a screening test is not diagnostic, but identifies a subgroup of the reference population at increased risk of the disease for which further tests should be carried out. Screening is always a trade-off between sensitivity and specificity. In this case, the reference population being screened comprises healthy, asymptomatic women.

No randomised trials have been undertaken to establish whether screening actually reduces mortality from cervical cancer. Evidence in support of screening has been extrapolated from reducing trends in incidence and mortality in those areas where screening has been introduced. This is most strikingly illustrated by considering data from Northern Europe: Iceland, Finland, Sweden and Denmark noted reductions in incidence and mortality soon after their screening programmes achieved target coverage of the population in the 1960s. Norway, on the other hand, with no organised programme in the 1960s, continued to show increasing incidence rates into the 1970s.¹⁵

A nationwide, organised (as opposed to opportunistic) cervical screening programme was introduced in England and Wales in 1988 with a national computerised call-and-recall system. The regions still have a degree of autonomy in planning their screening programme, but there is now a national coordinating network to ensure the adoption of common standards and working practices. The whole NHS cervical screening programme was rewritten in 2004 and a revised edition is available with new evidence (at present this is only available on the (BSCCP website).¹⁶ This new programme

differed from those that preceded it in that it incorporated all the available evidence and used this information to define a minimum standard and what was ‘best practice’. There were significant changes to 1) the age to commence screening, 2) the screening interval, 3) actions to be taken following a mildly abnormal smear and 4) follow-up of both treated and untreated women. There were also guidelines dealing with immune-suppressed and HIV-positive women. In general, the principle of management was to keep ‘low-risk’ women in the community and ‘high-risk’ women in the colposcopy service. There were further changes introduced into the national screening programme i.e. HPV testing to triage low-grade (borderline and mild) abnormalities and test of cure following treatment which were rolled out from March 2012. There were regional variations within the UK in the commencement and cessation of screening which will be dealt with later in this chapter.

Main changes to the programme

The screening interval

The screening interval changed from 3- to 5-yearly to be defined as:

- 3-yearly to 49 years;
- 5-yearly thereafter to 64 years.

Evidence shows that a 3-yearly screening programme could prevent substantially more cancers than a 5-yearly programme in the younger woman with little extra cost.^{17,18}

If maximum coverage for a 3-yearly programme is 91 per cent and the incremental gains become less and less thereafter with increasing screening frequency, therefore, in terms of cost–benefit, there is little justification for reducing the screening interval to less than 3 years in the younger age group.

The age to commence and stop screening

In England, Wales and Northern Ireland, screening begins at 25 years while it has been 20 years in Scotland. The incidence of cervical cancer in the under-25-year group is low and the incidence of transient infection and low-grade CIN is high. A recent review of the age to commence screening in England was undertaken as a result of media pressure following the death of a high-profile TV personality. The group concluded there was no new evidence to justify lowering the age of screening and good evidence to support the current policy of starting to screen at 25 years of age. Since 1 September 2013 Wales no longer invites women until they reach 25 and Scotland will change from 2015 onwards. Thus 25 will be the age to commence cervical screening throughout the UK. Cervical screening before 25 years of age may detect an abnormality that would resolve spontaneously, thus screening such young women could result in both physical and psychological morbidity with little evidence of benefit.

There are conflicting reports on the effect of large-loop excision of the transformation zone (LLETZ) on preterm

delivery. A systematic review and meta-analysis by Kyriou *et al.*¹⁹ reported an increase in preterm delivery following LLETZ. Since then more studies have been published which have suggested that the risk of preterm delivery may not be related to LLETZ but may be due to other confounding factors like smoking and socioeconomic status²⁰ and may be influenced by repeated LLETZ²¹ or depth and volume of LLETZ.²²

The reduction in mortality from cervical cancer in women over the age of 50 years is thought to be unrelated to the cervical screening process. Cervical screening is less effective in detecting CIN-3 in older women and the incidence of both CIN and cervical cancer over the age of 50 is low: 11/100,000 in well-screened women compared to 59/100,000 women in the population as a whole.²³ Women over the age of 50 who are diagnosed with cervical cancer usually have not fully participated in the cervical screening programme. The exit age of 65 years has been questioned, particularly on reducing the age of screening to 50 in women who have been well screened with a satisfactory negative history. The effectiveness of cervical screening in reducing invasive cancer varies with age, being greatest in younger age groups and least in women aged over 70 years. Age-specific declines in cervical cancer were confined to women aged 30 to 70 years with a nadir around ages 45–50 years.

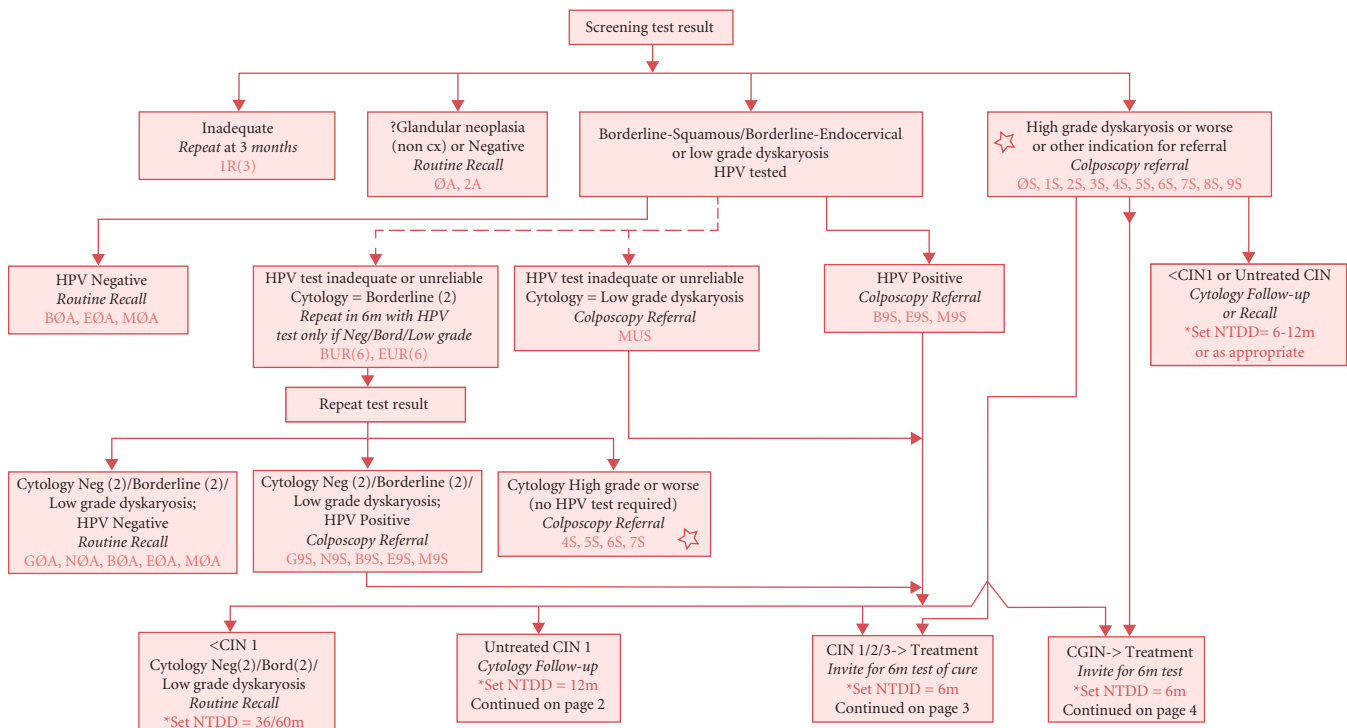

HPV TRIAGE

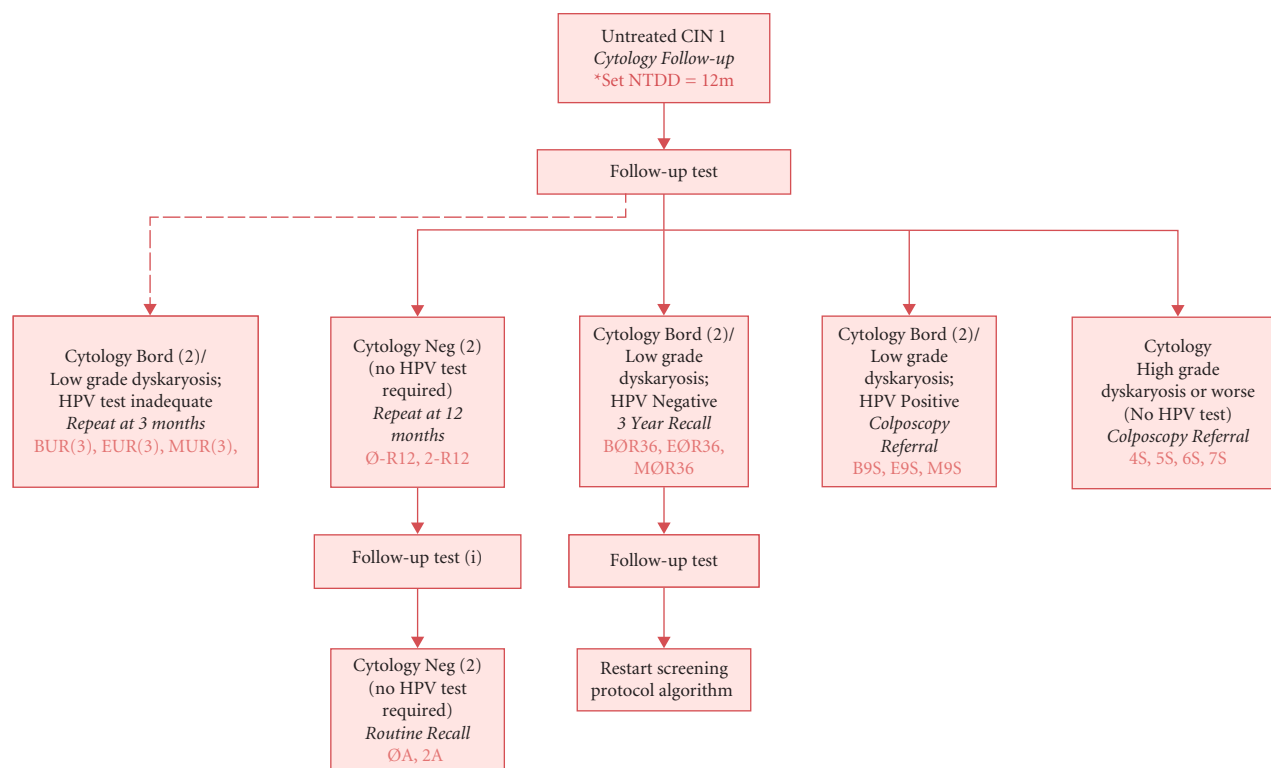

Previous guidance recommended that women with 2 or 3 borderline dyskaryosis and 1 or 2 mild dyskaryosis cytology samples be referred for colposcopy. The reason was an underlying risk of high-grade lesions detected on biopsies in a significant number of women with low-grade smears. The risk of high-grade disease in low-grade dyskaryosis was reported to be as high as

40 per cent.²⁴ The difference in guidelines and in management was also influenced by availability of services and variable evidence regarding the risk of underlying high-grade disease.

The high-risk (HR) HPV-positive rate in borderline and mild dyskaryosis was 53.7 per cent and 83.9 per cent respectively in the sentinel site studies;¹⁴ they also reported the positive predictive value of the HPV testing was 16.3 per cent and 6.1 per cent for CIN-2 or worse and CIN-3 or worse respectively. Studies have shown that HPV testing is acceptable to women. It also reduces anxiety in women because of the reduced number of repeat smears. Triage reduces requirement for repeat cytology and improves effective use of colposcopy services. However the overall referral rate to colposcopy is higher: hence it also increases pressure on the workforce because of increased colposcopy workload. Following the sentinel studies the operating framework for the NHS in England recommended implementation of HPV testing as triage for borderline and mild dyskaryosis for more patient-centred and cost-effective services.

Inclusion of HPV testing as a triage tool has introduced uniformity to the referral system of the screening programme. This has also reduced the time period of treatment and surveillance from a period of average 12 years to 9 months.²⁵ All smears reported as low-grade dyskaryosis (borderline/mild) are checked for HR-HPV DNA. This is called reflex HPV testing. HPV testing is done on the same sample that is taken for cytology. Women who are HR-HPV positive will be referred to colposcopy and women who are HPV negative will be returned to routine recall as women who are negative for HR-HPV are unlikely to develop cancer. If HPV testing is negative women are returned to routine recall as per national guidelines. Fig. 106.1 shows the HPV Triage protocol of the NHS cervical screening programme.

(i) The management of women with abnormal cytology at this second 12-month follow-up test will mirror that at the first 12-month repeat test.

Fig. 106.1 Flowchart for HPV-based triage (from reference 26, with permission)

The negative predictive value of the HR-HPV test is 93.8–99.7 per cent.²⁷ In a recent meta-analysis which evaluated the accuracy of hybrid capture assay (HC2) and other HR-HPV DNA assays for high grade CIN in ASCUS (atypical squamous cells of undetermined significance) triage (equivalent to borderline dyskaryosis), the pooled sensitivity was >90 per cent and significantly higher than that of repeat cytology; pooled specificity was >50 per cent and equivalent to cytology. The meta-analysis also found that other HPV DNA tests are comparable to HC2. The APTIMA mRNA test for five HPV types is not only equally sensitive but more specific too for detection of CIN-2⁺ in comparison to HC2.²⁸

On the other hand for LSIL (equivalent to mild dyskaryosis) though the pooled specificity for HPV triage in comparison to repeat cytology showed higher sensitivity, the specificity was significantly and substantially lower; similarly to ASCUS, testing with APTIMA viral mRNA is more specific without losing sensitivity.²⁸

Referral to colposcopy

The referral system to colposcopy in England and Northern Ireland has changed significantly and is based on HPV reflex testing for triage. Women with low-grade dyskaryosis (borderline and mild) with HR-HPV positive and one moderate or severe dyskaryosis will be referred to colposcopy.

An economic model suggested that HPV triage is more cost effective compared to cytology.

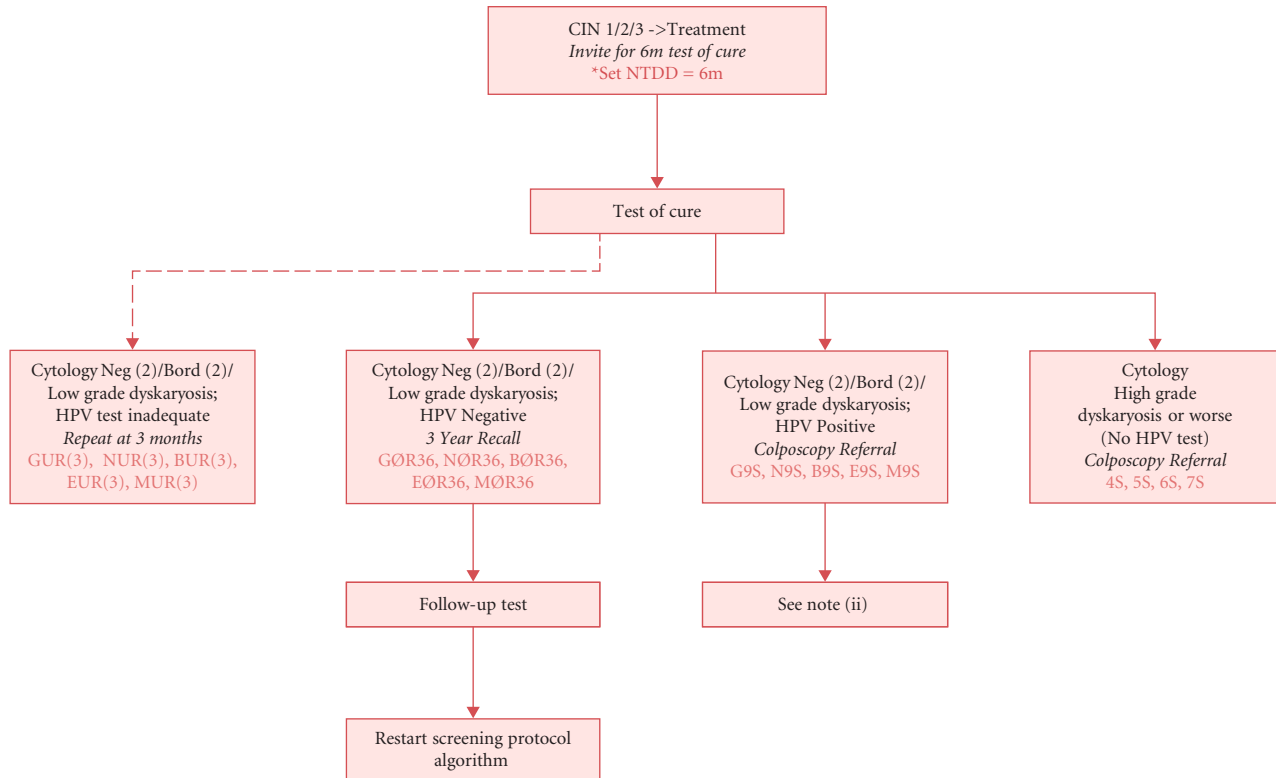

Follow-up of treated and untreated women

Test of cure

The NHS Cervical Screening Programme follow-up protocols are shown in Fig. 106.2.

High-risk HPV testing is used to predict residual or recurrent disease more quickly and accurately. After treatment for either high-grade or low-grade disease women are tested for HR-HPV. Women with negative result have a very low risk of residual disease and can be followed up as per routine 3/5-year follow-up.²⁹ Pooled sensitivity in a meta-analysis showed HR-HPV to be more sensitive than cytology (93% vs 72%). The specificity in comparison to cytology was no better.²⁸

There is no clear evidence suggesting that the diagnostic performance of cytology in combination with colposcopy for the detection of persistent disease after treatment for CIN is superior to cytology alone. However women treated for cervical glandular intraepithelial neoplasia (CGIN; see below) are at somewhat higher risk of developing recurrent disease than those with high-grade CIN.³⁰ In addition, recurrent CGIN is more difficult to detect by cytology. Smears should be taken for the same duration with the same frequency as after treatment

(ii) Women referred back to colposcopy (at TOC following treatment for CIN) due to borderline, low-grade dyskaryosis or negative cytology, who are HR-HPV positive, and who then have a satisfactory and negative colposcopy, can be recalled in 3 years.

of CIN-2/3 (minimum standard). Ideally, six-monthly smears would be taken for five years followed by annual smears for a further five years.

Management

Colposcopy

Further investigation of smear abnormalities is by colposcopy. A colposcope is a low-power binocular microscope that allows magnification from around $\times 4$ to $\times 25$. In the UK, colposcopy is a secondary investigation; in other countries that do not have organised cytological screening, it may be used as a primary tool.

It is important to recognise that the screening programme has the ability to generate considerable psychological morbidity.³¹ Appropriate counselling at the time of or before colposcopy is important, and the vast majority of women can be reassured prior to the examination that they are extremely unlikely to have cancer. This is very important to emphasise.

The cervix is first examined at low magnification ($\times 4$ – $\times 6$). A saline-soaked cotton wool ball is then applied, which moistens the epithelium, allowing the underlying blood vessels to be examined under higher magnification (preferably $\times 16$ or even $\times 25$). A green filter may be used as it makes the capillaries stand out more clearly. The shapes of the capillaries are studied and the intercapillary distances estimated. Acetic acid (3 or 5%) is then applied to the cervix. Areas of CIN

will appear as varying degrees of whiteness. This is termed ‘acetowhiteness’, in contrast to areas of hyperkeratosis or leukoplakia, which appear white before application of acetic acid. The exact reason why CIN tissue turns white with acetic acid is not fully understood. The cytoplasm becomes dehydrated so in areas of abnormality, where there is a high nuclear:cytoplasmic ratio in the cells, the nuclei become crowded and the light from the colposcope is reflected back. Such areas will therefore appear white. However, not all areas of high nuclear density are abnormal and so not all acetowhiteness necessarily correlates with CIN: areas of regenerating epithelium, subclinical papillomavirus infection and immature metaplasia may also appear acetowhite. One of the challenges facing the colposcopist is to decide which areas of acetowhiteness truly represent pre-malignancy and to avoid treating benign conditions. The classical vessel patterns of CIN are punctation and mosaicism. Bizarre-shaped vessels suggest cancer.

Another test used in colposcopy involves the application of Lugol’s iodine solution to the cervix. Normal squamous epithelium contains glycogen and stains dark brown when Lugol’s iodine is applied. Conversely, pre-malignant and malignant squamous tissue contains little or no glycogen and does not stain with iodine. This is Schiller’s test: areas that are non-staining with iodine are referred to as Schiller-positive and those that take up iodine as Schiller-negative. The test may be used following acetic acid colposcopy.

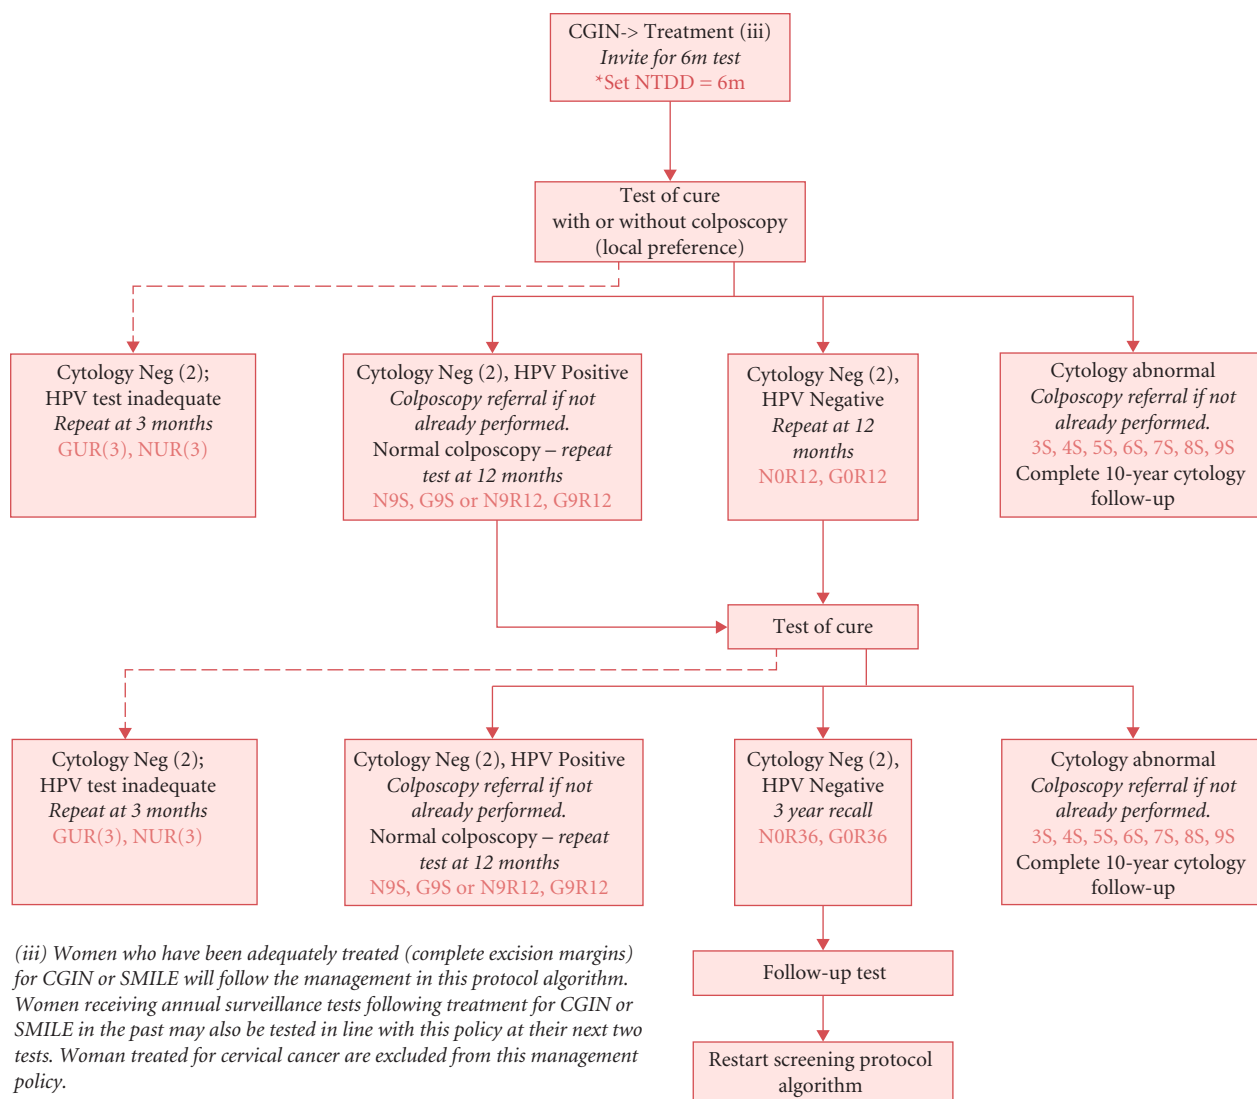

Fig. 106.2 Follow-up protocols based on HPV test of cure (from reference 26 with permission)

Dynamic Spectral Imaging System (DySIS) and Nirx are adjunctive colposcopic imaging systems that are newly available for examination of the cervix. DySIS uses photonics and computer-assisted methods to map and provide quantitative assessment of acetowhite areas. It is an objective assessment and identifies abnormal lesions to guide biopsy. It shows higher sensitivity to identify high grade lesions and NICE guidance recommends that DySIS should be considered when new colposcopic equipment is bought by the NHS as it is cost effective and works well. Nirx uses near-infrared light to scan epithelial tissue and the rebound scattered optical light is analysed to provide an image data in real time. NICE does not recommend Nirx as it is not cost effective.³²

Treatment

High-grade lesions (CIN-2/3) should be treated, but there is some debate about whether and when CIN-1 should be

treated, as a large proportion (60 per cent) will resolve spontaneously. If it is decided that treatment is needed, there are several options. Abnormal tissue can be removed (excisional techniques) or it can be destroyed (ablative techniques) (Table 106.3). Removing the entire transformation zone has the advantage of allowing a large specimen to be examined: the pathologist can comment on the most severe abnormality and can assess whether all the abnormal tissue has been removed. Destroying the transformation zone does not allow this, so it is mandatory to establish the diagnosis by taking a small biopsy before treatment. However, punch biopsy has been shown to be an inaccurate investigation when compared with subsequent loop excision from the same cervix.³³

Randomised trial data on the different methods of treating CIN do not point to one overwhelmingly superior technique.

Cryotherapy is cheap and easy to use, with low morbidity. It should be used as a double freeze-thaw-freeze

Table 106.3 Treatment modalities for cervical intraepithelial neoplasia

Excisional techniques	Ablative techniques
LLETZ – removal of the transformation zone using an electrodiathermy loop; requires local, regional or general anaesthesia	Radical electrodiathermy – burning the transformation zone; usually requires regional or general anaesthesia
Laser cone – removal of the transformation zone using the laser; requires local, regional or general anaesthesia	Cold coagulation – destroying the transformation zone by applying a probe heated to 100–120°C; usually requires local anaesthesia
Knife cone biopsy – taking a cone with a knife; usually requires regional or general anaesthesia	Cryocautery – freezing the tissue; does not require any anaesthesia
Hysterectomy – may be suitable if the woman has other gynaecological problems	Laser – vaporising the tissue; requires local, regional or general anaesthesia

technique. Success rates for treating CIN-3 vary between 77 and 93 per cent. Cryotherapy is a reasonable option for the treatment of low-grade disease, but not of high-grade disease. It may be suitable in resource-poor situations. All of the other ablative and excisional methods achieve cure (or success) rates of 90–98 per cent.³⁴ Women who are treated should be followed as per test-of-cure protocol.

Current treatments rely on the destruction or excision of affected tissue. However, with expanding knowledge about the role of HPV and the body's immune response to it, new immunological methods of disease prevention and therapy have been proposed. These aim to address the cause of the disease (i.e. HPV infection) and to either prevent (prophylactic vaccination) or treat (therapeutic vaccination) it. Prophylactic vaccination targets the viral capsid and aims to prevent infection or the early spread of infection through the production of neutralising antibody (see section on the vaccination programme and the potential for prevention). Therapeutic vaccines aim to boost the host's cell-mediated immune arm to attack established infection and have not shown efficacy to date.

Screening for HPV infection

As HPV infection is strongly implicated in the genesis of CIN and cervical cancer, it is logical to ask whether viral detection could improve the screening process. Two methods of detecting HPV that have been commonly used for population screening are the PCR and the hybrid capture system. Data from studies using earlier methodology can be disregarded. Applications of HPV testing can be at a primary or secondary level. Most published data refer to HPV testing as an adjunct to cytology and test the hypothesis that HPV detection improves the accuracy of cytology alone.^{35,36} Qualitative identification of HPV in women presenting with a high-grade smear is pointless, as the vast majority will be HR-HPV-positive anyway. It is becoming apparent that the same is true for women who have mild dyskaryosis (or LSIL). However, in women with a borderline smear, it may be more discriminatory. This is particularly so in situations in which the background prevalence of infection is lower (such as in women over 30 or 35 years of age). Testing with mRNA assays in research trials has also been used in search of a better test. The APTIMA³⁷ and Prelect

HPV-Proofer³⁸ mRNA testing has been shown to be more specific without compromising sensitivity but these markers' current ranges are lower than the full range of HR-HPV testing. Quantitative HPV estimation has been suggested as being more discriminatory than qualitative estimation. Methods of quantification vary and have limited reproducibility. Furthermore, data suggest that viral load varies in the natural history of disease and may be of limited predictive value.³⁹

Increasing knowledge of HPV and improvement in HPV-related assays have prompted consideration of using the HPV test as the primary screening method instead of the adjunct to cytology as it used now. In December 2012 a pilot study of screening using HPV as the primary tool was announced for England. The screening algorithm is detailed below. It included all women aged 25–64 on routine call/recall and early recall. The recall was 3 years for age 25–49 years and 5 years for women \geq 50 years. The routine recall was extended to 6 years for all age groups in the second year of the pilot. Fig. 106.4 shows the NHS HPV primary screening algorithm.

New data are available from a population-based cohort study using HPV testing as the primary test for cervical screening. Participation was higher in all age groups and detection rates were reported to be three times higher than cytology. The overall rate of referral to immediate colposcopy was similar to cytology, but increased by 4.6 per cent when considered together with the 1-year repeat that was done for women who were cytology negative in the first round. The 1-year repeat also contributed to 23 per cent of the CIN-2+ cases, underlying the importance of the need for high compliance with the screening algorithm. A higher specificity for CIN-2+ was reported with cut-offs of greater than 1.00 Relative Light Units/Positive Controls ratio (RLU/PC) for HC2 positivity. The benefits are the earlier detection of CIN and reduced need for repeat testing. An important concern to consider is the response of women to HPV testing and a perceived association by the public of HPV positivity with sexually transmitted infection.

Whilst HPV testing for primary screening may improve cost effectiveness and effectiveness of the colposcopy service in general one must bear in mind whether it would lead to unnecessary colposcopy and possible overdiagnosis and psychological stress. HPV screening is not recommended in women under the age of 30 due to high clearance of infection. Over 35 years HR-HPV testing mostly detects high-grade

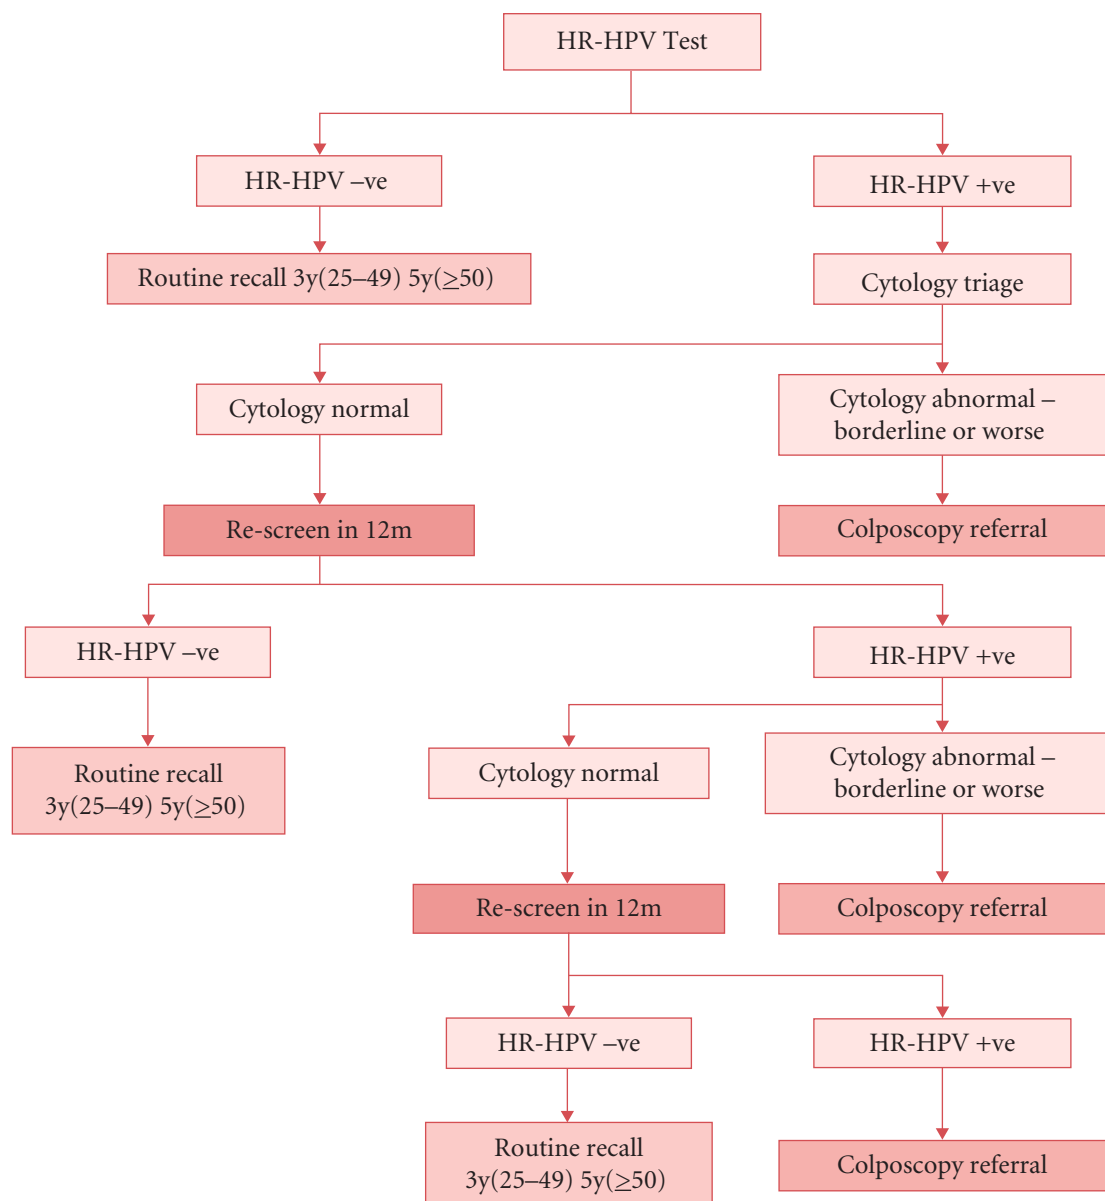

Fig. 106.3 NHS cervical screening programme: HPV primary screening algorithm (from reference 40 with permission)

non-regressive lesions and makes it beneficial. HPV testing between 30 and 35 is debatable but evidence suggests detection of more high-grade non-regressive lesions compared to cytology and hence HPV testing is being considered as beneficial.⁴¹ A systematic review of the surveys undertaken to find out if women were ready for the new screening protocol reported women to have concerns about HPV diagnosis and associated problems of disclosure of STIs and its impact on relationships. However despite the negative concerns repeat HPV testing was a preferable alternative to repeat cytology. It also highlighted the fact that much more needs to be done to educate women regarding HPV and improved information had a more positive impact.⁴² There also may be an interpretation bias of cytology as the cytologists would be aware of HR-HPV-positive results. There also may be a reluctance on the part of the clinicians to discharge patients

to community and may lead to over-interpretation of mildly abnormal colposcopies resulting in more negative biopsies being taken.

Other tests like HPV genotyping, viral load analysis, p16-INK4A staining, E6/E7 expression analysis and promotor methylation analysis of tumour suppression genes have been proposed as triage tools but so far cytology remains the best available triage tool.⁴³⁻⁴⁶ A promising alternative to cytology is p16-INK4A staining but for further confirmation larger studies are required.⁴⁷

Results are awaited from the various trials and pilot studies but it seems likely that cervical screening in future may be more HPV based than cytology. Education of women and clinicians, training, quality assurance, programme management and audits to maintain standards will all be crucial in maintaining the success of the cervical programme.

GLANDULAR PRE-INVASIVE DISEASE

Adenocarcinoma *in situ* (AIS), or high-grade cervical intraepithelial glandular neoplasia (CIGN) of the cervix, is a rare condition. It presents a particular challenge to the colposcopist, who may only see a few cases per year. Cytology screening for this condition is unsatisfactory, and the disease has no reliable colposcopic features. Diagnosis is often made by chance during the treatment of squamous pre-invasive disease, which commonly (30 per cent) coexists with AIS. Although the entire endocervical canal can be the site of disease, most lesions lie within 1 cm of the squamo-columnar junction. Skip lesions are rare, making fertility-sparing surgery a possibility, provided that endocervical margins are clear of disease. Recurrent disease occurs in 14 per cent of cases when cone margins are free of disease and rises to more than 50 per cent if the margins are involved. The method of conisation is immaterial provided that a large enough specimen is taken and that the pathologist can evaluate the endocervical and lateral margins. There are no guidelines on the optimal follow-up of conservatively managed women; however, most would recommend that regular endocervical cytology be performed in addition to conventional cytology and colposcopy.⁴⁸

KEY POINTS

- Virtually all cervical cancer is related to HPV infection [B].
- Cervical sampling now utilises liquid-based cytology.
- The treatment methods (other than cryotherapy) to eradicate CIN are all equally effective [A].
- HPV is an extremely common infection that rarely causes cancer [C].
- Organised cervical cytology with HPV testing programmes has been shown to reduce the incidence of invasive cancer [C].
- HR-HPV testing detects 30% more CIN-2+ and 22% more CIN-3+ in women over 30 years with 4-6% lower specificity.
- Negative HR-HPV test offers 50% better protection against CIN-3+ in comparison to a negative cytology.
- The screening of teenagers cannot be justified [E].
- Screening for HPV infection is not yet routinely recommended.
- Neither cytology nor colposcopy is a reliable method for detecting glandular disease [D].

THE VACCINATION PROGRAMME AND THE POTENTIAL FOR PREVENTION

Most, if not all, would now accept the central role played by oncogenic human papillomaviruses in the development of CIN and cervical cancer. Furthermore, there is also some understanding of the role played by the host's immune system

in preventing and eradicating infection. It was therefore inevitable that attempts would be made to exploit the virus's immunogenicity and develop vaccines to prevent infection.

There are now two commercially available vaccines, one a quadrivalent vaccine (Gardasil™) directed against HPV-6, -11, -16 and -18; the second is a bivalent vaccine (Cervarix™) directed against HPV-16 and -18. The design of both vaccines uses the ability of viral capsid proteins to self-assemble into virus-like particles (VLPs). The VLPs present the same antigenic signature to the host's immune system as a 'real' virus, but as they do not contain any internal DNA they are biologically non-infective and non-transforming.

Several large randomised studies have now been completed and published and they have shown that both types of vaccine effectively increase specific IgG, reduce or eliminate infection with type-specific virus and effectively eliminate pre-invasive disease related to the vaccinated subtypes.^{49,50} As we believe that up to 70 per cent of cervical cancers are the result of infections caused by either HPV-16 or -18, there is an expectation that a vaccination programme, if systematically applied, will result in a significant reduction in the burden of invasive and pre-invasive disease.

There are, however, some unanswered questions. The duration of the effect is unknown; although it would appear that it is at least 5 years.⁵¹ Recent modelling of long-term antibody persistence predicted that anti-HPV-16 and anti-HPV-18 will remain detectable for at least 20 years.⁵² An immunological-based study reported anti-HPV-16 antibodies to be persistent above those induced from natural infection for at least 12 years or potentially even for a lifetime.⁵³ These studies suggest that a booster dose may be not required. However, there is no guidance as yet as to when and how often, if any, booster vaccinations may be required. Although there is some evidence that vaccinating against one subtype may provide cross-resistance with other subtypes, we must still accept that up to 30 per cent of oncogenic subtypes remain potential threats to carcinogenesis and thus it is strongly recommended that despite the introduction of a vaccination programme, women should still be enrolled into the cervical screening programme.⁵⁴ Whether the natural spectrum of HPVs will be altered by widespread introduction of the vaccines is also unknown. There does not appear to be any evidence as yet of an increasing prevalence of non-16/18 HPV, although this effect will probably take decades to become noticeable.

The vaccines have not been shown to confer any significant benefit to those who have already been exposed to HPV and the current focus is schoolgirls aged 12 to 13 years with retrograde catch-up of older groups. The vaccination programme commenced in 2008 and is organised through schools. The NHS initially opted for the bivalent vaccine (Cervarix) and the quadrivalent vaccine (Gardasil) was available only on a private basis. The quadrivalent vaccine offers the advantage of additional protection against vulvovaginal warts. The quadrivalent vaccine, as well as protection against 16 and 18, also offers protection against HPV-6 and -11 that are responsible for causing 90 per cent of vulvovaginal warts. In

November 2011, the Department of Health (DH) announced that the UK HPV immunisation programme would switch to Gardasil. Since September 2012 the NHS has adopted Gardasil in line with DH recommendations. However, there is no evidence to suggest vaccinating boys alters CIN or HPV infection rates.

Prevention of HPV infection is a desirable goal and now, for the first time, there is clear evidence that at least some cervical cancer can be prevented. Further developments can be expected in this field and trials are underway to explore the therapeutic benefits of the vaccine. Further developments could develop, particularly in the immunological interventions. This may provide benefit to women already exposed and at risk of developing persistent disease.

VAGINAL INTRAEPITHELIAL NEOPLASIA

Pre-invasive disease of the vagina is extremely uncommon (about 150 times less common than CIN). In 70 per cent of cases of vaginal intraepithelial neoplasia (VAIN), there will be associated CIN. The average age of the woman with VAIN tends to be higher than for CIN. The major predisposing factor is the same, namely oncogenic HPV, but the reason for the lower incidence is the relative stability of the epithelium compared with the metaplastic cervical epithelium. Women exposed to diethylstilboestrol *in utero* have a higher incidence of VAIN and clear cell carcinoma of the vagina as here the areas of metaplastic transformation extend on to the vagina. Around 25 per cent of women with VAIN will have had a hysterectomy previously, for either CIN or a benign condition. Like CIN, VAIN is graded 1–3, but in common with vulval intraepithelial neoplasia (VIN), the invasive potential is less than for CIN. Treatment of VAIN-3 is by surgical excision; it is usually best removed vaginally. Small areas of VAIN can be removed with local excision or laser ablation. Prior to destructive treatment it is essential that invasion has been ruled out and it is best suited in patients where the entire lesion is visible. Medical treatment with 5-fluorouracil and imiquimod has also been described as an effective treatment.⁵⁵ Treatment of multiple lesions or involvement of the upper vaginal wall or following hysterectomy (in the vault involving suture line or dimples) may be difficult and a multimodal approach may be necessary and may even necessitate a vaginectomy which may be best performed by a combined abdomino-vaginal approach and an experienced surgeon. Chemosurgery using 5-fluorouracil prior to diathermy ablation is an experimental treatment that has shown some promising results. Radiotherapy (brachytherapy) is an alternative treatment for women who may not be suitable for surgery. Lower grades of disease can be observed. For women who have had a hysterectomy in which VAIN is seen at the vaginal vault, there may still be disease buried above the vault in the cuff that was closed over at hysterectomy. In view of this, if high-grade VAIN is detected at the vault of the vagina, it should be treated by excision rather than destruction.

KEY POINTS

- VAIN is uncommon and there is little evidence base on the subject.
- It usually coexists with CIN [D].
- The risk factors are similar to those for CIN [D].
- In-utero diethylstilboestrol exposure increases the risk of VAIN and vaginal adenocarcinoma [D].

VULVAL INTRAEPITHELIAL NEOPLASIA

Pre-malignant disease of the vulva is much less common than its cervical counterpart. HPV infection is recognised as a major factor in the aetiology of some, though not all, vulval intraepithelial neoplasia. The HPV types most commonly associated with VIN are HPV-16 and -33. HPV-associated VIN is increasing in incidence, particularly in younger women.⁵⁶ This increase may be explained by a number of factors, such as increased awareness amongst medical practitioners leading to improved detection, increased smoking by younger women, or changing sexual attitudes and increased exposure to HPV. These women should be examined for other intraepithelial neoplasia of the anogenital tract.

The pre-malignant potential of VIN has been estimated to range from 4 per cent for treated cases to 80 per cent for untreated cases.^{57,58} Most published series estimate a risk of 10 per cent or less.

VIN affects mainly the labia minora and the perineum. It can take a variety of forms and can be difficult to diagnose. Up to 60 per cent of affected women may complain of itching, soreness and burning, but many are asymptomatic and the abnormality can be a chance finding on examination.⁵⁹ The lesions may extend to the perianal and anal mucosa. Diagnosis is made by examining the vulva with a good light source, such as the colposcope at low magnification, and by taking representative biopsies. Like CIN, VIN is graded 1–3 in increasing severity of abnormal cell maturation and stratification. However, there are some striking differences between VIN and CIN (Table 106.4).

Current treatments for VIN are suboptimal in terms of their poor clinical response rates, high relapse rates and associated physical and psychological morbidities. The high recurrence rates following many therapies may reflect that they fail to remove the reservoir of HPV present in the vulval skin. Low-grade VIN should be observed. VIN-3 lesions can be treated by local excision or laser vaporisation. Recurrences of 39 and 70 per cent have been described after surgical excision and laser ablation, respectively.^{60,61}

A topical immunomodulator called imiquimod may be of use in the management of women with VIN, although it remains experimental at present. Cidofovir is also shown to have a clinical and histological response in the treatment of VIN and promises benefit.⁶² A randomised multicentre clinical trial (RT3 VIN) examines cidofovir and imiquimod in the treatment of VIN.⁶³

Table 106.4 Comparison of characteristics of vulval intraepithelial neoplasia grade 3 (VIN-3) and cervical intraepithelial neoplasia grade 3 (CIN-3)

	VIN-3	CIN-3
Proportion of cases of disease adjacent to malignancy	25%	90%
Invasive potential	Low (<10%)	Significant (40%)
Time to progress to invasion	20–30 years	10–15 years
Spontaneous regression	Up to 40%	Low

Non-HPV intraepithelial neoplasia is termed ‘differentiated VIN’ and oncogenesis involves alternative pathways to the HPV model. There appears to be an association with some inflammatory vulval epithelial disorders, such as lichen sclerosus, but the condition is poorly understood.

KEY POINTS

- VIN is uncommon and there is little evidence base on the subject.
- VIN in younger women is strongly associated with HPV [C].
- The most common presenting symptom is pruritus [D].
- Lesions may be multifocal and have a variety of appearances.
- Multicentric disease should be considered when VIN is diagnosed.
- Conservative surgery is currently the basis of treatment [E].
- Long-term follow-up is essential as recurrence is common [D].

MULTICENTRIC INTRAEPITHELIAL NEOPLASIA

There is a small group of women in whom intraepithelial neoplastic changes can be detected at more than one site in the lower genital tract. The sites involved are the cervix, vagina, vulva, perineum, anal canal and natal cleft. Although the number of women affected by multicentric intraepithelial neoplasia (MIN) is small, the number appears to be increasing, which may be a true reflection of more disease or it may be a result of increased awareness and detection. The aetiology of MIN is a combination of HPV infection and host immunosuppression of varying degrees. Patients with compromised cell-mediated immunity, such as women who have had organ transplantation or who carry HIV, often have recognisable HPV-associated changes in numerous sites in the lower genital tract. Conversely, women with humoral immunodeficiency do not have an increased risk of HPV-associated lesions.

MIN may be detected in a woman who has repeated abnormal smears despite treatment for CIN, or in a woman being assessed for VIN. Genito-urinary physicians who perform colposcopy may also encounter MIN in HIV-positive women under their care.

At the time of writing, there are no national guidelines for the management of women with MIN. Such cases are often complex and become chronic, with women sometimes having repeated surgery over several years. It is therefore important to be aware that these women may suffer adverse psychological sequelae as a result of their condition. As their numbers are small, women with MIN should be managed in large centres to concentrate experience and expertise. Investigations should be individualised, but may include multiple colposcopically directed biopsies, HPV typing, HIV testing and tests of T-cell function. Management aims to exclude invasive cancer and control symptoms while preserving anatomical and functional integrity where possible. The treatments of lesions of the vagina and vulva are described above. Lesions of the perineum and anal canal may require an initial colostomy prior to skin grafting. Such cases require a multidisciplinary team comprising a gynaecologist, colorectal surgeon, plastic surgeon, stoma nurse and possibly a psychologist.

New immunomodulating therapies currently under investigation, such as therapeutic vaccination and imiquimod, hold out some hope for women affected with MIN. Research to date suggests that they are suitable for around 30 per cent of cases and thus upholds the theory that MIN has varied causes.

KEY POINTS

- MIN is a rare condition and there is no evidence base.
- There is an association with conditions in which cell-mediated immunity is impaired [D].
- It is often a chronic, relapsing condition [D].
- The key aim of management is to do the least required to exclude invasion and control symptoms [E].

SUMMARY

Lower genital tract pre-malignancy is an important area of gynaecology. Most of the pre-cancers in this area have an association with HPV, but HPV infection is extremely common and causes no problems in the majority of individuals affected. Organised national screening seems to have been effective in reducing the incidence of, and mortality from, cervical cancer, but there has been a cost to pay in terms of over-investigation and treatment of women who have very minor changes that are unlikely ever to progress to cancer. Pre-cancers of the vagina, vulva and perineum are much less common, but require specialised skills for accurate diagnosis and appropriate management. Current treatment modalities for the pre-cancers involve ablation or excision. As our knowledge of the

aetiology of lower genital tract pre-malignancy expands, it may be possible to target the underlying cause more accurately through the use of therapeutic and prophylactic vaccinations.

Chapter 107 Endometrial cancer

Mahalakshmi Gurumurthy and Margaret Cruickshank

MRCOG standards

Theoretical skills

- Be able to describe pelvic anatomy.
- Understand the epidemiology and aetiology of malignant conditions of the uterus.
- Be able to manage pre-malignant conditions of the endometrium (including referral as appropriate).
- Be able to describe the diagnostic and imaging techniques in the diagnosis of endometrial cancer.
- Be able to describe the role of hysteroscopy and endometrial biopsy in the diagnosis of endometrial cancer.
- Be able to counsel and plan the initial management of endometrial cancer.
- Be able to describe the FIGO classification for endometrial cancer.
- Be aware of genetic abnormalities in relation to development of endometrial cancer.
- Be able to describe the indications, techniques, complications, and outcomes of oncological surgery, radiotherapy and chemotherapy.
- Understand the principles of symptom relief, palliative and terminal care.

Practical skills

- Be confident to perform outpatient endometrial biopsy.
- Be able to provide counselling to patients with endometrial cancer.

INTRODUCTION

Endometrial cancer usually arises in post-menopausal women. The incidence continues to increase in many developed countries and it is now the most common gynaecological cancer in the UK with more than 8000 cases in 2010.¹ Seventy-five per cent of women present with stage I disease and for most of them the management is surgical and the prognosis is very good.

INCIDENCE

Endometrial cancer is the fourth most common cancer in women in the UK. In 2010, there were 8288 new cases or 26 per 100,000 women per year (European age-standardised). This compares with 6531 new cases (17 per 100,000 women per year) in 2005 and 4850 new cases in 1997 (Office of National Statistics), demonstrating an upward trend in the incidence. This increase is most marked in the age group 60–79 years, while the rate in women aged less than 50 years has remained stable. Endometrial cancer is rare in women before the age of 40, at less than 2 per 100,000 women. The incidence increases between the ages of 40 and 55, thereafter reaching a plateau. The incidence of endometrial cancer is four-fold higher in developed countries and is significantly higher in Wales compared to the other constituent countries of the UK.¹

Survival has been improving and the five-year age-standardised relative survival is 77 per cent (CRC Cancer Statistics for England and Wales, 2000–2001) compared with 61 per cent for women diagnosed in 1971–75. However the survival figures remained the same between the two time periods (2005–2009 and 2000–2001). For stage I disease, there is an overall five-year survival of 85 per cent, but this falls to 25 per cent for stage IV disease.

AETIOLOGY

Women with relatively high levels of circulating oestrogens or prolonged oestrogenic influence are a recognised high-risk group for type 1 endometrial cancer. Type 1 tumours are more common and have a more favourable prognosis compared to type 2 tumours. Type 2 tumours include serous and clear-cell carcinomas which develop in association with endometrial atrophy. They are usually seen in the older patient. Type 1 tumours develop in a background of thickened endometrium and are well, moderately or poorly differentiated endometrioid tumours. They are seen in the following situations:

- obesity, due to the peripheral conversion of androgens in adipose tissue;
- tamoxifen therapy;
- oestrogen therapy unopposed by progestogens;

- polycystic ovarian syndrome (PCOS);
- early menarche and late menopause.

In contrast, type 2 endometrial cancers, which are more aggressive, have differing aetiology and pathogenesis. They are more common in post-menopausal women with a background of atrophic endometrium.

Endometrial hyperplasia (simple and complex types with or without atypia) results from protracted oestrogen stimulation. Those cases without atypia are benign, but when cellular atypia is present this is considered to be pre-malignant. The malignant progression ranges from 1 per cent for a simple hyperplasia to 25–82 per cent for complex atypical hyperplasia.

OBESITY

The rising incidence is associated with the obesity epidemic at a time when the use of HRT has fallen. This suggests that obesity is responsible for the rising incidence and everyday clinical experience confirms the increasing proportion of morbidly obese women amongst women with endometrial cancer. A recent epidemiological study has indicated that the malignancy most strongly associated with obesity is endometrial cancer.²

OESTROGEN REPLACEMENT

The use of unopposed oestrogen replacement therapy (ERT) is clearly linked to endometrial cancer and more than doubles the risk (RR 2.3 for users compared with non-users, 95% CI 2.1–2.5) [A].³ This meta-analysis of 30 studies found significant heterogeneity between the studies analysed, which was mostly due to differences in the dose and duration of oestrogen. Higher doses of oestrogen and duration of use of ten or more years have a relative risk of 9.5 (95% CI 7.4–12.3). The risk does reduce after stopping ERT and interrupted use does not lower the risk compared with daily use. This analysis clearly showed that there is a substantial risk from unopposed ERT and this should only be used for hysterectomised women.

The highest risk of HRT is for atypical endometrial hyperplasia, but there is also an effect on advanced cancer and mortality. The concurrent use of a progesterone reduces the relative risk to that of a non-ERT-user (RR 0.8, 95% CI 0.6–1.2), but the direction of this effect does vary between case-control and cohort studies. Unopposed ERT increases the rate of irregular bleeding and non-adherence to treatment [A].⁴ The addition of progesterone, whether cyclical or sequential, prevents the development of endometrial hyperplasia and improves compliance. Irregular bleeding is more likely with a continuous than with a sequential preparation (OR 2.3, 95% CI 2.1–2.5), but with longer duration of therapy, continuous is more protective than sequential in preventing endometrial hyperplasia. The UK Million Women study,⁵ a prospective cohort study

of 716,738 post-menopausal women, confirmed an increased risk in the order of 50 per cent among current users of ERT and 80 per cent in those using tibolone preparations. There was a reduced risk for ever vs never users of continuous combined therapy (RR 0.71, 95% CI 0.56–0.90, $p = 0.005$), but no significant difference in risk with combined cyclical preparations (RR 1.05, 95% CI 0.91–1.22, $p = 0.5$). BMI significantly affected these risks with the adverse effects of tibolone and ERT greatest in non-obese women, and the benefits of combined HRT greatest in obese women. The counteraction of progesterone on oestrogens on the endometrium is greater the more days every month that they are added to oestrogen and the higher the women's BMI [C].

GENETIC PREDISPOSITION

Endometrial cancer in women under the age of 45 may be associated with Lynch type II familial cancer syndrome, which is known as hereditary non-polyposis colorectal cancer (HNPCC). There does not appear to be a site-specific inherited form of endometrial cancer, but it is associated with a genetic predisposition as a component of the HNPCC syndrome. Families affected with this syndrome have a predisposition to bowel cancer and also to ovarian tumours. The other tumours associated with this syndrome are of small bowel, pancreas, skin and brain. A retrospective cohort study in Australia found that around one quarter of women with Lynch-associated colon cancer over the age of 70 developed endometrial cancer.⁶

PATHOLOGY

The uterine corpus lies above the level of the internal cervical os and is composed of the fundus above the tubal ostiae and the body below. The blood supply is the uterine artery, a branch of the anterior division of the internal iliac artery. There is collateral blood supply via the tubal artery from the ovarian artery, a direct branch from the aorta. Correspondingly lymphatic drainage from the fundus of the uterus drains to the para-aortic nodes at the level of the renal veins. The lymphatic drainage from the body of the uterus passes with the uterine artery to the internal, external and common iliac nodes and obturator fossa nodes.

The FIGO Committee on Gynaecological Oncology recommends that endometrial cancer is surgically staged.⁷ This includes histological verification of the tumour type, grading and the extent of tumour. The degree of tumour differentiation has an important impact on the natural history of the disease and on treatment selection. Ninety-five per cent of uterine cancers are adenocarcinomas arising from the endometrium. They are graded with regard to the degree of cell differentiation (Table 107.1).

Table 107.1 Grading of tumour differentiation

G1	5% or less of a non-squamous or non-morular solid growth pattern
G2	6–50% of a non-squamous or non-morular solid growth pattern
G3	50% or more of a non-squamous or non-morular solid growth pattern

Notable nuclear atypia that is inappropriate for the architectural grade raises it to the next tumour grade. Nuclear grading takes precedence in serous and clear-cell adenocarcinomas. Histopathological reporting should include:

- depth of myometrial invasion;
- tumour grade;
- histological subtype;
- presence or absence of hyperplasia in adjacent non-neoplastic endometrium;
- lymphovascular space invasion;
- lymph node involvement;
- involvement of cervix or adnexae;
- the status of peritoneal washings taken at surgery.

There are clearly recognised risk factors for lymph node involvement, distant metastasis and poor survival. These are tumour grade, non-endometrial tumour, deep myometrial invasion and lympho-vascular invasion. Papillary serous adenocarcinomas and clear-cell carcinomas are high-risk subtypes and they are associated with about 50 per cent of all relapses. Their five-year survival rates are 27 and 42 per cent, respectively. Mucinous, squamous and undifferentiated tumours are rare.

Histopathology by WHO/International Society of Gynaecological Pathology classification

WHO classification of endometrial carcinomas (2003):

- Adenocarcinoma
- Endometrioid
- Variant with squamous differentiation
- Villoglandular variant
- Secretory variant
- Ciliated cell variant
- Mucinous
- Serous
- Clear cell
- Mixed cell carcinoma
- Squamous cell carcinomas
- Transitional carcinomas
- Small cell carcinoma
- Undifferentiated carcinoma
- Carcinosarcoma

PRESENTATION AND DIAGNOSIS

Endometrial cancer usually presents with vaginal bleeding in post-menopausal women. Post-menopausal bleeding (PMB) is defined as bleeding from the genital tract one or more years after a woman's last period. Women who continue to menstruate after the age of 55 also merit investigation. Up to 10 per cent of women with PMB will have an endometrial carcinoma. The likelihood of an underlying cancer increases with age at presentation.

INVESTIGATION OF POST-MENOPAUSAL BLEEDING

Most women with PMB can be investigated effectively and safely as outpatients.

Transvaginal ultrasound scanning is an accurate method of excluding endometrial cancer [B]. Women can be assessed quickly and triaged for endometrial biopsy on the basis of their scan findings. TVS limits the need for endometrial biopsy to women with an endometrial thickness of ≤ 5 mm, an irregular endometrial outline or fluid within the uterine cavity. The majority of women have a thin, regular endometrium and can be reassured at a first visit without further investigation. A meta-analysis⁸ summarised accuracy data using likelihood ratios for various cut-off levels of abnormal endometrial thickness (measuring the thickness of both layers). The most common cut-offs were 4 mm (nine studies) and 5 mm (21 studies). Using the pooled estimates from four studies which used the best-quality criteria, a thickness of >5 mm raised the probability of carcinoma from 14.0 per cent (95% CI 13.3–14.7) to 31.3 per cent (95% CI 26.1–36.3) and a thickness <5 mm reduced the risk to 2.5 per cent (95% CI 0.9–6.4) [A]. This reduces the need for further intervention, service costs and patient anxiety, and provides rapid reassurance for those women with a normal result.

There are a number of devices for taking outpatient endometrial biopsies which have been compared in prospective studies. Samples taken by Pipelle are comparable with the Vabra and Novak aspirators in terms of specimen adequacy and diagnostic accuracy. In addition, this method produces less patient discomfort. Dilatation and curettage (D&C) is no longer recommended for the investigation of PMB.⁹ However, hysteroscopy with biopsy is preferable as the first line of investigation in women taking tamoxifen who experience post-menopausal bleeding.⁹ Hysteroscopy is often used to investigate PMB, as it allows direct inspection of the endometrium. It can detect 95 per cent of intrauterine abnormalities and is a sensitive means of identifying polyps and sub-mucous fibroids [B]. It can be used in the outpatient setting, and outpatient hysteroscopy is highly acceptable to women [B], although general anaesthesia may sometimes be necessary.

Dedicated PMB clinic

A dedicated clinic allows rapid assessment and reassurance for women with PMB using a one-stop clinic approach. Most clinics provide TV scanning by appropriately trained staff. Women with a history that meets the criteria of PMB can be fast-tracked to this service, with written information provided in primary care prior to their visit. The diagnosis of cancer can be excluded for most women at their first visit. Endometrial biopsy and outpatient hysteroscopy should be provided for those women with an abnormal scan result at their first assessment. The majority of consultant gynaecologists in a Scottish audit supported such outpatient investigation [C].

EBM: Diagnosis of endometrial cancer

- A meta-analysis of 35 studies found TVS scanning to be an accurate means of excluding endometrial cancer.
- Initial assessment of PMB should be provided as an outpatient service and TVS used to assess the endometrium.
- Seven prospective studies have evaluated TVS in women with PMB, comparing it against D&C or outpatient endometrial biopsy.
- The cost effectiveness and clinical effectiveness of outpatient investigation of PMB have not been evaluated.

WOMEN ON TAMOXIFEN

Tamoxifen is a non-steroidal oestrogen antagonist, which is used widely as adjuvant treatment for post-menopausal women who have breast carcinoma. The absolute improvement in recurrence is greatest during the first five years of treatment [A].⁹ Tamoxifen has been shown to decrease the overall progression of the disease and to prevent disease in the contralateral breast. Long-term tamoxifen use is controversial due to its oestrogenic effects on the endometrium. Although it acts as an anti-oestrogen on breast cancer cells, it has a mild oestrogenic effect on the endometrium, bone and cardiovascular system.

Long-term use is associated with proliferative endometrium, and a spectrum of benign and malignant changes of the endometrium has been reported, including hyperplasia, polyps and carcinoma. The incidence of endometrial carcinoma in post-menopausal women taking tamoxifen is significantly higher than in women not on tamoxifen [A].¹⁰

However, the absolute decrease in contralateral breast cancer is twice as large as the absolute increase in endometrial cancer, and overall the benefits of tamoxifen are greater than the risks.

Post-menopausal women who have a uterus and are taking tamoxifen should be advised of these effects.

Abnormal bleeding needs to be investigated fully and promptly. A Pipelle biopsy is appropriate as the first line of investigation, but a negative result is not conclusive. Women with a negative result still require hysteroscopy. TVS can be useful in triaging the urgency of further investigation. The fact that the ultrasonic appearances can be misleading needs to be considered. Tamoxifen has a sono-translucent effect on both the endometrial stroma and the myometrium. This can give rise to false-positive reports in cases of cystic atrophy, which appears as thickened cystic endometrium on scan. Histology confirms this to be multiple cystic spaces lined by atrophic epithelium within a dense fibrous stroma. Hysteroscopy may be the investigation of choice in this situation as it allows direct inspection of the endometrium, and full-thickness biopsies can be taken at the same procedure.⁷

There is no evidence that asymptomatic women on tamoxifen should be screened for endometrial changes [C]. Asymptomatic women taking tamoxifen have a greater endometrial thickness on TVS scan. Comparatively, those who present with bleeding have a significantly thicker endometrium and are more likely to have endometrial pathology [B]¹¹ and women with endometrial pathology are also more likely to present with symptoms. Outpatient hysteroscopy, although a good screening tool, is not as useful when biopsies are necessary. A randomised, cross-over study comparing TVS with outpatient hysteroscopy found the former together with sonohysterogram more sensitive, specific and acceptable to women.¹² There is no clinical or cost-effectiveness evidence to support the endometrial screening of asymptomatic women on tamoxifen [B], and the benefit in terms of breast cancer mortality far outweighs the risk to the endometrium. The evidence, however, is less clear for healthy women taking tamoxifen to reduce their risk of breast cancer. The International Breast Cancer Intervention Study 1 (IBIS 1)¹³ reported on the risk:benefit ratio of tamoxifen as preventative treatment in women at increased risk of breast cancer. This trial randomised 7145 women aged 35–70 years to five years of tamoxifen or placebo. There was a non-significant increase in endometrial cancers in the tamoxifen group. Although there was a 32 per cent risk reduction in breast cancer, the risk:benefit ratio was not clear due to increased deaths from other causes, including thromboembolic disease. An earlier American trial, the Breast Cancer Prevention Trial (BCPT-P-1), was stopped early when a 45 per cent decrease in new breast cancers was reported in the tamoxifen arm. There was also an increase in endometrial cancers. Newer selective oestrogen receptor modulators (SERMs) have a similar profile to tamoxifen without the uterotrophic effects. The IBIS 2 trial is looking into the effects of anastrozole (aromatase inhibitor) on breast cancer prevention in post-menopausal women. It will be interesting to await the results of the effects of anastrozole on breast and endometrium.

EBM: Tamoxifen and the endometrium

- A systematic review of 55 RCTs of adjuvant tamoxifen vs no tamoxifen before recurrence and with at least five years of follow-up data shows that tamoxifen substantially improves the ten-year survival of women with oestrogen-receptor-positive breast cancer. It also found that the incidence of endometrial cancer increases by a factor of 2 at one to two years and by a factor of 4 after five years of tamoxifen treatment.
- There is no evidence to support the screening of asymptomatic women on tamoxifen for endometrial abnormalities.

STAGING

The staging of endometrial cancer is surgico-pathological. Tumour grade and the depth of myometrial involvement are the main determinants of extrauterine spread. These two pathological criteria along with extensive lympho-vascular space invasion are often used to determine the risk of recurrence and to select women for postoperative radiotherapy. Metastatic spread occurs characteristically to the pelvic nodes initially and in 4 per cent of cases could have isolated para-aortic lymph node involvement. Distant metastasis is uncommon at presentation. The most common sites of distant spread are the vagina and lungs, but the inguinal and supraclavicular lymph nodes, liver and brain may also be involved. (See Table 107.2.)

Radiological imaging

Pre-operative evaluation and planning for treatment require clinical staging. The risk of pelvic and para-aortic lymph node involvement depends on the stage, grade and myometrial invasion. Twelve per cent of women with stage I disease will have lymph node metastasis. With grade 3 disease, this rises to 18 per cent, and when there is deep myometrial involvement, to 22 per cent. Without proper assessment and a treatment plan based on the risk of nodal disease, the prognosis is poorer [C].¹⁴

Endometrial biopsy will already have confirmed the diagnosis and given information on the tumour grade. Myometrial invasion can be assessed by TVS or MRI. TVS can assess the depth of myometrial invasion and can be used to triage women for appropriate management at a cancer centre or cancer unit. Although TVS is quicker and relatively cheap, it is less accurate than MRI. MRI appears to be the optimum method of evaluating the soft-tissue structures of the pelvis, including myometrial invasion and the status of the pelvic lymph nodes with acceptable accuracy and specificity, although micrometastasis will not be detected, reducing the overall sensitivity. CT scanning is less useful in imaging these

Table 107.2 FIGO tumour classification 2009

Stage I^a	Tumour confined to the corpus uteri
IA ^a	No or less than half myometrial invasion
IB ^a	Invasion equal to or more than half of the myometrium
Stage II^a	Tumour invades cervical stroma, but does not extend beyond the uterus ^b
Stage III^a	Local and/or regional spread of the tumour
IIIA ^a	Tumour invades serosa of the uterus and/or adnexae ^c
IIIB ^a	Vaginal and/or parametrial involvement ^c
IIIC ^a	Metastasis to pelvic and/or para-aortic lymph nodes
IIIC1	Positive pelvic nodes
IIIC2	Positive para-aortic lymph nodes with or without positive pelvic nodes
Stage IV^a	Tumour invades bladder and/or bowel mucosa and/or distant metastasis
IVA ^a	Invasion of bladder and/or bowel mucosa
IVB ^a	Distant metastasis, including intra-abdominal and/or inguinal lymph nodes
^a G1, G2 or G3.	
^b Endocervical glandular involvement only should be considered as stage I and no longer as stage II.	
^c Positive cytology has to be reported separately without changing the stage.	

soft tissues. The results are similar in predicting nodal disease, but less accurate at assessing the depth of myometrial invasion [B] and cervical involvement, but may be useful for women with high-risk histology to detect extra-pelvic disease. A chest X-ray should also be performed for staging, as the lungs are a common metastatic site.

Endometrial cancer imaging

MRI is the imaging method of choice for pre-treatment staging to assess myometrial invasion, cervical involvement and lymph node status.

MANAGEMENT

Women with disease localised to the corpus are usually curable by surgery. There are variations in the definition of intermediate and high risk, but the high-risk group generally includes deep myometrial invasion and grade 3 tumours including the type 2 tumours. High-risk features are associated with a poorer prognosis because of the increased risk of nodal disease and recurrence.

Women with endometrial cancer are often elderly with other medical problems, and pre-operative assessment for fitness for an anaesthetic and surgery is essential. Survival rates are reduced by 20 per cent when primary surgery is not feasible.

Early-stage disease

Most women present with early-stage disease and primary surgery is fundamental to achieving a cure. As laparoscopic surgery has become a common surgical practice, the treatment of choice should be total laparoscopic hysterectomy and bilateral salpingo-oophorectomy (TLH/BSO) if possible. It is not necessary to remove a vaginal cuff or parametrial tissue for early-stage disease [C]. Recurrence at the vaginal vault is related to recognised risk factors and particularly cervical stromal involvement – factors that reflect lymphatic vessel involvement. Endocervical glandular involvement only is now considered as stage I disease. Additional staging for type 2 tumours and high-grade type 1 tumours should be done which includes omental biopsy and peritoneal washings. Para-aortic lymph node dissection for stage I high-grade tumours is still contentious and not practised routinely.

Stage II disease could be treated the same as stage I disease by TLH/BSO or total abdominal hysterectomy (TAH)/BSO. Sometimes when there is obvious cervical stromal involvement on imaging, the treatment options are modified radical hysterectomy (Piver II) or radical hysterectomy with pelvic lymphadenectomy (Piver III) or TAH/BSO with lymphadenectomy followed by post-operative radiotherapy. However, lymphadenectomy and radiotherapy do carry the additional morbidity of lymphoedema which can develop years after treatment.

The choice of treatment depends on the tumour site, size and the fitness of the patient when considering the feasibility of extirpative surgery. The LAP-2 trial comparing laparoscopy versus laparotomy for surgical management of women with stage I–IIA uterine cancer (FIGO 2003 staging) found laparoscopic surgical management to be superior for short-term safety and length of stay. Laparoscopy was associated with similar overall and disease-free survival compared to laparotomy.¹⁵ This has been highlighted in the Cochrane review supporting laparoscopy in the initial surgical management of women with endometrial cancer.¹⁶

Role of lymphadenectomy

The role of pelvic lymphadenectomy has been advocated to improve surgical staging, but there is no clear evidence that it improves survival or that it rationalises the use of radiotherapy by excluding extrauterine disease. A recently reported RCT (MRC ASTEC trial) on the management of endometrial cancer¹⁷ has shown that lymphadenectomy did not improve recurrence-free, disease-free or overall survival. The hazard ratio (adjusted for baseline characteristics and pathology) was 1.04 (0.74–1.45; $p = 0.83$) and for recurrence-free survival was

1.25 (0.93–1.66; $p = 0.14$). The rate of reported post-surgical morbidity in ASTEC was low, but there were more cases of ileus, deep venous thrombosis (DVT), lymphocyst and major wound dehiscence reported in the women who had been randomised to lymphadenectomy.

Another large RCT of lymphadenectomy in endometrial cancer was reported just prior to ASTEC. In this Italian trial,¹⁸ there was again no evidence of a survival benefit despite improved surgical staging in the lymphadenectomy arm (13.3 vs 3.2 per cent). These trials indicate that routine lymphadenectomy is not beneficial in early-stage endometrial cancer.

Who should perform surgery?

Endometrial cancer categorised as low risk following full pre-operative assessment can be safely treated by TLH/BSO or TAH/BSO by a general gynaecologist with a cancer lead status. Women with high-risk disease with a risk of cervical or pelvic node involvement or type 2 tumours should be referred to a specialist gynaecological oncologist.

Role of radiotherapy

There have been no RCTs comparing surgery and primary radiotherapy. Women with intermediate- or high-risk early-stage disease considered to be at increased risk of recurrence are often given post-operative adjuvant radiotherapy.

Moderate and high risk patients include:

- 1b, G3;
- type 2 (serous papillary, clear cell) with any myometrial invasion;
- grade 3, ≥ 60 years with any myometrial invasion;
- $>50\%$ myometrial invasion, grade 1/2, ≥ 60 years;
- stage II (any grade).

The main role for radiotherapy is as adjuvant treatment following surgery to reduce the risk of pelvic relapse. Radiotherapy cure can be achieved in women with early-stage disease who are entirely unfit for surgery, but this is suboptimal treatment with risks of intrauterine failure.

Vault brachytherapy is used to prevent vault recurrence, and external-beam therapy to the pelvis is used to treat the parametrium and pelvic sidewalls. It should be remembered that there is no evidence to show that radiotherapy improves survival in an unselected patient population. A meta-analysis of over 2000 patients in RCTs on the management of endometrial cancer (MRC ASTEC/EN.5, PORTEC 1 and GOG 99)¹⁹ has shown no benefit from external-beam radiotherapy for early-stage endometrial cancer at intermediate and high risk in terms of disease-specific, recurrence-free or overall survival. Although there is a small reduction in isolated local pelvic recurrence, this does not confer any advantage to overall or recurrence-free survival. A meta-analysis of five randomised trials from Johnson and Cornes (2007) found a statistically significant survival advantage for patients

receiving external-beam radiotherapy following hysterectomy for high-risk tumours (Ic grade 3; FIGO 2003 staging²⁰). The isolated local recurrence rate without external-beam radiotherapy is small and can be reduced with local brachytherapy which is associated with less toxicity.

The recently reported post-operative radiation therapy in endometrial carcinoma (PORTEC)-2 trial has shown that brachytherapy is as effective as external-beam radiation in high-intermediate-risk patients with fewer radiation effects and should be the treatment of choice for these women.²¹

Currently, women are selected with care for post-operative radiotherapy because of the impact of the treatment regime and the associated complications related to quality of life. The incidence of bowel complications is 3 per cent and can be higher after pelvic lymphadenectomy. The PORTEC trial²² reported treatment-related complications in 25 per cent of radiotherapy patients, although a fifth of these were grade 1. Most of the complications were associated with the gastrointestinal tract. The symptoms resolved after some years in 50 per cent of women. Grade 1–2 genito-urinary symptoms occur in 8 per cent of women treated by surgery and radiotherapy, compared with 4 per cent of women treated by surgery alone. Two per cent of women discontinued radiotherapy due to acute related symptoms. In addition, patients with acute morbidity have an increased risk of late radiotherapy complications, including rectal bleeding, fistulae or radiation damage to the small or large bowel.

The prognosis for most women with endometrial cancer is good, and therefore any impact of radiotherapy on survival will come from salvaging the small number of patients who develop a pelvic recurrence.

Progesterone therapy

Progesterone therapy for women who have had surgery for early-stage endometrial cancer is not recommended, as overall survival is not improved [A].²³ Although deaths from endometrial cancer (OR 0.88, 95% CI 0.71–1.01) and the rate of disease relapse are reduced (OR 0.81, 95% CI 0.65–1.01), non-endometrial cancer-related deaths are more common (OR 1.33, 95% CI 1.02–1.73) [C]. However, progesterone therapy (either as a Mirena coil or high-dose medroxyprogesterone acetate) as a primary treatment of complex atypical hyperplasia and grade 1 stage IA endometrial cancer for women who wish to retain fertility or in inoperable cases has been used.

Hormone replacement therapy

Traditionally, ERT has not been advocated in the first two years following surgery for endometrial cancer because of the concern of activating any residual disease. However it is advisable to avoid ERT in women with endometrial stromal sarcoma, which are highly oestrogen-dependent tumours. There is, however, no evidence to support this, and the benefits of ERT may outweigh any theoretical risks [C]. In

women aged 45 years or less, treated for early-stage disease, ovarian preservation has no effect on cancer-specific survival (HR 0.58, 95% CI 0.14–2.44) or overall survival (HR 0.65, 95% CI 0.34–1.35).²⁴

Advanced-stage disease

At presentation, only 13 per cent of women have stage III and 3 per cent stage IV disease. In general, women with stage III disease have been treated with surgery and radiation or radiotherapy alone. Treatment with chemotherapy is increasing and is discussed below. Laparotomy will allow staging and tumour-reductive surgery including hysterectomy if possible. However, side-wall extension will prevent tumour resection. Radiotherapy is used when surgery is inappropriate or incomplete. This may be a combination of intracavitary and external-beam radiation, and cure rates of 30 and 20 per cent for stage III and IV disease, respectively, have been reported. If the woman is not fit for either surgery or irradiation, progesterone therapy is appropriate [C]. If radiotherapy achieves significant tumour shrinkage, ‘adjuvant’ surgery should be considered.

With stage IV disease, the tumour site and the resultant symptoms will dictate management. Chemotherapy is usually offered first. Bulky pelvic disease or heavy vaginal bleeding may be controlled by radiation, either intracavitary or external beam, or in combination. Local radiation can palliate symptomatic metastasis (e.g. to the lung, brain or bone).

Role of chemotherapy

There is no evidence that chemotherapy has an adjuvant role in primary treatment of low-risk disease. There is emerging evidence from phase 2 and 3 trials to support the selection of intermediate or high-risk women or those with advanced disease for adjuvant chemotherapy. The diagnosis of advanced endometrial cancer confers a relatively poor prognosis. Traditionally, treatment for women with stage III endometrial cancer has relied on radiotherapy, while women with stage IV disease have been treated with palliative chemotherapy. There has been a gradual shift towards incorporating chemotherapy into the treatment of women with stage III and IV endometrial cancer. There has been a series of Gynecologic Oncology Group (GOG) phase 1–3 studies to investigate the effectiveness of different combinations of chemotherapeutic agents for systemic control of disease with or without radiotherapy for enhanced loco-regional control. Acute and chronic toxicities are higher in women treated with chemotherapy rather than radiotherapy alone, but with improved response rates. The most effective agents for endometrial cancer appear to be carboplatin and paclitaxel. Two prospective randomised trials have demonstrated a superior response rate to doxorubicin and cisplatin as compared with doxorubicin alone; however, survival rates for the two regimens were similar. More recently, paclitaxel has been included in triplet regimens. When combined with a platinum agent, response rates of greater

than 40 per cent have been reported. A doublet regime of doxorubicin and paclitaxel has been investigated by the GOG (GOG 163) as an alternative to doxorubicin and cisplatin for women with advanced or recurrent disease. Both regimes had similar response and survival, but there was no difference in progression-free or overall survival. The most recent GOG trial compared doxorubicin and cisplatin to doxorubicin, cisplatin and paclitaxel. The triplet regimen had a statistically significant improved response rate, progression-free and overall survival, but at the cost of higher toxicity. The GOG is currently conducting a trial (GOG 209) comparing paclitaxel and carboplatin to doxorubicin, cisplatin and paclitaxel in women with advanced or recurrent disease because, if equivalent, paclitaxel and carboplatin are less toxic.

PORTEC-3,²⁵ a randomised phase 3 trial comparing concurrent chemoradiation plus adjuvant chemotherapy with pelvic radiation alone, in high-risk and advanced-stage endometrial cancer, opened in 2008 and aims to recruit 500 women over five years. For clear-cell endometrial cancer, a review by the Society of Gynecologic Oncology²⁶ recommends comprehensive surgical staging and platinum-based adjuvant chemotherapy with taxol and/or doxorubicin. Radiotherapy has not been shown to be clearly beneficial for clear-cell endometrial cancer.

EBM: Treatment of endometrial cancer

- Two surgical RCTs relating to early-stage endometrial carcinoma with intermediate- or high-risk features show that pelvic lymphadenectomy does not increase survival and is not recommended as a routine in addition to TLH/BSO.
- Two meta-analyses show that laparoscopic surgery is as clinically effective as abdominal hysterectomy and is associated with lower post-operative morbidity, although operating time is longer.
- A meta-analysis has shown adjuvant radiotherapy reduces the rate of pelvic recurrence, but without any improvement in overall survival and a 50 per cent increase in moderate and severe complications and late radiotherapy sequelae.
- A meta-analysis of six RCTs and a large RCT have both shown no reduction in death rates for endometrial cancer with progesterone therapy.
- The use of combined chemotherapy appears beneficial in women with high-risk histological tumours, but with increased toxicity.

PROGNOSIS

Survival is related to stage at presentation and grade of tumour (Table 107.3). There is a wide variation in rates of recurrence with early-stage disease, from 10 per cent in low-risk women (stage Ia G1 disease) to almost 50 per cent in

Table 107.3 Five-year survival rates for endometrial adenocarcinoma by stage

Stage	Five-year survival (%)
Stage I	80
Stage II	65
Stage III	30
Stage IV	10

high-risk women (stage Ic G3 disease). The latest revision of FIGO staging reflects more clearly clinically relevant factors. When the only evidence of extrauterine spread is positive peritoneal washings, the influence on outcome is unclear, and there is no evidence that adjuvant therapy is of value unless extrauterine disease is present [C].^{27,28}

PALLIATIVE CARE

Palliation for women with endometrial cancer should be approached with a multidisciplinary team and in a holistic way. This should be discussed with women who have advanced-stage disease with a poor ECOG performance status or widespread recurrence. (Eastern Cooperative Oncology Group is used to assess functional status of a patient. It is graded from 0-5 with 0 being the ideal performance status and 5 corresponds to death). Palliative care could be offered in the secondary care, respite or community setting. The multidisciplinary team comprises the gynaecological oncologist, cancer nurse specialist, medical and clinical oncologists, palliative care team, GP and the community team. Vaginal bleeding can be controlled initially with high-dose progestogens but if heavy or uncontrolled, radiotherapy may be used with palliative intent. Various other symptoms include nausea, constipation, poor appetite and pain. A decision for a palliative approach should be discussed with the woman and her family by the oncological team. Access to the cancer nurse specialist and the community team should be offered to the woman.

Recurrent disease

Women with recurrence limited to the pelvis who have not previously received radiotherapy may be salvaged by radiotherapy, with a five-year survival of about 25–50 per cent. For women with localised vaginal vault recurrence following external beam radiotherapy and who have an acceptable ECOG performance status; the decision for pelvic exenteration should be considered after in depth discussion by the Multidisciplinary team. Para-aortic lymph nodes may be palliated by radiotherapy and, as with localised pelvic recurrence, this can be curative when there has been no previous irradiation. The prognosis for distant metastatic endometrial cancer is poor and management concentrates on symptom control.

KEY POINTS

- Investigation of PMB should be provided as a rapid-access outpatient service.
- Understand the two types of endometrial cancer (type 1 and type 2) and their differing management.
- The benefits of tamoxifen in breast cancer treatment outweigh the increased risk of endometrial cancer. Any abnormal vaginal bleeding while on tamoxifen requires full investigation.
- Surgery with total laparoscopic hysterectomy and bilateral salpingo-oophorectomy offers good prognosis in early-stage disease, but routine systematic pelvic lymphadenectomy is not recommended as it does not improve survival.
- Endometrial carcinoma is radiosensitive, but the benefits of loco-regional control from external-beam radiotherapy do not improve survival and it is not recommended for early-stage intermediate-risk endometrial cancer (<Ib, G3).
- Adjuvant radiotherapy should be restricted to early-stage high-risk disease and advanced disease.
- Combined chemotherapy has an increased role in the treatment of high-risk endometrial cancer.
- Progesterones will produce a clinical response in about 20 per cent of women with recurrent disease [C] and appear to be more effective in women with a long disease-free interval prior to recurrence. Standard agents are megestrol and medroxyprogesterone. Chemotherapy may have a limited palliative role for women with advanced or recurrent disease not amenable to radiation.

SUMMARY

Endometrial cancer usually presents with PMB at an early stage. Staging is surgical/pathological, and pre-operative imaging should include a chest X-ray and imaging for depth of myometrial penetration. Early-stage disease should be managed by TLH and BSO, with peritoneal washings which are reported separately, but without changing the stage. Pelvic lymphadenectomy is not recommended. While post-operative radiotherapy reduces the rate of local recurrence, it does not improve overall survival and it is associated with increased toxicity. Brachytherapy is the adjuvant treatment of choice for high-intermediate-risk disease with external-beam radiation being restricted to high-risk early disease.

Chapter 108 Cervical cancer

Pierre L Martin-Hirsch

MRCOG standards

The established standards relevant for this topic are:

Theoretical skills

- Revise the anatomy of the cervix, blood supply and lymphatics.
- Understand the epidemiology and pathology of disease.
- Know the optimum pre-treatment assessment.
- Know how to manage surgically and non-surgically.

Practical skills

- Be able to recognise suspicious cervical lesions.
- Be able to take appropriate diagnostic biopsies.
- Be able to counsel patients with regard to diagnosis, management options and prognosis.

EPIDEMIOLOGY

Cervical cancer is the most common form of cancer in women in developing countries and the third most common form of cancer in women in the world as a whole. Three quarters of affected women live in developing countries and it is estimated that up to 450,000 new cases of invasive cancer of the cervix occur per year in these countries, leading to 275,000 deaths. Cervical cancer accounts for 6 per cent of all malignancies in women.

There were an estimated 11,818 new cases of invasive cancer of the cervix and 3939 deaths in the United States in 2010. In the United Kingdom in 2010, there were 2851 registrations and 972 deaths. Although cervical screening has been carried out in the UK since the 1960s, the benefits of screening are only now becoming apparent, following the reorganisation of the service in 1988. The incidence of cervical cancer has fallen in the UK by 44 per cent since 1975, and mortality from 7.1 per 100,000 in 1988 to 2.4 per 100,000 in 2011.

This decrease is almost certainly due to the widespread coverage of screening, which rose from less than 35 per cent in 1988 to 85 per cent in 1998 through the introduction of an effective call–recall system for cervical screening. The reduction in deaths is due to a reduction in both incidence and the proportion of advanced disease with around a third of cancers being diagnosed as stage I. The incidence rate for cervical cancer peaks at 17 per 100,000 women at the age range of 30–40 years, declines in incidence for older age groups but peaks again in the early 80s age band.

Epidemiological studies convincingly demonstrate that the major risk factor, indeed a necessary event, for the development of pre-invasive and invasive carcinoma of the cervix is human papillomavirus infection, which far outweighs other known risk factors such as high parity, increasing number of sexual partners, young age at first intercourse, low socioeconomic status and positive smoking history. In an international study consisting of 1000 specimens collected from patients with invasive cervical cancer in 32 hospitals in 22 countries, HPV DNA was present in 99.7 per cent of cervical cancers.¹ HPV-16 was the predominant type in all countries except Indonesia, where HPV-18 was more common.¹ The advent of prophylactic vaccines directed against types 16/18 HPV could reduce the incidence of cervical cancer by at least 70 per cent in a high-coverage population.²

PATHOLOGY

Squamous cell and adenosquamous carcinomas comprise approximately 85 per cent and adenocarcinoma approximately 15 per cent of cervical cancers. Squamous carcinomas are large-cell keratinising, large-cell non-keratinising and small-cell types. The rare but dangerous small-cell neuroendocrine type typically behaves like similar disease arising from the bronchus. Adenocarcinomas can be pure or mixed with squamous cell carcinomas – the adenosquamous carcinoma. About 80 per cent of cervical adenocarcinomas are made up of cells of the endocervical type with mucin production. The remaining tumours are populated by endometrioid, clear cell, intestinal or a mixture of more than one type of cell.

KEY POINTS

- Cervical cancer is the most common form of cancer in women in developing countries.
- The incidence of and deaths from cervical cancer are decreasing in the UK due to cervical screening.
- HPV DNA is present in virtually 100 per cent of cervical cancers.
- Squamous cell and adenosquamous carcinomas comprise approximately 85 per cent and adenocarcinomas approximately 15 per cent of cervical cancers.

CLINICAL MANAGEMENT

The goals of the management of cervical cancer are to stage the disease and to treat both the primary lesion and other sites of spread. Cervical cancers spread by direct spread into the cervical stroma, parametrium and beyond, and by lymphatic metastasis into parametrial, pelvic sidewall and para-aortic nodes. Blood-borne spread is unusual. Among the major factors that influence prognosis are:

- stage;
- volume;
- grade of tumour;
- histological type;
- lymphatic spread;
- vascular invasion.

In a large surgico-pathological staging study of patients with clinical disease confined to the cervix, the factors that predicted lymph node metastases and a decrease in disease-free survival were capillary–lymphatic space involvement by tumour, increasing tumour size and increasing depth of stromal invasion.^{3,4} A similar study of 626 patients with locally advanced disease demonstrated that para-aortic and pelvic lymph node status, tumour size, clinical stage, patient age and performance status were all significant prognostic factors for a reduction in progression-free interval and survival.⁵ The incidence of para-aortic and pelvic lymph node disease according to stage is illustrated in Table 108.1.

Staging

Women should be fully staged using the FIGO system (Table 108.2). FIGO staging is based largely on clinical assessment, chest X-ray and cystoscopy. Radiological staging, particularly by MRI, which permits more accurate determination of disease extent,¹² also permits assessment of lymph node status. Routine use of imaging enhances the selection of women in whom surgery alone is likely to be curative. MRI has become so accurate at staging disease that examination under anaesthetic combined with cystoscopy is often not required. In a limited number of pilot studies, positron emission tomography has demonstrated enhanced accuracy at diagnosing involved lymph nodes and local invasion, but more robust

Table 108.1 Incidence of nodal disease in cervical cancer according to stages^{6–11}

Stage	No.	Positive pelvic lymph nodes (%)	Positive para-aortic lymph nodes (%)
IA1 (<1 mm)	23	0	0
IA1 (1–3 mm)	156	0.6	0
IA2 (3–5 mm)	84	4.8	<1
IB	1926	15.9	2.2
IIA	110	24.5	11
IIB	324	31.4	19
III	125	44.8	30
IVA	23	55	40

studies are required. If performed prior to pelvic exenteration a whole-body PET or PET/CT scan may improve selection of patients and therefore improve survival and reduce morbidity. If performed prior to radiotherapy a whole-body PET or PET/CT scan may change planned radiotherapy fields.

Treatment

Specialised gynaecological oncology teams should determine the management of women with cervical cancer. Decisions about how best to treat early disease in young women in particular require considerable experience. Both surgery and radiotherapy are effective in early-stage disease, whereas locally advanced disease relies on treatment by radiation or chemoradiation. Surgery does provide the advantage of conservation of ovarian function.

Factors that influence the mode of treatment include stage, age and health status. Radiation can be used for all stages, whereas surgery should only be considered an option for early-disease, stage I and stage IIA. A large randomised trial reported identical five-year overall and disease-free survival rates when comparing radiation therapy with radical hysterectomy, but women who had surgery and adjuvant radiotherapy suffered significantly higher morbidity than those who had either surgery or radiotherapy alone [B].¹³

There are clear advantages to surgery in women at low operative risk. Surgery permits conservation of ovarian function in pre-menopausal women and also reduces the risk of chronic bladder, bowel and sexual dysfunction associated with radiotherapy. Complications in the hands of skilled surgeons are uncommon. Surgery also permits the assessment of risk factors, such as lymph node status, that will ultimately influence prognosis. Complications of surgery include fistulae (≤ 1 per cent), lymphocyst, primary haemorrhage and bladder injury. Chronic bowel and bladder problems that require medical or surgical intervention occur in up to 8–13 per cent of women¹³ due to parasympathetic denervation secondary to surgical clamping at the lateral excision margins.

Table 108.2 FIGO staging

Stage I	Stage I	Carcinoma strictly confined to the cervix; extension to the uterine corpus does not affect the stage
	Stage IA	Invasive cancer identified only microscopically. All gross lesions, even with superficial invasion, are stage IB cancers. Invasion is limited to measured stromal invasion with a maximum depth of 5 mm and no wider than 7 mm
	Stage IA1	Measured invasion of the stroma no greater than 3 mm in depth and no wider than 7 mm diameter
	Stage IA2	Measured invasion of stroma greater than 3 mm, but no greater than 5 mm in depth and no wider than 7 mm in diameter
	Stage IB	Clinical lesions confined to the cervix or preclinical lesions greater than stage IA
	Stage IB1	Clinical lesions no greater than 4 cm in size
	Stage IB2	Clinical lesions greater than 4 cm in size
Stage II	Stage II	Carcinoma that extends beyond the cervix, but has not extended on to the pelvic wall. The carcinoma involves the vagina, but not as far as the lower third
	Stage IIA1	No obvious parametrial involvement. Involvement of up to the upper two thirds of the vagina, <4 cm
	Stage IIA2	No obvious parametrial involvement. Involvement of up to the upper two thirds of the vagina, >4 cm
	Stage IIB	Obvious parametrial involvement, but not on to the pelvic sidewall
Stage III	Stage III	Carcinoma that has extended on to the pelvic sidewall. On rectal examination, there is no cancer-free space between the tumour and the pelvic sidewall. The tumour involves the lower third of the vagina. All cases with a hydronephrosis or non-functioning kidney should be included, unless they are known to be due to other causes
	Stage IIIA	No extension on to the pelvic sidewall, but involvement of the lower third of the vagina
	Stage IIIB	Extension on to the pelvic sidewall or hydronephrosis or non-functioning kidney
Stage IV	Stage IV	Carcinoma that has extended beyond the true pelvis or has clinically involved the mucosa of the bladder and/or rectum
	Stage IVA	Spread of the tumour on to adjacent pelvic organs
	Stage IVB	Spread to distant organs

Stage IA disease

Micro-invasive disease is one in which neoplastic cells invade from the epithelium to a maximum depth of 5 mm and a maximum horizontal spread of 7 mm. Any invasion beyond these dimensions upstages the disease to stage IB. The identification of early disease allows the selection of a group of women who are not at risk of lymph node disease and can be treated with less aggressive and, importantly, fertility-sparing therapy.

Micro-invasive disease comprises 20 per cent of invasive cancers. Stage IA1 disease (invasion ≤ 3 mm) is rarely associated with lymph node metastases (see Table 108.1). This disease should be formally diagnosed by cone biopsy or diathermy excision. Knife cone biopsy does not cause any thermal damage, and the extent of disease may be more accurately assessed than on a loop excision specimen. If the disease and any associated intraepithelial neoplasia are removed with clear margins, no further treatment is necessary. If disease is present at the margins, further excision or hysterectomy is required. A simple abdominal total hysterectomy is sufficient, as there is no risk of parametrial involvement. Because invasive disease of ≤ 3 mm invasion is associated with a very low risk of lymph node disease (see Table 108.1), lymphadenectomy is not indicated. Lymphadenectomy should, however, be considered for stage IA2 (invasion 3–5 mm) disease as the

rate of node involvement reaches 5 per cent, particularly if the tumour is poorly differentiated.

Stage IB–IIA

Stage IB is divided into IB1 (≤ 4 cm diameter) and IB2 (>4 cm diameter); stage IIA means upper vaginal, but not parametrial involvement.

Surgical therapy for stage IB and IIA tumours ≤ 4 cm across usually involves radical hysterectomy and pelvic lymphadenectomy. Radical hysterectomy involves removing the tumour with adequate disease-free margins, by means of excising the parametrial tissue around the cervix and upper vagina, with removal of part or all of the cardinal and uterosacral ligaments, depending on the extent of the dissection. More radical dissections are associated with a higher incidence of peri-operative morbidity and chronic bladder and bowel dysfunction with no survival advantage [B].¹⁵

The lymph node dissection should include obturator, internal, external and common iliac nodes. The presence of suspicious lymph nodes on pre-operative MR scan in early-stage disease should dictate chemoradiation as a sole treatment modality. If there is any doubt of the nature of enlarged nodes laparoscopic biopsy or PET imaging should be considered before the treatment plan is finally decided

Lymphadenectomy may result in lymphocyst formation. Lymphoedema following pelvic lymphadenectomy can occur, although its incidence increases if adjuvant radiotherapy is given.

In cases in which positive nodes are encountered, there are differing views. Some would advocate abandoning surgery in favour of radical chemoradiation. Others would argue that, if possible, radical surgery should be completed to achieve an adjuvant setting for radiotherapy. If suspicious nodes are identified and confirmed to be diseased at frozen section, it is probably best to remove resectable nodes and treat with chemoradiation, including brachytherapy, which requires the uterus to be *in situ*. Radical surgery followed by radical radiotherapy is associated with increased morbidity.

Adjuvant radiotherapy is normally recommended for women with resected positive pelvic nodes to reduce the risk of recurrence. Patients with 'close' vaginal margins (≤ 0.5 cm) may also benefit from pelvic irradiation.¹⁵

Indirect evidence from non-randomised studies suggests that radiotherapy can improve pelvic control, but there is no firm evidence of increased survival [C].^{17,18} Careful pre-operative radiological imaging reduces the risk of encountering unexpected lymphadenopathy or unexpectedly large tumours.

Because bulky IB tumours have a higher risk of positive nodes and close surgical margins, these are now regarded by many as being better treated with chemoradiation as opposed to surgery or radiotherapy alone. Some women with small-volume stage IB disease who wish to conserve their fertility might be suitable for trachelectomy (radical excision of the cervix) combined with either laparoscopic or open lymphadenectomy. The most common approach is a vaginal trachelectomy; however, more recently some surgeons are favouring an abdominal approach facilitating greater excision of the parametrium with this technique. Meta-analyses and large UK case series based on the vaginal approach have demonstrated recurrence rates of around 4 per cent, and a 70 per cent term delivery rate.^{19,20} Some surgeons recommend the insertion of an abdominal isthmic cervical cerclage to reduce the risk of late miscarriage. Indeed, in selected cases of IB1 disease that are just greater than 7 mm in horizontal spread, a large-cone biopsy may be adequate for central control, even though it may need to be combined with lymphadenectomy.

Stage IIB and above

It is not feasible to perform surgery with curative intent in these advanced stages of disease. Radical radiotherapy and chemoradiation are the only modalities of treatment that offer the potential for cure. One randomised trial has suggested that pre-operative chemotherapy to shrink disease followed by radical surgery may be superior to radical radiotherapy, but this has not been confirmed.²¹ It is inevitable that pre-operative chemotherapy followed by surgery will still require some women to undergo adjuvant or non-adjuvant radiotherapy that is more likely to result in unacceptable toxicity.

Radical radiotherapy

Radical radiotherapy is indicated for women unfit for surgery, or with bulky stage IB2 disease and more advanced disease. The goals of such treatment are to treat primary disease and to control metastatic pelvic lymph nodes. The radical dose is delivered by external-beam (teletherapy) and intracavitary treatment (brachytherapy). The standard technique now is of remote after-loading (e.g. using the Selectron). Intracavitary treatment is designed to give high doses locally to the primary site. Teletherapy is designed to treat any pelvic spread. The challenge in administering radiotherapy is in achieving an optimal dose throughout the primary tumour and pelvic sidewall without causing high morbidity. The peripheral field of treatment of intracavitary radiotherapy delivers an insufficient dose to treat the pelvic sidewalls. The dose-limiting normal tissues within the pelvis are the rectum posteriorly, the bladder anteriorly and any loops of small bowel within the pelvic radiation fields.

Prescribing rules have been devised for determining the precise dose of radiotherapy within the pelvis, and improved planning by CT has enabled more accurate targeting of external-beam radiation in particular. An example is the Manchester system. This uses a number of predetermined source sizes and radioactive loadings such that a constant dose rate is delivered to a point A. Point A is defined as a point 2 cm lateral to the central axis of the uterus and 2 cm from the lateral fornix. A second point (B) lying in the same plane 3 cm lateral to point A is used to determine the dose to parametrial tissues. Following the insertion of the sources for each patient, a dose distribution is calculated. The total dose is a product of the dose rate and treatment time. The usual doses delivered are 70–80 Gy to point A and 60 Gy to point B, limiting the bladder and rectal dose to 60 Gy. To achieve this, it is necessary to have adequate packing to keep the bladder and bowel away from the intracavitary source. External-beam radiation is usually given two to three weeks after intracavitary treatment to allow for involution of the primary disease. External-beam radiotherapy is fractionated over 20–30 days' treatment, as this technique allows a cancericidal effect while enabling normal tissue recovery between fractions.

Routine extended field radiotherapy designed to include para-aortic nodes has not been proven to improve survival compared with pelvic radiotherapy alone, and it is associated with significantly more gastrointestinal complications [B].²² While there does not appear to be significant benefit from extended field irradiation for all cases, para-aortic node irradiation is appropriate in cases of proven para-aortic node involvement as indicated by diagnostic imaging or surgical staging.

Chemoradiation

Five randomised trials from the US^{23–27} have shown an overall survival advantage for cisplatin-based therapy given concurrently with radiation therapy [B]. The patient populations

in these studies included women with FIGO stages IB2–IVA cervical cancer treated with primary radiation therapy and women with FIGO stages I–IIA disease found to have poor prognostic factors (metastatic disease in pelvic lymph nodes, parametrial disease or positive surgical margins) at the time of primary surgery. Although the trials vary somewhat in terms of stage of disease, dose of radiation and schedule of cisplatin and radiation, they all demonstrate significant survival benefit for this combined approach, the risk of death from cervical cancer being decreased by 30 per cent. These trials reported higher rates of short- and medium-term complications with chemoradiation, and although longer follow-up is required to examine the true morbidity of this treatment regimen, there is now international acceptance that chemoradiation is superior to radiation alone.

Recurrent cervical cancer

Treatment for recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Women who have had initial treatment by surgery should be considered for radiotherapy, and those who have had radiotherapy should be considered for exenterative surgery, provided the recurrence is central and there is no evidence of distant recurrence. These women require very careful pre-operative assessment and counselling in order to understand the consequences of defunctioning surgery. Exenterative surgery in carefully selected cases can result in five-year survival of 50 per cent [D]. Positive nodes at the time of attempted salvage surgery and positive resection margins are associated with a poor prognosis. Anterior exenteration requires excision of the bladder and most of the vagina *en bloc* with the recurrence, and posterior exenteration requires excision of the sigmoid rectum with formation of a colostomy. Sometimes a combination of the two is required. This type of surgery should only be undertaken by teams of highly skilled pelvic surgeons. Relapse within two years of primary treatment, the presence of hydronephrosis and symptoms of pain are all associated with poorer outcomes in terms of exenterative surgery.

Palliation of progressive cervical disease

Chemotherapy is palliative and should be reserved for patients who are not considered curable by the other two treatment modalities. Urinary tract symptoms are particularly common in advanced cervical disease. Ureteric obstruction with subsequent pain, infection and ultimately impaired renal function are common features. Mechanical diversion by nephrostomy or ureteric stenting is only usually justified as part of treatment with curative intent. Fistulae can occur in late-stage disease and can cause intolerable symptoms. If there is a prospect of surviving more than 8 weeks, palliative surgery should be offered in order to divert faeces or urine.

In progressive late-stage disease, there is usually ureteric obstruction, which heralds a terminal phase. Pain can be particularly distressing due to infiltration of the lumbosacral

nerve plexuses. Meticulous attention to pain control and psychological and emotional support are essential.

KEY POINTS

- Early micro-invasive disease can be treated by cone biopsy or excisional treatment alone [C].
- Surgery and radiotherapy for stage IB/IIA disease have similar five-year overall and disease-free survival rates, but women who have had surgery and adjuvant radiotherapy combined have significantly higher morbidity than those who have had either surgery or radiotherapy alone [B].
- Pre-operative imaging with MRI scans reduces the number of women undergoing both modalities of treatment [C].
- Chemoradiation increases survival over radiotherapy alone for advanced disease, but toxicity is increased [B].

Chapter 109 Benign and malignant ovarian masses

Sudha Sundar

MRCOG standards

- To understand and demonstrate appropriate knowledge in relation to: epidemiology, aetiology, genetic associations, diagnosis, prevention, screening, management, staging, prognosis, complications and anatomical considerations of pre-malignant and malignant conditions of the ovary.
- To understand and demonstrate appropriate knowledge in relation to: indications, techniques, complications and outcomes of oncological surgery, radiotherapy and chemotherapy for ovarian cancer.

INTRODUCTION

By the age of 65, 4 per cent of women will have been admitted to hospital with an ovarian cyst, making this the fourth most common gynaecological cause for hospital admission in England. Ovarian masses are common in pre-menopausal women and up to 10 per cent of women will undergo surgery during their lifetime for the presence of an ovarian mass.¹ Among pre-menopausal patients, more than 90 per cent of surgically managed cases are benign, as opposed to just 60 per cent in the post-menopausal population. Although differentiating malignant from benign disease is critical in optimising management for the individual, non-invasive diagnosis continues to be elusive. Women with complex masses considered benign can undergo laparoscopic or conservative management, whereas women with malignancy who undergo thorough surgery by gynaecological oncologist have the best outcomes.^{2,3}

Ovarian cancer is the fifth most common cancer among women in the UK (2010), accounting for 4 per cent of all new cases of cancer in females. In 2010 there were 7011 new cases of ovarian cancer in the UK. The crude incidence rate shows that there are 22 new ovarian cancer cases for every 100,000 females in the UK.⁴ Ovarian cancer is the fourth most

common cause of cancer death among females in the UK, accounting for 6 per cent of all female deaths from cancer with 4272 deaths in 2011.⁵

The lifetime risk of developing ovarian cancer is 1 in 54.⁶ Eighty per cent of patients will present at advanced stage and all-stage 5-year survival rate is about 40 per cent. Ovarian cancer is predominantly a disease of older, post-menopausal women; however 1000 women under 50 will be diagnosed annually.⁶ Ovarian cancer survival is stage dependent (5-year relative survival 92% Stage I vs 5% Stage IV).⁷ Five-year survival from ovarian cancer has increased significantly over the last decade. This may be as a result of improved chemotherapy regimens, treatment by dedicated multidisciplinary teams and radical surgery performed by gynaecological oncologists.

HISTOPATHOLOGY AND CLASSIFICATION OF OVARIAN MASSES

An ovarian mass may be neoplastic or physiological, and most adnexal masses are benign. The current edition of *International Classification of Tumours*, published by the WHO,⁷ provides a classification of ovarian tumours that has been universally accepted.⁸ Epithelial tumours are derived from the surface epithelium of the ovary and are further classified as benign, borderline or malignant, according to cell type and behaviour (Figs. 109.1 and 109.2).

Epithelial tumours account for 60–65 per cent of all ovarian tumours and approximately 90 per cent of those that are malignant. Sex-cord stromal tumours are, as their name suggests, derived from the sex cords and stroma of the ovary and account for approximately 8 per cent of all ovarian tumours. Germ-cell tumours, derived from the germ cells, account for 30 per cent of ovarian tumours, largely in the form of mature cystic teratomas (dermoid cysts). Although germ-cell tumours account for only 1–3 per cent of all ovarian malignancies, they represent more than 60 per cent of ovarian cancers in children and adolescents.

Fig. 109.1 Haematoxylin and eosin staining of a section of tumour demonstrating the typical epithelium of a benign serous cystadenoma – note single layer and bland appearance

Note: the term **ovarian cancer** is used in this chapter to include not only epithelial ovarian malignancies, but also malignant sex-cord stromal and germ-cell neoplasms.

Epithelial ovarian tumours

The ovary first appears in fetal life as an aggregation of cells covered with primitive coelomic epithelium. Subsequently, germ cells migrate from the yolk sac into the gonadal area. The coelomic epithelium that covers the ovary also gives rise to a variety of epithelia of Müllerian origin, which line the genital tract structures, including the Fallopian tubes, the uterus and the cervix, and are similar to those found in epithelial tumours of the ovary. Well-differentiated serous carcinoma resembles epithelium of the Fallopian tube, whereas the cell type in endometrioid tumours has a similar appearance to the cells found in endometrial glands. The WHO classification of epithelial ovarian tumours is based on this similarity in cell type (Table 109.1).

^aThe Morphology codes are from the International Classification of Diseases for Oncology (ICD-O) {575A}. Behaviour is coded /0 for benign tumours, /1 for unspecified, borderline or uncertain behaviour, /2 for carcinoma *in situ* and grade III intraepithelial neoplasia and /3 for malignant tumours; ^bThe classification is modified from the previous WHO classification of tumours {1906A}, taking into account changes in our understanding of these lesions; *These new codes were approved by the IARC/WHO Committee for ICD-O in 2013.

Approximately 90 per cent of ovarian cancers are carcinomas (malignant epithelial tumours) and, based on histopathology, immunohistochemistry and molecular genetic analysis, at least five main types are currently distinguished: high-grade serous carcinoma (HGSC, 70 per cent); endometrioid carcinoma (EC, 10 per cent); clear-cell carcinoma (CCC, 10 per cent); mucinous carcinoma (MC, 3 per cent); and low-grade serous carcinoma (LGSC, <5 per cent).

It is now understood that primary mucinous cancers of the ovary are rare, and the majority of mucinous cancers that were attributed to ovarian origin are in fact metastases from the intestinal tract. Bilaterality of epithelial ovarian malignancies is common. Although endocrine function is most commonly a feature of sex-cord stromal tumours, it may also occur in association with epithelial ovarian tumours. Paraneoplastic syndromes are a rare feature of these tumours.

Sex-cord stromal tumours

These tumours are composed of granulosa cells, theca cells, Sertoli cells, Leydig cells, fibroblasts or the precursors of these cells in varying proportions. The classification of these tumours (based on the WHO classification) is shown in Table 109.1. They may be associated with an oestrogenic, androgenic or (more rarely) progestogenic effect, but functional activity does not correlate with the appearance of the cell. Many of these tumours are benign and most of the clinically malignant forms are granulosa cell tumours. Fibromas are well known for their association with ascites and right hydrothorax (Meigs syndrome).

Germ-cell tumours

Approximately 30 per cent of benign and malignant ovarian tumours are of germ-cell origin (Table 109.1). However, as only a small proportion are malignant, they account for less than 5 per cent of all ovarian cancers. Nonetheless, they are the commonest ovarian malignancy in the first two decades of life.

Dysgerminoma is the commonest germ-cell malignancy, and 75 per cent of cases present with stage I disease. In contrast with other malignant germ-cell tumours, 10–15 per cent are bilateral, with contralateral involvement usually being microscopic. Five to 10 per cent occur in phenotypic females with abnormal gonads (androgen insensitivity syndrome or gonadal dysgenesis).

Teratomas are tumours that are composed of tissue derived from two or three embryonic layers. The mature cystic teratoma is the commonest ovarian germ-cell tumour and is usually benign. Most are unilateral, but 15–20 per cent are bilateral. They are the commonest ovarian tumours leading to torsion. Hair and teeth may be present in the cysts, the latter resulting in the classical appearance on plain abdominal X-ray. Malignant transformation is reported in up to 2 per cent, squamous carcinoma being the commonest malignancy to develop. A diagnosis of struma ovarii is made

when these tumours are predominantly composed of thyroid tissue. Primary ovarian carcinoid tumours are also variants of monodermal teratomas and usually have a favourable prognosis. However, secondary carcinoids (not associated with a monodermal teratoma) are usually metastatic from the gastrointestinal tract and have a poor prognosis.

Immature teratoma is the second commonest germ-cell malignancy and accounts for approximately 20 per cent of ovarian malignancies in females under 20 years of age. Virtually all immature teratomas are unilateral and they are currently classified according to a grading system that is based on the degree of differentiation and the quantity of immature tissue.

Embryonic markers

Most patients with ovarian yolk sac tumours have elevated levels of alpha-fetoprotein (AFP), but normal levels do not exclude this diagnosis. Embryonal carcinomas are extremely rare. They usually secrete beta-human chorionic gonadotrophin (b-hCG) and may secrete AFP. Ovarian choriocarcinoma secretes b-hCG and polyembryoma secretes b-hCG and AFP. These are also very rare tumours. The commoner immature teratoma and pure dysgerminoma do not secrete these tumour markers.

Gonadoblastoma

This rare tumour consists of admixed germ-cell and sex-cord stromal elements. This is usually a tumour of the second decade of life and rarely occurs in normal ovaries. Eighty per cent occur in phenotypic females who are virilised, and 20 per cent in phenotypic males with developmental abnormalities of the external genitalia. The most common karyotypes are 46XY and 45XO/46XY (mosaic).

Secondary ovarian malignancies

Up to 10 per cent of ovarian masses are metastases from some other organ and in many cases the ovarian metastases are detected before the primary tumour. The most common metastatic cancers are those arising from the colon, stomach, breast and, of course, the female genital tract. Bilaterally enlarged ovaries that contain signet-ring cells on microscopic assessment have been named after Krukenberg, who described these ovarian tumours in patients with metastatic gastric or (less commonly) colonic cancer.

Primary peritoneal carcinoma

Primary peritoneal carcinoma is a highly malignant tumour arising from the peritoneum and resulting in signs and symptoms very similar to those of primary epithelial ovarian cancer. Rare benign and borderline variants have been described. Thus a patient who has previously had both ovaries removed may develop a condition that clinically simulates ovarian cancer. Primary peritoneal cancer and primary Fallopian tube cancer are rare malignancies but share many similarities with

ovarian cancer. Clinically, these three cancers are managed in a similar manner.

Primary Fallopian tube cancer

This rare cancer accounts for approximately 0.3 per cent of all female genital tract cancers. The classical presenting triad consists of:

- a prominent watery discharge (hydros tubae profluens);
- pelvic pain;
- a pelvic mass.

It is similar to primary epithelial ovarian cancer in histological appearance and clinical behaviour. Management is therefore essentially the same.

Rare ovarian tumours

Rare ovarian tumours include primary small-cell carcinoma and various types of sarcoma, all having a poor prognosis. Lymphoma or extramedullary leukaemia may also manifest initially as an ovarian tumour.

Molecular classification of ovarian cancer

Currently, on the basis of molecular characteristics, ovarian cancer can be divided into two types – type 1 which comprises clear-cell, mucinous, endometrioid and low-grade serous cancer histology, and type 2 which comprises high-grade serous cancers. Type 1 cancers tend to be slow growing, indolent and more likely to be detected earlier by ultrasound whereas type 2 cancers are typically fast growing. Paradoxically type 1 cancers can prove harder to treat as most respond less well to chemotherapy. Improved understanding of ovarian cancer biology has led to a fundamental rethink of the origin of ovarian cancer.

The theory of ‘incessant ovulation’ causing ovarian cancer on the epithelial surface of the capsule has now been replaced after greater insight into genetic drivers of this disease. It is now believed that many serous ovarian cancer arises in the fimbrial end of the fallopian tube and disseminates within the peritoneal cavity. It is likely that high-grade serous cancer, Fallopian tube cancer and primary peritoneal cancer are different phenotypes of the same biological disease entity.⁹

With advancements in gene-sequencing technology, landmark studies have revealed that *p53* is mutated in almost all serous ovarian cancer, whereas other histology types have specific molecular alterations (e.g. *ARID1A* in clear-cell cancers).¹⁰ A greater understanding of these will lead to improved treatments in the next decade.

Germline *BRCA* mutations have been detected in almost 17 per cent of all high-grade serous cancer, and there is a

sound case for *BRCA* testing in every patient with high-grade serous cancer.¹¹ Whilst this approach carries implications in terms of resource and the impact on extended family members, patients with *BRCA* mutations in ovarian cancer may also benefit from a newer class of drugs – poly ADP ribose polymerase inhibitors.

KEY POINTS

- The mature cystic teratoma is the commonest ovarian germ-cell tumour, is benign and the commonest ovarian tumour leading to torsion.
- 90 per cent of malignant ovarian tumours are epithelial, but germ-cell tumours account for 60 per cent of ovarian cancers in adolescents and children.
- High-grade serous ovarian cancers probably arise from the fimbrial end of the Fallopian tube.
- 17 per cent of patients with high-grade serous ovarian cancer have germline mutations of the *BRCA* gene.
- Bilaterality of epithelial ovarian malignancies is common.
- Up to 10 per cent of ovarian masses are secondary to metastases from some other organ.

EPIDEMIOLOGY, INCIDENCE AND AETIOLOGY OF EPITHELIAL OVARIAN CANCER

In 2008, it was estimated that 225,500 women were diagnosed with ovarian cancer and 140,200 women died from this disease worldwide. Thus ovarian cancer is the eighth most common type of cancer and the seventh most common cause of cancer-related death among women. Like many other types of cancer, there is substantial geographical variation in ovarian cancer incidence and mortality, with a higher incidence in economically developed regions of the world.¹² In England and Wales, ovarian cancer is the second most common gynaecological malignancy to uterine cancer but ovarian cancer accounts for more deaths in these countries than the other gynaecological malignancies together.

The incidence and mortality rates are influenced by country of origin and race. In general, epithelial ovarian cancer is most common and most lethal in industrialised countries (excepting Japan) and has the lowest rates in the non-industrialised world. In contrast, germ-cell tumours represent up to 15 per cent of ovarian cancers in black and oriental populations, in whom epithelial ovarian cancers are less common.

Most epithelial ovarian cancers occur in post-menopausal women, with less than 1 per cent affecting females under the age of 21 years. In this age group, more than 60 per cent of ovarian malignancies are of germ-cell origin.

Precursor lesions to epithelial ovarian cancer

Patients with *BRCA* mutation (breast–ovarian cancer syndrome) undergoing risk-reducing salpingo-oophorectomy were found to have high-grade serous tubal intraepithelial carcinoma (STIC) not in the ovary but in the Fallopian tube and, particularly, in the fimbria. Although not considered invasive lesions, STICS have been known to metastasise; it is likely that these lesions are the earliest phase of epithelial ovarian cancer. In addition, precursor tubal lesions termed ‘*p53* signatures’ have been found in one third of all women and are believed to represent the initial events of serous carcinogenesis: DNA damage of secretory cells and *p53* mutations.¹³

Opportunistic postpartum salpingectomy is now being evaluated in British Columbia as a prevention strategy for epithelial ovarian cancer. Long-term incidence and mortality data are eagerly awaited.¹⁴

Aetiology

Environmental factors

The causes of ovarian cancer and environmental factors contributing to these are not clearly defined. In general, combined oral contraception and factors that limit the number of ovulations are associated with a reduced risk of ovarian cancer.

Genetic factors contributing to ovarian cancer

The concept that there is a familial predisposition to ovarian cancer was initially suggested by epidemiological studies that have consistently documented an increased relative risk for ovarian cancer associated with a family history of the disease.

There is a growing recognition that hereditary ovarian cancers are likely to represent about 20 per cent of all ovarian cancers. In 1994, following intense linkage analysis, a large gene was cloned and sequenced and confirmed to be the *BRCA1* – BReast CAncer 1 – gene. Confirmatory studies have identified more than 100 mutations. It has been estimated that germline mutations in *BRCA1* are responsible for approximately 5 per cent of ovarian cancers in women less than 40 years of age.

Although the estimated risk of developing either ovarian or breast cancer by the age of 70 is 82 per cent, most carriers do not develop both diseases, and thus the penetrance for development of ovarian cancer is lower and estimated at 42 per cent. Mutations in the *BRCA2* gene also increase the risk of ovarian cancer in carriers, the site of mutation possibly correlating with risk, as in the case of *BRCA1*.

HNPCC has been classified into two syndromes termed Lynch I and II. The latter has an association with cancers at other sites, including the ovary and endometrium. The genes responsible for HNPCC have now been identified. The lifetime risk of ovarian cancer among gene carriers has not been

precisely documented but may be as high as seven times that of non-carriers.

Other gene mutations that confer an increased risk of ovarian carcinoma, include *RAD51C* and *RAD51D*, however testing for these is not in routine practice. Narod and colleagues have reported in a case–control study that women from families with hereditary ovarian cancer syndromes reduce their risk of developing ovarian cancer by ever use of the combined oral contraceptive pill.¹⁵ Risk-reducing salpingo-oophorectomy (RRSO) has been widely adopted as a key component of breast and gynaecological cancer risk-reduction for women with *BRCA1* and *BRCA2* mutations once they have completed their families.¹⁶

SCREENING FOR OVARIAN CANCER

The possibility of pre-symptomatic genetic testing raises a number of medical, psychological, ethical, legal and social issues. Due to the limitations of genetic testing at the present time, it is imperative that it is offered only to high-risk individuals in cases for which the result of the test will affect medical management. In this context it must be remembered that a woman with a single affected relative has a lifetime risk of developing ovarian cancer of only 3–4 per cent (see Published guidelines).

Women who are at high risk for developing ovarian cancer (i.e. 10 per cent or more lifetime risk based on family history) may be offered ovarian screening. A large study, UK Familial Ovarian Cancer Screening Study (UKFOCCS), is due to report results soon, after a surveillance strategy of CA125 and ultrasound in *BRCA* carriers to detect ovarian cancer early.

However, data regarding the efficacy or potential morbidity of ovarian screening in the asymptomatic general population are lacking. Screening this population is contraindicated until such time as studies show that it is justified (see Published guidelines).

It is also unclear if ongoing surveillance should be offered for women who are deemed to be at 10 per cent or more risk of developing ovarian cancer, but if provided then it should be done in the context of familial screening clinics, usually run jointly by a clinical geneticist and a gynaecological oncologist. However initial assessment should be available to consider management choices and to highlight current uncertainties surrounding surveillance for high-risk women. Women who attend general gynaecological clinics with concerns about their familial risk of ovarian cancer should be referred to such services. They will be asked to complete a questionnaire which enables their risk to be calculated objectively and then rational choices can be made regarding whether to offer screening.

Two large trials on screening and testing asymptomatic populations for ovarian cancer have been conducted. In the

PLCO (prostate, lung, colon and ovarian cancer screening) trial conducted in the US, women between 55 and 74 were tested with CA125 and ultrasound.¹⁷ This trial found no benefit in terms of cases or stage of ovarian cancer detected. The UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) is a large trial evaluating an algorithm (risk of ovarian cancer algorithm) which is based on changing levels of CA125 and a rigorous ultrasound protocol. Preliminary results from this trial suggest that screening strategies using ultrasound and CA125 levels are feasible but further results are awaited on the impact on mortality of such strategies.¹⁸ It has completed recruitment and results are expected in 2015.¹⁸ Currently, there is no evidence to support screening for ovarian cancer in asymptomatic women.

Symptoms of ovarian cancer

In 2011 NICE, the UK body which advises on standards of clinical care, issued guidance on the recognition and initial management of ovarian cancer.¹⁹ NICE recommended that symptoms considered 'suspicious' should trigger diagnostic testing in the primary care setting and referral to rapid-access clinics based in secondary care within 2 weeks (2-week-wait clinics). NICE guidance aimed to improve cancer mortality by permitting primary care access to rapid diagnostic testing previously only accessible via secondary care, thereby aiding earlier diagnosis in ovarian cancer, and earlier interventions. The objectives underpinning this guidance were to diagnose the disease at an earlier stage and thus improve mortality. NICE recommended a diagnostic pathway involving sequential testing of serum CA125 followed by an abdomino-pelvic ultrasound if the serum CA125 was ≥ 35 IU/L in women presenting to primary care with symptoms on a persistent or frequent basis of: persistent abdominal distension/'bloating', feeling full and/or loss of appetite, pelvic/abdominal pain, increased urinary urgency and/or frequency, unexplained weight loss, fatigue, or changes in bowel habit. No age limits were issued at the time of guidance; however it was emphasised that the high-risk group were those aged over 50 years. Of note, both diagnostic tests were recommended to be performed in the primary care setting. No guidance on what constituted an abnormal ultrasound was issued.

NICE recommendations were based on evidence from case-control studies. Since guidance was issued, two well-conducted prospective studies have been published demonstrating that symptom-triggered diagnostic testing with CA125 and ultrasound for ovarian cancer does not result in a stage shift in ovarian cancer but may result in lesser volume stage 3 disease being detected.^{20,21} At present, the impact on mortality with a strategy of symptom-triggered diagnostic testing is not known. The ROCKETS trial aims to identify the best tests and diagnostic pathways in pre and postmenopausal women with symptoms in primary and secondary care and will report in 2018, www.birmingham.ac.uk/ROCKETS.

KEY POINTS

Aetiology of ovarian cancer

- Postpartum salpingectomy is a potential prevention strategy for epithelial ovarian cancer.
- Pregnancy, breastfeeding, tubal ligation, hysterectomy and the combined oral contraceptive pill protect against the development of epithelial ovarian cancer.
- Hereditary ovarian cancers are unlikely to represent more than 20 per cent of all ovarian cancers.
- Bilateral salpingo-oophorectomy is protective in *BRCA* mutation carriers [1].
- HNPCC has an association with cancer of the ovary and endometrium.

MANAGEMENT OF THE ADNEXAL MASS

An adnexal mass may present either as a result of symptoms, which may be severe in the case of a cyst accident, or as an incidental finding when performing a pelvic examination or radiological investigation. Cyst accidents include torsion, haemorrhage and rupture. Pelvic pain radiating down the inner aspect of the leg is a common presenting symptom, and torsion classically presents as severe pain associated with vomiting. Although rupture of a small cyst may be asymptomatic with few associated signs, the abdomen of a patient experiencing a cyst accident is usually tender, with guarding and rigidity. Rupture of a large cyst may produce signs of peritonitis, particularly if the cyst contents are irritant (e.g. endometriotic cyst or dermoid cyst), and the patient may be shocked in cases of extensive rupture or continuing haemorrhage.

Investigation

A complete history and examination are essential, as the diagnosis is usually based on clinical findings. The history should include information about the duration and growth of the mass. Symptoms, past history or family history increasing the likelihood of malignancy should be sought. The duration of use of combined oral contraception should be noted. General, abdominal, vaginal and rectal examinations are mandatory.

Full blood count, group and save, serum amylase, urea, electrolytes and liver function tests should be performed. Tumour markers should be measured if the mass is complex; if this information is not available, serum may be stored until histopathology has been reported. Pregnancy must be excluded and urinalysis performed. A midstream specimen of urine should be sent for culture and sensitivity. Other investigations may be indicated by the patient's condition, for example cross-match and coagulation screen in cases of haemorrhage.

A pelvic ultrasound, preferably transvaginal, will reveal the dimensions and morphology of the mass and is the single most important investigation in predicting whether an ovarian mass is benign or malignant. Most ovarian masses are cystic,

but the presence of solid areas makes a tumour most likely and a malignancy possible. However, some benign tumours are solid, for example thecoma, fibroma and Brenner tumours. Thickened walls and septae are other features of malignancy. The results of colour Doppler imaging have been disappointing, and this technique has not proven superior to morphological assessment.

Diagnosis of adnexal mass

The triage of an adnexal mass into possibly benign or malignant categories can be challenging and a number of tests have been investigated in the literature.

It is important here to distinguish between post-menopausal women and pre-menopausal women, in whom the risk of ovarian cancer is low, benign adnexal cysts are very common and CA125 can be elevated frequently. A number of non-specific conditions, including menstruation, endometriosis and peritoneal irritation secondary to haemorrhage, can contribute to a raised CA125 level. RCOG guidelines on managing pre-menopausal women with ovarian cyst recommend that patients be referred to a gynaecological oncologist if CA125 >200.¹ Alternatively, International Ovarian Tumour Analysis (IOTA) is a consortium of experts in ultrasound who have established ultrasound models that can differentiate benign and malignant ovarian tumours.¹ (see Published guidelines).

In post-menopausal women, RCOG recommends use of the Risk of Malignancy Index (see below). However, normal levels of CA125 are found in 50 per cent of stage I ovarian cancers. Equally CA125 levels are also raised in benign conditions such as hepatorenal disease, diverticulitis, chest complaints and benign cysts. Human epididymis protein 4 (He4) is a new marker, not in routine practice in the UK, which may be of benefit.²²

Jacobs and colleagues included ultrasound findings and menopausal status with CA125 in an algorithm termed the 'Risk of Malignancy Index' (RMI) and reported 87 per cent sensitivity, 89 per cent specificity and 75 per cent positive predictive value (given an RMI cut-off value of 200).⁸ The RMI is the product of the serum CA125 level (in units per millilitre), the ultrasound score (0, 1 or 3) and the menopausal status (1 if pre-menopausal, 3 if post-menopausal: see Table 109.2). The ultrasound score is calculated by giving one point for each of the following findings:

- multilocular cyst;
- solid areas;

- bilateral lesions;
- metastases;
- ascites.

The RMI provides a means of triaging women for referral to a gynaecological oncologist. The cut-off for referral to a cancer centre varies according to local practice.

ORGANISATION OF CARE IN THE UK

The use of the RMI has been endorsed by both RCOG and NICE guidelines (see Published guidelines). Since the introduction of Improving Outcomes Guidance in the United Kingdom in 1999²³, gynaecological cancer care is delivered in a hub-and-spoke model. With respect to ovarian cancer, cancer units triage patients with adnexal masses. In general, women are referred for management in the cancer centre for surgery by a gynaecological oncologist when the RMI is over 250. All women with RMI >250 should be discussed at the cancer centre multidisciplinary team meeting.

The appropriate location for the management should reflect the new structure of cancer care in the UK.^{3,4} As the risk of malignancy increases, the appropriate location for management changes, so that while a general gynaecologist might manage women with a low risk of malignancy, those at intermediate risk should be managed in a cancer unit and those at high risk in a cancer centre. It is recommended that ovarian cysts in post-menopausal women should be assessed using CA125 and transvaginal grey-scale sonography. There is no routine role yet for 3D or Doppler ultrasound, MRI, CT or PET. The best prognosis for women with ovarian cancer is offered if a laparotomy and full staging procedure is carried out by a trained gynaecological oncologist.

RCOG guidance states that women should be managed as below.

Low risk: Less than 3% risk of cancer:

- Management in a gynaecology unit.
- Simple cysts less than 5 cm in diameter with a serum CA125 level of less than 30 may be managed conservatively.
- Conservative management should entail repeat ultrasound scans and serum CA125 measurement every four months for one year.
- If the cyst does not fit the above criteria or if the woman requests surgery then laparoscopic oophorectomy is acceptable.

Moderate risk: approximately 20% risk of cancer:

- Management in a cancer unit.
- Laparoscopic oophorectomy is acceptable in selected cases.
- If a malignancy is discovered then a full staging procedure should be undertaken in a cancer centre.

High risk: greater than 75% risk of cancer:

- Management in a cancer centre.
- Full staging procedure as described above.

Table 109.2 An example of a protocol for triaging women using the risk of malignancy index (RMI)

RMI	Women (%)	Risk of cancer (%)
Low <25	40	<3
Moderate 25-250	30	20
High >250	30	75

Conservative and surgical management

Management depends on the presentation (cyst accident or asymptomatic finding) and the risk of malignancy. Surgical intervention is usually required when an ovarian cyst presents with acute symptoms, although a conservative approach may be taken in mild cases where the findings indicate a low risk of malignancy. Most functional cysts can be managed conservatively and disappear spontaneously within two cycles if managed with combined oral contraceptives or observation alone.⁹ Patients with peritonitis or hypovolaemic shock require prompt resuscitation. RCOG recommends conservative management in post-menopausal women with simple unilateral cysts <5 cm and CA125 <30. These cysts can be kept under surveillance with regular transvaginal ultrasound scans and CA125 levels and women discharged from follow-up if the cyst resolves or remains unchanged at the end of one-year follow-up.

The benefits of laparoscopic surgery are widely reported, and large studies have been published demonstrating the safety and efficacy of this approach (see Published guidelines). However, specialised and skilled gynaecologists performed the surgery in these series, and the unfortunate consequences of laparoscopic management of undiagnosed ovarian cancers have been reported. If an adequate pre-operative assessment indicates that the risk of malignancy is low, a laparoscopic approach should be considered. However, laparoscopic aspiration of cysts should not be performed to make a diagnosis of cancer, as the negative predictive value of cyst fluid cytology is low in most departments and aspiration adversely affects the prognosis of a stage I malignancy. Furthermore, therapeutic aspiration of ovarian cysts is usually ineffective, as most recur. It is recommended that an RMI should be used to select women for laparoscopic surgery, to be undertaken by a suitably qualified surgeon. It is recommended that laparoscopic management of ovarian cysts in postmenopausal women should involve oophorectomy (usually bilateral) rather than cystectomy. In a post-menopausal woman the appropriate laparoscopic treatment for an ovarian cyst, which is not suitable for conservative management, is oophorectomy, with removal of the ovary intact in a bag without cyst rupture into the peritoneal cavity.

Patients at intermediate risk of malignancy may also be considered for laparoscopic assessment when the operator is skilled, there is a safe method of retrieval of the mass and there are facilities for prompt frozen section analysis. In this situation, access to immediate surgical staging must be available. All patients with obvious malignancy should be referred to a gynaecological oncologist for further management. The role of laparoscopy in the management of ovarian cancer is not proven and is not in routine practice in the UK.

At laparoscopy, a careful assessment is performed and washings taken. If the findings are suspicious for malignancy, a biopsy is taken if metastases or surface excrescences are identified. An appropriate procedure is then rescheduled following the results of histopathology (see below). If there are no suspicious findings, the surgeon may proceed to cystectomy or oophorectomy as indicated.

KEY POINTS

- At the present time, there is no role for ovarian screening in the asymptomatic population.
- All women presenting with vague pelvi-abdominal symptoms warrant a complete history and examination, including vaginal.
- The RMI is used to stratify the risk of ovarian cancer for women with an ovarian cyst and to identify cases for referral to a gynaecological oncologist.

CLINICAL MANAGEMENT OF OVARIAN CANCER

Clinical presentation and diagnosis

Primary ovarian cancer is most common in women in the seventh decade of life. Hereditary cancers usually present in younger women, occurring approximately 10 years earlier. Most women with Ovarian cancer have non specific symptoms. A complete history and examination are essential to make the diagnosis, to identify patients with secondary ovarian malignancy and to assess fitness for surgical and non-surgical management.

Symptoms

When the tumour is confined to the ovary, the patient may present with pressure symptoms (urinary frequency, constipation, pelvic pain/pressure, dyspareunia) and, rarely, symptoms of a cyst accident. In advanced-stage disease, symptoms are usually due to metastases affecting the bowel and mesentery, and ascites. Resulting symptoms (bloating, constipation, early satiety, loss of appetite) may be misinterpreted as irritable bowel syndrome. Symptoms due to pressure effects in the pelvis may also occur. Abnormal vaginal bleeding (in pre-menopausal and post-menopausal women) is a less common presenting feature. Unfortunately, given that symptoms in ovarian cancer are so vague, delays in presentation to the GP and subsequent delay in diagnosis are common and well known.

Clinical signs

Assessment should include examination of supraclavicular, axillary and inguinal nodes, breast examination, chest examination (pleural effusion) and abdominal examination, including assessment of liver size. In women presenting with the above symptoms, a pelvic examination (including per-rectal examination) is mandatory. The presence of a solid, irregular mass is highly suspicious, particularly when associated with an upper abdominal mass (omental cake).

Investigations

Investigations are performed to assess the likelihood of malignant disease, to assess fitness for anaesthesia and surgery, and to plan the extent of surgery. Ultrasonography (see above) should include assessment not just of the pelvis but also of the kidneys and liver. Liver parenchymal metastases increase the likelihood of a non-ovarian primary, and significant hydronephrosis should be identified pre-operatively. Chest imaging is essential. CA125 (see above) and carcinoembryonic antigen (CEA) levels should be measured, the latter to identify primary gastrointestinal malignancy. In young women <40 years, AFP and b-hCG levels should also be measured, as germ-cell tumours are the commonest gynaecological malignancy in the first two decades of life. Full blood count, urea, creatinine, electrolytes and liver function tests (including total protein and albumin) should also be done.

CT scan of the abdomen and pelvis can be very helpful in delineating the extent of upper abdominal disease and can guide choice between primary surgery or chemotherapy. MRI of the pelvis may also assist surgical planning in patients with a fixed pelvic mass to determine adherence to large bowel or the pelvic sidewalls. A chest X-ray must be performed to assess the possibility of Stage IV disease (see Table 109.3). In patients with abnormal vaginal bleeding, full assessment of the cervix and uterus, including outpatient endometrial biopsy, should be considered as an ovarian mass may be the site of secondary spread from a primary cervical or endometrial carcinoma. Endoscopy of the upper or lower gastrointestinal tract is indicated in women whose symptoms, tumour marker profile or CT suggest a primary gastrointestinal malignancy.

Staging of primary ovarian cancer

Ovarian cancers are staged according to FIGO recommendations (Table 109.4). Staging is based on findings at laparotomy, but pre-operative assessment is required to assess extraperitoneal spread. Accurate staging is of

Table 109.3 Metastases in apparent early-stage epithelial ovarian carcinoma, presented as percentages. Adapted with permission from: Moore DH. Primary surgical management of early epithelial ovarian carcinoma. In: Rubin CR, Sutton GP (eds). *Ovarian Cancer*. 2nd edn. Philadelphia: Lippincott Williams and Wilkins, 2001, 201–18.

Percentage of cases with occult metastases	
Diaphragm	7.6
Omentum	7.1
Cytology	18.8
Peritoneum	9.8
Pelvic lymph nodes	8.9
Para-aortic lymph nodes	12.3

paramount importance, as it determines not only prognosis but also to a large extent the requirement for adjuvant treatment. FIGO reports the five-year survival of patients with stage I disease as 70 per cent. This is in contrast to survival rates of more than 90 per cent reported in studies on patients with properly staged disease, and suggests that a significant proportion of women are not undergoing careful surgical staging. Gynaecological Cancer Intergroup (GCIG) recommendations to FIGO staging suggest that in early-stage disease, grading and in advanced disease, the amount of residual disease must be reported.

FIGO staging (Table 109.4)

Staging for ovarian cancer was revised at the end of 2013.²⁴ The new classification allows for surgical rupture of cyst to be clearly distinguished from pre-operative rupture and also quantifies the extent of lymph node metastasis.

Technique for surgical staging

A midline incision extending above the umbilicus is essential to allow adequate access for thorough surgical staging and should be performed whenever an ovarian malignancy is anticipated. A systematic exploration of all peritoneal surfaces and viscera is performed. The staging laparotomy involves the following steps:

- sending ascites or peritoneal washings for cytological assessment;
- performing a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH/BSO);
- omentectomy;
- peritoneal biopsies of all suspicious areas;
- assessment of pelvic and para-aortic lymph nodes;
- careful assessment of upper abdomen including diaphragm, liver, spleen, lesser sac, Morrison's pouch

The rationale for TAH/BSO is the high incidence of bilateral tumours (metastatic or primary) and metastases to the uterus. Furthermore, the endometrium may be the site of a coincidental primary carcinoma, particularly in the case of endometrioid carcinoma of the ovary. The omentum is removed, as it is the major site of abdominal metastases. An infra-colic omentectomy is most universally performed, but a supracolic procedure may be preferable and, indeed, is often essential to achieve adequate cytoreduction of gross omental disease. Washings may be positive in apparent stage Ia disease, substantially altering decision making with regard to adjuvant treatment.

Table 109.3 illustrates the rate of occult metastases when adequate surgical staging is performed by combining results from 13 published series involving a total of over 1000 cases.

Appendectomy has not yet been universally accepted as part of the standard procedure but is currently under consideration. However, the appendix is commonly the site of metastases in advanced-stage disease and is reported to be a site of occult disease in a significant proportion of apparent stage I disease as

Table 109.4 International Federation of Gynecology and Obstetrics (FIGO) 2013 staging

Stage I	Tumour is confined to the ovary/ovaries or Fallopian tube(s)
IA	Only one ovary or Fallopian tube is affected by the tumour, the ovary capsule is intact
	No tumour is detected on the surface of the ovary or Fallopian tube
	Malignant cells are not detected in ascites or peritoneal washings
IB	Both ovaries or Fallopian tubes are affected by the tumour, the ovary capsule is intact
	No tumour is detected on the surface of the ovaries or Fallopian tube
	Malignant cells are not detected in ascites or peritoneal washings
IC	The tumour is limited to one or both ovaries or Fallopian tubes, with any of the following: Surgical spill The ovary capsule is ruptured before surgery The tumour is detected on the ovary or fallopian tube surface Malignant cells are detected in the ascites or peritoneal washings
Stage II	Tumour involves one or both ovaries or Fallopian tubes with pelvic extension (below pelvic brim) or primary peritoneal cancer
IIA	The tumour has extended and/or implanted into the uterus and/or the fallopian tubes and/or ovaries
IIB	The tumour has extended to another organ in the pelvis
Stage III	The tumour involves one or both ovaries or Fallopian tubes, or primary peritoneal cancer, with confirmed (cytologically or histologically) spread to the peritoneal surfaces involving both pelvic and abdominal peritoneum and/or metastasis to the retroperitoneal lymph nodes
IIIA1	Positive retroperitoneal lymph nodes only (cytologically or histologically proven) Metastasis up to 10 mm in greatest dimension Metastasis more than 10 mm in greatest dimension
IIIA2	Microscopic extrapelvic peritoneal involvement with or without positive retroperitoneal lymph nodes
IIIB	Microscopic peritoneal metastasis beyond the pelvis 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes
IIIC	Microscopic peritoneal metastasis beyond the pelvis 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (includes extension of tumour to capsule of liver and spleen without parenchymal involvement of either organ)
Stage IV	Distant metastasis beyond the peritoneal cavity (including parenchymal liver/splenic metastases and extra-abdominal metastases)
IVA	Pleural effusion with positive cytology
IVB	Parenchymal metastases and metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

well. Furthermore, the ovary may be a site of secondary disease in the rare case of an appendiceal primary and may be associated with pseudomyxoma peritonei. It should be removed if it appears abnormal at laparotomy.

SURGICAL AND NON-SURGICAL MANAGEMENT OF OVARIAN CANCER

The management of ovarian cancer is discussed below in seven consecutive sections.

Primary surgery: early epithelial ovarian cancer

In cases of early-stage disease, the surgical objective is to identify occult metastases through meticulous systematic exploration. The commonest pattern of metastatic spread of epithelial ovarian cancer is transcoelomic. The cells disseminate and implant along the peritoneal surfaces following the circulatory path of peritoneal fluid. Lymphatic dissemination to pelvic and para-aortic nodes is also common and may occur in apparent early-stage disease. Haematogenous spread is uncommon at the time of diagnosis, but the liver

and lung are the preferred sites. The importance of adequate surgical staging in apparent early disease cannot be overemphasised.

The standard surgical procedure for early-stage disease has already been described. However, when operating on a young patient for whom fertility is important, it is advisable to perform an adequate staging procedure while minimising the risk to future fertility. Although frozen section may be useful if it produces a definitive diagnosis of malignancy, the heterogeneity and size of ovarian malignancies result in under-diagnosis in a considerable proportion of cases. Delaying a sterilising procedure until the final histopathology is available allows a decision regarding further surgical management to be made in consultation with the patient. An initial procedure in such a case would involve complete surgical staging as described, but the uterus and contralateral ovary would be left *in situ* following careful inspection. A decision regarding completion of surgery and adjuvant treatment should then be made in consultation with the patient and based on the advice of the cancer centre's multidisciplinary team.

Laparotomy is currently the gold-standard surgical procedure for the diagnosis and staging of early ovarian cancer. The role of laparoscopy is undefined and it should only be used as part of well-designed prospective clinical trials.

Primary surgery: advanced epithelial ovarian cancer

In contrast with early ovarian cancer, the surgical emphasis in advanced disease is on tumour cytoreduction. Cytoreductive surgery typically involves performing a TAH/BSO, complete omentectomy and resection of any metastases.

Complete cytoreduction i.e. removal of all visible cancer deposits is the goal of surgery in ovarian cancer. If this is not possible, the surgeon aims to reduce the tumour load to achieve 'optimal' status (no residual disease >1 cm).

Resectability of disease depends not only on the skill of the surgeon, but also on the site of disease. Optimal cytoreduction is unlikely if there is extensive disease in the liver parenchyma, porta hepatis or root of the small bowel mesentery.

Retrospective data suggest that this type of surgery is feasible in 70–90 per cent of cases when performed by a gynaecological oncologist.

Ultra-radical surgery in ovarian cancer

Recently, centres of excellence from the United States and Europe have published single institutional case series that demonstrate a marked improvement in progression-free and overall survival by the utilisation of complex surgical procedures (radical and ultra-radical surgery) that result in complete removal of all cancer deposits in addition to standard surgery to remove the uterus and ovaries.^{25–28} A Cochrane review of studies comparing standard vs radical/ultra-radical surgery showed that the utilisation of extensive surgery to remove all cancer deposits in addition to conventional

surgery can significantly improve survival in women with carcinomatosis (adjusted HR = 0.64, 95% CI 0.41–0.98).²⁹ NICE recommends that complete cytoreduction be the aim of surgery in ovarian cancer. Currently, there is no RCT evidence evaluating supra-radical surgery and other key factors including the quality of life in these women are not known. Verleye *et al.* have published a series of quality standards to be maintained in patients undergoing surgery in ovarian cancer.³⁰

Major morbidity from such procedures is approximately 1–3 per cent and operative mortality 1 per cent. Although prognosis depends on the extent of residual disease following surgery, it is also determined by the patient's age, the volume of ascites and performance status (independent prognostic variables). In planning management, these factors must be taken into consideration.

A prospective multicentre observational study of outcomes, including patient reported outcomes (Quality of life) is now underway, www.birmingham.ac.uk/SOCQER. It is also possible that the biology of the disease determines resectability and prognosis. The only prospective randomised trial of cytoreductive surgery [Ib]¹¹ has demonstrated a survival advantage for patients randomised to a second resection of disease as an interval procedure.³¹

TIMING OF SURGERY – PRIMARY SURGERY VERSUS INTERVAL DEBULKING SURGERY AFTER NEOADJUVANT CHEMOTHERAPY

It has been known for some time that patients who have no residual disease after surgery and those who respond to platinum – 'platinum sensitive' patients – have the best survival after ovarian cancer. Two important trials have investigated the role of timing of surgery with relation to chemotherapy – EORTC and CHORUS. These multicentre RCTs investigated whether primary surgery followed by chemotherapy or surgery after neoadjuvant chemotherapy (chemotherapy where three or four cycles are given pre-surgery) would lead to more complete cytoreductive surgery and survival. Both trials have now reported and are consistent in their findings that in patients with large tumour burden and poor performance status, both approaches – primary surgery or interval debulking surgery after neoadjuvant chemotherapy had similar survival outcomes. Interval debulking surgery was associated with lesser morbidity and a reduced number of major resections.³²

It is therefore clear that women who have complete interval cytoreduction have outcomes equivalent to those of patients who have optimal surgery performed as a primary procedure. Therefore, in cases in which initial surgery has involved biopsy only, with no attempt at cytoreduction of advanced disease, it is reasonable to consider definitive surgery after three cycles of chemotherapy, with three further cycles being given following surgery.

KEY POINTS

- The importance of adequate surgical staging in apparent early-stage ovarian cancer cannot be overemphasised.
- Primary cytoreductive surgery followed by chemotherapy has similar survival outcomes to interval debulking surgery in patients with advanced ovarian carcinoma, in patients with poor performance status and large tumour burden.

CHEMOTHERAPY

In general, it is agreed that patients with (adequately staged) low-grade stage IA and IB disease have a very good prognosis and do not require adjuvant treatment [Ia].

However, patients with early-stage disease and poor prognostic factors *may* benefit from adjuvant treatment, as they have a substantial risk of micrometastases. Two large randomised trials addressing this issue (ICON-1 and ACTION – over 900 patients studied) demonstrate a statistically significant improvement in recurrence-free survival and overall survival in women receiving adjuvant chemotherapy if they had not been completely staged at surgery. A multivariate analysis of studies of prognostic variables involving 1545 patients found that degree of differentiation and cyst rupture were independent poor prognosticators. This topic has been reviewed by Winter-Roach *et al.*³³

Currently, for patients with high-risk early-stage disease and for advanced-stage ovarian cancer, the recommended standard treatment is combination chemotherapy with carboplatin and paclitaxel, or carboplatin alone, for six cycles. The latter is usually preferred in less fit patients.

Pelvic radiation alone is not as effective as adjuvant treatment but may be occasionally used to palliate isolated pelvic recurrence, for example a bleeding mass at the vaginal vault.

ICON-7 is a multicentre RCT that evaluated the addition of an antiangiogenic agent, bevacizumab, to carboplatin/taxol chemotherapy. This trial demonstrated that in stage IV cancer and in those with residual disease after surgery, bevacizumab concurrent with chemotherapy and maintenance up to 12 months showed significant improvement in survival over standard chemotherapy.³⁴ The drug is also commonly used in recurrent cancer, in the first relapse setting. Intraperitoneal chemotherapy also shows great promise after a number of trials demonstrated that administering chemotherapy intraperitoneally confers significant improvement in survival after the patient has been completely cytoreduced. However, critics of intraperitoneal chemotherapy point to the high toxicity rates associated with this form of treatment. At the present time, the role of intraperitoneal chemotherapy is unclear. The PETROC trial should finally address this question comprehensively and is ongoing.

Although 70 per cent of patients receiving adjuvant chemotherapy will respond initially to platinum-based chemotherapy at least half will relapse within 18 months. Treatment at relapse is palliative in intent. With the increasing

use of supportive factors such as granulocyte colony-stimulating factor (G-CSF) in chemotherapy, patients receive more cycles of chemotherapy and more lines of chemotherapy than previously and survival for five to six years is achievable in a minority. Carboplatin and taxol are first choice for relapse six or more months (platinum-sensitive or partially sensitive disease) after completing previous chemotherapy. Second-line chemotherapy (combinations different to carboplatin with or without taxol) is indicated in cases of recurrent or progressive platinum-resistant or refractory disease. Response rates are much lower than for primary treatment for second-line therapy (15–35 per cent vs 80 per cent), although better response rates are found in women with longer disease-free intervals before recurrence. In patients with platinum-sensitive disease (i.e. women with a progression-free interval of at least 12 months since platinum-based therapy), re-treatment with platinum or paclitaxel is appropriate. In platinum-resistant cases, an agent without cross-resistance is required. These include alkylating agents (liposomal doxorubicin), gemcitabine, anthracyclines, topoisomerase inhibitors (etoposide, topotecan) and others (tamoxifen). There is some evidence from observational studies that tamoxifen may produce a response in a modest proportion of women with relapsed ovarian cancer. Single-agent regimens are often adopted due to ease of administration and low toxicity.

The OVO5 trial clarifies that monitoring patients who have been treated for ovarian cancer with serial CA125 and administering chemotherapy on the basis of rising CA125 levels in asymptomatic patients does not improve survival in comparison to re-treatment with chemotherapy when the patient becomes symptomatic of recurrence.³⁵

This means it is reasonable to manage patients with symptom-based follow-up rather than serial measurements of CA125.

KEY POINTS

- Additional therapy may be considered for patients who have early-stage disease associated with high-risk factors.
- Standard adjuvant therapy for ovarian cancer involves intravenous chemotherapy.
- Response rates to second-line chemotherapy are much lower than for primary treatment.
- Patients with low-grade stage IA and IB disease do not require adjuvant treatment [Ia].
- In stage I invasive epithelial ovarian carcinoma, degree of differentiation, capsular penetrance, surface excrescences, malignant ascites and cyst rupture are independent poor prognosticators [Ia].
- Platinum-based therapy is better than non-platinum therapy [Ia] and combination therapy improves survival compared with platinum alone [Ia].
- The addition of bevacizumab to chemotherapy marginally improves survival in a subset of patients with stage IV or incompletely resected disease but is associated with more morbidity.

SECONDARY CYTOREDUCTIVE SURGERY

As complete cytoreductive surgery is associated with improved outcomes in patients with advanced ovarian cancer, it has been suggested that there is a role for debulking in patients with persistent or recurrent disease. This group of patients is highly heterogeneous, but may be broadly categorised as follows:

- patients with persistent disease following completion of primary treatment;
- patients with recurrent disease after completion of primary treatment.

Patients with persistent or recurrent disease following completion of primary treatment

Patients whose disease progresses during chemotherapy, those with persistent disease at the completion of chemotherapy and those who develop recurrence early have a limited median survival. Treatment should therefore be directed at optimising quality of life. As a result, cytoreductive surgery is rarely indicated in these groups. However, patients who have had complete clinical responses to primary treatment and who develop localised recurrences, with no ascites after a disease-free interval of six months or more, may benefit from cytoreductive surgery. Best prognostic indicators suggest reserving this approach for single-site recurrence with good performance status, no ascites and where optimal debulking had previously been achieved. A large multicentre trial is now underway (DESKTOPIII) to address the issue of whether secondary surgery or chemotherapy is better for survival in this setting.

PALLIATIVE SURGERY

The most common indication for palliative surgery is bowel obstruction, which is a common feature of recurrent disease but may also be the presenting feature in undiagnosed patients. Most patients have small-bowel obstruction, approximately one third have large-bowel obstruction and a minority have both. However, in many cases of small-bowel obstruction due to ovarian cancer, the site of obstruction is not single and on occasions the entire small bowel is rendered dysfunctional due to extensive peritoneal and mesenteric involvement (carcinomatous ileus). As these latter cases are not amenable to surgery, careful case selection is the essence of good management. Surgery may involve bowel resection, but most commonly intestinal bypass and/or stoma formation is required.

The median survival for patients undergoing palliative surgery for bowel obstruction is 3–12 months. Those who are young, with a good nutritional status (normal albumin levels)

and who do not have rapidly accumulating ascites have the best prognosis. Reported morbidity and mortality rates are 30 per cent and 10 per cent respectively.

TARGETED THERAPIES IN OVARIAN CANCER

Given current survival rates there is great scope to improve survival from ovarian cancer with targeted therapies. Current large trials investigate PARP inhibitors for patients with *BRCA* mutations. Recent drugs that have shown positive improvements in progression-free and overall survival in the recurrence setting are bevacuzimab, an antiangiogenic agent, and cediranib, a multiple tyrosine kinase inhibitor. Several targeted agents are in early-phase trials and in the pipeline. However scheduling of these agents with conventional chemotherapy and choice of which agent to use to obtain optimal benefit for the patient are questions that have not been answered. Funding of these agents remains under purview of NICE reviews.

MANAGEMENT OF RARER TUMOUR TYPES

Borderline ovarian tumours

Approximately 15 per cent of epithelial ovarian tumours are borderline (tumours of low malignant potential). They affect younger women than primary epithelial ovarian cancers and may present in pregnancy. They are usually of low stage and have a very good prognosis. Surgical resection is the primary modality of treatment, as there are no prospective data suggesting that adjuvant treatment prolongs survival. Pre-menopausal women who wish to preserve fertility may be treated by conservative surgery (recurrence rate is about 7 per cent in women managed by conservative surgery). Nonetheless, it should be emphasised that a small subgroup of these patients has rapidly progressive disease and a poor prognosis. Long-term follow-up is advised, as late recurrences do occur. Higher stage, incomplete staging, residual tumour after surgery and cystectomy rather than oophorectomy are independent prognostic factors for disease recurrence.³⁶

Germ-cell tumours of the ovary

Adequate surgical staging, removal of primary tumour and adjuvant chemotherapy is current standard therapy for germ-cell tumours of the ovary. As these malignancies usually occur in young women, conservation of the contralateral ovary and

uterus is appropriate. However, the importance of a complete and thorough staging procedure cannot be underestimated – patients with stage IA dysgerminoma and stage I, grade 1 immature teratoma require no further therapy if comprehensively staged. All other patients should be treated with three or more cycles of combination chemotherapy (bleomycin, etoposide and cisplatin). Most patients with these tumours are cured of disease and most survivors can anticipate normal menstrual and reproductive function. Tumour markers are often useful in monitoring disease and planning management. In the UK, the care of women with germ-cell tumours is centralised, with three key centres at Charing Cross, Dundee and Sheffield coordinating care. This is likely to improve outcomes and facilitate research in this poorly studied field.

Sex-cord stromal tumours

Although they are reported to be most common among postmenopausal women, these tumours often affect children and young adults. They are the most hormonally active of all ovarian tumours and there is an association with endometrial hyperplasia and well-differentiated adenocarcinoma of the endometrium. Surgery is the cornerstone of management, but early-stage disease may be managed by unilateral oophorectomy and endometrial biopsy when fertility sparing is important. Late recurrence is the hallmark of these tumours.

Pseudomyxoma peritonei

This condition involves the accumulation of gelatinous material in the peritoneal cavity. It occurs in association with mucinous tumours of the appendix and/or ovary. It is extremely rare and has a very poor prognosis. Cases should be referred for specialist opinion as early as possible. There are two centres in the UK, at the Christie Hospital in Manchester and in Basingstoke. A histopathological diagnosis of pseudomyxoma ovarii would warrant such a referral.

QUALITY OF LIFE

Most patients with ovarian cancer present late and die of the disease. Cure is the ultimate goal of patient and oncologist, but is not achieved for the majority. Therefore a careful balance must be struck between the pursuit of that goal and optimisation of the quality of the period of life remaining. Specific treatments and their potential impact on disease must be weighed against the morbidity of each therapy. The optimum balance between these opposing aims will be different for each patient. The informed patient's voice is critical to finding the best compromise for her and should be heard. Management decisions should be made with the balance of probabilities and the patient's desires clearly in focus.

CONCLUSION

The management of ovarian cancer represents a major challenge and requires close multidisciplinary team working amongst medical, clinical and surgical oncologists, radiologists, pathologists, clinical nurse specialists and specialists in palliative care. The centralisation of gynaecological cancer services has improved compliance with management guidelines, provided specialist training and treatment, facilitated research and consequently improved patient care and outcomes which are particularly pertinent to the care of women with ovarian cancer.

Chapter 110 Vulval and vaginal cancer

John Tidy

MRCOG standards

(Core Curriculum Module 17: Gynaecological Oncology)

Knowledge criteria

- Epidemiology, aetiology, diagnosis, prevention, management, prognosis, complications and anatomical considerations of vulval and vaginal cancer.
- FIGO classifications for vulval and vaginal cancer.
- Indications, techniques, complications and outcomes of surgery and radiotherapy for vulval and vaginal cancer.

Clinical competency

- Awareness of the role of the multidisciplinary meetings in determining gynaecological cancer management.
- Recognise, counsel and plan initial management of vulval cancer.

INTRODUCTION

Vulval and vaginal cancers are rare, accounting for about 1000 new cases per year in the UK. It is important to recognise the symptoms and signs associated with these cancers to make an early diagnosis. As in all cancers, appropriate treatment at an early stage in the disease will lead to a better outcome for the patient, as reported by a population-based study of a series of 411 women in the West Midlands [D].¹ Most of the evidence for the management of these cancers is derived from case-controlled series, and the rarity of these tumours is a major obstacle in undertaking randomised trials.

VULVAL CANCER

Vulval cancer is a disease primarily of the older age group, with the majority of cases presenting between the ages of 60 and 75. An increasing proportion of young women do present with

this disease and therefore this diagnosis must always be borne in mind.

Approximately 800 new cases of vulval cancer are diagnosed in the UK each year. The incidence has remained steady over the past three to four decades despite the increasing recognition of patients with vulval intraepithelial neoplasia (VIN). The majority (90–95 per cent) of vulval carcinomas are of squamous origin, although adenocarcinomas can arise from the Bartholin's gland and also in conjunction with Paget's disease of the vulva. Melanoma of the vulva is the second most common malignancy arising in the vulva, accounting for 4–9 per cent of cases. Basal cell and verrucous carcinomas also occur in the vulva.

Aetiology

Pathology

Certain pre-existing vulval dermatoses are known to be associated with the development of vulval carcinoma. VIN is often found in association with vulval cancer and VIN-3 is regarded as a pre-invasive condition. The risk of this condition progressing to invasive cancer is highly variable, according to the literature. In women who have previously been treated for VIN, the risk is estimated at between 7 and 8 per cent,² whereas in one study in which women remained untreated, the progression rate of VIN to invasive cancer was 80 per cent at 10 years [D].³ Lichen sclerosus is a common vulval inflammatory dermatosis affecting older women and is generally thought to carry an increased chance of malignant progression, although the exact risk is unknown because the ascertainment of LS is inexact. Recently it has been postulated that women with LS who develop differentiated VIN are at greatest risk of progressing to invasive cancer.⁴ Differentiated VIN is more frequently associated with invasive cancers compared with undifferentiated VIN and other dermatoses. In the past this condition may have gone unrecognised and so unreported. Extramammary Paget's disease of the vulva is a rare form of VIN and is occasionally associated with cancer of the apocrine gland.

Molecular biology

Approximately 30 per cent of all vulval cancers are associated with human papillomavirus and about 80–90 per cent of these vulval cancers develop in women under the age of 50.

Variations in the cell-cycle regulatory protein p53 are reported in approximately 30 per cent of cancers and for the remainder there currently appears to be no aetiological or molecular biological event. Recent studies have shown similar molecular changes, including alterations in p53 expression, to be present in both vulval cancer and the surrounding LS.

Smoking may be an important cofactor in the development of HPV-related VIN and is linked to a lower survival rate for women with vulval cancer.

KEY POINTS

Vulval cancer: epidemiology and pathology

1. Vulval cancer is uncommon and most evidence arises from observational studies and case series.
2. Population-based observational studies confirm better outcomes with early detection.
3. There appear to be different aetiologies; one linked to infection with oncogenic HPV and another linked to pre-existing vulval maturation disorders.
4. The reported malignant potential of VIN varies between 5 and 80 per cent. This probably reflects the variations in the observational studies rather than a widely varying biological effect.

Diagnosis

Women with vulval cancer usually present with symptoms, although an asymptomatic mass may be an unusual presentation. The associated symptoms are usually vulval soreness and itching and there may be a mass that is painful and bleeds. Investigation of post-menopausal bleeding should always include examination of the vulva. The most common site of involvement is the labium majus (about 50 per cent of cases). The labium minus accounts for 15–20 per cent of cases. The clitoris and Bartholin's glands are less frequently involved. In the majority of cases, a vulval cancer is obvious to the alert clinician, but very early cancers may be clinically indistinguishable from florid warty VIN.

Investigations

When women present with vulval symptoms, a full clinical examination should be performed, paying particular attention to palpation of the groins for lymphadenopathy. A full-thickness biopsy should be taken from the tumour and should include the interface between the apparent normal surrounding tissue and the cancer. This allows for the most accurate histological interpretation and for the depth of invasion to be assessed, which is important in determining the future management. The cervix should be visualised to exclude a cervical cancer, which may occasionally coexist. Assessment of the inguinal glands is not absolutely reliable with any imaging technique at present, but should there be a clinical suspicion of inguinal lymph node enlargement, a

CT or MRI assessment of the pelvis should be undertaken to exclude obvious pelvic lymphadenopathy.

Treatment

There is increasing emphasis placed on the individualisation of treatment for women with vulval cancer. In deciding the optimum treatment, it is best to consider early and advanced vulval cancers separately and to manage the primary lesion and the regional lymph glands on individual merit. Because of the rarity of vulval cancer, and the need for careful assessment to optimise both vulval preservation and care, these women should be managed by specialised gynaecological oncologists in cancer centres. In addition to imaging, the pathological assessment of these tumours is extremely important in forming decisions about adjuvant treatment. All cases must be discussed at the local specialist gynaecological oncology MDT meeting.

Early stage vulval cancer

Primary lesion

Treatment of the primary lesion is in part determined by the risk of local vulval recurrence and the risk of groin node involvement at the time of diagnosis. A retrospective surgical–pathological study of 135 cases found that if a pathological disease-free margin of 8 mm can be achieved, the risk of local recurrence is zero [D].⁵ Therefore the primary lesion should be excised with a 1-cm disease-free margin including the deep margin. The 1-cm margin will allow for tissue shrinkage due to fixation of the specimen. In most early cancers this can be achieved by a wide radical local excision and will allow for the preservation of non-involved structures. If the primary lesion is associated with a vulval maturation disorder or VIN, this may be removed as well. However, if the VIN is very widespread, this could necessitate a very large excision requiring myocutaneous flaps. Under these circumstances it may not be considered essential to remove all VIN as part of the primary surgical procedure to remove a carcinoma. Re-excision of the vulval lesion to achieve at least 1 cm of disease-free margin has been the standard of care but recent data have shown a low rate of residual disease but high rate of surgical complications. Careful observation and re-excision of any new disease may be a suitable alternative approach.⁶

Regional lymph nodes

Depth of invasion is the best predictor of risk of nodal metastasis in vulval cancer. The most recent staging criteria for vulval cancer (Table 110.1) have recognised the concept of micro-invasive or superficially invasive vulval cancer (Stage IA), as the risk of nodal involvement in tumours with depth of invasion up to 1 mm is virtually zero [D].⁷ These tumours may therefore be treated by wide local excision alone.

Lateral vulval tumours

The management of regional lymph nodes can be modified for patients presenting with lateral vulval tumours. Although there is extensive lymphatic crossover in the midline of the

Table 110.1 Staging of vulval cancer. FIGO classification 2009

Stage I	Tumour confined to the vulva
IA	Lesion ≤ 2 cm in size, confined to vulva or perineum and with stromal invasion ≤ 1 mm invasion*, no nodal metastasis
IB	Lesion > 2 cm in size or with stromal invasion > 1 mm invasion*, confined to vulva or perineum, with negative nodes
Stage II	Tumour of any size with extension to adjacent perineal structures (one third lower urethra, one third lower vagina, anus) with negative nodes
Stage III	Tumour of any size with extension to adjacent perineal structures (one third lower urethra, one third lower vagina, anus) with positive inguino-femoral lymph nodes
IIIA	(i) With lymph node metastasis (≥ 5 mm), or (ii) 1-2 lymph node metastases (< 5 mm)
IIIB	(i) With 2 or more lymph node metastases (≥ 5 mm), or (ii) 3 or more lymph node metastases (< 5 mm)
IIIC	With positive nodes with extracapsular spread
Stage IV	Tumour invades other regional (two thirds upper urethra, two thirds vagina) or distant structures
IVA	Tumour invades any of the following: (i) upper urethra and/or vaginal mucosa, bladder mucosa, rectal mucosa or fixed to pelvis bone, or (ii) fixed or ulcerated inguino-femoral lymph nodes
IVB	Any distant metastasis including pelvic lymph nodes

* The depth of invasion is defined as the measurement of the tumour from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of the invasion.

vulva, lateral tumours (i.e. those with the medial border at least 2 cm lateral to a line drawn between the clitoris and the anus) require only an ipsilateral inguinal node dissection. If the ipsilateral nodes are negative, the contralateral nodes are rarely involved [D].⁸ However, should these nodes be positive, a contralateral node dissection should be undertaken. In a prospective trial, the outcome for 26 women who underwent ipsilateral lateral groin node dissection alone was similar when compared with historical controls [C].⁹

Inguinal node dissection

Surgical dissection of inguinal nodes is considered mandatory in early-stage vulval cancer when depth of invasion is greater than 1 mm. A randomised trial comparing inguinal node dissection with radiotherapy to the groin in women with clinically normal inguinal nodes found a survival advantage in favour of the surgical arm; however, this trial has been criticised because an inadequate dose of radiotherapy was given to the inguinal nodes.¹⁰ A subsequent systematic review, of only three eligible studies, suggested that surgery is superior to radiotherapy [A].¹¹

Attempts have been made to reduce the morbidity associated with this procedure. Unfortunately, superficial inguinal node dissection, which removes only the lymph nodes above the cribriform fascia, is associated with a higher rate of inguinal recurrence compared with inguino-femoral node dissection, which removes tissue below the cribriform fascia (this is the layer deep to the fascia lata) and medial to the femoral vein. In a prospective clinical trial, 155 women underwent a superficial inguinal node dissection and although the overall survival rate was the same compared with a series of historical controls, the rate of inguinal node recurrence was significantly higher.⁹ It is therefore recommended that a full dissection should still be performed in cases of early vulval cancer [C]. The routine removal of pelvic lymph nodes in early stage vulval cancer is not recommended. Recent data have suggested that by sparing the long saphenous vein, the short-term and long-term morbidity associated with lymphoedema may be reduced [D].

Another approach to reduce morbidity is the identification and removal of the sentinel node. The idea depends on the sentinel node (i.e. the first node to drain the vulval tumour) being identified and, if histologically normal, the remainder of the inguinal lymph node dissection could be omitted. The most reliable technique is probably a hybrid of pre-operative intralesional injection of radiolabelled technetium combined with intralesion injection of blue dye at the time of surgery and scanning of the nodal tissue for a radioactive signal. In the collected series to date, the sentinel node – the anatomical location of which is highly variable – has been identified in almost 100 per cent of cases and there have been only a very few cases reported in which the sentinel node was normal but other nodes were positive for tumour [C].¹² In the GROINSS-V study a sentinel node procedure was performed in 623 groins of 403 women with squamous cancer of the vulva. Out of 259 women with unifocal disease and negative sentinel node, six developed groin recurrence (2.3 per cent). Women who had a positive sentinel node and underwent a full groin excision experienced significantly more morbidity. The current study, GROINSS-VII, is evaluating a protocol in which women with negative nodes have no further groin surgery and those with a positive sentinel node are offered radiation therapy without full groin dissection.¹³

Advanced vulval cancer

Women in whom the cancer has spread beyond the vulva will benefit from a multimodality approach to their management. Neoadjuvant chemotherapy and radiotherapy can be used to shrink the tumour and so permit surgery, which may preserve urethral and anal sphincter function. Reconstructive surgery can potentially reduce physical morbidity by filling large tissue defects and may reduce psychological morbidity as well.

Surgery to the primary lesion

The size and location of the tumour will influence the surgical approach to the primary lesion. The surgical goal is to remove the tumour with at least a 1 cm disease-free margin. In the majority of cases a triple-incision technique can be employed.

Several clinical series have shown that the incidence of skin bridge recurrence between the primary lesion and the inguinal node dissection is low, even if there is evidence of lymphatic channel involvement [D].¹⁴ However, if there is evidence of tumour within the skin bridge between the primary tumour and the inguinal nodes at the time of surgery, a radical vulvectomy with en-bloc inguinal node dissection (butterfly incision) should be considered. If extensive areas of vulval tissue need to be removed, reconstructive surgery with the use of skin grafts or myocutaneous flaps may be essential to achieve healing.

Management of inguinal nodes

In cases in which there is clinical suspicion of inguinal node involvement, an inguinal node dissection should be undertaken. As stated above, if there is concern about lymphatic permeation, an en-bloc dissection should be considered. In cases in which the nodes are fixed or ulcerated, biopsy of these or fine-needle aspiration should be considered, followed by radiotherapy to the inguinal and pelvic lymph nodes. Surgical removal of large inguinal or pelvic nodes should be attempted if feasible, since standard radiotherapy doses to the inguinal nodes may be inadequate to bring about a complete regression.

KEY POINTS

Surgical management of vulval cancer

- Vulval cancer should be managed in cancer centres.
- Vulval tumours should be excised with a minimum margin of 10 mm of normal epithelium.
- This will vary from a wide local excision to radical vulvectomy, depending on the size of the tumour and the nature of adjacent epithelium.
- Lymphadenectomy is required for all but superficially invasive squamous tumours.
- Routine lymphadenectomy is not required for basal-cell and verrucous carcinomas and melanomas.
- Lateral tumours initially require only ipsilateral lymphadenectomy.
- Formal inguino-femoral lymphadenectomy remains the procedure of choice.
- A triple-incision technique will suffice unless there is evidence of skin bridge involvement at the outset, when an en-bloc approach should be used.
- Pelvic lymphadenectomy is not routinely used in the treatment of vulval cancer.
- Advanced disease requires a multimodality approach.

The management of other vulval cancers

Basal-cell carcinomas and verrucous carcinomas of the vulva are usually only superficially invasive to a depth of 1 mm and are rarely associated with lymph node metastases.

These tumours can be adequately managed by means of a wide local excision. Basal-cell carcinomas can be treated with radiotherapy if surgery would compromise the sphincter function, but this is rarely necessary.

Melanomas of the vulva should be managed by wide local excision. Inguinal node dissection does not influence outcome in these cases, and management should be determined as for the criteria for other sites of cutaneous melanoma. Close liaison with the melanoma MDT is recommended.

Cancer can develop within the Bartholin's gland and may be either squamous or adenocarcinoma. Its management is the same as for squamous vulval cancer.

Neoadjuvant therapy

Radiotherapy may be given pre-operatively to the primary lesion to allow for tumour shrinkage. This is particularly useful if primary surgery would necessitate removal of the urethral or anal sphincters. A total maximum dose of 55 Gy may be given with concurrent 5-fluorouracil (5-FU). Subsequent tumour shrinkage may then enable the preservation of sphincters.

Radical chemoradiotherapy with curative intent

Radical radiotherapy with chemotherapy may be used as an alternative to surgery in the management of advanced squamous vulval carcinomas. There are no published data comparing surgery with chemoradiotherapy in the primary treatment of vulval cancer. Radical radiotherapy alone in the UK has usually been confined to patients who decline surgery or in whom medical morbidity prevents surgery. The recommended dose of radiotherapy is 65 Gy with concurrent 5-FU and cisplatin. In a study of 14 women who were not candidates for standard surgery (nine stage III and five stage IV), nine (64 per cent) had a complete response to radiation (50–65 Gy) in combination with cisplatin (50 mg/m²) and 5-FU (100 mg/m² per 24 to 96 hours).¹⁵

Adjuvant radiotherapy

Surgical margins

Post-operative radiotherapy should be considered in patients with close or positive surgical margins. There is no minimum disease-free margin at which radiotherapy should be considered. However, patients with <4.8 mm of disease-free margin have a 57 per cent chance of disease recurrence.⁵ Where possible, consideration should be given to re-excision of the vulva to improve the disease-free margin rather than radiotherapy [E].

Inguinal nodes

Post-operative radiotherapy should be considered in patients who have nodal involvement with metastatic disease. Several case series have found that prognosis is only affected when two or more nodes are involved [D]. The presence of extracapsular spread in any lymph node is an adverse factor and warrants adjuvant treatment [D]. Adjuvant radiotherapy should be confined to the affected side and should include pelvic nodes

as well. In a randomised trial comparing adjuvant pelvic radiotherapy with pelvic lymphadenectomy, in 114 women with positive inguinal nodes, there was a significant survival advantage (68 per cent vs 54 per cent at 2 years) in favour of radiotherapy [B].¹⁶ A total dose of radiotherapy between 45 and 50 Gy without 5-FU is recommended.

KEY POINTS

Non-surgical management of vulval cancer

- Vulval tumours can be treated by primary radical radiotherapy if surgery is declined or not possible.
- Adjuvant radiotherapy is recommended when surgical margins are inadequate (<8 mm) if re-excision might compromise function.
- Radiotherapy to the groin and pelvic node sites is recommended if more than one node is involved or there is evidence of any extracapsular spread.
- Radiotherapy may be used prior to surgery to attempt to reduce the morbidity and functional loss associated with surgery in large lesions.
- Radiotherapy with concurrent chemotherapy may improve outcome, but as yet there are no data in support of this approach.

Treatment-related morbidity

A more conservative approach to the management of vulval cancer and individualisation of care have led to a reduction in treatment-related morbidity. However, there still remains a significant rate of wound infection and wound breakdown. Lymphoedema of the legs is a major cause of long-term morbidity and there are also high levels of psychological and psychosexual morbidity associated with the disfiguring nature of the surgery employed.

Morbidity associated with recurrent disease

Recurrent disease affecting the vulva itself should be managed by further surgical excision and, if necessary, radiotherapy. Recurrence involving the inguinal nodes or pelvic nodes should be treated with radiotherapy. However, this can usually only be palliative, and most patients with groin recurrence die of the disease.

Follow-up of treated patients

Patients should be followed up on a 3-monthly basis for the first 2 years following treatment, as this allows for the detection of early recurrence and the management of treatment-related morbidity. Once they have completed 2 years of follow-up, they may be seen 6-monthly for the following 3 years.

VAGINAL CANCER

Vaginal cancers are rare gynaecological tumours accounting for only 1–2 per cent of all gynaecological cancers. The majority of vaginal cancers are squamous in origin (about 85 per cent), but adenocarcinoma can also develop in young women between the ages of 17 and 21 and is associated with a higher incidence of metastatic disease to the lymph nodes and lungs. Melanomas and sarcomas are rare causes of vaginal cancer. Clear-cell adenocarcinomas of the vagina are linked to women with a history of in-utero exposure to diethylstilboestrol (DES). An increased incidence of this tumour was first reported in the mid-1970s, but there has been a steady decline in its incidence over recent years with the withdrawal of DES from clinical practice.

Aetiology

Little is known about the aetiology of vaginal cancer, but it is presumed to share similarities with vulval and cervical cancer. Vaginal intraepithelial neoplasia (VAIN) grade 3 is a recognised pre-cancerous condition affecting the vagina and it is frequently seen in combination with cervical intraepithelial neoplasia (CIN). It may occur in one of two ways: as a lateral extension of the CIN out onto the vaginal fornices at the time of treatment for CIN, or in women who have previously undergone hysterectomy for CIN, which was incompletely excised by this procedure. In these latter cases, the VAIN is often found within the surgical margin of the vaginal vault. The percentage of women who present with this condition and who subsequently develop vaginal cancer is unknown, but there is a significant risk of invasive disease. Factors that influence the outcome of vaginal cancer are the size of the tumour and the age of the patient.

Diagnosis

The diagnosis of vaginal cancer may be suspected at the time of colposcopic examination of the vagina. An adequate biopsy, which includes the entire thickness of vaginal epithelium, should be obtained for histological confirmation. This is important, as the depth of invasion of the tumour into the vaginal mucosa and muscle is significant in the staging of the disease (Table 110.2). A diagnosis of cancer of the vagina can only be made with certainty in the presence of a normal cervix or following hysterectomy, as described above.

Investigations

The cervix should be carefully examined if still *in situ* to exclude cervical involvement. An MRI of the pelvis will help to determine the extent of any spread from the vagina and also the status of the regional pelvic nodes.

Table 110.2 Staging of vaginal cancer. FIGO classification 2006

I	Tumour confined to vagina
II	Tumour invades paravaginal tissues but not to pelvic sidewall
III	Tumour extends to pelvic sidewall
IVA	Tumour invades mucosa of bladder or rectum and/or extends beyond the true pelvis
IVB	All cases with distant metastases

Treatment

In planning definitive treatment, consideration should be given not only to the stage of disease at presentation, but also to the size and location of the tumour. Surgery in combination with pelvic radiotherapy, when appropriate, can be effective in the management of stage I and II disease, with survival rates of 68 per cent and 48 per cent respectively [D].¹⁷

Stage I vaginal cancer

Tumours <0.5 cm deep

Early vaginal cancer may be managed either by surgery or by intracavity radiotherapy. Surgery should include wide local excision or total vaginectomy with reconstruction of the vagina where possible. Intracavity treatment with 60–70 Gy to the tumour should be given and in cases where the tumour lies within the lower third of the vagina, external-beam radiotherapy to the pelvic and inguinal lymph nodes should be considered.

Tumours >0.5 cm deep

Surgery for this condition should include wide vaginectomy, pelvic lymphadenectomy and reconstruction of the vagina where possible. For lesions in the lower third of the vagina, inguinal lymphadenectomy should be performed as well. Radiotherapy for this condition should be a combination of brachytherapy to the tumour and external-beam radiotherapy to the pelvic and inguinal nodes if the tumour is present in the lower third of the vagina.

Although surgery or radiotherapy can be used in the primary management of stage I disease, the usual practice in the UK has been to offer radiotherapy, which has the advantage of vaginal preservation.

Stage II vaginal cancer

Radical surgery can be considered for this condition and should include radical vaginectomy with lymph node dissection or possibly pelvic exenteration. Radiotherapy may also be used, with a combination of brachytherapy to the tumour and external-beam radiotherapy to the pelvic and inguinal lymph nodes.

Stage III and IV vaginal cancer

These cases should be managed by a combination of brachytherapy to the primary tumour and external-beam radiotherapy to the pelvis and inguinal lymph nodes.

Morbidity

Treatment-related morbidity can be significant. Sexual dysfunction due to vaginal atrophy and damage to the bladder and rectum are not infrequent. Recurrent vaginal cancer can be treated with radical pelvic radiotherapy if recurring after surgery. If disease recurs after radiotherapy, palliative surgery may be possible in selected cases.

Follow-up

Patients should be followed up on a 3-monthly basis for the first 2 years following treatment, as this allows for the detection of early recurrence and the management of treatment-related morbidity. Once they have completed 2 years of follow-up, they may be seen 6-monthly for the following 3 years.

KEY POINTS

Vaginal cancer

- There is limited published evidence concerning the treatment of vaginal cancers.
- Case series support the use of surgery in selected cases, with cure rates similar to those of primary radiotherapy in early-stage disease.
- A combination of brachytherapy and external beam radiation has the advantage of vaginal preservation.

SUMMARY

Vulval and vaginal cancers are rare and affect an older age range. Individualisation of care has led to a reduction in morbidity without affecting cure rates. Multimodality treatment is often required in advanced cases. All vulval and vaginal cancers should be managed at a cancer centre.

Chapter 111 Gestational trophoblastic disease

Fieke E M Froeling and Michael J Seckl

MRCOG standards

Theoretical skills

- Understand the pathogenesis.
- Have good knowledge of gynaecological diagnosis and management.
- Have an appreciation of the needs for monitoring and/or medical intervention.

Practical skills

- Be able to counsel a woman with gestational trophoblastic disease.
- Be able to recognise the clinical features of gestational trophoblastic disease.
- Be able to perform evacuation of molar pregnancy under supervision.

INTRODUCTION

Gestational trophoblastic disease (GTD) is an uncommon complication of pregnancy. An average consultant obstetrician may deal with only one new case every second year. The term gestational trophoblastic disease describes a group of inter-related diseases, including the pre-malignant disorders of partial and complete hydatidiform mole (PHM and CHM) and the malignant diseases of invasive mole, choriocarcinoma and the rare placental site trophoblastic tumour/epithelioid trophoblastic tumour (PSTT/ETT). The malignant diseases are also collectively named gestational trophoblastic neoplasia (GTN). Although persistent GTD most commonly follows a molar pregnancy, it can be seen after any type of gestation, including term pregnancy, abortion and ectopic pregnancy. Gestational trophoblastic tumours produce hCG which is important in the diagnosis, management and follow-up of these patients, providing an example of an 'ideal' tumour marker. The first complete responses to methotrexate chemotherapy were described in the 1950s, and presently almost 100 per cent of patients are cured.

EPIDEMIOLOGY

The incidence and aetiological factors of GTD have been difficult to assess. As GTD follows all kinds of pregnancies, the denominator for the incidence should ideally include all livebirths, stillbirths, abortions and ectopic pregnancies. The accepted convention, however, has been to report incidence data according to the livebirth rate. Furthermore, reports from different countries often use different denominators, and figures for hospital-based populations are likely to overestimate the incidence compared with community-based figures, particularly in developing countries. Under-reporting may also occur, especially, but not uniquely, in communities where medical attention is suboptimal.

In the UK, all patients are nationally registered with central pathology review and the incidence is estimated at 3 per 1000 pregnancies for PHM and 1–3 per 1000 pregnancies for CHM. The incidence is approximately twice as high in some Asian countries and also in native Americans, which can be a reflection of discrepancies between hospital- and population-based data, availability of central pathology review or true differences because of dietary and genetic influences.¹ Maternal age appears to be the most consistent risk factor associated with molar gestation. Age-specific incidence reports usually reveal a 'J curve', with extremes of reproductive life associated with an increased incidence. Pregnancies below the age of 15 years have a moderately increased risk, whereas those occurring over the age of 50 years are associated with a substantially increased risk. This increased incidence in the youngest and oldest age groups seems to be a consistent finding in all regions and races. Women who have had a previous mole have an increased risk of further molar pregnancies. Following one mole, the risk of a further complete or partial mole is 1–2 per cent. After two molar pregnancies the risk of a third mole increases substantially to 15–20 per cent and is not decreased by changing partner. Occasionally, family clusters have been seen, implicating an underlying genetic disorder in such cases. Nutritional factors also appear to be risk factors for molar pregnancy in some populations, with a low dietary intake of carotene and animal fat reported to be associated with an increased incidence of CHM.¹

The incidence of choriocarcinoma and PSTT is less clear. Following a term delivery, choriocarcinoma develops in approximately 1 in 50,000 women. However, CHM precedes choriocarcinoma in 29–83 per cent of cases and therefore the overall incidence of choriocarcinoma is probably much higher. Rarely, PHMs can give rise to choriocarcinoma or PSTT. PSTT is the rarest form of GTD, representing 0.2 per cent of all registered cases of GTD in the UK.²

PATHOLOGY AND GENETICS

All forms of GTD arise from components of the placenta, either the villous trophoblast (hydatidiform moles and choriocarcinoma) or the interstitial trophoblast (PSTT). Most complete and partial moles have distinct morphological characteristics (Table 111.1) but suspected cases should be reviewed by specialist histopathologists. Complete hydatidiform moles are usually diploid and androgenic in origin, the most common type being 46XX from duplication of the haploid genome of a single sperm (~ 80%). In approximately 20 per cent, a molar pregnancy develops from dispermic fertilisation. In either scenario, the maternal chromosomes are lost before or after fertilisation (Fig. 111.1A, B). Some patients with recurrent CHM can have a biparental karyotype due to familial recurrent hydatidiform mole (FRHM), an autosomal recessive disease (Fig. 111.1C). Mutations in two genes, *NLRP7* and, more rarely, *KHDC3L*, have been associated with this condition.³ PHMs are generally triploid, most often from dispermic fertilisation of normal ova (Fig. 111.1D). When a

fetus is present it often has the features of triploidy, including growth retardation and multiple congenital malformations, and is never viable.

In current-day practice, the earlier evacuation of suspected molar pregnancies has meant that there is more likelihood of misdiagnosis by the pathologists as classical features may be less well developed. Complete moles are now often characterised by subtle morphological abnormalities that may result in their misclassification as partial moles or non-molar abortions, especially when associated with chromosomal abnormalities. Abortions due to trisomy, monosomy, maternally derived triploidy and translocations often develop some degree of hydropic change which can cause diagnostic confusion with molar pregnancies. CHM can be excluded with the help of additional techniques such as immunostaining with p57^{KIP2}, an imprinted marker expressed only by the maternal genome and therefore negative in CHM but positive in non-molar pregnancies or PHM. Ploidy analysis by in-situ hybridisation or flow cytometry (triploid in PHM) or molecular genotyping can help to distinguish PHM from CHM and non-molar hydropic abortions.⁴ The clinical entity of invasive mole occurs when a complete or, less commonly, a partial mole invades deeply into the myometrium. Unfortunately, there are no pathological or molecular features that reliably predict which patients will develop persistent GTD (malignant change in a CHM or PHM) and therefore all patients with an evacuated molar pregnancy will need surveillance with hCG.

Gestational choriocarcinoma is the malignant form of GTD and may originate from a previous hydatidiform mole

Table 111.1 Pathological features of complete and partial hydatidiform mole

	CHM	PHM
Macroscopic	Characteristic grape-like structures	Can resemble an hydropic abortion with avascular and oedematous villi*
		May have recognisable fetal tissues
Microscopic	Diffusely hydropic villi	Patchy villous hydropic change
	Diffuse trophoblast hyperplasia	Patchy trophoblast hyperplasia
	Stromal hypercellularity	Scattered, abnormally formed villi with trophoblastic pseudo-inclusions
	Stromal karyorrhectic debris	
	Collapsed villous blood vessels	
	Usually appropriately diagnosed from uterine products	Often misdiagnosed as hydropic abortion or CHM
Karyotype	46XX (androgenic monospermic, majority)	69XXY
	46XY (androgenic dispermic, around 20%)	
	46XX (biparental, rare cases of familial recurrent HM, <1%)	

*Usually spontaneous abortion, in which the embryo either never developed or ceased development very early in gestation. Macroscopically, the hydrophobic changes can resemble molar pregnancies, in particular PHM

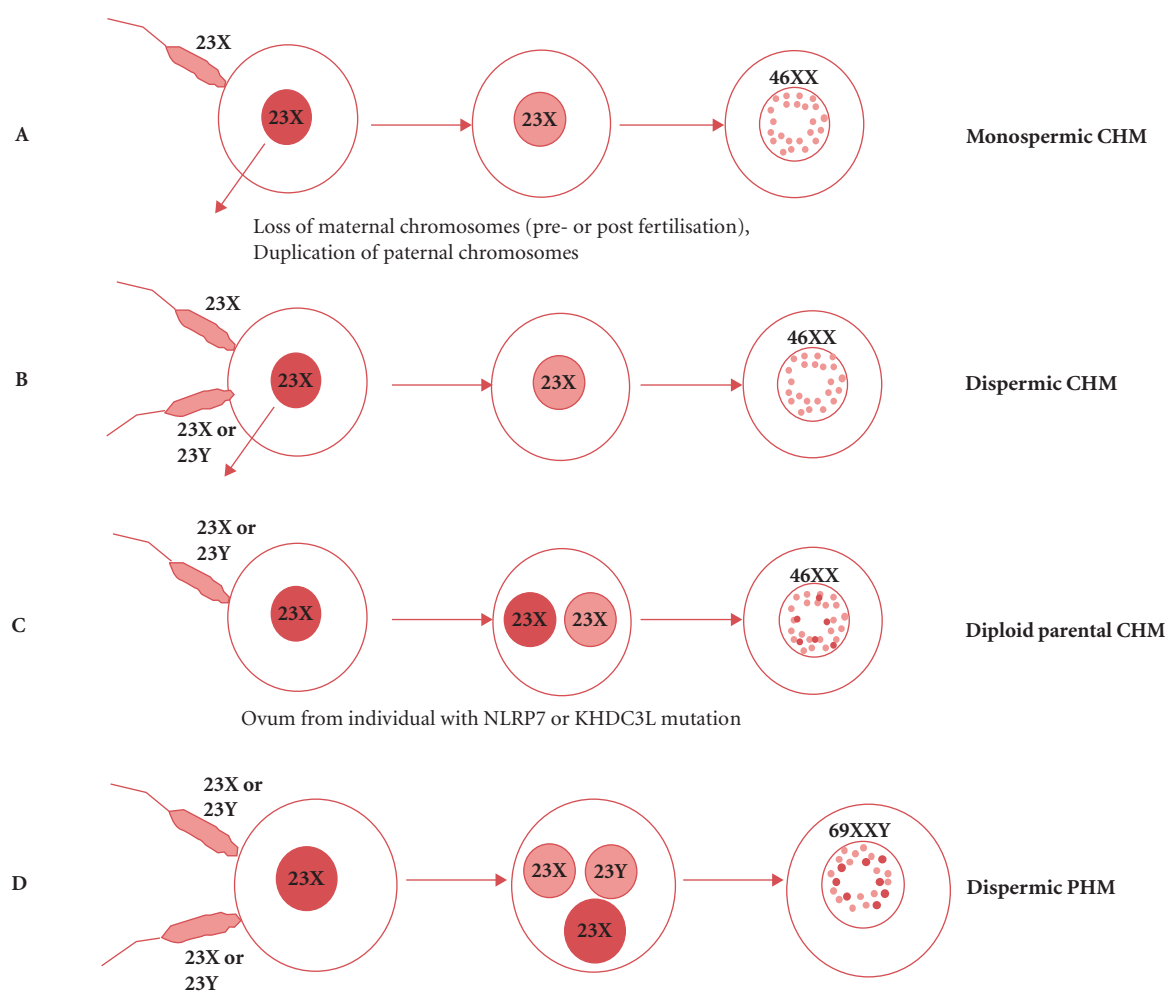

Fig. 111.1 The origins of molar pregnancies

or from a normal conception. The definitive histopathological diagnosis of choriocarcinoma requires the demonstration of a dimorphic population of both cytotrophoblast and syncytiotrophoblast without the presence of formed chorionic villi, plus evidence of myometrial invasion. However, because of the availability of a sensitive tumour marker, the majority of patients are treated without the benefit of a histological diagnosis. Gestational choriocarcinoma metastasises widely, particularly to the lungs, pelvic organs and brain.

PSTT and the newly recognised variant ETT may develop after any type of pregnancy and originate from intermediate trophoblastic tissue. They produce less hCG, grow more slowly, infiltrating and pushing apart the myometrial cells, and metastasise later in their disease course with a slightly increased propensity for involving the lymphatics.¹ After the placenta is lost from the uterus, small nodules of placental tissue can remain in the myometrium. These usually resorb over time but in some, they persist as placental site nodules (PSNs). We have recently realised that these may develop

atypical features (atypical placental site nodules: APSNs) that include increased mitoses and can progress to PSTT/ETT.⁵

CLINICAL FEATURES

The majority of patients with PHM or CHM are diagnosed prior to 16 weeks of gestation and most patients present with vaginal bleeding in the first trimester. The clinical presentation of CHM has changed considerably over the past few decades. Excessive uterine size, anaemia, hyperemesis, pre-eclampsia, theca lutein cysts, hyperthyroidism and metastatic disease are seen far less often, except in countries with less well-developed healthcare systems. Invasive mole can produce heavy bleeding, lower abdominal pain or intraperitoneal haemorrhage. Occasionally, the bladder or rectum is infiltrated, producing haematuria or rectal bleeding. Invasive moles may regress spontaneously or they may embolise, particularly to the

lungs, but they do not usually exhibit the progression of true malignancy.

The clinical features of a PHM are usually less severe than those of a CHM and this condition is frequently diagnosed on histological review of curettings from what appeared clinically to be a miscarriage. Even in earlier studies, increased uterine size, theca lutein cysts and pre-eclampsia were seen in only a small percentage of cases.^{6,7}

DIAGNOSTIC INVESTIGATIONS

The classic 'snowstorm' sonographic pattern of CHM seen in the second trimester, with associated theca lutein ovarian cysts, is rarely seen due to earlier presentation with bleeding. Ultrasound in the first trimester will show no clear evidence of a normal pregnancy and so prompt early evacuation. The sonographic features are not diagnostic of CHM or PHM and histological analysis by a specialist histopathologist is essential in making the correct diagnosis.⁸ In locally invasive moles, increased areas of echogenicity are seen within the myometrium.

Trophoblastic disease is virtually unique in that it produces a specific marker in the form of hCG, which can be measured in urine and/or blood and correlates precisely with the amount of disease present. This is a large placental glycoprotein composed of two peptide subunits and is produced naturally during pregnancy. The alpha subunit is similar to those of other pituitary glycoprotein hormones, but the beta subunit is specific to hCG alone. Higher than normal levels of hCG (particularly when >200,000 IU/L) are suggestive of molar pregnancy but, in particular, in PHM the levels are only infrequently above the range for a normal pregnancy. As a diagnostic marker for molar pregnancy, hCG measurement is therefore of limited value.

Assays to detect hCG use antibodies that detect the beta subunit. However, beta hCG can exist in a number of forms/fragments including nicked hCG, beta-core, C-terminal segment, hyperglycosylated hCG and free beta subunit. When it is measured in trophoblastic disease it is therefore important that the assay being used detects all main forms of hCG.¹

EVACUATION OF MOLAR PREGNANCY

Suction curettage is the method of choice for evacuation of molar pregnancies and because of the lack of fetal parts in CHM, a suction catheter of up to 12 mm is usually sufficient. Sharp curettage is now not generally recommended because of the possibility of uterine perforation and of increasing the risk of Asherman's syndrome (uterine synechiae). Ultrasound during the procedure can help to guide the procedure and ensure complete uterine evacuation. Following suction curettage of a PHM, patients should have anti-RhD prophylaxis.

Medical termination should be avoided where possible. There is a theoretical concern about the routine use of potent oxytocic agents because of the possibility of forcing trophoblastic tissue into the venous spaces of the placental bed and disseminating disease to the lungs. It is recommended that, when necessary, ergometrine which produces sustained rather than rhythmic contractions is only commenced once evacuation is complete. Ergometrine is preferred to syntocinon due to its persistent uterotonic effect. If there is significant haemorrhage prior to or during evacuation and some degree of control is needed, such agents may be used according to clinical judgement. It is also suggested that prostaglandin analogues should be reserved for cases for which oxytocic therapy is ineffective. Since evacuation of a large mole is a rare event, advice and help from an experienced colleague should be sought where appropriate. In partial molar pregnancies where the size of fetal parts deters the use of suction curettage, medical termination can be used. Data from the management of molar pregnancies with mifepristone are incomplete; evacuation of complete mole with this agent may be best avoided, as it increases the sensitivity of the uterus to prostaglandins.

The difficulty in making the diagnosis before evacuation mandates the histological assessment of material obtained from incomplete miscarriages. Also, since persistent trophoblastic disease may develop after any pregnancy, all products of conception obtained after evacuation performed for persisting symptoms should be histologically examined.⁹

EBM

Though there is much published on evacuation of molar pregnancy, the above text reflects mainly UK expert opinion and practice [C].

Twin molar pregnancy

Twin pregnancies comprising a normal fetus and a hydatidiform mole are estimated to occur in between 1:20,000 and 1:100,000 pregnancies. A successful pregnancy outcome occurs in around 40 per cent of cases, with no obvious increase in the risk of malignant change.¹⁰ Based on these results, it appears reasonably safe to allow patients with twin pregnancies in which one of the conceptions is a CHM or PHM to continue to term, provided there are no other complications.

Ectopic molar pregnancy

As with normal pregnancy, hydatidiform mole may occur in ectopic sites, most often in the Fallopian tube. Tubal ectopic moles are rare and overdiagnosed, but strict follow-up of confirmed cases is essential, as these are more likely to require chemotherapy for persistent disease [E].¹¹

REGISTRATION

In the UK, a trophoblastic registration scheme has been in operation since it was initiated by RCOG in 1973. Three centres – in London (Charing Cross Hospital), Sheffield (Weston Park Hospital) and Dundee (Ninewells Hospital) – coordinate the registration and monitoring of all patients. However, only Charing Cross and Weston Park have the specialist facilities to offer appropriate chemotherapy. Patients with CHM or PHM, twin pregnancy with complete or partial hydatidiform mole, limited macroscopic or microscopic molar change judged to require follow-up, choriocarcinoma, PSTT or APSNs should all be registered. Recently the service has expanded to include patients with APSNs as a small proportion of patients with this pathological abnormality may go on to develop PSTT/ETT.

Persistent trophoblastic disease (gestational trophoblastic neoplasia)

After any molar pregnancy, the onset of malignant change or persistent GTD is nearly always indicated by a persistently elevated hCG or continuing clinical symptoms, particularly vaginal bleeding. In the UK, this occurs after 15 per cent of CHM and 0.5–1 per cent of PHM.¹ Excessive uterine size, markedly elevated hCG levels and prominent theca lutein cysts may predict persistent trophoblastic disease. The UK surveillance scheme involves periodic assays of urine and/or serum hCG being performed for six months or longer, depending on when the hCG level reaches normal. This has ensured that the great majority of patients requiring chemotherapy for persistent disease are recognised early.

We have been able to adopt a conservative approach using stringent criteria for the initiation of chemotherapy (Box 111.1). Based on recent data, which showed that continued observation six months after evacuation was safe and effective, the previous UK and FIGO recommendation to start chemotherapy if the hCG was still elevated but falling six months after evacuation has been omitted (as long as the hCG continues to fall).^{5,12}

Box 111.1 Indications for chemotherapy

Indications for chemotherapy

- Plateaued or rising hCG levels that are plateaued over three consecutive or rising over two consecutive samples after evacuation
- Heavy vaginal bleeding or evidence of gastrointestinal or intraperitoneal haemorrhage
- Histological evidence of choriocarcinoma
- Evidence of metastases in the brain, liver, gastrointestinal tract or radiological opacities of >2 cm on chest radiograph
- Pulmonary, vulval or vaginal metastases unless hCG falling
- Serum hCG of $\geq 20,000$ IU/L more than four weeks after evacuation (risk of uterine perforation)

The role of repeat curettage for patients with stage I disease (Table 111.2) in reducing the need for chemotherapy remains controversial. Current data suggest that it should only be considered in patients where the hCG is still <5,000 IU/L and the abnormalities on ultrasound are confined to the uterine cavity. In all other cases the chances of avoiding chemotherapy seem to be very low. Indeed, given that cure rates of almost 100 per cent are obtained with chemotherapy, versus the risks involved with suction curettage, chemotherapy is the treatment of choice.¹

EBM

The indications for when to use chemotherapy vary internationally. The above guidance relies on retrospective, uncontrolled but substantial data from UK studies [C].

CHOICE OF CHEMOTHERAPY

Once the decision has been made to initiate chemotherapy, the regimen is chosen by assessing the patient's prognostic risk.¹³ This involves using a number of factors from the history, examination and investigations to allow the patient to be assigned to a risk group, which in turn facilitates the selection of the least toxic, most effective treatment for that individual (Table 111.3). The most important prognostic variables include the duration of the disease (risk of drug resistance of GTN varies inversely with time), the serum hCG concentration (correlation with viable tumour volume) and the presence of liver and/or brain metastases. Patients will need a Doppler pelvic ultrasound and, as pulmonary metastases are most common, a chest X-ray (CXR). Since possible pulmonary micrometastases do not influence the outcome, CT of the chest is not needed if the CXR is normal. However, if pulmonary lesions are seen, a CT of the body and MRI of the brain are indicated to exclude more widespread disease.

In 2000, an international committee recommended a combined FIGO anatomical staging and prognostic scoring system, which was accepted in 2002. All centres managing GTN should now use this scoring system to allow comparison of data.¹³ The majority of patients have a FIGO score of 0–6 and have disease at low risk of becoming resistant to single-agent chemotherapy with methotrexate or actinomycin D; those with a FIGO score greater than 6 are at high risk of drug resistance and should therefore be treated with combination-agent chemotherapy. Several treatment regimens have been developed for both low- and high-risk GTN. The most commonly used first-line treatment for low-risk disease is methotrexate with folinic acid rescue (MTX/FA). For high-risk disease, Charing Cross Hospital developed a treatment regimen consisting of EMA (etoposide, methotrexate, actinomycin D) alternated weekly with CO (cyclophosphamide and vincristine); this has been adopted worldwide and

Table 111.2 FIGO scoring system 2000 for gestational trophoblastic neoplasia (here, with some adaptations)

FIGO 2000 scoring system				
Prognostic factor score	0	1	2	4
Age (years)	<40	≥ 40	-	-
Antecedent pregnancy (AP)	Mole	Abortion	Term	-
Interval (months) from end of AP to chemotherapy	<4	4-6	7-12	>12
Serum hCG (IU/l)	<10 ³	10 ³ -10 ⁴	10 ⁴ -10 ⁵	>10 ⁵
Largest tumour mass	-	3-5 cm	>5 cm	-
Number of metastases	0	1-4	5-8	>8
Site of metastases	Lung	Spleen and kidney	GI tract	Brain and liver
Prior chemotherapy	-	-	Single drug	≥2 drugs
The total score is calculated by adding the individual scores for each prognostic factor. Low risk, 0-6; high risk, ≥7.				
FIGO staging system, to be used for PSTT				
I	Disease confined to the uterus			
II	Disease extending into the pelvis			
III	Disease spread to lungs and/or vagina			
IV	All other metastatic sites including liver, kidney, spleen and brain			

Table 111.3 Treatment regimens for low-risk and high-risk disease

Treatment for low-risk patients	
Methotrexate (MTX)	50 mg intramuscular, repeated every 48 hours for total of 4 doses
Folinic acid	15 mg orally 30 hours after each MTX injection
Cycles repeated every 2 weeks	
Treatment for high-risk patients	
EMA Day 1	
Etoposide	100 mg/m ² IV over 30 minutes
Actinomycin D	0.5 mg IV bolus
Methotrexate	300 mg/m ² over 12 hours
EMA Day 2	
Etoposide	100 mg/m ² IV over 30 minutes
Actinomycin D	0.5 mg IV bolus
Folinic acid	15 mg IV or orally every 12 hours for 4 doses (starting 24 hours after commencing the MTX infusion)
CO Day 8	
Vincristine	1 mg/m ² IV bolus
Cyclophosphamide	600 mg/m ² IV over 30 minutes
EMA alternates with CO every week	

is most commonly used within the UK as first-line treatment for high-risk disease (Table 111.3). Overall, the cure rate approaches 100 per cent and both the low- and high-risk treatments have no significant effect on subsequent fertility.^{5,14}

EBM

There is considerable published evidence on the role of chemotherapy in persistent GTD, based mostly on non-randomised, controlled or non-controlled trials [C].

POSTPARTUM CHORIOCARCINOMA

This is a very rare and serious complication with a reported UK incidence of 1 in 50,000 livebirths. Most cases present with abnormal vaginal bleeding following delivery, and diagnosis may be delayed, with many patients presenting with metastatic disease. Any woman of child-bearing age with metastatic disease should have her hCG level measured. If this is elevated the patient should be urgently discussed with the national specialist GTD centre as biopsy to confirm the diagnosis may promote life-threatening haemorrhage and may not be necessary. Instead, prompt recognition and early transfer to the specialist national centres is likely to maximise chances of cure with chemotherapy.

THE ROLE OF SURGERY

Older patients with stage I disease who are fit and have completed their family may request a hysterectomy. They should however be advised that although hysterectomy eliminates the complications of local invasion, it does not prevent metastatic disease or the possible need for chemotherapy and that therefore monitoring of hCG concentrations should still be done. As GTD is highly chemosensitive, the need for surgical intervention once the diagnosis has been established is small. At present, there are essentially two indications for hysterectomy, namely to control severe uterine haemorrhage and to eliminate disease that is confined to the uterus and

Box 111.2 Indications for hysterectomy

Indications for hysterectomy in the management of gestational trophoblastic disease

- Choice (older patient, localised disease, family complete)
- Excessive uterine bleeding (before, during or after treatment) that cannot be controlled by embolisation
- Chemoresistant (localised) uterine tumour
- Placental site trophoblastic tumour/epithelioid trophoblastic tumour

resistant to chemotherapy (Box 111.2). In order to minimise the risk of causing trophoblastic emboli, the vessels draining the uterus should be ligated at an early stage and the uterine tissues should be handled as gently as possible. Conservative uterine surgery, whereby local excision of a bleeding invasive trophoblastic tumour is performed, may be reasonable in young women, as their disease may then be cured medically, thus preserving their fertility.

A rare problem is that of vaginal bleeding after completion of successful chemotherapy due to a post-molar arteriovenous malformation. Selective embolisation or ligation may preserve fertility, but sometimes hysterectomy is necessary.

Surgery also has an important role, in selected patients, for the removal of chemotherapy-resistant metastases. Thoracotomy – for which the indications are previous multi-agent chemotherapy, a solitary lung lesion confined to one lung and no other sites of active disease – may achieve remission in over two thirds of patients. Stereotactic radiosurgery (and less frequently resection) is now recommended in the UK for the treatment of accessible deposits before starting chemotherapy because of the risk of precipitating haemorrhage.

PSTT/ETT

Surgery provides the cornerstone of management for the rare placental site trophoblastic tumours. These tumours have a slow growth rate and can present many years after term delivery, non-molar miscarriage or complete mole. The usual presentation is with local disease leading to vaginal bleeding or amenorrhoea, but they may also metastasise, particularly to the lung. Surgery alone is the treatment of choice for localised disease; combination chemotherapy is needed for metastatic PSTT. In contrast to choriocarcinoma, once the hCG has normalised residual masses are removed surgically, including the uterus as this can potentially harbour microscopic disease.²

ROUTINE FOLLOW-UP

Patterns of clinical and hCG surveillance for further molar problems vary across the world, determined by local factors and also by knowledge of the difference in risk of sequelae between complete and partial moles. The clinical course of partial mole is almost invariably 'benign'. Persistent trophoblastic disease after partial mole is much less common than after complete mole and almost all cases are low risk. However, it has been confirmed that partial mole can transform into choriocarcinoma or PSTT.¹⁵

All patients with confirmed PHM as well as CHM should undergo hCG follow-up. In the UK, patients who have received chemotherapy for persistent trophoblastic disease will continue with weekly serum hCG for six weeks post-chemotherapy, then in serum and urine two weekly until six months, before switching to just urine assessments monthly with decreasing frequency until eventually they send samples just six monthly. Follow-up is currently for life until there are

sufficient data to know when it is safe to stop monitoring. As a few patients have relapsed following subsequent pregnancies years later, an hCG sample is requested six and ten weeks at the end of each new pregnancy.¹ However, the risk of molar problems is greatest in the first 12 months following chemotherapy with an overall relapse rate of about 3 per cent. To enable efficient hCG follow-up, patients are therefore advised to delay a further pregnancy beyond this period. Some patients either ignore this advice or accidentally become pregnant during this time; fortunately, in the vast majority of cases, the outcome is good.¹ Current advice is therefore to avoid early pregnancy but, when it does occur, to allow the pregnancy to continue with careful clinical, ultrasound and hCG monitoring.

CONTRACEPTION

Early studies from Charing Cross Hospital suggested that women who used oral contraceptives before the hCG had normalised after evacuation of a molar pregnancy had a slower rate of hCG decrease and increased risk of developing persistent trophoblastic disease.¹⁶ However, at least two other studies in the US and elsewhere have noted no increased risk with oral contraceptive use. Moreover, a recent study in UK women using more modern low-dose contraceptive pills also failed to show any evidence of increased risk of malignant sequelae after molar pregnancy. Consequently, it seems sensible to allow women to use the oral contraceptive to prevent a further pregnancy following molar evacuation. There is agreement that intrauterine contraceptive devices should be avoided until hCG levels are normal, because of the risk of uterine perforation and bleeding.

AUDITABLE OUTCOMES

These auditable outcomes are recommended by RCOG:

- 1 The proportion of women with GTD registered with the relevant screening centre;
- 2 The proportion of women with a histological diagnosis of molar pregnancy who have an ultrasound diagnosis of molar pregnancy prior to uterine evacuation;
- 3 The proportion of women who undergo medical management for evacuation of products of conception with an ultrasound diagnosis of molar pregnancy.

KEY POINTS

The following RCOG recommendations⁹ are based on limited but robust evidence that relies on expert opinion and has the endorsement of respected authorities.

1. Registration of any molar pregnancy is essential.
2. Ultrasound has limited value in detecting partial molar pregnancies.

3. In twin pregnancies with a viable fetus and a molar pregnancy, the pregnancy can be allowed to proceed after appropriate counselling.
4. Surgical evacuation of molar pregnancies is advisable.
5. Routine repeat evacuation after the diagnosis of a molar pregnancy is not warranted.
6. The combined oral contraceptive pill and hormone replacement therapy are safe to use after hCG levels have reverted to normal.
7. Women should be advised not to conceive until the hCG level has been normal for six months or follow-up has been completed (whichever is sooner).

Chapter 112 Rare tumours

Nicholas Reed

MRCOG Standards

Theoretical skills

- To understand the epidemiology, aetiology, pathology, clinical characteristics and prognostic features of rare gynaecological cancers.
- To understand the most appropriate way to manage these rare and uncommon tumours.
- Specific mention is made of referral pathways and processes for ensuring that optimal care is offered to patients with these rare tumours.

Practical skills

- To be able to manage in broad terms a rare tumour and know the pathway for referrals to specialist multidisciplinary teams.
- To recognise that in some circumstances, fertility-sparing surgery may be offered.
- To be able to share follow-up care with regional teams.

KEY POINTS

- These are by definition rare cancers and many fall into the category of ultra-rare or orphan tumours. Orphan disease status has been defined as fewer than 500 cases per million population whilst ultra-orphan is described as fewer than 4 cases per million population.
- All of these tumours should be managed by multidisciplinary teams composed of experts who have a recognised interest in the field.
- Consideration should be given to supra-regionalisation of care especially in smaller countries.
- Histopathological review is essential as there is a high rate of reclassification with central review.
- Registries of rare tumours should be set up to help document the true incidence, along with the development of tumour banks.
- Careful consideration should be given to fertility-preserving surgery in younger women where clinically appropriate.
- National and international guidelines are needed to improve quality of care.

DEFINITION, INCIDENCE AND PREVALENCE

This chapter focuses on rare gynaecological cancers which represent an extraordinarily high number of the gynaecological cancers. Over a third of gynaecological cancers fall into the rare or uncommon group, which is the highest for any of the common solid cancers.¹ There are a number of definitions of the term 'rare' but incidences range from around 30 to 100 cases per million population. The latter number, used by NICE, described an incidence up to 7000 cases per annum but this is likely to include many cancers considered to be of 'intermediate commonness'.² There is no universally agreed standard definition. Most of these tumours by definition will have an incidence of less than 2000 cases per annum in the UK (less than 50 per million population) so while the incidence of these tumours is by definition low, the relative prevalence may be higher as some of them are slow growing and be associated

with late relapses, for example many sex cord and stromal tumours and low-grade uterine sarcomas.

This therefore means that there is obviously less experience and less evidence base on which to support management. In view of their rarity, it is thus necessary to state that there is usually no established standard of care for these tumours but the points below will offer guidance for their management. There are well-established guidelines which include the rarer tumours, specifically by ESMO (European Society of Medical Oncology) which covers non-epithelial cancers,³ and by the NCCN (National Comprehensive Cancer Network)⁴ and in a recently published textbook on rare gynaecological cancers.⁵

However to complicate matters further, the classifications of some of the commoner gynaecological cancers are now being subdivided, for example ovarian epithelial cancers are now subdivided into five types, namely high-grade and low-grade serous, endometrioid, clear cell and mucinous. Whilst high-grade serous account for over 70 per cent, the remaining four types of these would fall within the definition of rare cancers as they account for less than 25 per cent of ovarian

Table 112.1 EOC [epithelial ovarian cancer] histotype and molecular pathway

Ovarian cancer	Pathway
High-grade serous	P53, PI3K, mTOR
Low-grade serous	KRAS
Endometrioid	KRAS, B-catenin, MSI
Mucinous	KRAS (50%), BRAF (20%)
Clear cell	ARID1A (50%) PIK3

epithelial cancers. This is not simply due to histotyping on morphological grounds but takes account of the aetiology and different molecular pathways that are recognised to cause tumour development (see Table 112.1). Furthermore the recognition of the different pathways has led to new therapeutic approaches that target these pathways, commonly known as personalised or stratified medicine. This approach will be applied to many other tumours in the course of the next few years as our knowledge of molecular pathways increases.⁶⁻⁸ This is excellently reviewed in a recent review paper by Merritt and Cramer, with the only danger being the built-in obsolescence of these kinds of papers due to rapidly evolving technology.

However there are many other uncommon gynaecological cancers including carcinosarcomas, small cell tumours, sex cord and stromal tumours, germ cell tumours and the miscellaneous sarcomas of the genital tract (Table 112.2). The incidence of many of these will be less than 10 per million population, sometimes significantly lower, so they may be considered 'ultra-rare', although some of these tumours have a relatively higher prevalence due to their slow natural pattern of relapse.

A topical debate is whether it is better to classify these tumours by site of origin, by histological type or increasingly by the molecular pathways that are involved and this latter is gradually taking precedence and probably will be important in terms of defining future treatment strategies. For example, are small cell cancers of the ovary and cervix the same? Probably not especially as there are at least two types of small cell ovarian cancer! Translational medicine is emerging as the basis of the new classification systems that unite them. Similarly mucinous tumours may occur in a variety of gynaecological organs but to date there is no common identified pathway, and there is even greater debate as to whether so-called primary ovarian mucinous carcinomas do really arise in the ovary but from the GI tract. Hence the classification systems do to some extent mix and match using organ site morphology and molecular pathways.

The list above is not exhaustive but is meant to illustrate that some rarer variants apply across the board such as mucinous, clear cell and small cell, but others are specific to the organ such as granulosa cell tumours and sex-cord/stromal tumours of the ovary and the smooth muscle and stromal tumours of uterus.

EPIDEMIOLOGY

Because of their relative rarity it is often not possible to comment on the epidemiology. No particular patterns have been established and relatively few of these tumours have as yet been identified to be hereditary. The molecular pathways have often yet to be identified. One example recently established a FOXL2 pathway in adult granulosa cell tumours.⁹ The previously referred-to papers also discuss pathways in rarer ovarian cancer subtypes.⁶⁻⁸

Table 112.2 Examples of rare and uncommon cancers of gynaecological organs, comparing anatomical site of origin with histological type

Ovary	Cervix	Corpus	Vagina and vulva
Small cell cancers of pulmonary type, SCCOPT	Small cell cancers	Small cell cancers	Small cell cancers
Small cell cancers of hypercalcaemic type, SCCOHT			
Sarcomas	Sarcomas	Carcinosarcomas	Sarcomas
Germ cell tumours		Stromal sarcomas	
Sex cord and stromal tumours			Smooth muscle tumours incl. LMS and STUMP
Low-grade serous		Serous tumours	
Mucinous	Mucinous	Mucinous	
Endometrioid			
Clear cell	Clear cell	Clear cell	
Carcinoid tumours	Adeno-carcinomas	Adenosarcomas	Adenoid-cystic

STUMP, smooth muscle tumour of unknown malignant potential
LMS, leiomyosarcoma

PRESENTATION

Because of the diverse nature of these tumours it is not possible to discuss this in detail. Ovarian rare cancers may present with bloating in the same way as common epithelial cancers, but post-menopausal bleeding may be less likely in the rarer uterine tumours as they do not often develop in the endometrial layer. There may be very varied ways in which these tumours are diagnosed. There are a few more obvious patterns. For example in younger women with ovarian tumours, there should be a greater suspicion of germ cell tumours or sex cord and stromal tumours, whilst the finding of hypercalcaemia or syndrome of inappropriate anti-diuretic hormone (SIADH) secretion may suggest a small cell tumour of the ovary. Post-menopausal bleeding associated with endometrial hyperplasia and a solid adnexal mass may raise suspicion of a functioning sex cord tumour. Menorrhagia in the peri-menopausal women is common, as are fibroids. It remains challenging to identify the occasional patient who has an occult uterine sarcoma and it is hoped that new imaging techniques may help to identify these in the future.

MANAGEMENT

Evidence based medicine

For the vast majority of these tumours, there are no randomised clinical trials pertinent to the management of rare gynaecological cancers. Most of the evidence is based on small phase-2 studies, institutional series reports and case reports. Recently published guidelines from the GCIG have been published at the end of 2014. They are principally based on evidence grades C, D and E. The promotion of clinical trials and studies is to be encouraged and supported through international collaboration.

These patients should be investigated and assessed in the standard manner and staging and histological diagnosis are the key points in the management of these tumours. They should all be presented and discussed at the MDT meeting. Discussion should take place with radiologists to select the most appropriate imaging. This may include ultrasound, CT, MRI and PET-CT. MRI is tending to emerge as the better imaging technique for scanning pelvic masses but CT or PET-CT are more useful in searching for distant metastases. Tumour markers again may be useful depending on the tumour type, and in germ cell tumours they may be diagnostic whilst in sex cord and stromal tumours, they may be valuable in diagnosis and serial monitoring and follow-up. In the younger woman with an ovarian mass, it is necessary to check for elevated AFP and beta-hCG to exclude a germ cell tumour, and in sex cord/stromal tumours beta inhibin and AMH may be useful for diagnosis and serial monitoring; in the post-menopausal woman FSH, LH and oestradiol levels can be measured. These tumour markers also have an important role in follow-up.

When surgery is considered, discussions will take place regarding whether this should be done locally or centrally in the gynaecological oncology centre, and whether surgery is 'radical' or fertility sparing.^{10,11} If there are any unusual or suspicious features then it would be a wise counsel to recommend that these patients are referred to the specialist gynaecological oncology team so that appropriate surgical staging can be carried out if clinically indicated. Even in the emergency situation, it should be rare that a decision cannot wait 12–24 hours to discuss with a specialist team especially when fertility-sparing surgery is an option.

For post-menopausal women with ovarian and uterine suspected tumours, the standard of care will usually include total hysterectomy, bilateral salpingo-oophorectomy and consideration of omentectomy and nodal dissection. However, many of these tumours do occur in younger women and this requires careful consideration and discussion of fertility preserving procedures. This may require a two-step procedure. Curative treatment should always be offered to younger women, and particularly for suspected germ cell tumours fertility-sparing surgery should be at the forefront of the mind when planning the procedure as chemotherapy is highly effective and fertility can usually be preserved in spite of additional treatments. This again should be carefully discussed and documented at the MDT which will take into account the tumour markers, imaging and other factors. This will include taking into account the patient's wishes where possible. For some conditions, supra-regional services may be considered; good examples of these include management of trophoblastic cancers, and this could be extended to other rare tumour types.

Post-operative management

Pathology

Specialist pathology review is essential by a histopathologist with a recognised subspeciality interest in gynaecological pathology. These rare tumours are often quite difficult to interpret and the differential diagnosis may be quite wide. Even with specialist immunocytochemistry there may be some degree of uncertainty about the final diagnosis. Within the UK, the British Association for Gynaecological Pathologists and their network may be valuable in arranging cross-referral for second opinions.

If the specimen indicates that this is a tumour associated with secretion of tumour markers then post-operatively this should be checked, but a strong case can be made for storing serum on all younger patients pre-operatively so that analysis of the markers can be taken if the germ cell or sex cord tumour is identified. The GCIG published their rare tumour guidelines in late 2014 in a supplement to the *International Journal of Gynaecological Cancer*.^{13,14}

Adjuvant treatments

Full and thorough staging is essential to allow decisions on the need for any adjuvant therapy or surveillance programme. All cases should be discussed at the MDT. For many cases which

are stage I, a watch-and-see policy with surveillance may be advised. This will include frequent measurement of tumour markers and scans as determined by appropriate protocols. Again due to the diversity of these tumours it is not possible to cover all of these. However a number of these tumours may be associated with a greater risk of late relapse, sometimes well beyond 10 years, for example sex cord and stromal tumours, uterine STUMPs, low-grade leiomyosarcomas and endometrial stromal sarcomas. Thus these are patients who need longer-term follow-up, beyond the standard five years and arguably lifelong. Locally available protocols should identify how frequently clinical examination and imaging should be done. However because of their risk of late relapse, follow-up beyond the normal five years will be advised for selected rare subtypes.

For more advanced cancers additional treatment will be required. The type of chemotherapy for germ cell tumours is well established and usually involves treatment with the BEP (bleomycin, etoposide, cisplatin) regime or variants of this, usually between two and four cycles depending on the prognostic factors.^{3,12} For advanced sex cord and stromal tumours again regimes such as BEP or EP or carboplatin/paclitaxel will tend to be used. Some more slowly growing tumours with strong expression of oestrogen or progesterone receptor positivity may be treated with hormonal therapy. This will include low-grade endometrial stromal sarcomas (LGESS), low-grade leiomyosarcomas (LMS) and some sex cord tumours. At the opposite end of the spectrum are high-grade undifferentiated sarcomas (HGUS) and highly mitotic leiomyosarcomas; they are particularly challenging to treat with few patients surviving beyond 24 months. Although adjuvant chemotherapy often with a doxorubicin- or doxorubicin and ifosfamide-based regime is offered, the prognosis is usually very poor. Several new studies are investigating the use of adjuvant treatments including chemotherapy for LMS (GOG Trial 277) and molecular targeting in HGUS.

For uterine and ovarian carcinosarcomas, adjuvant treatment with carboplatin and paclitaxel is frequently advised and radiotherapy is usually not given unless there is residual disease. The only two randomised trials (GOG 150 and EORTC 55874) failed to show any overall survival benefit for radiation in this group.^{15,16} For LMS there is at present no documented evidence to support the use of adjuvant radiation or chemotherapy outwith the clinical trial setting, but the current GOG study (protocol 277) is investigating adjuvant chemotherapy. Ovarian carcinosarcomas tend to be treated like epithelial ovarian cancers although probably carry a worse prognosis.

The small cell cancers of ovary, cervix and uterus are very rare and there is no commonly accepted regime. Schedules such as platinum and etoposide or carboplatin and paclitaxel are commonly used. Much lively debate centres around the role of adjuvant radiotherapy in small cell ovarian cancer. It is probably necessary to use multiple modality therapy in these patients and even then only about one third will be long-term survivors. For the ultra-rare gynaecological cancers, there are usually no guidelines so these must be discussed at MDT.

Arguments can be made for supra-regional specialisation as is seen with gestational trophoblastic tumours (GTTs) and shared-care follow-up with local services.

Follow-up

It is important that all these patients are followed up but there are issues as to how to follow them up, who should follow them up, where they should be followed up and for how long. It is the author's belief that these uncommon and rare tumours should be followed up by the specialist MDTs in the gynaecological cancer centres, whether it be the gynaecological, surgical, clinical or medical oncologist. Access to specialist opinion is the key factor. There should be local champions or enthusiasts who take on the mantle to oversee their care and write the local guidelines which should fit in with best available evidence and any national guidelines. Where there are issues of remoteness of the cancer centre from the patient's home it may be possible to offer some form of shared care. Nevertheless management by an experienced team is important. Patients will generally be seen at intervals of around three to four months in the first and second year and then switch to six-monthly visits thereafter but certain subgroups will be seen more frequently, for example stage I germ cell tumours on surveillance will be seen much more frequently in the first two years with monitoring of tumour markers and imaging as per locally agreed protocols to detect early recurrence which can be salvaged. This differs from epithelial ovarian cancers where intervention due to rising markers does not influence survival, but in some of these rarer cancers, rising markers and imaging may lead to interventions that can improve outcome. Imaging protocols will need to be developed where unexpected malignancy has been identified after surgery, often for uterine sarcomas and some germ cell and sex cord ovarian tumours; immediate post-operative CT scan should be carried out for 'baseline purposes' and again depending on the tumour type it may be necessary to image at six and 12 months and annually or bi-annually for up to five years. HRT is also controversial, especially in tumours that may show high levels of expression of oestrogen and/or progesterone. The cautious approach is to withhold its use but consider using it in carefully selected cases where symptoms affect quality of life and the patient is fully informed of the potential risk.

KEY POINTS

- These tumours are by definition uncommon although some of the larger cancer centres will see relatively more as they often act as referral centres. Because of their complexity they must be managed by MDTs and within the cancer centres it may be desirable for a small number of individuals to take on the responsibility of looking after these tumours so that they can individually develop greater expertise and competence.
- In younger women fertility-sparing surgery should always be considered as an option and discussed before rushing in to

do a pelvic clearance and careful discussion at the tumour board should always be carried out.

- Setting up of registries and databases is important to record the numbers of patients being treated and this is also useful for access to histological material, serum, biomarkers and material for translational research which will be important in managing these patients in the future.
- National or international guidelines are being introduced to try to harmonise the treatment but this will not always be simple or straightforward. The GCIG is trying to facilitate clinical trials in these rare tumours but again there are huge issues regarding confidentiality and security of international data and tissue transfer and additionally motivation to go through the huge effort of submitting protocols through national ethics committees when only one or two patients may be seen a year. Suitably motivated centres will do this. An argument could be made for having supra-regional centres to deal with some of these rarer tumours within each nation together with a more enlightened approach to dealing with ethical issues for trials in rare conditions.

CONCLUSIONS

Gynaecological cancers include a high proportion of rare and uncommon diseases. These cause major clinical challenges, particularly in younger patients where issues of fertility-sparing surgical approaches must always be considered. Patients must be discussed at multidisciplinary teams. Specialist imaging and histopathology opinions are essential to the basic MDT who will carry out the surgery and adjuvant chemotherapy or radiotherapy. Localised databases are important to learn more about these tumours and, for the future, the identification of molecular pathways is likely to bring about improvements in diagnosis and treatment.

Modelled after the current MRCOG curriculum, the new edition of this bestselling book provides all the information a specialist registrar in obstetrics and gynaecology or senior house officer needs during training or when preparing for the MRCOG examination.

Obstetrics & Gynaecology: An Evidence-based Text for MRCOG covers the latest professional guidelines and developments in obstetrics and gynaecology and continues to provide an easily accessible source of information for those practising as specialists.

The book's subsections within obstetrics and gynaecology are divided in line with the RCOG trainee logbook. The text is consistently structured throughout to ensure ease of reference with standardized headings including definitions, incidence, aetiology, investigations and management.

Focusing on standards and an evidence-based approach, each chapter includes material on MRCOG standards in an easy-to-consult format. Information on evidence-based medicine is also included to provide a rapid summary of the evidence relating to the interventions and treatments discussed.

This text will continue to be an invaluable companion to the higher training of obstetricians and gynaecologists and a useful ready reference for those in established practice.
