OBSTETRICS & GYNAECOLOGY: AN EVIDENCE-BASED TEXT FOR MRCOG, THIRD EDITION

Using the VitalSource® ebook

Access to the VitalBook™ ebook accompanying this book is via VitalSource® Bookshelf – an ebook reader which allows you to make and share notes and highlights on your ebooks and search across all of the ebooks that you hold on your VitalSource Bookshelf. You can access the ebook online or offline on your smartphone, tablet or PC/Mac and your notes and highlights will automatically stay in sync no matter where you make them.

1. **Create a VitalSource Bookshelf account at** <https://online.vitalsource.com/user/new> or log into your existing account if you already have one.

2. **Redeem the code provided in the panel below to get online access to the ebook.**

Log in to Bookshelf and select **Redeem** at the top right of the screen. Enter the redemption code shown on the scratch-off panel below in the **Redeem Code** pop-up and press **Redeem**. Once the code has been redeemed your ebook will download and appear in your library.

No returns if this code has been revealed.

DOWNLOAD AND READ OFFLINE

To use your ebook offline, download BookShelf to your PC, Mac, iOS device, Android device or Kindle Fire, and log in to your Bookshelf account to access your ebook:

On your PC/Mac

Go to <https://support.vitalsource.com/hc/en-us> and follow the instructions to download the free **VitalSource Bookshelf** app to your PC or Mac and log into your Bookshelf account.

On your iPhone/iPod Touch/iPad

Download the free **VitalSource Bookshelf** App available via the iTunes App Store and log into your Bookshelf account. You can find more information at <https://support.vitalsource.com/hc/en-us/categories/200134217-Bookshelf-for-iOS>

On your Android™ smartphone or tablet

Download the free **VitalSource Bookshelf** App available via Google Play and log into your Bookshelf account. You can find more information at <https://support.vitalsource.com/hc/en-us/categories/200139976-Bookshelf-for-Android-and-Kindle-Fire>

On your Kindle Fire

Download the free **VitalSource Bookshelf** App available from Amazon and log into your Bookshelf account. You can find more information at <https://support.vitalsource.com/hc/en-us/categories/200139976-Bookshelf-for-Android-and-Kindle-Fire>

N.B. The code in the scratch-off panel can only be used once. When you have created a Bookshelf account and redeemed the code you will be able to access the ebook online or offline on your smartphone, tablet or PC/Mac.

SUPPORT

If you have any questions about downloading Bookshelf, creating your account, or accessing and using your ebook edition, please visit <http://support.vitalsource.com/>

This book contains information obtained from authentic and highly regarded sources. While all reasonable efforts have been made to publish reliable data and information, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. The publishers wish to make clear that any views or opinions expressed in this book by individual editors, authors or contributors are personal to them and do not necessarily reflect the views/opinions of the publishers. The information or guidance contained in this book is intended for use by medical, scientific or health-care professionals and is provided strictly as a supplement to the medical or other professional's own judgement, their knowledge of the patient's medical history, relevant manufacturer's instructions and the appropriate best practice guidelines. Because of the rapid advances in medical science, any information or advice on dosages, procedures or diagnoses should be independently verified. The reader is strongly urged to consult the relevant national drug formulary and the drug companies' and device or material manufacturers' printed instructions, and their websites, before administering or utilizing any of the drugs, devices or materials mentioned in this book. This book does not indicate whether a particular treatment is appropriate or suitable for a particular individual. Ultimately it is the sole responsibility of the medical professional to make his or her own professional judgements, so as to advise and treat patients appropriately. The authors and publishers have also attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Except as permitted under U.S. Copyright Law, no part of this book may be reprinted, reproduced, transmitted, or utilized in any form by any electronic, mechanical, or other means, now known or hereafter invented, including photocopying, microfilming, and recording, or in any information storage or retrieval system, without written permission from the publishers.

CONTRIBUTORS	ix
PREFACE	xiii
ACKNOWLEDGEMENTS	xv
LIST OF ABBREVIATIONS USED	xvii
HOW TO USE THIS BOOK	xxv

SECTION ONE INTRODUCTORY/GENERAL

Section Editor: James Drife

1 Evidence-based medicine and medical informatics	<i>Jane Thomas</i>	3
2 The general principles of surgery	<i>Fiona M Reid</i>	14
3 Communication and counselling	<i>Richard Porter</i>	23
4 The law, medicine and women's rights	<i>Sheila McLean</i>	27
5 Clinical risk	<i>Sam Pretlove</i>	33
6 Rationale for advanced skills training	<i>Timothy Draycott and Islam Gamaleldin</i>	39

SECTION TWO ANTENATAL OBSTETRICS

Section Editor: Mark Kilby

7 Routine antenatal care: an overview	<i>Nina Johns</i>	51
8 Chronic hypertension	<i>Kate Bramham and Andrew Shennan</i>	60
9 Diabetes mellitus	<i>Clare L Tower</i>	68
10 Cardiac disease	<i>Catherine Nelson-Piercy</i>	78
11 Thyroid disease	<i>Andrew Shennan and Joanna Girling</i>	83
12 Haematological conditions	<i>Sarah Wharin and Sue Pavord</i>	88
13 Renal disease	<i>Catherine Nelson-Piercy</i>	111
14 Autoimmune conditions	<i>Catherine Nelson-Piercy</i>	116
15 Liver and gastrointestinal disease	<i>Catherine Nelson-Piercy</i>	122
16 Respiratory conditions	<i>Louise Kenny</i>	128
17 Neurological conditions	<i>Louise Kenny</i>	137
18 Dermatological conditions	<i>Louise Kenny</i>	148
19 Drug and alcohol misuse	<i>Louise Kenny</i>	152
20 Smoking	<i>Andrew Shennan</i>	160
21 Anaemia	<i>Will Lester</i>	163
22 Abdominal pain	<i>Clare L Tower</i>	168
23 Malignancy	<i>Louise Kenny</i>	175
24 Maternal infections in pregnancy	<i>Tara Jayne Selman</i>	184
25 Gestational diabetes	<i>Clare L Tower</i>	191
26 Pre-eclampsia and non-proteinuric pregnancy-induced hypertension	<i>Andrew Shennan</i>	198
27 Medication in pregnancy	<i>Clare L Tower</i>	206
28 Maternal mortality	<i>James Drife</i>	213

SECTION THREE FETAL CONDITIONS

Section Editor: Mark Kilby

29 Biochemical screening	<i>Michele P Mohajer</i>	227
30 Ultrasound screening	<i>Michele P Mohajer</i>	231
31 Invasive and non-invasive prenatal diagnosis	<i>Michele P Mohajer</i>	237
32 Understanding genetics and genetic tests	<i>Fiona Mackie and Denise Williams</i>	241
33 Management of fetal anomalies	<i>Michele P Mohajer</i>	253
34 Previous history of fetal loss	<i>Abi Merriel and Arri Coomarasamy</i>	257
35 Multiple pregnancy	<i>Bill Martin</i>	262
36 Fetal infections	<i>Tara Jayne Selman</i>	267

37 Tests of fetal wellbeing	<i>Alexander Heazell</i>	274
38 Small for gestational age and intrauterine growth restriction	<i>Jennifer A Tamblyn and R Katie Morris</i>	281
39 Aberrant liquor volume	<i>Jennifer A Tamblyn and R Katie Morris</i>	292
40 Fetal hydrops	<i>Caroline Fox and Sailesh Kumar</i>	300
41 Malpresentation	<i>Alexander M Pirie</i>	306
42 Prolonged pregnancy	<i>Devender Roberts and Rajeshwari Myagerimath</i>	310
43 Routine intrapartum care: an overview	<i>Mary Higgins</i>	316

SECTION FOUR LATE PREGNANCY AND INTRAPARTUM EVENTS

Section Editor: Mark Kilby

44 Preterm labour	<i>Myles Taylor and Stuart Rundle</i>	327
45 Pre-labour rupture of the membranes	<i>Myles Taylor and Stuart Rundle</i>	338
46 Antepartum haemorrhage	<i>Lucy Kean</i>	345
47 Intrauterine fetal death	<i>Lucy Kean</i>	360

SECTION FIVE FIRST STAGE OF LABOUR

Section Editor: Mark Kilby

48 Induction of labour	<i>Nina Johns</i>	373
49 Management after previous caesarean section	<i>Lucy Kean</i>	381
50 Poor progress in labour	<i>Graham Tydeman and Alexandra Rice</i>	389
51 Fetal compromise in the first stage of labour	<i>Jenny Blackman and Myles Taylor</i>	395
52 Obstetric anaesthesia and analgesia	<i>David M Levy and Duncan S Cochran</i>	404
53 Caesarean section	<i>Tracey A Johnston</i>	416

SECTION SIX SECOND STAGE OF LABOUR

Section Editor: Mark Kilby

54 Fetal compromise in the second stage of labour	<i>Myles Taylor</i>	427
55 Shoulder dystocia	<i>Jenny Blackman and Myles Taylor</i>	431
56 Instrumental vaginal delivery	<i>Tracey A Johnston</i>	437
57 Breech presentation	<i>Alexander M Pirie</i>	443
58 Perineal trauma	<i>Lucy Kean</i>	457

SECTION SEVEN POSTPARTUM COMPLICATIONS

Section Editor: Mark Kilby

59 Perinatal asphyxia	<i>Andrew Currie</i>	471
60 Neonatal resuscitation	<i>Andrew Currie</i>	476
61 Common neonatal problems	<i>Andrew Currie</i>	485
62 Perinatal mortality	<i>James Drife</i>	493
63 Postpartum collapse	<i>Peter J Thompson</i>	502
64 Postpartum haemorrhage	<i>Peter J Thompson</i>	507
65 Postpartum pyrexia	<i>Peter J Thompson</i>	512
66 Disturbed mood	<i>Peter J Thompson</i>	516
67 Problems with breastfeeding	<i>Peter J Thompson</i>	520

SECTION EIGHT REPRODUCTIVE GYNAECOLOGY

Section Editor: Arri Coomarasamy

68 Normal and abnormal development of the genitalia	<i>Rebecca Deans and Sarah M Creighton</i>	525
69 Karyotypic abnormalities	<i>Diana Fothergill</i>	536
70 Menarche and adolescent gynaecology	<i>Diana Fothergill</i>	539

71 Ovarian and menstrual cycles	<i>Mohammed Khairy and Rima Dhillon</i>	543
72 Contraception and termination of pregnancy	<i>Kulsum Jaffer</i>	551
73 Endometrial function	<i>Hilary OD Critchley and Christine P West</i>	570
74 Uterine fibroids	<i>Christine P West</i>	574
75 Abnormal uterine bleeding	<i>Christine P West</i>	583
76 Dysmenorrhoea and pelvic pain	<i>Christine P West</i>	592
77 Endometriosis	<i>Christine P West</i>	602
78 Adenomyosis	<i>Christine P West</i>	613
79 Premenstrual syndrome	<i>Christine P West</i>	617
80 Normal conception	<i>Yakoub Khalaf</i>	625
81 Female infertility	<i>Yakoub Khalaf</i>	629
82 Male infertility	<i>Yakoub Khalaf</i>	638
83 Unexplained infertility	<i>Smriti Bhatta and Siladitya Bhattacharya</i>	643
84 Assisted reproduction	<i>Abey Eapen and Arri Coomarasamy</i>	648
85 Polycystic ovary syndrome	<i>Adam H Balen</i>	654
86 Hirsutism and virilism	<i>Mostafa Metwally and William Ledger</i>	663
87 Amenorrhoea and oligomenorrhoea	<i>Mostafa Metwally and William Ledger</i>	668
88 Menopause	<i>Tina Sara Verghese, Jenny Williamson and Lynne Robinson</i>	672
89 Miscarriage	<i>James Hounslow and Ying Cheong</i>	678
90 Ectopic pregnancy	<i>Ghada Salman, Davor Jurkovic</i>	685
91 Premature ovarian insufficiency	<i>Nowmi Zaman, Jenny Williamson and Lynne Robinson</i>	698
92 Fertility preservation	<i>Hoda Harb and Arri Coomarasamy</i>	707
93 Psychosexual medicine	<i>Susan V Carr</i>	712

SECTION NINE UROGYNAECOLOGY AND SEXUAL HEALTH AND WELLBEING

Section Editors: Linda Cardozo and Dudley Robinson

94 Assessment of lower urinary tract function	<i>Angie Rantell</i>	719
95 Urinary incontinence	<i>Dudley Robinson and Linda Cardozo</i>	736
96 Other lower urinary tract disorders	<i>Ganesh Thiagamoorthy and Sushma Srikrishna</i>	765
97 Lower urinary tract infections	<i>Ilias Giarenis and Dudley Robinson</i>	773
98 Urogenital prolapse	<i>Sushma Srikrishna and Dudley Robinson</i>	780
99 Infection and sexual health	<i>Melanie Mann</i>	791
100 Dyspareunia and other psychosexual problems	<i>Melanie Mann</i>	810
101 Child sexual abuse	<i>Catherine White</i>	817
102 Rape and sexual assault	<i>Catherine White</i>	822
103 Female genital mutilation	<i>Ben Chisnall and Janice Rymer</i>	830

SECTION TEN LOWER GENITAL TRACT

Section Editor: Simon Leeson

104 Benign vulval problems	<i>Lubna Haque and Margaret Cruickshank</i>	839
105 Vulvodynia	<i>Shuchi Dixit and David Nunns</i>	848
106 Pre-invasive disease	<i>Nirmala Rai and Gabrielle Downey</i>	854

SECTION ELEVEN GYNAECOLOGICAL ONCOLOGY

Section Editors: David Luesley and Simon Leeson

107 Endometrial cancer	<i>Mahalakshmi Gurumurthy and Margaret Cruickshank</i>	873
108 Cervical cancer	<i>Pierre L Martin-Hirsch</i>	883
109 Benign and malignant ovarian masses	<i>Sudha Sundar</i>	889
110 Vulval and vaginal cancer	<i>John Tidy</i>	906
111 Gestational trophoblastic disease	<i>Fieke E M Froeling and Michael J Seckl</i>	913
112 Rare tumours	<i>Nicholas Reed</i>	922

Nowmi Zaman

Specialty Trainee Year 3 in Obstetrics and Gynaecology, Birmingham Women's NHS Foundation Trust, Birmingham

Preface

It is often difficult to know when a new edition of an established textbook is required. It certainly feels as if the intervals get shorter and the demands of updating are greater with each new edition. However, there are constant revisions of our professional guidelines and new developments in the specialities of obstetrics and gynaecology are emerging.

Comparing the content of this, the third edition, with the first edition published in 2004 is both rewarding and somewhat frightening. The rapid pace at which new knowledge and new evidence becomes available seems likely to overwhelm our ability to organise and present it in a format that will fulfil the requirements of aspiring obstetricians and gynaecologists and continue to provide an easily accessible source of information for those practising as specialists.

The popularity of the previous two editions signifies that we are achieving these objectives and the tested template of aligning the text to the RCOG curriculum appears to meet the needs of most readers. The basic core knowledge upon which our discipline is built does not evolve as rapidly as other aspects of our specialism and an in-depth understanding of this core knowledge is an essential prerequisite to success in the MRCOG examination and a solid basis on which to build a career as a practising specialist. It is natural with the passage of time that contributors to our previous editions will have retired or moved on elsewhere and it is right to bring in new contributors who have enthusiasm and often bring a fresh perspective to their subject matter.

We remain of course immensely grateful for the grounding provided by our previous contributors. It is their previous efforts, and the skilful updating and rewriting of our new contributors, that have maintained the high quality of the presented material. Updating, adding and omitting provides a massive editorial challenge if the 'feel' of the text is to be preserved. We believe that we have done the best that we can and that this textbook will continue to be an invaluable companion to the higher training of obstetricians and gynaecologists and a useful repository of knowledge and evidence for those in established practice.

To reiterate the final paragraph of our last preface: *Textbooks do not make good doctors but good doctors must practise from a sound basis of knowledge.* We believe that this, the third edition, continues to satisfy the goals that were laid out in the first edition.

List of abbreviations used

5-FU	5-fluorouracil	ASA	American Society of Anesthesiologists
7-DHCO	7-dehydrocholesterol	ASCUS	atypical squamous cells of undetermined significance
AAA	arterio-arterial anastomatosis	ASD	atrial septal defect
ABC	airway, breathing, circulation	ASRM	American Society of Reproductive Medicine
AC	abdominal circumference	AST	aspartate aminotransferase (aspartate transaminase)
ACE	angiotensin-converting enzyme	ATP	adenosine triphosphate
ACEI	angiotensin-converting enzyme inhibitor	AUB	abnormal uterine bleeding
AChE	acetylcholinesterase	AUM	ambulatory urodynamic monitoring
ACHOIS	Australian Carbohydrate Intolerance Study in Pregnant Women	AVA	arteriovenous vessel
aCL	anticardiolipin	AVM	arteriovenous malformation
ACOG	American Congress of Obstetricians and Gynecologists	AZT	zidovudine
ACTH	adrenocorticotrophic hormone	β -hCG	beta-human chorionic gonadotrophin
ADPKD	autosomal dominant polycystic kidney disease	β -IFN	beta-interferon
AEDF	absent end-diastolic flow	BASHH	British Association for Sexual Health and HIV
AED	anti-epileptic drug	BCG	bacille Calmette Guérin
AF	amniotic fluid	BCPT	Breast Cancer Prevention Trial
AFC	antral follicular count	BCSH	British Committee for Standards in Haematology
AFE	amniotic fluid embolism	BEP	bleomycin, etoposide, cisplatin
AFI	amniotic fluid index	BFLUTS	Bristol Female Lower Urinary Tract Symptoms
AFLP	acute fatty liver of pregnancy	BG	blood glucose
AFP	alpha-fetoprotein	BHIVA	British HIV Association
AFS	American Fertility Society	BMD	bone mineral density
AFV	amniotic fluid volume	BMI	body mass index
AGA	appropriate for gestational age	BMJ	British Medical Journal
AHA	American Heart Association	BNF	British National Formulary
AIDS	acquired immunodeficiency syndrome	BP	blood pressure
AIS	adenocarcinoma <i>in situ</i>	BPD	biparietal diameter
ALF	acute liver failure	bpm	beats per minute
ALO	<i>Actinomyces</i> -like organism	BPP	biophysical profile
ALSO	advanced life support in obstetrics	BPS	bladder pain syndrome
ALT	alanine transaminase	BSAC	British Society for Antimicrobial Chemotherapy
AMH	anti-Müllerian hormone	BSCC	British Society for Cervical Cytology
ANA	antinuclear antibody	BSO	bilateral salpingo-oophorectomy
AP	antecedent pregnancy; anterior to posterior	BV	bacterial vaginosis
APACHE	Acute Physiology and Chronic Health Evaluation	bvm	bag-valve-mask
APH	antepartum haemorrhage	BW	birthweight
APL	antiphospholipid	CAH	chronic active hepatitis; congenital adrenal hyperplasia
APLS/APS	antiphospholipid syndrome	CAIS	complete androgen insensitivity syndrome
APSN	atypical placental site nodule	cAMP	cyclic adenylyl monophosphate
APTT	activated partial thromboplastin time	CASA	computer-assisted sperm analysis
AR	androgen receptor	CBT	cognitive behavioural therapy
ARB	angiotensin II type 1 receptor blocker (angiotensin receptor antagonist)	CC	clomifene citrate
ARC	antenatal result and choice	CCC	clear-cell carcinoma
AREDV	absent or reversed end-diastolic flow		
ARM	artificial rupture of membranes		
ART	antiretroviral therapy; assisted reproduction technique		

CCAML	congenital cystic adenomatous malformation of the lung	CSE	child sexual exploitation; combined spinal–epidural
CCG	Clinical Commissioning Group	CSF	cerebrospinal fluid
CCP	cyclic citrullinated peptide	CSII	continuous subcutaneous insulin infusion
CCSS	Childhood Cancer Survivor Study	CSM	Committee on Safety of Medicines
CDSR	Cochrane Database of Systematic Reviews	CT	computed tomography
CEA	carcinoembryonic antigen	CTG	cardiotocography
CEE	conjugated equine oestrogen	CTOCS	collaborative trial of ovarian cancer screening
CEFM	continuous electronic fetal monitoring	CTPA	computed tomography pulmonary angiogram
CEMACH	Confidential Enquiry into Maternal and Child Health	CVA	cerebrovascular accident
CEMD	Confidential Enquiry into Maternal Death	CVP	central venous pressure
CEPOD	Confidential Enquiry into Perioperative Death	CVS	chorionic villus sampling
CESDI	Confidential Enquiry into Stillbirth and Death in Infancy	CXR	chest X-ray
CEU	Clinical Effectiveness Unit	CYP	cytochrome p450
CF	cystic fibrosis	D&C	dilatation and curettage
cffDNA	cell free fetal DNA	D&E	dilatation and evacuation
CFU	colony-forming units	DARE	Database of Reviews of Effectiveness
CGH	comparative genomic hybridisation	DAT	direct antiglobulin test
CGIN	cervical glandular intraepithelial neoplasia	DC	dichorionic
CHC	combined hormonal contraception	DC/DA	dichorionic diamniotic
CHIVA	Children’s HIV Association	DES	diethylstilbestrol
CHM	complete hydatidiform mole	DEXA	bone mineral density scan
CI	confidence interval	DF	degrees of freedom
CIGN	cervical intraepithelial glandular neoplasia	DFID	Department for International Development
CIN	cervical intraepithelial neoplasia	DH	Department of Health
CIS	carcinoma <i>in situ</i>	DHEA	dehydroepiandrosterone
CKD	chronic kidney disease	DHT	dihydrotestosterone
CL	corpus luteum	DI	donor insemination
CMA	Canadian Medical Association	DIC	disseminated intravascular coagulopathy
CMACE	Centre for Maternal and Child Enquiries	DKA	diabetic ketoacidosis
CMV	cytomegalovirus	DLE	diathermy loop excision
CNS	central nervous system	DM	diabetes mellitus
CNV	copy number variant	DMPA	depot medroxyprogesterone acetate
COC(P)	combined oral contraceptive (pill)	DMSO	dimethyl sulphoxide
CODAC	cause of death and associated conditions	DOB	date of birth
COH	controlled ovarian hyperstimulation	DS	donated sperm
COMET	Comparative Obstetric Mobile Epidural Trial	DSD	disorders of sex development
COS	controlled ovarian stimulation	dsDNA	double-stranded DNA
COX-2	cyclooxygenase-2	DV	ductus venosus
CP	cerebral palsy	DVP	deepest vertical pool/pocket
CPD	cephalo–pelvic disproportion	DVT	deep venous thrombosis
CPM	confined placental mosaicism	DySIS	dynamic spectral imaging system
CPR	cardiopulmonary resuscitation	DXA	dual-energy X-ray absorptiometry
CQC	Care Quality Commission	E2(V)	oestradiol (valerate)
CRH	corticotrophin-releasing hormone	E3	oestriol
CRL	crown–rump length	E3G	oestrone-3-glucuronide
CRP	C-reactive protein	EAS	external anal sphincter
CS	caesarean section	EBM	evidence-based medicine
CSA	child sexual abuse	EC	emergency contraception; endometrial carcinoma
		ECG	electrocardiogram
		ECL	echogenic cystic lesion

ECOG	Eastern Cooperative Oncology Group	FIGO	International Federation of Gynaecology and Obstetrics
ECV	external cephalic version		
EDF	end-diastolic flow	FISH	fluorescence in-situ hybridisation
EDTA	ethylenediaminetetraacetic acid	FL	femur length
EE	ethinylestradiol	FM	fetal movement
EEG	electroencephalogram	FMAIT	fetal maternal alloimmune thrombocytopenia
EFM	electronic fetal monitoring		
EFW	estimated fetal weight	FME	forensic medical examiner, previously known as a police surgeon
EGF	epidermal growth factor		
eGFR	estimated glomerular filtration rate	FOCSS	familial ovarian cancer screening study
EIA	enzyme immunoassay	FRHM	familial recurrent hydatidiform mole
EMA	etoposide, methotrexate, actinomycin D	FSH	follicle stimulating hormone
		FSRH	Faculty of Sexual and Reproductive Healthcare
EMG	electromyography		
ENA	extractable nuclear antigen	FTA-Abs	fluorescent treponemal antibody absorption (test)
ENG	etonogestrel		
EPA	early pregnancy assessment	FTP	failure to progress
ER	extended-release; oestrogen receptor	FVL	factor V Leiden
ERCP	endoscopic retrograde cholangiopancreatography	GA	general anaesthetic; gestational age
		GABA-A	gamma-aminobutyric acid type A
ERCS	elective repeat caesarean section	GAG	glycosaminoglycan
ERP	enhanced recovery programme	GBS	group B <i>Streptococcus</i>
ERPC	evacuation of products of conception	GCIG	Gynaecologic Cancer Intergroup
ERT	oestrogen replacement therapy	G-CSF	granulocyte colony-stimulating factor
ESA	erythropoiesis-stimulating agent	GDF	growth differentiation factor
eSET	elective single embryo transfer	GDG	Guideline Development Group
ESG	European Society of Gynaecology	GDM	gestational diabetes mellitus
ESHRE	European Society of Human Reproduction and Embryology	GH	growth hormone
		GHRH	growth hormone-releasing hormone
ESMO	European Society of Medical Oncology	GI	glycaemic index
ESR	erythrocyte sedimentation rate	GIFT	gamete intrafallopian tube transfer
ESSIC	European Society for the Study of Bladder Pain Syndrome/Interstitial Cystitis	GMC	General Medical Council
		GnRH	gonadotrophin-releasing hormone
ET	embryo transfer	GOG	Gynecologic Oncology Group
ETT	endotracheal tube; epithelial trophoblastic tumour	GP	general practitioner
		GR	glucocorticoid receptor
FA	fertility awareness	GRADE	grading of recommendations, assessment, development and evaluation
FAI	free androgen index		
FAS	fetal alcohol syndrome	GRIT	Growth Restriction Intervention Trial
FBC	full blood count	GS	gestational sac
FBS	fetal blood sampling	GT	gestational thrombocytopenia
FDA	Food and Drug Administration (USA)	GTD	gestational trophoblastic disease
FDP	fibrin degradation product	GTN	gestational trophoblastic neoplasia; glyceryl trinitrate
FDV	first desire to void		
FET	frozen embryo transfer	GTT	gestational trophoblastic tumour
FEV	forced expiratory volume	GUM	genito-urinary medicine
FFLM	Faculty of Forensic and Legal Medicine	HAART	highly active antiretroviral therapy
		HAPO	hyperglycaemia and adverse pregnancy outcomes
ffn	fetal fibronectin	Hb	haemoglobin
FFP	fresh frozen plasma	HbSS	sickle cell anaemia
FFPRHC	Faculty of Family Planning and Reproductive Healthcare	HBV	hepatitis B virus; honour-based violence
		HC	head circumference; hybrid capture
FGM	female genital mutilation	hCG	human chorionic gonadotrophin
FGR	fetal growth restriction	HCM	hypertrophic cardiomyopathy
FHR	fetal heart rate	HCV	hepatitis C virus

HDFN	haemolytic disease of the fetus and newborn	IDDM	insulin-dependent diabetes mellitus
HDL	high-density lipoprotein	IDU	injecting drug user
HDN	haemolytic disease of the newborn	IE	infective endocarditis
HDU	high dependency unit	Ig	immunoglobulin
HELLP	syndrome of haemolysis, increased liver enzymes and low platelets	IGF-1/2	insulin-like growth factor 1/2
HERS	Heart and Oestrogen Progestogen Study	IGFBP	insulin-like growth factor binding protein
HES	Hospital Episode Statistics	IgG	immunoglobulin G
HFEA	Human Fertilisation and Embryology Authority	IgM	immunoglobulin M
HGSC	high-grade serous carcinoma	IGT	impaired glucose tolerance
HGUS	high-grade undifferentiated sarcoma	IH	immune hydrops
HIE	hypoxic–ischaemic encephalopathy	IHD	ischaemic heart disease
HIV	human immunodeficiency virus	IIQ	Incontinence Impact Questionnaire
HLA	human leukocyte antigen	ILCOR	International Liaison Committee on Resuscitation
HMB	heavy menstrual bleeding	IM	intramuscular
hMG	human menopausal gonadotrophins	IMB	intermenstrual bleeding
HNPCC	hereditary non-polyposis colorectal cancer	IMSI	intracytoplasmic morphological sperm injection
HP	hidradenoma papilliferum	INI	integrase inhibitor
hPL	human placental lactogen	IOL	induction of labour
HPLC	high-performance liquid chromatography	IQ	intelligence quotient
HPO	hypothalamic–pituitary–ovarian	IQR	interquartile range
HPV	human papilloma virus	ISD	intrinsic sphincter deficiency
HQIP	Healthcare Quality Improvement Partnership	ISSHP	International Society for the Study of Hypertension in Pregnancy
HR	hazard ratio; high risk	ISSVD	International Society for the Study of Vulvovaginal Diseases
HRQoL	health-related quality of life	ISVA	independent sexual violence advisor
HRT	hormone replacement therapy	ITP	idiopathic/immune thrombocytopenic purpura
HS	harmonic scalpel; hidradenitis suppurativa	ITT	intention to treat
HSDD	hypoactive sexual desire disorder	IUCD	intrauterine contraceptive device
HSG	hysterosalpingography	IUD	intrauterine death; intrauterine device
HSIL	high-grade squamous intraepithelial lesions	IUFD	intrauterine fetal death
HSV	herpes simplex virus	IUGA	International Urogynaecology Association
HSV-1	herpes simplex type 1 virus	IUGR	intrauterine growth restriction
HSV-2	herpes simplex type 2 virus	IUI	intrauterine insemination
HTA	Health Technology Assessment Database; Human Tissue Authority	IUS	intrauterine system
HUS	haemolytic uraemic syndrome	IUT	intrauterine transfusion
IADPSG	International Association of Diabetes and Pregnancy Study Group	IV	intravenous
IBD	inflammatory bowel disease	IVD	instrumental vaginal delivery
IBIS	International Breast Cancer Intervention Study	IVF	in-vitro fertilisation
IBS	irritable bowel syndrome	IVF-ET	IVF and embryo transfer
IC	interstitial cystitis	IVM	in-vitro maturation
ICH	intracranial haemorrhage	IVS	intravaginal slingplasty
ICIQ	International Consultation on Incontinence Questionnaire	IVU or IVP	intravenous urogram
ICP	intracranial pressure	KHQ	King's Health Questionnaire
ICS	International Continence Society; intra-operative cell salvage	LAC	lupus anticoagulant
ICSI	intracytoplasmic sperm injection	LAM	lactational amenorrhoea method
ICU	intensive care unit	LARC	long-acting reversible contraception
		LBC	liquid-based cytology
		LDH	lactate dehydrogenase
		LDL	low-density lipoprotein
		LEEP	loop electrosurgical excision procedure
		LFT	liver function test

LGESS	low-grade endometrial stromal sarcoma	MI	myocardial infarction
LGSC	low-grade serous carcinoma	MIG	metformin with insulin in gestational diabetes
LH	lutinising hormone		
LHCGR	shared leutinizing hormone/hCG receptor	MIN	multicentric intraepithelial neoplasia
LLETZ	large loop excision of the transformation zone	MIS	Müllerian inhibiting substance
LMP	last menstrual period	MLPA	multiplex ligation-dependent probe amplification
LMS	leiomyosarcoma	MLS	Maternal Lifestyles Study
LMWH	low-molecular-weight heparin	MMF	mycophenolate mofetil
LN	lymph node	MMP	matrix metalloproteinase
LNG	levonorgestrel	MMR	maternal mortality rate
LNG-IUS	levonorgestrel-releasing intrauterine system	MMT	methadone maintenance treatment
		MNC	modified natural cycle
LoC-IUT/SDI	letter of competence in intrauterine techniques/subdermal implants	MOET	managing obstetric emergencies and trauma
LOD	laparoscopic ovarian drilling	MoM	multiple of the normal median
LP	lichen planus	MPA	medroxyprogesterone acetate
LS	lichen sclerosus	MPD	maximum pool/pocket depth
LSIL	low-grade squamous intraepithelial lesion	MRC	Medical Research Council
LUNA	laparoscopic uterine nerve ablation	MRCS	maternal request caesarean section
LUTS	lower urinary tract symptom	MRg-FUS	magnetic resonance-guided focused ultrasound
LV	liquor volume	MRI	magnetic resonance imaging
MA	monoamniotic	MRKH	Mayer–Rokitansky–Kuster–Hauser syndrome
MAOI	monoamine oxidase inhibitor		
MAP	mean arterial pressure; morbidly adherent placenta	MRSA	methicillin-resistant <i>Staphylococcus aureus</i>
MAR	mixed antibody reaction	MS	multiple sclerosis
MAS	McCune–Albright syndrome; meconium aspiration syndrome	MSAFP	maternal serum alpha-fetoprotein
		MSH	melanocyte-stimulating hormone
MBRRACE-UK	Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the UK	MSM	men who have sex with men
		MSU	midstream urine
MC	monochorionic; mucinous carcinoma	MSV	Mauriceau–Smellie–Veit
MCA	Mental Capacity Act; middle cerebral artery	MTCT	mother-to-child transmission
		MTX/FA	methotrexate with folinic acid
MCAD	medium-chain acyl-coenzyme A dehydrogenase deficiency	MUP	motor nerve unit potential
		MVA	manual vacuum aspiration
MC/DA	monochorionic diamniotic	MVP	maximum vertical pool/pocket
MCH	mean corpuscular haemoglobin	NAAT	nucleic acid amplification tests
MCHC	mean cell haemoglobin concentration	NANC	non-adrenergic non-cholinergic
MCV	mean cell volume	NAS	neonatal abstinence syndrome
MCP-1	monocyte chemotactic peptide-1	NCCN	National Comprehensive Cancer Network
MDG	Millennium Development Goal		
MDKD	multicystic dysplastic kidney disease	NCEPOD	National Confidential Enquiry into Patient Outcome and Death
MDMA	3,4-methylenedioxymethamphetamine	NCSP	National Chlamydia Screening Programme
MDR	multidrug-resistant		
MDRD	modified diet in renal disease	NET-EN	norethisterone enanthate
MDT	multidisciplinary team	NFP	natural family planning
MEA	microwave endometrial ablation	NGF	nerve growth factor
MeSH	medical subject heading	NHS	National Health Service
MEWS	modified early warning system	NHSCSP	National Health Service Cervical Screening Programme
MFPR	multi-fetal pregnancy reduction		
MG	myasthenia gravis	NHSLA	NHS Litigation Authority
MHRA	Medicines and Healthcare products Regulatory Agency	NICE	National Institute for Health and Care Excellence

NICHD	National Institute of Child Health and Human Development	PEPSE	post-exposure prophylaxis for HIV following sexual exposure
NICU	neonatal intensive care unit	PET	positron emission tomography;
NIDDM	non-insulin-dependent diabetes mellitus		pre-eclampsia
NIH	National Institute of Health; non-immune hydrops	PFMT	pelvic floor muscle training
NIPT	non-invasive prenatal testing	PFR	peak flow rate
NMG	neonatal myasthenia gravis	PG	prostaglandin
NNT	number needed to treat	PHM	partial hydatidiform mole
NNTB	number needed to treat to benefit	PI	pulsatility index
NOMAC	nomegoestrol acetate	PICO	population, intervention, comparison, outcome
NPEU	National Perinatal Epidemiology Unit	PID	pelvic inflammatory disease
NPSA	National Patient Safety Agency	PIH	pregnancy-induced hypertension
NRTI	nucleoside reverse transcriptase inhibitor	PI/r	ritonavir-boosted protease inhibitor
		PIVKA	prothrombin induced by vitamin K absence
NSAID	non-steroidal anti-inflammatory drug	PLCO	prostate, lung, colon and ovarian cancer
NSC	National Screening Committee	PIGF	placental growth factor
NST	non-stress test	PM	postmortem
NT	nuchal translucency	PMB	post-menopausal bleeding
NTD	neural tube defect	PMCS	perimortem caesarean section
NYHA	New York Heart Association	PMDD	premenstrual dysphoric disorder
OA	occiput anterior	PMR	perinatal mortality rate
OAA	Obstetric Anaesthetists' Association	PMS	premenstrual syndrome
OAB	overactive bladder	PND	perinatal death notification
OC	obstetric cholestasis	POEC	progesterone-only emergency contraception
OCP	oral contraceptive pill		
OCR	optical character recognition	POI	premature ovarian insufficiency;
OGTT	oral glucose tolerance test		progestogen-only implant
OHSS	ovarian hyperstimulation syndrome	POIC	progestogen-only injectable contraception
OI	ovulation induction		
OMR	optical mark reader	POP	progestogen-only pill
ONS	Office for National Statistics	POP-Q	Pelvic Organ Prolapse Quantification
OR	odds ratio	PORTEC	postoperative radiation therapy in endometrial carcinoma
OROS	oxybutynin preparation using an osmotic system		
		PORTO	prospective observational trial to optimise paediatric health in IUGR
OSAT	objective structured assessment of technical skill		
		PPH	postpartum haemorrhage
OWAM	organisation with a memory	PPI	proton pump inhibitor
PAIS	partial androgen insensitivity syndrome	PPIUS	Patient Perception of Intensity of Urgency Scale
PAMG-1	placental alpha macroglobulin-1		
PAPP-A	pregnancy-associated plasma protein-A	PPROM(T)	preterm premature rupture of membranes (close to term)
PARP	poly ADP ribose polymerase		
PBC	primary biliary cirrhosis	PPS	pentosan polysulphate
PCA	patient-controlled analgesia	PPT	postpartum thyroiditis
PCB	postcoital bleeding	PR	progesterone receptors
PCEA	patient-controlled epidural analgesia	PROM	pre-labour rupture of membranes
PCOS	polycystic ovary syndrome	PROMPT	Practical Obstetric Multiprofessional Training
PCR	polymerase chain reaction		
PDA	patent ductus arteriosus	PSN	placental site nodule
PDS	polydioxanone suture	PSN	presacral neurectomy
PE	pulmonary embolism	PSTT	placental site trophoblastic tumour
PECOT	population, exposure, comparison, outcome and time	PT	prothrombin time
		PTNS	posterior tibial nerve stimulation
PEEP	positive end-expiratory pressure	PTSD	post-traumatic stress disorder
PEFR	peak expiratory flow rate	PTU	propylthiouracil
PEP	post-exposure prophylaxis	PUFA	polyunsaturated fatty acids

PUL	pregnancy of unknown location	SGA	small for gestational age
PUVA	psoralens and ultraviolet A	SGOT	serum glutamic-oxaloacetic transaminase
QALY	quality-adjusted life years	SGPT	serum glutamic pyruvic transaminase
QF-PCR	quantitative fluorescence polymerase chain reaction	SHBG	sex hormone-binding globulin
QoL	quality of life	SIADH	syndrome of inappropriate anti-diuretic hormone
RA	rheumatoid arthritis	SIDS	sudden infant death syndrome
RAADP	routine antenatal anti-D prophylaxis	SIGN	Scottish Intercollegiate Guidelines Network
RCA	root cause analysis	SIMS	single-incision mini sling
RCM	Royal College of Midwives	SLE	systemic lupus erythematosus
RCOG	Royal College of Obstetricians and Gynaecologists	SMBE	simulation-based medical education
RCPCH	Royal College of Paediatrics and Child Health	SMD	standardised mean difference
RCR	Royal College of Radiologists	SMR	severe mental retardation
RCT	randomised controlled trial	SNRI	serotonin noradrenaline reuptake inhibitors
ReCoDe	Relevant Condition at Death	SOA	Sexual Offences Act
REDF	reversed end-diastolic flow	SOAP	subjective, objective, assessment, plan
REM	rapid eye movement	SPR	screen positive rate
RFM	reduced fetal movement	SPRM	selective progesterone modulator
rFSH	recombinant FSH	SROM	spontaneous rupture of membranes
Rh	Rhesus	SRY	sex-determining region of the Y chromosome
RI	resistance index	SSR	surgical sperm retrieval
RiCoF	ristocetin-induced cofactor activity	SSRI	selective serotonin reuptake inhibitor
RITA	radiofrequency interstitial thermal ablation	STAN	ST analysis
RLU/PC	relative light unit/positive controls	STD	sexually transmitted disease
RMI	risk of malignancy index	STI	sexually transmitted infection
ROBUST	RCOG operative birth simulation training	STIC	serous tubal intraepithelial carcinoma
RPOC	retained products of conception	STUMP	smooth muscle tumour of unknown malignant potential
RPR	rapid plasma reagin	STV	short-term variability
RR	relative risk	SUDEP	sudden unexpected death in epilepsy
RRSO	risk-reducing salpingo-oophorectomy	SVD	spontaneous vaginal delivery
RTA	road traffic accident	SVT	supraventricular tachycardia
RT-PCR	reverse transcriptase-polymerase chain reaction	T3	triiodothyronine
SADS	sudden adult death syndrome	T4	thyroxine
SANDS	Stillbirth and Neonatal Death Society	TA	transabdominal
SARC	sexual assault referral centre	TAH	total abdominal hysterectomy
SCBU	special care baby unit	TAMBA	Twins and Multiple Births Association
SCC	squamous cell carcinoma	TAP	transversus abdominis plane
SCCOHT	small-cell cancer of hypercalcaemic type	TAPS	twin anaemia polycythaemia sequence
SCCOPT	small-cell cancer of pulmonary type	TB	tuberculosis
SCD	sickle cell disease	TBA	thermal balloon ablation
SCD	sudden cardiac death	TBG	thyroid-binding globulin
SCI	spinal cord injury	TCA	tricyclic antidepressant
SCJ	squamo-columnar junction	TDF	testis-determining factor
SD	standard deviation	TED	thromboembolic deterrent/disease
SDP	single deepest pool/pocket	TENS	transcutaneous electrical nerve stimulation
SDV	strong desire to void	TIA	transient ischaemic attack
SEM	static and dynamic surface electromyography	TIBC	total iron-binding capacity
SENG	endoglin	TLH	total laparoscopic hysterectomy
SERM	selective oestrogen receptor modulator	TM-ET	transmyometrial embryo transfer
SFH	symphysis-fundal height	TPHA	<i>Treponema pallidum</i> haemagglutination assay
sFLT	soluble fms-like tyrosine kinase-1		

TRAP	twin reversed arterial perfusion	UT	uterus
TRH	thyrotrophin-releasing hormone	UTI	urinary tract infection
TRUFFLE	Trial of Randomised Umbilical and Fetal Flow in Europe	UV	umbilical vein
TSH	thyroid-stimulating hormone	VACTERL	vertebral, anal, cardiac, trachea-oesophageal, renal, limb association
TTN	transient tachypnoea of the newborn	VaIN	vaginal intraepithelial neoplasia
TTP	thrombotic thrombocytopenic purpura	VAS	vibro-acoustic stimulation
TTTS	twin–twin transfusion syndrome	VBAC	vaginal birth after caesarean section
TV	<i>Trichomonas vaginalis</i>	VCU	videocystourethrogram
TVS	transvaginal ultrasound scanning	VDRL	Venereal Disease Research Laboratory
TVT	tension-free vaginal tape	VEGF	vascular endothelial growth factor
UA	umbilical artery	VIN	vulval intraepithelial neoplasia
UAE	uterine artery embolisation	VLP	virus-like particles
UDCA	ursodeoxycholic acid	VP	vasa praevia
UDI	urogenital distress inventory	VSD	ventricular septal defect
U&E	urea and electrolyte	VT	ventricular tachycardia
uE3	unconjugated oestriol	VTE	venous thromboembolism
UFH	unfractionated heparin	VVA	veno-venous anastomoses
UGT	uridine 5'-diphosphate glucuronosyltransferase	vWD	von Willebrand's disease
UKGTN	UK Genetic Testing Network	vWF	von Willebrand factor
UKMEC	UK Medical Eligibility Criteria	VZIG	varicella zoster IgG
UKOSS	UK Obstetric Surveillance System	VZV	varicella-zoster virus
UPA	ulipristal acetate	WBC	white blood cell
UPP	urethral pressure profilometry	WHI	Women's Health Initiative
UPSI	unprotected sexual intercourse	WHO	World Health Organization
US(S)	ultrasound (scan)	WHOMEC	WHO Medical Eligibility Criteria
USI	urodynamic stress incontinence	WY	woman years
		ZIFT	zygote intrafallopian transfer

How to use this book

The following features are used throughout the book to highlight the key information and to clearly identify the evidence base.

MRCOG standards

An MRCOG standards box at the start of a chapter lists the relevant standards and/or theoretical and practical skills relating to the topic. Where there are no standards specified in the MRCOG curriculum, we have given a summary of best practice.

EBM

Evidence-based medicine boxes are included to provide a rapid summary of the evidence relating to the interventions and treatments discussed in each chapter. Where evidence is limited, this is also stated.

KEY POINTS

Key points boxes summarise the main points in a section or chapter.

Evidence scoring

It is one of the key principles of this book that doctors assess the quality and applicability of available evidence. The evidence considered by the authors has been graded according to the structure below, in accordance with the system used in Guidelines published by the RCOG.

Classification of evidence levels

- A** systematic review or meta-analysis
- B** one or more well-designed randomised controlled trials
- C** non-randomised controlled trials, cohort study, etc.
- D** retrospective, uncontrolled
- E** 'expert opinion'

Chapter 1 Evidence-based medicine and medical informatics

Jane Thomas

MRCOG standards: Epidemiology and statistics

- Demonstrate the skills needed to critically appraise scientific trials and literature
- Understand the production and application of clinical standards, guidelines and care pathways and protocols
- Understand the difference between audit and research
- Understand how to perform, interpret and use clinical audit cycles
- Understand how to plan a research project
- Demonstrate a full understanding of common usage of computing systems, including the principles of data collection, storage, retrieval, analysis and presentation

INTRODUCTION

This chapter outlines some key concepts of clinical epidemiology and statistics that will help you to understand the terms used within this book, in clinical research and in the MRCOG examination.

Traditionally, medical practice was based on pathophysiological mechanisms of disease and the experience of authoritative experts. The term 'evidence-based medicine' (EBM) was first coined by Gordon Guyatt around 1990 to describe the process of bringing critical appraisal of research evidence to the bedside and basing clinical decisions on clinical research evidence, clinical expertise and patients' values.¹ This title was intentionally provocative.² Developing in parallel with EBM there was recognition that randomised controlled trials are the best way of establishing the effectiveness of treatments, and recognition, that whilst a single study is useful, pooling the findings from all studies provides the best evidence.³ *Effective Care in Pregnancy and Childbirth*⁴ was the first attempt in medicine to look thoroughly for research evidence and

systematically summarise the effect of treatments in a clinical area. This led on to the setting up in 1993 of the Cochrane Collaboration, an international network to prepare, maintain and disseminate systematic reviews.

EBM has evolved, and there is now greater emphasis on evidence in the context of patients' values and preferences. Critical appraisal of a body of evidence takes time, and it is inefficient use of resources to search the literature for every treatment of every patient. Increasingly, therefore, processed research, such as systematic reviews, summary digests of reviews or evidence-based clinical guidelines, can offer the highest level evidence on which to base decisions.² Nevertheless, it remains important that clinicians can appreciate the principles of EBM so that they can distinguish what is trustworthy reliable evidence from what is not.² *Testing Treatments*³ and the website 'Bad Science' provide an accessible introduction to the use and abuse of evidence.⁵

The practice of EBM comprises five steps:⁶ these steps are also used by guideline developers to develop evidence-based clinical guidelines:

- 1 defining a clinical question,
- 2 finding the best evidence,
- 3 appraising the evidence for its validity (closeness to the truth), impact (size of effect) and applicability (usefulness in clinical practice),
- 4 integrating the findings of the critical appraisal with clinical expertise and patient values,
- 5 reviewing (auditing) clinical practice and the efficiency of the above steps.

STEP 1. SETTING THE CLINICAL QUESTION

Generating an answerable clinical question that is precise and specific is the basis of EBM. The development of a search strategy will flow from this. Focused clinical questions include four components, abbreviated as 'PICO':^{6,7}

- **P** – the population: a description of the patients, such as their age, parity, clinical problem and the healthcare setting;

- **I** – the intervention(s) (or exposure): these are the main actions, such as treatment, diagnostic test or risk factor;
- **C** – the comparison group: for example, placebo or an alternative treatment;
- **O** – the outcome: for example, the change in health expected as a result of the intervention.

The type of study that will be sought is determined by the type of clinical question. For example, for a question about treatment, the highest level of evidence is based on randomised controlled trials (RCTs); for diagnostic test accuracy, studies that compare the 'new' test to a 'gold standard' test are needed; for questions about prognosis, studies that follow up groups of patients for a specified period of time (cohort studies) are needed. For a question about risk factors, cohort or 'case-control' studies may be more appropriate. For cohort studies, the intervention may be an exposure (rather than a treatment intervention) and additional factors (length of follow-up or time) may be included. This is sometimes a population, exposure, comparison, outcome and time (PECOT) question.⁷

An example of a vague clinical question is: 'Should we use antibiotic prophylaxis at caesarean section?' This question could be focused in a number of ways.

- *Population*: are you interested in all caesarean sections, or a specific subgroup such as emergency or repeat caesarean section? The country in which you are practising, and the resources available, may also be important to specify.
- *Intervention*: antibiotic prophylaxis. Do you want to specify the antibiotic? Are you interested in the dose/duration of use?
- *Comparison*: is this compared with no antibiotics or with another intervention or another antibiotic – or to a different dose or treatment schedule?
- *Outcome*: what will be different as a result of giving the antibiotics? Will they reduce postoperative wound infection, or other outcomes such as endometritis or urinary tract infection (UTI), or other measures of febrile or infective morbidity such as length of hospital stay? What are the possible adverse effects or risks, for example allergy? What are the longer-term problems for mother or baby?

An example of a focused question is: 'For women having emergency caesarean section, does co-amoxiclav reduce the risk of postoperative endometritis compared with amoxicillin?' This is a question about treatment, so we would look for systematic reviews of randomised control trials.

STEP 2. FINDING THE BEST EVIDENCE

Where to search

There are numerous different library databases; different databases index different journals and they may be general or topic

specific. MEDLINE is produced by the US National Library of Medicine and is widely available free of charge through PubMed. EMBASE has a greater European emphasis in terms of the journals it indexes and has a higher level of pharmacologic content. Nursing and midwifery research may not be indexed by MEDLINE or EMBASE: to find such research, databases such as MIDIRS, BNI and CINAHL should be searched. Psychological literature is indexed on Psychinfo or Psychlit. The best resource for high-quality systematic reviews is the Cochrane Library:

- Cochrane Database of Systematic Reviews (CDSR)
- Database of Reviews of Effectiveness (DARE)
- Health Technology Assessment Database (HTA) (this includes UK and international HTA assessments).

DARE and HTA are also available on www.tripdatabase.com and www.crd.york.ac.uk. The latter also includes a new database, PROSPERO, an international prospective database of systematic reviews in health and social care. Systematic reviews are often also published in peer-reviewed journals and are indexed on library databases. The Cochrane Library has the Cochrane Central Register of Controlled Trials (CENTRAL). In addition, it can be useful to include a citation search of ISI Web of Science or SCOPUS, which will locate research papers that have referenced the papers you intend to include in your research.

There are two online databases specifically for guidelines:

- 1 AHRQ National Guidelines Clearing House, www.guideline.gov (2500 guidelines, free to search and with links to most guidelines)
- 2 The Guidelines International Network library, <http://www.g-i-n.net/library/international-guidelines-library>, with 6500 guidelines, is free to search but you need membership to access guidelines.

Summaries of guidelines are now often also published in journals. If included in the guidelines clearing house they can be found through PubMed, a search of Turning Research Into Practice (TRIP) www.tripdatabase.com or alternatively an internet search for the websites of guideline producers such as NICE SIGN or specialist societies.

- Scottish Intercollegiate Guidelines Network (SIGN) (<http://www.sign.ac.uk/index.html>)
- National Institute for Health and Care Excellence (NICE) (<http://guidance.nice.org.uk/CG/Published>)
- Royal College of Obstetricians and Gynaecologists (RCOG): <http://www.rcog.org.uk>
- Canadian Medical Association (CMA) (<http://www.cma.ca/clinicalresources/practiceguidelines>)

Developing a search strategy

Within general library databases, methodological indexing of study design has greatly improved. Specific strings of search terms that identify study designs, for example systematic

reviews or RCTs, are available: these are designed to have high sensitivity. A good example of these is available in the Cochrane Handbook⁸ – search filters. There are methodological filters, which aim to include all relevant papers, but this may result in relatively low precision. Making your search more precise may be at the expense of sensitivity, i.e. a higher proportion of citations retrieved by your search may be relevant, but it might not include all relevant citations on the topic if these have not been indexed in a way that the filters would pick up.

Developing a search strategy usually involves combining free text and controlled text terms. Using the components of your clinical question (population, intervention, comparison, outcome and study design), make a list of the synonyms, abbreviations and spelling variations (e.g. labor or labour) that might have been used by the authors to describe the concept. If you already know of relevant papers, scan them for more possible search terms. This list can be your ‘free text’ terms.

The next stage is to list useful controlled text terms or subject headings. In MEDLINE, these are known as MeSH (Medical Subject Headings). In most databases they will be found in the thesaurus or index. If you know of a relevant paper, check the subject headings under which it is indexed.

Having developed a focused four-part question (PICO), create a separate search strategy for each component. The next stage is to combine these searches. Combination is achieved by ‘Boolean Logic’ and works in a manner similar to combining numbers in algebra. Boolean Logic uses the terms ‘and’, ‘or’ and ‘not’ to create a set of results that should contain papers relevant to the clinical question. For example, combining cervical *and* cancer will retrieve all the papers that contain both terms. Combining cervical *or* cancer will retrieve all papers in which either one or both terms are found. To find papers relating to postoperative infection, it would be necessary to combine both the lists of controlled and free text terms for both words with *or*. Combining induction *not* labour will retrieve all papers that contain the word induction but do not also include the term labour. Care should be used when combining terms with *not*, as it will exclude any papers that discuss both the term of interest and the one to be excluded. All databases also have useful search commands and symbols, but these vary among databases.

If you are conducting a systematic review, either for publication or as the evidence base for a guideline, it is good practice to keep your search strategies and record:

- how many articles were found by the search,
- the number and source of any other records identified,
- any duplicate reports, which should be removed
- the number of records screened
- the number of full text records assessed,
- those included in a qualitative and quantitative assessment (a meta-analysis),
- exclusions – with the reason.

This information should be combined into a flow chart and published along with your review.⁹

STEP 3. APPRAISING THE EVIDENCE

The best evidence for guiding practice is an accurate, complete summation of current research knowledge such as systematic reviews.³ In order to minimise bias, the methods of a systematic review should be explicit and well structured⁹ and should include clearly defined PICO questions, an extensive search of the literature, appraising the quality of studies located by the search with explicit criteria, and analysing the research findings using appropriate methods. Data from each of the individual studies may be pooled and analysed using a technique known as meta-analysis. Clinical guidelines should be based on systematic reviews, so it is important that you are able to understand the principles of appraising clinical guidelines, systematic reviews and the primary studies on which they are based, so that you are able to judge the validity and applicability of the conclusions to your specific circumstances.

Improved reporting standards of primary and secondary research through statements such as PRISMA,⁹ CONSORT 2010,¹⁰ STARD¹¹ and STROBE¹² ensure the information necessary for critical appraisal is more likely to be available. In addition there are numerous guides to critical appraisal.^{6,13}

Critical appraisal is the process of deciding if the research you have found can help you in answering your clinical question. The first filter is: ‘Does this paper address my clinical question?’ (i.e. is PICO the same or similar to that in your question?) If there are some slight differences, what are these?⁶

The second stage is to look at the study design (the methods section of a paper). The acceptable study design is determined by your clinical question. For questions about treatment interventions, RCTs or systematic reviews of RCTs provide the least biased estimate of effectiveness.^{3,6,8} For diagnostic test accuracy, studies that compare the ‘new’ test to a ‘gold standard’ test are needed. For questions about prognosis, studies that follow up groups of patients for a specified period of time (cohort studies) are needed.

Bias

A systematic review summarises the results from a body of research, usually RCTs but also observational studies. Quality assessment is an essential part of the process of systematic review. If the ‘constituent studies’ are flawed, the conclusions of systematic reviews may also not be valid.^{6,13} Bias is a systematic difference between groups that distorts the comparison so that the ‘true’ effect is either exaggerated or reduced. The quality of a study is the degree to which the study design, conduct and analysis have minimised bias. External validity examines the extent to which the results of a study are applicable to other clinical circumstances, i.e. its generalisability. Internal validity examines the extent to which systematic error (or bias) is minimised within the study. Such biases include:

- **selection bias** – the difference in the patient characteristics (such as prognosis) between comparison groups. In an RCT this is minimised by the method of randomisation

(only non-predictable is acceptable) and by keeping allocation concealed to prevent subversion;

- **performance bias** – differences in the provision of care apart from the treatment under evaluation (achieved through blinding patients, assessors and analysts);
- **detection bias** – differences in the measurement or assessment of outcomes;
- **attrition bias** – the occurrence and handling of patient withdrawals or attrition;
- **reporting bias** – many outcomes may be measured but may not all be reported, reporting is varied dependent on findings, positive findings are more likely to be published and published sooner.

Different study types are prone to different biases; therefore, there are different validity checklists for different studies based on the conduct, design and analysis.^{6,8} Appraising the quality of a study is dependent not only on what was done but on how the study was reported, and it is essential that the research is published so that the findings contribute to what is known.⁵

Understanding RCTs and systematic reviews of RCTs

For the MRCOG, it is important to understand the design of an RCT and of reviews of RCTs; therefore, the rest of this section focuses only on appraising RCTs. The RCT is the ‘gold standard’ method for evaluating the effectiveness of therapeutic interventions as it gives the least biased estimate of effect of treatment interventions.^{3,5}

A confounder is a factor (such as disease severity) that may influence the choice of treatment and the outcome of care. Confounding is one reason for the tendency of non-randomised trials to overestimate treatment effects when compared with RCTs. With a well-conducted RCT, randomisation will create groups that are comparable with respect to any known or unknown potential confounding factors (providing the sample size is sufficiently large). The key questions to ask when appraising (assessing possible bias and quality) an RCT are outlined below, with an explanation of why these are important.⁸ The first four questions relate to study validity, and the fifth to interpreting the results.

1. Was the assignment of treatment randomised?

The process of randomisation requires that those recruiting to a trial or participating in the trial cannot predict which group the subjects will be allocated to. The process of randomisation involves two stages:

- generation of an unpredictable allocation sequence (random number),
- concealment of this sequence from those enrolling participants in the trials.

Failure to secure the concealment of the sequence may allow selective enrolment depending on prognostic factors.

A trial in which it is possible to predict the treatment allocation is more likely to be biased. The ‘gold standard’ for randomisation used in large multicentre trials is ‘central computer’ randomisation. The use of sealed envelopes (especially if they are not sequentially numbered) may be subverted (for example by holding the envelope up to the light); methods that could be predictable are date of birth, alternate days and hospital number.

2. Were the groups similar at the start of the trial?

The aim of randomisation is the creation of groups that are comparable with respect to any known or unknown potential confounding factors (providing the sample size is sufficiently large). Randomisation reduces bias in those selected for treatment and guarantees that treatment assignment is not based on patients’ prognosis. RCTs will have eligibility criteria, but within these trials report the characteristics of the patients according to the treatment received in Table 1 of the results section. The characteristics (such as age, parity) of the two groups should not be different.

3. Were the groups treated equally?

Apart from the intervention being studied, the groups should be treated identically – differences in treatment between groups may occur if treatment allocation is known. This is called performance bias and can be minimised by standardisation of the care protocol and by ‘blinding’. RCTs may blind patients, and those administering treatment, assessing outcomes and analysing the data. If they are aware of allocation, the treatment of both patient groups may differ or patients themselves may deviate from protocols because of awareness of allocation.

Detection (or measurement) bias applies to the measurement or assessment of the outcome. This should be standardised across all patients. Again, knowledge of treatment allocation may influence assessors. For an objective outcome (such as death), this may be less important, but, for outcomes that are subjective, interpretation may differ if the assessor has prior knowledge of allocation. This bias can be minimised by using objective outcomes and by ensuring that those assessing outcomes are unaware of treatment allocation. This approach is used in surgical RCTs: although the surgeon undertaking the treatment has to be aware of the treatment allocation, identical surgical dressings are used for all patients, and the assessment of recovery is done by another person who is not aware of treatment allocation.

4. Are all the patients accounted for at the conclusion?

The process of randomisation gives us comparable groups at the start of a trial, but results are valid only if we can account for all these patients at the end of the trial. Therefore, once randomised, a patient should be included in the analysis of that group even if he or she discontinues therapy, crosses over

or never receives treatment. Loss of patients to follow-up or exclusion of patients from the analysis can lead to bias. Some losses may occur even in the best-quality studies, but this should not differ between groups, should be of similar types of patients and should not exceed the outcome event rate. Loss to follow-up of more than 20 per cent of recruits poses a serious threat to the validity of a study.

Intention to treat (ITT) analysis of RCTs ensures that comparisons of effects of care are made only between patients in the groups to which they were originally randomly allocated. ITT analysis includes all patients regardless of the treatment actually received or subsequent withdrawal or deviation from the protocol. Some treatments may result in large numbers of drop-outs, for example if side effects are unpleasant. Failure to account for these when examining interventions may cause false conclusions to be reached. These attritional issues are central to the generalisability of a treatment's final effect in clinical practice.

5. Are these findings important?

The analysis of RCTs is often a simple comparison of percentages. The difference in the event rate (outcome of interest) in the treatment group compared with that in the comparison group is:

$$\begin{aligned} &\text{Control event rate (\%)} - \text{experimental event rate (\%)} \\ &= \text{absolute risk reduction or risk difference (\%)} \end{aligned}$$

If an effect is seen in a trial, the final question is: 'Could this difference have arisen by chance?' In general, it is accepted that there is a 5 per cent chance of our concluding that there is a difference when in fact there is not – this is a 5 per cent chance of making a type 1 error, and hence we use a 95 per cent confidence interval (95% CI). Also by convention we accept an 80 per cent chance that we will detect a difference if one exists (this is the 'power' of a study). Increasing the number of patients in a study will reduce the chance of either error or increase the certainty of our estimates. The chance of these errors is also related to the size of difference we want to detect (we will need a larger study to detect a small difference between the two groups) and the frequency of the event (evaluating a very rare outcome such as occurs in 1:1000 people will need more people than an outcome that occurs in 1:100 or 1:10 people).

CIs can be calculated for this risk difference. The CI estimates the range of values likely to include the 'true' value. Usually, we use 95% CIs.

Finally, if you have a result that suggests a significant difference in outcome between two groups, you may want to consider what this means in practice. An alternative way of expressing this difference is the 'number needed to treat' (NNT). The NNT is simply 1 divided by the absolute risk reduction.

When communicating information about the benefits and risks of a treatment, a screening test is best done using natural frequencies rather than probabilities, so, for example, a 90% chance is expressed as 90 out of 100 patients or 9 out of

10 patients. It is preferable to keep the denominator constant and as small as possible.¹⁴

STEP 4. INTEGRATING THE EVIDENCE

In this section, we will consider how to apply evidence in clinical practice and when producing clinical guidelines. Clinical practice guidelines are defined by the Institute of Medicine as 'statements that include recommendations intended to optimise patient care, that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options'.¹⁵

Clinical decision-making can be complex. Guidelines have the potential to help clinicians and patients with complex choices, to improve the quality of care, and to help ensure the best use of limited resources.^{16,17} To ensure that guidelines inform rather than misinform, it is important that they build on the best available research evidence, and make explicit and transparent value judgements that are incorporated in reaching these recommendations. A systematic review identified 40 appraisal tools for guidelines; the most well-known and validated tool is AGREE 11.^{18,19}

In addition to your first filter, 'Does this paper address my clinical question?', the key features of guidelines that make an impact on their validity are:

- Guideline developers: did they include all relevant professional groups and patients?
- PICO format clinical questions, with outcomes important to patients specified
- Systematic review of the literature with explicit criteria for selecting the evidence
- A summary of the quality of the evidence – balance of risks and benefits for critical outcomes
- A clear process for moving from evidence to recommendations (e.g. using GRADE,²⁰ see below)
- External peer review and piloting
- Editorial independence and declaration of potential conflicts of interests of the group.

Formulating recommendations

The Grading of Recommendations Assessment, Development and Evaluation (GRADE) Working Group emphasised the link between the quality of a body of evidence and a recommendation.²⁰ Systematic reviews of RCTs provide high-quality evidence, but GRADE allows for factors that may reduce the assessment of quality and diminish our confidence in the findings such as:

- 1 RCTs within a systematic review are of poor quality so the risk of bias is increased;
- 2 inconsistency – heterogeneity in the findings of different studies not explained by clinical differences;
- 3 indirectness – any part of the PICO question may be slightly different to those in your question;

Table 1.1 A summary of the GRADE approach to grading the quality of evidence for each outcome²¹

Source of body of evidence	Initial rating of quality	Factors that may reduce the quality	Factors that may increase the quality	Final quality of a body of evidence*
RCTs or SR of RCTs	High	1. Risk of bias 2. Inconsistency 3. Indirectness 4. Imprecision	1. Large effect 2. Dose-response 3. All plausible residual confounding would reduce the demonstrated effect or would suggest a spurious effect if no effect was observed	High [⊕⊕⊕⊕ or A] Moderate [⊕⊕⊕○ or B] Low [⊕⊕○○ or C]
Observational studies	Low	5. Publication bias		Very low [⊕○○○ or D]

*The final grade for quality of a body of evidence [Level of evidence] is given letters (A,B,C,D) rather than numbers (I-IV) as previously used by SIGN and RCOG. There are only two grades of recommendation: strong or weak.

- 4 imprecision – where studies are too underpowered to be certain of the effect size;
- 5 publication bias.

Observational studies start as low quality, but in some circumstances, such as when looking at evidence of adverse effects, risks or harm, our confidence may be increased where there is a large effect, or a dose–response, and/or where all plausible residual confounding would reduce the demonstrated effect or would suggest a spurious effect if no effect were observed. This is because such adverse effects should be rare events and RCTs are powered to look at benefits and are usually not large enough to provide accurate estimates for rare events.

High-quality evidence [Level I, Grade A] can be interpreted as ‘further research is very unlikely to change confidence in the estimate of effect’. Moderate quality [Level II, Grade B] means that further research is likely to have an important impact on confidence in the estimate of effect and may change the estimate: this is often RCT-based evidence with limitations. Low quality [Level III, Grade C] means further research is very likely to have an important impact on confidence in the estimate of effect and is likely to change the estimate. Low-quality evidence mainly comes from observational studies. Most observational evidence will be low quality whether it comes from case–control studies, cohort studies or other forms of observation. The final category is very low [Level IV, Grade D], in which any estimate of effect is very uncertain. For each guideline question the overall quality of evidence is usually determined by the lowest quality of evidence for any of the outcomes (benefits or risks) selected. In addition, within GRADE ‘expert opinion’ is not considered a form of evidence but an interpretation of sometimes unsystematic evidence. RCTs may include a variety of different outcomes so the quality of evidence for each outcome in a systematic review may vary. Quality assessments for evidence on different outcomes can now be seen in Summary of Findings tables within Cochrane systematic reviews, in journals and in the evidence tables within guidelines.⁸

Within GRADE there are only two grades of recommendation: strong or weak. When there is less confidence in estimates of benefits and harms of an intervention, weaker recommendations are more likely to be made. Strong recommendations are made when it is very certain that benefits outweigh risks and costs or vice versa. A strong recommendation implies that virtually all informed patients would make the same choice. Weak recommendations are made when the benefits, risks and burdens appear to be finely balanced, or when there is appreciable uncertainty about the magnitude of benefits and risks: they imply that different values and preferences may play a crucial role in an individual’s decision.

Implementation

One of the consistent findings of health services research is the gap between research evidence and practice.²³ It is a challenge for clinicians to keep up to date, but perhaps even harder is the challenge to alter established patterns of care. This can be a challenge not only for individuals, but also for the organisations they work in. If the change required is complex or involves change in the organisation and/or patients’ attitudes, it is harder to achieve. There is no single strategy for getting research into practice that is sufficient on its own or significantly better than alternative strategies. Therefore a number of approaches are needed.

Research evidence is more likely to influence practice if it confirms our preconceptions.²² In interpreting research evidence, we also need to be aware of our own biases; we are likely to be less questioning of research evidence that affirms our own beliefs or practice, while scrutinising more closely the evidence that challenges them.²³

STEP 5. AUDIT

Research is concerned with discovering the right thing to do; audit is concerned with ensuring that the right thing is done. The purpose of clinical audit is to improve the quality

of patient care and outcomes through systematic evaluation of care against explicit criteria (setting a standard of care and measuring practice against this standard) and the implementation of change (improvement where possible).²⁴ A review of the evidence has concluded that audit is an effective method of improving the quality of care.²⁵ The same review also describes the audit methods associated with successful audit projects. In the UK, the General Medical Council (GMC) requires that you demonstrate that you regularly participate in 'robust, systematic and relevant' quality improvement activity such as clinical audit or a review of clinical outcomes.

Audit may evaluate the outcome of care against an agreed standard, or the process of care, or the structure (organisation or provision) of services. For example, research evidence suggests that the outcome for patients with ovarian cancer is better if they are operated on by an appropriately subspecialty-trained gynaecological oncologist and managed within the framework of a multidisciplinary team. An audit of the referral and management of patients with ovarian cancer can provide an overview of service provision in this area.

Process measures are the 'interventions' in your PICO question: they are practices that have good-quality research evidence to show for their influence on outcomes. For example, the use of antenatal steroids has improved perinatal outcome; evaluation of this process of care would entail measuring the proportion of appropriate cases (women at risk of giving birth preterm) who received antenatal steroids.

An outcome measure (as used to develop the PICO questions above) is the physical or behavioural response to an intervention. Most interventions are carried out with the intention of improving health outcomes but they also carry the risk of adverse effects. The assessment of outcomes such as cancer survival rates, or live birth rates following IVF (in vitro fertilisation), is fundamental to measuring quality of care, but outcomes are not a direct measure of the quality of care provided. Good outcomes are more likely if the quality of care is good but are influenced by other factors such as disease stage, co-morbidity, level of education and deprivation; therefore, mechanisms to take these differences into account are required (e.g. case-mix adjustment for co-morbidity or standardised measures such as mortality ratios). Outcomes may be delayed, and not all patients who experience substandard care will have a poor outcome, but the purpose of healthcare is to improve health outcomes so outcome measures provide essential information.

When differences arise thought and care are needed to explore the possible reasons for them. It should not be assumed that poor outcomes equate to poor care;^{26,27} differences in case mix and inconsistent coding can influence disease rates and adjustments. For example, the availability of hospices for palliative care will influence the number of patients receiving palliative care and the mortality rates within hospitals, and the frequency of coding for palliative care within a hospital will also have an impact. Ranking, as used in league tables, is a weak test and has not yet been shown to lead to improvements in healthcare: such tables create perverse incentives and encourage 'gaming', reducing access to care for patients with a poor prognosis and changing coding patterns. 'Critical

incident' or 'adverse event' reporting involves the identification of patients who have experienced an adverse event (e.g. to the NHS National Patient Safety Agency). Clinical activity, outcome indicators and adverse events are included in clinical dashboards such as the maternity dashboard.

Undertaking audit

Audit can be considered to have five principal steps (commonly referred to as the audit cycle):

- (i) select a topic,
- (ii) identify an appropriate standard,
- (iii) collect data to assess performance against the pre-specified standard,
- (iv) implement change to improve care, if necessary,
- (v) collect data for a second, or subsequent, time to determine whether care has improved.

It is essential to establish clear aims and objectives when choosing what to audit, so that the audit is focused towards addressing specific issues within the selected topic. A key consideration is: 'How will we use the results of this audit to change or improve practice?' Priority should be given to common health problems, areas associated with high rates of mortality, morbidity or disability, and those for which good-quality research evidence is available to inform practice (strong guideline recommendations), or aspects of care that use considerable resources. It is important to involve those who will be implementing change, those using the service and your local audit department at the planning stage. Good planning and resources are also necessary to ensure their success.

In audit, review criteria are generally used for assessing care. The criterion is the reference point against which current practice is measured. The first four steps above should be the starting point for developing criteria. Audit standards are often included in clinical guidelines. Review criteria should be explicit rather than implicit and need to lead to valid judgements about the quality of care, and relate to aspects of care that are important to patients or impact on clinical outcomes. The standard/target level of performance is defined as 'the percentage of events that should comply with the criterion' (e.g. the proportion of women delivered by caesarean section who received thromboprophylaxis, or the proportion of women with dysfunctional uterine bleeding who were offered endometrial ablation). 'Benchmarking' is defined as 'the process of defining a level of care set as a goal to be attained', such as used to define levels within clinical dashboards. There is insufficient evidence to determine whether it is necessary to set target levels of performance in audit.

Data collection

Data collection in criterion-based audit is generally undertaken to determine the proportion of cases in which care is in accordance with the criteria. In practice, the following points need to be considered. The methods of data collection, data

handling and analysis described here for audit could also be used for a research project.

Consideration needs to be given to which data items are needed in order to answer the audit question. For example, if undertaking an audit on caesarean section (CS) rates, collecting information on the number of caesarean sections alone will not give sufficient information to measure the CS rate. Data on the number of other births that took place are also required, and in addition factors that may influence the likelihood of CS are needed, such as maternal age, parity, and previous CS. The availability of data-sets and the data items within sets is a key consideration. Many data-sets classify disease using ICD-10 codes and treatments using OPCS-4 co-morbidity (patients' other diagnostic or treatment) codes. Clarity about the codes to be used is needed; for example, if collecting data on rupture of membranes, you may need to specify whether this is spontaneous or artificial.

Data handlers should always be aware of their responsibilities to the Data Protection Act 1998. Data in obstetrics and gynaecology are likely to be personal, with identifiers such as name, date of birth (DOB) and address, confidential and sensitive. Consent is required for data sharing. Anonymisation (using a computer program) and restricting access (encryption and password protection) to data is good practice to protect integrity. It is an offence to collect personal data of an individual without consent. Personal information such as age, ethnicity and postcode may enable factors that influence healthcare to be taken into account when interpreting findings such as deprivation. There has been consensus that clinical audit is part of direct patient care (assessing care and improving quality) and therefore consent to the use of data for audit can be implied through consent to treatment, if patients are informed that their data may be used in this way. It is not generally acceptable to use patient identifiers such as names and addresses, but some form of pseudo-anonymised identifiers (NHS number, DOB, postcode) may be used. However, current plans by NHS England to link data-sets (general practice to Hospital Episode Statistics [HES] care data) using pseudo-anonymous data have been delayed because of concerns (presumed consent for data sharing, the sensitive nature of information and the risk of identification). Audit (measuring practice against an agreed standard) does not need Research Ethics Committee approval. Aggregate data for providers is published by the NHS but application and approval are required for individual data or linking data-sets.

Routinely collected data should be used where possible, if the data items required are available and the completeness and coverage are known to be satisfactory. Where the data source is clinical records, training data abstractors and the use of a standard pro forma can improve the accuracy and reliability of data collection. The use of multiple sources of data may also be helpful, but this can also be problematic as it will require linking of data from different sources with common unique identifiers.

Designing data collection tools and questionnaires

Questionnaires are often used as a tool for data collection. Questions may be open or closed. Generally, questionnaire design using open questions (e.g. 'What was the indication for caesarean section?' followed by space for free text response) is easier, but analysis of these data is difficult, as there will be a range of responses, and interpretation can be problematic. Open questions may be more difficult and time-consuming for respondents to answer and can lead to non-response, resulting in loss of data.

Questionnaires can be composed entirely of closed questions (i.e. with all possible answers predetermined). More time needs to be spent in developing this type of questionnaire, but the analysis is generally easier. The following is an example of this.²⁸

'Which of the following statements most accurately describes the urgency of this caesarean section?

- A Immediate threat to the life of the fetus and the mother.
- B Maternal or fetal compromise that is not immediately life threatening.
- C No maternal or fetal compromise but needs early delivery.
- D Delivery timed to suit the woman and staff.

Closed questions assume that all possible answers to the question are known but not the distribution of responses. Time and consideration need to be given to the options available for response because, if a desired response is not available, the question may just be missed out, it may put people off completing the rest of the questionnaire or they may tick an available but inaccurate category. The 'other' category can be used with the option 'please specify', which gives an opportunity for the respondent to write in a response. If this is used, however, thought must be given beforehand as to how these free text responses will be coded and analysed. In some situations, not having an 'other' category may lead to the question not being answered at all, which means data will be lost.

If questionnaires are developed for a specific project, they need to be piloted and refined to ensure their validity and reliability before use as a tool for data collection. Whilst those who developed the questionnaire understand the questions being asked, the aim of piloting is to check that those who have to fill in the questionnaire are able to understand and respond with ease. Questionnaires that are not user friendly are associated with lower response rates and the quality of data collected will be poor, hence the results will be of little value. Thought also needs to be given to how the data are going to be collected and by whom, as well as to the time and resources that will be involved.

Analysing the data

When data from an existing source are used, the formats and compatibility of software need to be checked. Data can be transferred using statistical transfer software but this can

introduce errors and so data must be checked after transfer. Data that are collected on paper forms are usually entered on to electronic databases or spreadsheets such as Microsoft Access, Epi Info or Excel for cleaning and analysis. Data entry may be done by Optical Character Recognition (OCR) software, Optical Mark Readers (OMR) or manually. OCR is most accurate for questionnaire data using tick boxes but less accurate for free text responses. The method of data entry needs to be taken into account when designing the questionnaire or data collection sheet. For manual data entry, accuracy is improved if double data entry is used, but this can be a time-consuming exercise. If the facilities and resources are available, electronic collection of data can be considered. In this case, data are entered immediately at source into a computer and saved on to disks. Whilst this is quick and requires minimal storage space, it can be difficult to handle unexpected responses. As information is entered directly into a computer, it cannot be verified or double entered.

Consideration also needs to be given to the coding of responses on the database. For ease of analysis of closed questions, it is generally better to have numerical codes for responses. For example, yes/no responses can be coded to take the value 0 for no and 1 for yes. Missing data will also need to be coded, for example with the number 9. The code assigned for missing data should be distinguished from the code used when the response is 'not known' (if this was an option on the questionnaire). To minimise errors, it is advisable to incorporate consistency checks as data are being entered.

Simple statistics are often all that is required. Statistical methods are used to summarise data for presentation in the form of summary statistics (means, medians or percentages) and graphs. Statistical tests are used to find out the likelihood that the data obtained have arisen by chance, and how likely it is that a real difference exists between two groups. Before data collection has started, it is essential to know what data items will be collected, whether comparisons will be made, and the statistical methods that will be used to make these comparisons.¹⁸

Data items that have categorical responses (e.g. yes/no or A/B/C/D) can be expressed as percentages. Some data items are collected as continuous variables, for example mother's age, height and weight. Either these can be categorised into relevant categories and then expressed as percentages or, if they are normally distributed (bell-shaped curve), the mean and standard deviations may be reported. If they are not normally distributed, a median and range can be used. These summary statistics (percentages and means) are useful for describing the process, outcome or service provision that was measured.

Comparisons of percentages between different groups can be made using a χ^2 test; *t*-tests can be used to compare means between two groups, assuming these are normally distributed. Non-parametric statistical methods can be used for data that are non-normally distributed. These comparisons are useful in order to determine if there are any real differences in the observed findings, for example when comparing audit results obtained at different time points or in different settings. In some situations, a sample size calculation may be necessary

to ensure that the audit is large enough to detect a clinically significant difference between groups if one exists. In this situation, it is important to consult a statistician during the planning stages of the audit project. These simple statistics can be easily done on Microsoft Excel spreadsheets and Access databases. Other useful statistical software packages include Epi Info, SAS, SPSS, STATA and Minitab.

Implementation of findings

Data analysis and interpretation will lead to the identification of areas of clinical practice that need to change. Several methods may be needed to ensure this change takes place, but simple strategies such as feeding back findings are sometimes effective. Change does not always occur in audit, and consideration of the reasons for failure may take place after the second data collection. Resistance to change among local professionals or in the organisational environment or team should be considered. Patients themselves may have preferences for care that make change difficult.

ACKNOWLEDGEMENT

This chapter was written for the first edition of the book by Fiona M. Reid and Anthony R.B. Smith. It has been updated for both second and third editions by Fiona M. Reid.

GLOSSARY OF TERMS

Auditable standard An agreed standard against which practice can be assessed.

Case-control study The study reviews exposures or risk factors, comparing the exposure in people who have the outcome of interest, for example the disease or condition (i.e. the cases), with patients from the same population who do not have the outcome (i.e. controls).

Cohort study The study involves the identification of two groups (cohorts) of patients, one of which has received the exposure of interest and one of which has not. These groups are followed forward to see if they develop the outcome (i.e. the disease or condition) of interest.

Confounder A factor that may offer an alternative explanation for the observed association between an exposure and the outcome of interest.

Cross-sectional study The observation of a defined population at a single point in time or time interval. Exposure and outcome are determined simultaneously.

Denominator data Data describing the population within which a study group has been identified (e.g. in a hospital study of caesarean section the denominator data refer to every birth that occurred within the unit during the audited period, irrespective of the type of delivery that was undertaken).

HES Hospital Episode Statistics To receive payment for care delivered, every NHS hospital in England must submit

information about activity including admissions, outpatient appointments and A&E attendances. Each HES episode contains a wide range of information, including:

- clinical information about diagnoses and operations (as ICD10 and OPCS-4 codes)
- information about the patient, such as age group, gender and ethnicity (demographics)
- administrative information, such as time waited, and dates and methods of admission and discharge
- geographical information such as where patients are treated and the area where they live.

It contains admitted patient care data from 1989 onwards, outpatient attendance data from 2003 onwards and A&E data from 2007 onwards. The HSCIC (Health and social care information centre) provides data, IT and information for the NHS. It publishes aggregated data and synthesised information. The NHS can access data for quality improvement activity. The primary purpose of HES is administrative, the quality of the data has been criticised but it has been used in research and audit (eg by the RCOG). The sale of the information has raised concerns about confidentiality and data protection. Plans to merge it with GP datasets in care.data are currently stalled. If anonymised population data is invaluable for research and is available in Scotland and much of Scandinavia. **ICD10 = ICD-10** is the 10th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD), a medical classification list by the World Health Organization (WHO). It contains codes for diseases, signs and symptoms, abnormal findings, complaints, social circumstances, and external causes of injury or diseases. ICD-10 was first mandated for use in the UK in 1995. The ICD-10 4th Edition was approved for NHS implementation on 1 April 2012 by the Information Standards Board for Health and Social Care.

Mean This is the summary statistic used when the data follow a normal distribution. It is the sum of all the values divided by the number of values. The standard deviation gives a measure of the spread of individual values about the mean.

Median If the data are arranged in an increasing order, the middle value is the median. The range is the difference between the largest and smallest values. The interquartile range (IQR) is the difference between the bottom quarter and top quarter of the data. This is the summary statistic used when the data are not normally distributed.

Meta-analysis An overview of a group of studies that uses quantitative methods to produce a summary of the results.

Number needed to treat This is the number of patients who need to be treated to prevent one outcome.

Odds ratio This describes the odds that a case (a person with the condition) has been exposed to a risk factor relative to the odds that a control (a person without the condition) has been exposed to the risk. The crude odds ratio describes the association without taking into consideration the possible effect of any confounders. Adjusted odds ratios describe the association having been adjusted for the effect of confounders.

OPCS-4 an alphanumeric nomenclature, with a 4 character code system similar to that found in ICD-10, but OPCS-4 classifies procedures and interventions, rather than diagnoses. It is used throughout the NHS in the UK to codify procedures and interventions performed during in-patient stays, day case surgery and some out-patient treatments. It is based on the earlier Office of Population Censuses and Surveys Classification of Surgical Operations and Procedures (4th revision), it retains the OPCS abbreviation from this now defunct publication.

Positive predictive value This describes the percentage of people who have a positive test who really have the condition. The predictive value is dependent upon the prevalence of the disease in the population being tested, i.e. if the disease is rare, the predictive value is low, due to the greater influence of false-positive tests.

Power The chance that we will detect a difference if one exists; by convention this is often set at an 80 per cent chance that we will detect a difference if one exists. Power is increased with an increased study size and reduced with a smaller study.

Randomised controlled trial A group of patients is randomised into an experimental group and a control group. These groups are followed up for the variables and outcomes of interest. This study is similar to a cohort study, but the exposure is randomly assigned. Randomisation should ensure that both groups are equivalent in all aspects except for the exposure of interest.

Risk difference The difference in risk of developing the outcome of interest between the exposed and control groups.

Risk ratio Risk is a proportion or percentage. The risk ratio is the ratio of risk of developing the outcome of interest in an exposed group compared with the risk of developing the same outcome in the control group. It is used in RCTs and cohort studies.

Sensitivity The ability of a test to detect those who have the disease, i.e. the proportion (percentage) of people with the condition who are detected as having it by the test.

Specificity The ability of the test to identify those without the disease, i.e. the proportion of people without the condition who are correctly reassured by a negative test.

Systematic review (SR) A literature review that aims to minimise bias and random errors by using a system that is documented in a materials and methods section, and which may or may not include meta-analysis.

Chapter 2 The general principles of surgery

Fiona M Reid

INTRODUCTION

‘Choose well, cut well, get well.’ Surgery has three phases. In the preoperative phase, the correct operation should be chosen for a patient, who should be in an optimal condition. A well-trained, competent surgeon should then perform the surgery in a safe environment. During the postoperative phase, the patient should be monitored, encouraged and advised. Each phase is equally important. These are the basic principles of surgery, and this chapter examines how they may be achieved.

THE PREOPERATIVE PHASE

There is always more than one treatment option and it is the role of a gynaecologist to counsel the patient about the appropriate options. The process of selecting the best procedure for a patient is inseparable from that of obtaining informed consent. A booklet of guidelines to obtaining consent is available from the General Medical Council or on the internet at www.gmc-uk.org.

When counselling patients about treatment options, effective communication is imperative. This may necessitate the use of written material or visual aids. It may require the use of interpreters for foreign or sign language. Preferably, interpreters should be independent professionals and not family members, who could have a vested interest in a particular treatment.

Patients should be informed of the advantages and disadvantages of each procedure, the success rates, failure rates, side effects and common complications. Risk should be quantified rather than being described subjectively with terms such as ‘slight’ or ‘rare’.

Increasingly, the adequacy of consent is assessed legally by the concept of ‘material risk’. A risk is material if:

*In the circumstances of the case, a reasonable person in the patient’s position, if warned of the risk, would be likely to attach significance to it or if the medical practitioner is, or should reasonably be, aware that the particular patient, if warned of the risk, would be likely to attach significance to it.*¹

In practice, this implies that even rare complications that are serious or that carry significance to an individual’s social life or employment should be addressed.

Patients should have adequate time to reflect on the information they have been given prior to making a decision. It should not be assumed that a patient understands the general risks of surgery such as anaesthetic complications.

The General Medical Council’s guidelines on informed consent state that ultimately it is the responsibility of the person performing the procedure to ensure informed consent has been obtained.

Optimising preoperative health

Although most gynaecological surgery is performed on relatively healthy women, it is imperative that all patients undergoing surgery are in their optimum condition. Smokers should be encouraged to stop at least 24 hours before surgery to reduce the level of carboxyhaemoglobin in the blood and minimise the cardiovascular effect of nicotine.² Screening for sexually transmitted infections or bacterial vaginosis prior to pelvic procedures should be considered.³

Basic preoperative screening involves a detailed history and a general examination. Routine screening blood tests have not been shown to influence cancellations or perioperative complications, and the majority of abnormal results could have been predicted from the history and examination.⁴ A study by Golub *et al.*⁵ in the USA demonstrated that avoiding batteries of routine preoperative tests could save US\$397 per patient.

Ideally, preoperative investigations should be specific to each individual. Even routine sickle testing of at-risk adults has been challenged because patients with sickle cell disease would already have been detected as children due to chronic haemolytic anaemia. Also no sickling complications have been reported in sickle cell trait patients for the past 15 years.⁶

The morbidity and mortality of surgery and anaesthesia are increased in patients with coexisting disease (Box 2.1).⁷

Elective surgery should be delayed for 6 months after a myocardial infarct because 35 per cent will re-infarct before 3 months and this risk falls to 4 per cent after 6 months.⁸ Of the deaths reported in the National Confidential Enquiries into Perioperative Deaths (CEPOD) Report 2001, 60 per cent of patients had ischaemic heart disease.⁹ The history is as important as the investigations: a preoperative electrocardiogram

Box 2.1 Medical conditions most commonly associated with increased surgical morbidity

Ischaemic heart disease
 Congestive cardiac failure
 Arterial hypertension
 Chronic respiratory disease
 Diabetes mellitus
 Cardiac arrhythmia
 Anaemia

Box 2.2 The American Society of Anesthesiologists' (ASA) physical status classification system

ASA 1 Normal healthy patient
 ASA 2 Patient with mild controlled systemic disease which does not affect normal activity
 ASA 3 Patient with severe systemic disease which limits activity
 ASA 4 Patient with severe systemic disease which is incapacitating and a constant threat to life
 ASA 5 Moribund patient not expected to survive 24 hours with or without operation

(ECG) on patients with proven ischaemia will be normal in 20–50 per cent of cases.¹⁰

Protocols should be available on the ward for the management of common conditions such as diabetes mellitus.

It is the surgeon's responsibility to liaise with the anaesthetist and other specialties if patients have concurrent illness. At times it can be difficult to convey the complexity of a patient's condition, and the American Society of Anesthesiologists' (ASA) scoring system¹¹ can be a useful communication tool (Box 2.2).

Venous thrombosis embolism (VTE) is one of the most serious complications of surgery. An estimated 25,000 people in the UK die from preventable hospital-acquired VTE every year. The 2010 NICE guidance CG92¹² recommends that the risk of thromboembolism should be assessed in all hospital patients. All units should have clear protocols for thromboprophylaxis. Risk factors for thrombosis are shown in Box 2.3. A risk assessment is summarised in Table 2.1. Thromboprophylaxis should be prescribed after considering the balance of risk of bleeding and risk of VTE. Flow charts for specific clinical scenarios can be found on the NICE website for CG92 (www.NICE.org.uk). This includes continuing VTE prophylaxis for 28 days following major gynaecology procedures.

The Department of Health has recommended that all patients undergoing elective surgery should be screened preoperatively for meticillin-resistant *Staphylococcus aureus* (MRSA). All patients with positive skin screen for MRSA should undergo skin decolonisation therapy with a recommended skin wash. For procedures that require antibiotic prophylaxis patients with current or previous MRSA colonisation should receive teicoplanin or vancomycin intravenously.

Box 2.3 Patient-related risk factors of venous thromboembolism

Active cancer or cancer treatment
 Age over 60 years
 Critical care admission
 Dehydration
 Known thrombophilias
 Obesity (BMI >30 kg/m²)
 One or more significant medical co-morbidities (e.g. heart disease; metabolic, endocrine or respiratory pathologies; acute infections; inflammatory conditions)
 Use of HRT
 Use of oestrogen-containing contraceptive therapy
 Personal or first-degree relative with a history of VTE
 Pregnancy or up to 6 weeks postpartum
 Use of oral contraception or hormone replacement therapy (HRT)
 Varicose veins with phlebitis

Table 2.1 Risk factors for venous thromboembolism (VTE)

Medical admissions	If mobility significantly reduced for ≥3 days OR
	If expected to have ongoing reduced mobility relative to normal state plus any VTE risk factor
Surgical admissions	If total anaesthetic + surgical time >90 minutes OR
	If surgery involves pelvis or lower limb and total anaesthetic + surgical time >60 minutes OR
	If acute surgical admission with inflammatory or intra-abdominal condition OR
	If expected to have significant reduction in mobility OR
	If any VTE risk factor present

Over the last 10 years enhanced recovery programmes (ERPs) which started in colorectal surgery have spread to gynaecology. A recent systematic review of 5099 patients in 38 trials found ERPs reduced the length of stay and reduced the risk of all complications within 30 days.¹³

There are four elements to the enhanced recovery programme:

- 1 Preoperative assessment, planning and preparation before admission;
- 2 Reducing the physical stress of the operation;
- 3 A structured approach to immediate postoperative management including pain relief;
- 4 Early mobilisation.

KEY POINTS

Consent

Selecting the best procedure is inseparable from gaining informed consent.

It is the operator's responsibility to ensure that informed consent has been obtained.

Effective communication is imperative: interpreters or visual aids may be necessary.

Patients should receive detailed information on benefits and risks.

Patients should have adequate time to reflect on this information.

Optimising preoperative health

Smoking should be stopped 24 hours before surgery.

Combined oral contraceptives should be stopped 1 month before major surgery.

Preoperative screening should be by history and examination; routine blood tests are rarely helpful.

Routine surgery should be delayed for 6 months after myocardial infarction.

If there is concurrent illness, liaison with the anaesthetist and other specialists is essential.

All units should have clear protocols for thromboprophylaxis.

All patients undergoing elective surgery should be screened for MRSA.

Box 2.4 Adults at risk of infective endocarditis

Acquired valvular heart disease

Valve replacement

Structural congenital heart disease including surgically corrected defects but excluding isolated atrial septal defects, fully repaired ventricular septal defects or fully repaired patent ductus arteriosus, and closed devices that are judged to be epithelialised

Hypertrophic cardiomyopathy

Previous infective endocarditis

If infection is present then patients at high risk of endocarditis should receive antibiotics to cover the organisms that cause infective endocarditis. Patients considered to be at risk of infective endocarditis are shown in Box 2.4.

Facemasks in general abdominal surgery and certainly in laparoscopic procedures do not appear to affect infection rates. However, eye protection or face shields to protect the surgeon's mucous membranes from the patient's bodily fluids are sensible. Without serum testing it is impossible to know if a patient has hepatitis or human immunodeficiency virus (HIV) and therefore all patients are a potential risk. All health-care workers should be immunised against hepatitis B. Cotton gowns provide protection of one's nakedness only!

Drains may be used if clinically indicated and not as an alternative to good haemostasis. There is no robust evidence to support their use. A drain is probably advisable when a urinary tract injury has been repaired, in case of urinary leakage. Possible complications of drains include trauma during insertion, blockage, infection, erosion of adjacent tissue and retention of a foreign body.

INTRAOPERATIVE CARE

A full knowledge of abdominal and pelvic anatomy is essential for gynaecological surgery. In cases in which the anatomy is distorted, the surgeon should attempt to restore normal anatomy and work from first principles. Tissue planes should be utilised and tissues should be handled gently. Many gynaecologists gain most of their early surgical experience in the obstetric theatre, where speed tends to be valued above all else. Technique should be valued above speed.

Adequate access is essential. A senior surgeon called to a difficult case often first improves access. This includes good bowel packing.

Asepsis is obviously important, but some aseptic practices are traditions and are not based on evidence. Preoperative shaving, for example, is aesthetic to the surgeon and allows for the painless removal of the dressing postoperatively, but it does not appear to alter wound infection rates.¹⁴ The use of a single dose of prophylactic antibiotics to prevent wound infection or septicaemia is now widely accepted.¹⁵ However, prolonged courses of antibiotics or use of unnecessary antibiotics should be avoided due to the risk of *Clostridium difficile* infection.

NICE has published guidance stating antimicrobial prophylaxis against infective endocarditis is not required in patients undergoing urological, gynaecological and obstetric procedures where infection is not already present.¹⁶

TECHNICAL EQUIPMENT FOR SURGERY

Surgeons should have an understanding of the principles of the equipment they use.

Diathermy (electrocautery) involves the passage of electrical current through the patient's body. Electrocutation does not occur because the frequency of current used in diathermy is much higher than that of mains electricity. Mains electricity is a low-frequency alternating current (50 Hz in the UK). Low-frequency currents cause depolarisation and neuromuscular stimulation. Diathermy utilises a very-high-frequency (400 kHz to 10 MHz) alternating current. It does not cause depolarisation but it does excite ions, and this causes heat, particularly when in a high-density form.

In monopolar diathermy, the active electrodes and the return electrode are some distance apart. In bipolar diathermy, the two electrodes are only millimetres apart.

Factors that influence the diathermy effect are current density, the resistance of the tissue, the waveform and the duration of activation.

At high current density, heat is produced. The size of the electrode influences current density. At the tip of an active

electrode the current density is high, and therefore heat is generated. The return electrode's surface area is large, so the current density is low and no heating occurs.

The resistance of tissues is indirectly proportional to their water content: higher water content reduces resistance. Tissues with high resistance require a higher output (watts), from the diathermy generator, to generate heat.

Cutting is achieved by using a low-voltage but high-frequency current that is constantly flowing. The current is concentrated in a very small area and the high energy level causes so much ion excitation that the cells explode, releasing steam. If coagulation is required, an intermittent high-voltage current is used, with current flowing for only 6 per cent of the time. Thus a cutting current is inherently safer because of the lower voltage reducing the risk of inadvertent current discharge.

The safety of diathermy systems is continually improving. Initially, grounded generators were used, whereby current could return to ground via the path of least resistance. Since 1968, solid-state isolated generators have been used. These avoid burns at other sites such as drip stands because current will not flow unless current is returning to the generator. However, return electrode burns can still occur if the pad is not attached completely. Systems of contact quality monitoring have been available since the 1980s to prevent return electrode burns.

There are some specific hazards related to electrosurgery in laparoscopic procedures.

Direct coupling is the inadvertent flow of current from one instrument to another and may be secondary to insulation failure. Insulation failure can result from damaged equipment or the use of excessive voltage with coagulation current. Capacitance coupling can occur if a capacitor is created. Two conductors separated by an insulator form a capacitor, for example an insulated laparoscopic instrument passing through a metal port. The current stored in the capacitor can discharge into the patient, causing burns. The higher the current passing through the instrument, the greater will be the capacitance current. Plastic ports do not eliminate the risk of capacitance coupling because the patient's bowel or omentum can act as the second conductor. Capacitance coupling can be avoided with active electrode monitoring systems.

Other causes of diathermy burns are careless technique, not checking the dial setting before use, the use of spirit-based skin preparation near diathermy, or someone other than the surgeon activating the current flow.

Diathermy is the most commonly used energy source for tissue dissection and haemostasis, but others are used. These include ultrasonic energy (Harmonic Scalpel – HS) and laser (light amplification by stimulated emission of radiation). In the HS electrical energy is supplied to a piezoelectric ceramic element that expands and contracts rapidly (55,500 Hz). The ultrasonic energy mechanically breaks hydrogen bonds leading to protein denaturation and coagulation. The advantages of HS are lower temperatures, no current flow, no smoke or tissue charring, very little vapour and less lateral spread.

Two laser systems established themselves in gynaecological practice during the 1980s: carbon dioxide laser and the neodymium:yttrium–aluminium–garnet (Nd:YAG) laser. Both require specialised training.

KEY POINTS

Technique should be valued above speed.
Adequate access is essential.
Asepsis is important but some practices are not evidence based.
Single-dose antibiotic prophylaxis is now widely accepted.
All patients are a potential risk and all healthcare workers should be immunised against hepatitis B.
Drains should be used only when clinically indicated.
Surgeons should understand the principles of the equipment they use: this applies particularly to diathermy.

Minimal access surgery

Diseases that harm call for treatments that harm less.

William Osler (1849–1919)

The most common endoscopic techniques used in gynaecology are laparoscopy and hysteroscopy.

Laparoscopy

The possible benefits of laparoscopy are shown in Box 2.5. Many of these purported benefits have not undergone robust analysis. In a randomised trial of open versus laparoscopic colposuspension, in which the patients were blinded to the type of surgery, there was no significant difference in the length of hospital stay, but the laparoscopic group returned to normal activities significantly earlier than the open group.¹⁷

Many complications specific to laparoscopic surgery are related to the method of entry into the peritoneal cavity. The risk is as great for a diagnostic laparoscopy as it is for a

Box 2.5 Benefits of laparoscopy

Patients

Less pain¹⁷
Less blood loss^{17,18}
Less scarring
Faster recovery¹⁷

Surgeon

Safer 'closed/no touch surgery'
Better display of anatomy

Healthcare providers

Reduced inpatient stay
Reduced social cost

major operative laparoscopic procedure. The risk of bowel injury is 0.4–3 per 1000 and of vascular injury 0.2–1 per 1000 laparoscopies.¹⁹ Bowel adhesions to the anterior abdominal wall occur in 0.5 per cent of patients with no previous surgery, increasing to 20 per cent if they have had a previous pfannenstiell incision and to 50 per cent if they have had a midline incision.²⁰ To minimise this risk, safe entry techniques have been recommended (Box 2.6). Open laparoscopy has been advocated, particularly by general surgeons, because it appears to reduce the risk of vascular injury, but it does not reduce the risk of bowel injury. Microlaparoscopy at Palmers' point can also be used. Published recommendations on safe entry are formed from expert opinion,¹⁹ [E] not clinical trials, because the number of subjects required to perform trials to investigate entry techniques is prohibitively large.

Hysteroscopy

This common procedure has specific safety issues. Distension media for hysteroscopy include carbon dioxide, 0.9% saline or glycine. Water is not used as a distension medium because it is hypo-osmolar and, once absorbed, causes haemolysis.

If intrauterine electrosurgery is to be performed using monopolar equipment, the solution must be non-conductive so that the electrical current is not dissipated. Solutions containing electrolytes can be used with recently developed bipolar electrosurgery equipment.

The complications of hysteroscopy include uterine perforation and fluid absorption. Uterine perforation can be associated with damage to the bowel or intraperitoneal haemorrhage. A high index of suspicion and early recourse to diagnostic laparoscopy are advisable.

Fluid may be absorbed at the time of hysteroscopy. If excessive, it can result in hyponatraemia and hypo-osmolality, clinically characterised by nausea, vomiting, seizures, coma and even death. The amount of fluid absorbed is dependent on the volume infused and the infusion pressure. Owing to the short duration of a diagnostic procedure, excessive fluid retention is unlikely to be a problem.

Large-volume fluid absorption is most likely when large vessels are opened at endometrial resection. The main

Box 2.6 A safe entry technique for laparoscopy

The patient should be lying flat
 Ensure the bladder is empty and check the abdomen for masses
 Make the primary incision at the base of the umbilicus
 Insert the Veress needle through the base of the umbilicus, sensing a double click
 Insert 2–3 mL of saline through the Veress; it should run in freely
 Aspirate back: nothing should be aspirated
 Fill with CO₂ to a pressure of 25 mmHg
 Repeat the saline test
 Insert the primary trocar

precaution to avoid excessive absorption is accurate measurement of the fluid deficit throughout the procedure.

Fluid absorption increases significantly when the intrauterine pressure exceeds the mean arterial pressure (MAP). When gravity (the height of the bag) is used to drive the fluid, the lowest pressure (height) to distend the cavity should be used. It should not exceed the MAP. If the giving set contains a drip chamber, the height of the fluid is taken from the drip chamber, but, if this fills, the pressure is calculated from the fluid level in the bag.

KEY POINTS

Laparoscopy

Many of the purported benefits have not undergone robust analysis.

Many of the complications relate to the method of entry into the peritoneal cavity: safe entry techniques, formed from expert opinion, have been published [E].

Hysteroscopy

Non-conducting distension media must be used for intrauterine electrosurgery with monopolar equipment.

Uterine perforation may occur: a high index of suspicion is needed, with early recourse to laparoscopy.

Excessive fluid absorption may lead to seizures and even death. Accurate measurement of fluid deficit is needed throughout the procedure.

Local anaesthetic

Two common complications to consider when using local anaesthetic are systemic toxicity and delayed haemorrhage if it is combined with adrenaline. The duration of action and safe dosages are shown in Table 2.2.

Initial symptoms of toxicity are perioral paraesthesiae, tinnitus or visual disturbance. These may be followed by convulsions or cardiotoxicity, arrhythmia, complete heart block or cardiac arrest.

Sedation

A trained doctor should administer sedation. This doctor should be responsible only for administering the sedation and

Table 2.2 Properties of local anaesthetic agents

Agent	Duration of action (hours)	Maximum dosage	
		Plain solution	With adrenaline
Lidocaine	1–3	3	7
Bupivacaine	1–4	2	2
Prilocaine	1–3	4	8

cardiorespiratory monitoring. He or she should not perform the surgery.

The objective is to produce a level of sedation at which the patient is relaxed, calm and rational, and verbal communication is continuously possible. Sedation can result in unconsciousness or general anaesthesia. Facilities must be available to manage an anaesthetised patient.

All patients should be monitored with a pulse oximeter during sedation. Reversal agents should be avoided as their half-life may be shorter than the sedative, leading to delayed respiratory depression. Patients should be observed for at least 2 hours prior to discharge.

KEY POINTS

Local anaesthetic

Common complications of local anaesthetic are systemic toxicity and (if combined with adrenaline) delayed haemorrhage.

Sedation should be administered by a trained doctor who is not performing the surgery.

Facilities must be available to manage an anaesthetized patient.

Patients should be observed for at least 2 hours prior to discharge.

POSTOPERATIVE CARE

This can be divided into three phases:

- 1 immediate: theatre recovery;
- 2 early: until discharge from hospital;
- 3 late: home.

Theatre recovery

Airway, breathing and circulation (ABC) are the important parameters immediately after the operation. All staff should maintain life-support skills. Up-to-date resuscitation guidelines are available on the internet (www.resus.org.uk). Patients should be stable when they leave the recovery area. This includes the relief of pain.

Ward care

A doctor should review postoperative patients at least daily. A useful acronym for daily postoperative assessments is SOAP (subjective, objective, assessment, plan) (Box 2.7).

Modified early warning scores (MEWS) are now widely used in hospitals, and various different scoring systems have been used. A score of 5 or more on the one shown in Table 2.3 is associated with a statistically significant risk of admission to intensive care or death.²¹ Many hospitals now link their early warning score to a 'track-and-trigger' system in which a high score will electronically trigger a call to a medical practitioner.

Adequate analgesia should be prescribed. Units can rationalise prescribing using guidelines, for example an analgesic ladder – paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs), patient-controlled analgesia (PCA)/opioid and epidural.

Fluid balance is important. Most gynaecological patients will tolerate a 'standard fluid recipe' of 2500 mL/day. However, careless prescribing can lead to hyponatraemia or pulmonary oedema. Evidence-based practice of postoperative fluid management is sparse and equivocal but recent NICE guidance CG174 now provides useful algorithms for intravenous (IV) fluid therapy.²² Patients requiring IV fluids for maintenance should receive 25–30 mL/kg per day of water. Daily requirements of sodium and potassium are 1 mmol/kg. However, the effects of stress hormones associated with surgery are poorly understood, and electrolytes should be checked every 24–48 hours if a patient remains on IV fluids, to guide fluid prescription.

Glucose 50–100 g/day should also be prescribed to limit starvation ketosis.

Box 2.7 Daily postoperative assessment

SOAP

Subjective: how does the patient feel?

Objective: blood pressure, temperature and fluid balance

Assessment: physical examination

Plan: plan of care for the next 24 hours

Table 2.3 MEWS

Score	3	2	1	0	1	2	3
Systolic BP (% below or above normal)	<45	30	15	Normal	15	30	>45
Heart rate		<40	41-50	50-100	101-110	111-129	>0.130
Respiratory rate		<9		9-14	15-20	21-29	>30
Temperature (°C)		<35		35-38.4		>38.5	
AVPU				A	V	P	U

Oliguria is a urine output of less than 20 mL/h, in each of two consecutive hours. Oliguria due to hypovolaemia may result from:

- active haemorrhage;
- unreplaced blood loss;
- ileus: fluid loss into the gastrointestinal tract;
- loss of plasma into the abdomen;
- oedema.

If fluid balance is difficult, it may require central venous pressure monitoring and transfer to a high-dependency unit (HDU) or intensive care unit (ICU). The National CEPOD 2001 enquiry found that 16 per cent of patients were not admitted to ICU/HDU despite there being a demonstrable need.⁹

Fluids for volume expansion should be 500 mL bolus of crystalloid or blood. In the management of critically ill patients in intensive care, the TRICC study found that the group managed with a conservative transfusion strategy (Hb 7–9 g/dL) did significantly better than a group given a liberal transfusion management (Hb 10–12 g/dL) in terms of in-hospital mortality, adverse cardiac events, rate of organ dysfunction and overall transfusion rates²³ [D]. Further up-to-date guidance on all aspects of blood transfusion can be found at <http://www.transfusionguidelines.org.uk>.

DISCHARGE

Discharge should be planned. The patient should be aware of normal recovery rates, and be given advice about when to return to work, social activities and sexual intercourse. However, this information is usually based on traditional practice rather than evidence.

The general practitioner (GP) should be informed of the patient's treatment. An effective way to inform GPs is to give a brief discharge letter to the patient to take to the GP, followed by a formal letter. It may be necessary for social services, Macmillan nurses or district nurses to be involved in discharge procedures.

The need for follow-up visits is dependent on the surgery performed. The advantages and disadvantages are listed in Box 2.8.

DAY CASE SURGERY

There are special considerations to be accounted for in day case surgery, including patient selection and discharge arrangements.

Day surgery units should have clear protocols for patient selection to ensure patient safety and minimise cancellations (Box 2.9): patients should be generally fit and ambulant; they

Box 2.8 Follow-up clinics

Advantages

- Audit
- Proactive detection of complications
- Provide ongoing treatment
- Completeness of treatment episode

Disadvantages

- Delay in reviewing complication
- Anxiety waiting for results
- Time spent seeing well people
- Cost to the health service
- Cost to the patient in travel and time off work

KEY POINTS

POSTOPERATIVE CARE

Immediate

All staff should maintain life support skills.

Early

A doctor should review patients at least daily. Analgesia and fluid balance are important.

Discharge

Patients should be given full advice about recovery rates and activities.

The GP and, if necessary, other services should be promptly informed.

Not all procedures require routine follow-up.

Box 2.9 Common conditions that require further assessment

- Uncontrolled hypertension, BP >170/100 mmHg
- Cardiac failure
- MI/TIA/CVA in past 6 months
- Severe asthma/respiratory disease
- Diabetes – type 1 or poorly controlled type 2 (BG >11 mmol/L)
- Renal or hepatic disease
- Alcoholism or narcotic addiction
- Advanced multiple sclerosis or myasthenia
- Severe cervical spondylosis
- Severe psychiatric disease
- Drugs: MAOIs, digoxin, steroids, anticoagulants, GTN, diuretics and antiarrhythmics

BP, blood pressure; MI, myocardial infarction; TIA, transient ischaemic attack; CVA, cerebrovascular accident; BG, blood glucose; MAOIs, monoamine oxidase inhibitors; GTN, glyceryl trinitrate.

should be able to climb one flight of stairs; they should not be grossly obese (BMI >35 kg/m²).²⁴

Day surgery units should have written criteria for patients' discharge.^{25,26} Patients should have stable vital signs, be oriented in time and place, and able to tolerate oral fluids; they should be able to dress and walk unaided; they must have a responsible and physically able adult to collect them and care for them overnight; they should have adequate analgesia and be aware of the action to take in the event of complications. A contact telephone number should be given for advice after discharge.

KEY POINTS

DAY CASE SURGERY

There should be:

- clear protocols for patient selection;
- written criteria for discharge.

RISK MANAGEMENT

Risk management is the process of examining procedures to prevent accidents and assessing incidents to prevent recurrence. Some of the most serious mistakes occur from the simplest system errors.

The introduction of simple protocols can avoid common mistakes such as retained swabs and ensure that the correct operation is performed on the correct patient.

The positive impact of a simple surgical checklist was demonstrated in a large multinational study. Data on clinical processes and outcomes were collected on 3733 patients undergoing non-cardiac surgery in 8 different countries. Following the introduction of a 19-item Surgical Safety Checklist, data were collected on 3955 patients. The death rate was 1.5% before the checklist was introduced and declined to 0.8% afterwards ($P = 0.003$). Inpatient complications occurred in 11% of patients at baseline and in 7% after introduction of the check list ($P < 0.001$)²⁷ [C].

Examining 'near misses' is as important as examining actual 'incidents'. Hospitals should have a reporting procedure that is accessible to all staff.

KEY POINTS

RISK MANAGEMENT

There should be reporting systems for incidents and 'near misses'.

CONCLUSIONS

Technicians can perform procedures, whilst surgeons should orchestrate care.

Surgeons have a responsibility to ensure they are adequately trained, have counselled the patient preoperatively and are performing the correct operation, and to provide postoperative care.

Audit is important to review practice and should be part of a surgeon's remit. Surgeons must be provided with the time and resources required to audit their practice. League tables of surgical care will be informative only when all aspects of care are included in the assessment. The National Confidential Enquiry into Perioperative Deaths is a national surgical audit that can be found at www.ncepod.org.uk.

ACKNOWLEDGEMENT

This chapter was written for the first edition of the book by Fiona M Reid and Anthony RB Smith. It has been updated for both second and third editions by Fiona M Reid.

Chapter 3 Communication and counselling

Richard Porter

MRCOG standards

There are no specific standards in the MRCOG curriculum for this topic. Everything in this chapter is – or should be – self-evident. Communication is the foundation stone of our clinical practice.

INTRODUCTION

Humans communicate in myriad ways. Doctors do not always give the impression of being entirely alert to this. It is possible to be a proficient diagnostician or a highly competent surgeon, or both, and to be a poor communicator with patients. But I would argue that it is not possible to be a good doctor in the modern world without being a good communicator. After all, communication with patients is what principally distinguishes us from veterinary surgeons – with all due respect to veterinary surgeons.

This chapter does not presume to list the methods used in medical schools to improve patient–doctor communication. Medical school (undergraduate) curricula have developed teaching programmes that focus on this topic, and there is a body of academic research that underpins the strategies used by clinicians in eliciting and imparting information from and to patients as effectively as possible. Primary care training rightly regards the teaching of communication skills as one of the most important parts of the introduction of a trainee to general practice. However, in specialist training in obstetrics and gynaecology, one might be forgiven for thinking that there is a belief that the lessons have been adequately learned in medical school, so little formal teaching is given on the topic in many training schemes.

This is, however, being addressed. Examination for membership of the Royal College of Obstetricians and Gynaecologists includes Objective Structured Clinical Examination (OSCE) stations that incorporate contact with actors, who indeed give feedback on the standards of the doctors.

However, it is important to remember that doctors do not only communicate with patients and their relatives.

This chapter is an attempt to apply a sideways and personal look at the broader area of communication in clinical practice: communication between doctor and patient, between doctor and doctor, and between doctors and other professionals – in other words, the wider picture.

COMMUNICATION WITH PATIENTS (AND THEIR RELATIVES AND FRIENDS)

In obstetrics and gynaecology, good communication with patients generally requires:

- *Respect for the patient as an individual.* Even if she holds opinions and beliefs that may not be the same as ours.
- *Respect for women.* In cultures where this is not automatic, it is frequently observed that communication is at a lamentably low level, even when women interact with other women doctors. At its most extreme, women will simply avoid contact with medical services, with dire consequences for health outcomes, such as maternal and perinatal mortality. If an obstetrician/gynaecologist does not respect patients as women, it is difficult to understand why such a doctor remains in this specialty.
- *The ability of the doctor to understand the patient, and the patient to understand the doctor.* Language barriers are not a justification for substandard clinical care on either a medico-legal or a moral level.¹ We may require the use of interpreters, but we must remember that the problem may not just be with the words used. Even when a doctor and a patient ostensibly speak the same language, they may not be using the words in the same way, and this can be a cause of major and potentially dangerous misunderstanding.
- *The ability to listen.* This is not an open-ended commitment: some patients will want to tell us far more than we need, want or have time to hear. But achieving the right balance is essential, and sometimes very challenging.
- *Flexibility.* Any doctor who says that he or she takes a history in the same way under all circumstances is being

either extraordinarily naive or economical with the truth. A good doctor is constantly looking for nuances in the nature of the communication with the patient that will show the way forward in that contact.

Verbal communication with patients

Assuming that you and the patient are speaking (literally) more or less the same language:

- *Do you introduce yourself?* The recent ‘My name is ...’ campaign is a simple but effective wake-up call for the medical profession. The campaign arose from the experience of a medically qualified patient who had been told of her terminal diagnosis by a doctor who did not introduce him- or herself. Was this perhaps shyness, or possibly difficulty handling the exchange of painful information? Who knows – but whatever else it was deeply wounding to the patient, and wholly avoidably insensitive.
- *Are you using a vocabulary that is appropriate to her?* I well remember watching a brilliant researcher explaining in detail to a totally bemused mother the physics of Doppler waveforms. This was in response to her anxious question – while being scanned at 34 weeks’ gestation – ‘Whassat doing then?’ This was (to be honest) hilarious to watch – but a tragic illustration of the limitations of intelligence.
- *Are you going too fast?* How often do we see colleagues checking with patients, after imparting manageable (bite-sized?) chunks of information, whether or not they have understood? Not nearly often enough, I would predict. If we wait until the end of a long discussion, with masses of pieces of information, can we be surprised if the patient surrenders and says that she has understood – just to make us go away? In fact, I cherish the lesson I learnt from a patient who, after I had explained that she needed her urodynamics repeating (I assumed that she knew what I was talking about because she had had the test before), was asked by the sister when leaving the room, ‘So, did you understand all that?’, and said loudly (she was a bit deaf), ‘Not a word dear’.
- *Are you ‘talking down’ to her?* In this new era of patients accessing information on the internet, few things are more likely to raise hackles than giving the impression that you assume that they are ignorant.
- *Are you giving her more information than she wants?* This is one of the most difficult areas in current practice (see Obtaining consent, p. 26). How much is enough, and how much too much? In oncology care, this is a particularly important issue, and is beyond the scope of this chapter. The problem is compounded by perceptions about a litigious environment. Yet we must recognise that we have a duty of care to our patients, and that may mean that we should make judgements about the appropriateness or otherwise of imparting every iota

of information. (In this area the RCOG Consent Advice documents [available on-line from www.rcog.org.uk] are, on the one hand, particularly helpful templates and, on the other, arguably examples of potential information overload. Different patients will respond differently, and individualisation should be the nature of the interaction.)

- *Do you recognise the cultural sensitivities influencing her decisions?* In our multicultural society, we are becoming better at not trampling on the sensitivities of, for example, women who have religious reasons for not wanting to see men in a medical context, but it is still incumbent upon us to be alert to the possibility of unexpected beliefs and taboos.
- *Do you involve the patient in the decision-making?* Joseph-Williams *et al.* (2014) (*Power Imbalance Prevents Shared Decision Making*)² demonstrate how complex this dynamic is. We act as doctors in an environment that is considerably more complex than used to be the case. Gone – fortunately – are the days of unarguable ‘top-down’ distribution of medical decisions, but many doctors are unaware of the subtly coercive position we still occupy (even though that may be the polar opposite of what we might intend). This is of course not merely a moral and ethical challenge, it is also one underpinning an increasing amount of litigation in our specialty. Joseph-Williams *et al.* make the point that attitudinal issues are pre-eminent in this area.

Non-verbal communication with patients

A patient is more often than not in a state of some unease when meeting a doctor, and she will be responding to far more than what is said or not said. The nature of the space where the meeting takes place, the smells of the environment, the extraneous noises – all will influence both her perception of the event and the way in which she takes the information on board. A doctor cannot often immediately influence these factors, but can certainly add to or detract from the experience by means of non-verbal communication.

Much of this is a matter of common courtesy, but it is easy to let our standards slip on occasion – and patients notice it, you can be sure. Surely the guiding principle here is that you should act towards your patients exactly as you would wish to be acted towards yourself – and the use of the word ‘act’ is not accidental, for every contact with a patient is to a degree a theatrical event.

The following are some examples.

- *How do you greet the patient?* Do you stand up? Do you have your back to her when she comes in? Do you shake her hand? Do you invite her to sit? I suspect that we have all seen ‘eminent’ doctors greet a patient by continuing to talk to medical students. What sort of an impression does that give?

- *What is your facial expression?* A smile, a furrowed brow, a scowl, a deadpan expression – all will convey some message to the patient. Is the message the one you want to convey? The problem can, of course, get slightly out of hand: the phoney facial expression is just as unsettling as the unthinking one. Think of a politician delivering an unpalatable message with a sanctimonious look. None of us would like to be compared with politicians, I assume.
- *Do you look her in the eye when talking to her, or do you stare at the floor?* This again may reflect your cultural background, or even perhaps your innate modesty, but it may lead to unintended inferences by the patient. Would you propose marriage while looking at the floor? (Of course some might: I am reminded of the schoolmaster who did so by asking his intended if she wanted his surname on her gravestone. Tastes differ)
- *How do you sit during a consultation?* Are you leaning forward in an attentive pose, or slouching in the chair? Body language is powerful, and can be deeply unsettling for your patient.
- *When you stand (e.g. in a bedside consultation), how far away are you?* Are you too close for the patient's comfort, or are you so far that you give the impression that you regard the patient as another life form? Remember that differences in height – e.g. when you stand over a patient who is lying on a bed – can result in, to put it mildly, unintended distortions in communication.
- *Have you ensured that she is at her ease?* Is she embarrassed (more than is usual) by her state of undress? As ever, the question is: would you or your nearest and dearest want to be treated like this?

I have no doubt that every reader of this chapter can add other examples of good and bad practice that they have encountered in their professional lives. None of us succeeds at all times in making good communication with patients and their families and friends, but we should at least strive to stand back at times and analyse our performance, and to continue to improve.

Communication with a complaining or angry patient

I personally know of no more challenging area of communication, and this is clearly not an area where 'dry runs' are particularly easy to construct. However, for better or for worse, these situations are becoming more common as patients and their families become more vocal – and beyond doubt more critical (rightly or wrongly). Good communication can make the difference between a problem that is resolved there and then and one that lingers, often with complex ramifications. The principles of communication are essentially the same as above, but the application of the principles may prove exceedingly difficult. Staying calm may prove to be the most difficult part of the equation.

COMMUNICATION WITH OTHER STAFF

Although communication with patients is of paramount importance, the issue of communication with other professionals is also crucial. In hospital medicine, there is no such thing as a single-handed department, and dysfunction all too easily follows from poor inter-professional communication.

Any trainee who has worked in a department where rivalries pollute the atmosphere will know how destructive that can be. Many of these problems themselves arise from poor communication skills, but poor communication will surely follow from these rivalries.

The areas of importance are discussed below.

Doctor–doctor communication

Juniors need to communicate with other more senior doctors (and vice versa), and doctors of the same grade as themselves. Now that trainers are themselves being more commonly trained to train, and in the increasingly informal atmosphere in which we work in hospital practice, it should follow that this 'vertical downward' communication will be better handled. This is also assisted by the reduction in 'patronage' over the last few years, which makes for a far healthier training environment. However, that is beyond the scope of this chapter.

Yet, strangely perhaps, few if any trainees have been taught how to communicate 'upwards' with their trainers. Does this need to be taught? I would suggest that it does. Consider the 2 a.m. phone call to the consultant on call. Does the trainee have any idea what this feels like for the recipient of the call, roused from sleep? Possibly the best advice I received about this was the suggestion that the caller should be taught immediately to communicate the status of the call. Was it a call that (a) required the consultant's presence, (b) required the consultant's advice or (c) was merely to inform the consultant?

This is an example of learned communication that hugely enhances the transfer of information, almost certainly to the advantage of the patient.

The most formal type of doctor–doctor communication is case presentation. This is a skill and, like many others in postgraduate training, it is currently barely, if at all, taught. Yet without this skill there can be serious difficulties within the clinical team.

The simplest advice is, I believe, the best: present cases in three parts – the synopsis, the detail and the summary (or, in other words, tell them what you are going to say, tell them what you want to say and then remind them what you have just told them).

All trainees should practise these skills as often as possible, and should learn to teach them to the next generation.

Doctor–midwife/nurse communication

The other area of inter-professional communication – doctor–midwife/nurse communication – is just as important. Gone, thankfully, are the days of the presumed superiority of doctors. Instead we now respect the professional contributions of each other for what they are: interdependent and worthy of mutual respect. Nevertheless, all have to work to maintain the best possible level of communication at all times. Examples abound of departments where communication has failed – and the overall departmental dysfunction that ensues is massive, detrimental to patient care and wholly unnecessary. Like any relationship, this one will have ups and downs. The mark of maturity is when the system can tolerate these, and learn from them.

Written communication

The two areas are clinical records and letters to other professionals. The skills required are similar, but different in detail.

Clinical records

The quality of clinical records is of vital importance. Well-constructed clinical records communicate with other professionals and protect patients. They may also protect the writer from future medico-legal attack. Poor-quality clinical records, by contrast, confuse other professionals and endanger patients. Records should be (as far as possible for those of us whose handwriting is only marginally more decipherable than Egyptian hieroglyphs) legible. They must also be dated, timed and signed (identifiably), if referring to an inpatient. There should be no exceptions to this.

The thicker clinical records become, the less useful they are as modes of information transfer. Thought must therefore be given to what and how much you write. Write only what is necessary and sufficient. Historically, midwives have written more than is necessary, and doctors far less than is necessary. Fortunately, that gap has recently narrowed considerably. Nevertheless, all those involved in medico-legal practice express continuing concern about the quality of note keeping.

Letters

A generation ago, letters between doctors were more stylish, idiosyncratic and interesting. Unfortunately, they were also far less useful in transferring medical information. We live in an era in which letters are increasingly computer generated. Whether these letters are more effective in transferring information is yet to be determined, but I would suggest that the best letters are a compromise. If they are too short, they will be easily read, but they may omit relevant and necessary detail. If they are needlessly long, they risk losing the attention of the reader and remaining unread. Your letter should be relevant to the recipient. I remain astonished by some letters in clinical practice, written by highly intelligent clinicians,

which seem not to recognise what the aim of the exercise is (it is communication, not intellectual gratification).

You must also remember that letters are crucially important medico-legal documents: you must ensure that what is typed is what you intended.

OBTAINING CONSENT

This is an area in which communication skills are sorely tested. How much information is required to enable a patient to give truly informed consent? For example, all surgery could lead to death, but is it necessary to include that in the discussion? As it stands, it is probably fair to say that today's practice will appear wrong within a short time. Even the test of 'How much would you like to know if it were you signing the consent form?' is probably an unreliable yardstick. The sensitive clinician will increasingly need to enter into the discussion with an open mind and good antennae, as well as (in UK practice) familiarity with the General Medical Council requirements in this field.³ (See also the RCOG Consent Advice documents referred to above.)

COUNSELLING

As obstetricians and gynaecologists, we become involved in counselling in several types of difficult circumstances (e.g. malignant disease, prenatal screening dilemmas, pre-conception counselling). As stated above, counselling is the application of the full range of communication skills in a specific area of professional expertise. There is no added magic in the process.

CONCLUSIONS

This is an area where common sense rules. Integrity and respect for others are 'all' that is required. Always ask yourself if you, or your closest relatives, would want to be communicated with in this manner. Most of the time it really is that simple.

Chapter 4 The law, medicine and women's rights

Sheila McLean

INTRODUCTION

It is probably true to say that the relationship between law and medicine in the past has sometimes been characterised by confrontation, even hostility. Increasingly, however, doctors are turning to the law themselves as a way of obtaining guidance as to what is and what is not permissible in their practice. Thus, rather than law being seen simply as a mechanism for judging allegations of negligence, it has taken on the role of standard setter, particularly in some areas of medicine, such as obstetrics and gynaecology.

This change has arisen largely as a consequence of medicine's capacities in managing pregnancy. The ability to monitor fetal development in particular has radically altered the way in which physicians perceive their role in respect of the pregnant woman, and has in some cases led to legal action. It has been said that, in the past, women told their doctors about their pregnancies, but now doctors tell women. The ability to visualise the fetus in the womb means that it becomes endowed, however subconsciously, with the characteristics of a child much earlier in pregnancy than would previously have been the case. The temptation therefore is to treat the fetus as a separate and unique patient. As Harrison says:

*The fetus has come a long way – from biblical 'seed' and mystical 'homunculus' to an individual with medical problems that can be diagnosed and treated. Although he cannot make an appointment and seldom even complains, this patient will at times need a physician.*¹

In some countries, this has led to a growing recognition of the alleged 'rights' of the fetus, which may on occasion conflict with the rights and interests of the pregnant woman. So common is this problem that it has been given a descriptive name of its own – maternal/fetal conflict – yet, as Hubbard says:

*It makes no sense, biologically or socially, to pit fetal and maternal 'rights' against one another. Indeed, legal 'rights' do not offer a proper framework for assessing the situation of a pregnant woman and her fetus. As long as they are connected, nothing can happen to one that does not affect the other.*²

However, one thing must be made clear at the outset. In law, the fetus has no rights, and therefore to talk about fetal rights is misleading. None the less, it is generally conceded that the embryo or fetus of the human species is worthy of some respect.³ To say this, however, is quite different from asserting that it is a rights holder and worthy of equal consideration with the pregnant woman.

Most women will have no difficulty in behaving throughout their pregnancy in ways that maximise the potential health and safe delivery of their child. But not all women feel this way, or act this way, and this may be for reasons that appear to third parties unintelligible – even downright offensive or callous. However, the fact that women are free, autonomous actors means that their decisions – however unpalatable – must be given respect. This is not always easy for clinicians to accept, particularly when the woman's behaviour threatens the survival of an otherwise viable fetus. Indeed, a number of cases have reached courts in which doctors have asked that the choices of women should be overturned in the interests of fetal survival, as well as, sometimes, in the interests of saving the woman's life.

However, the basic legal position is clear. If a woman is otherwise legally competent, then her wishes must be respected, even if the result is her death or the death of an otherwise viable fetus. No matter how harsh this sounds, it is the law, and there are good reasons for the law to adopt this position. While recognising that this may be problematic for those caring for the pregnant woman, the fact of pregnancy does not reduce the rights of women to make autonomous, self-regarding decisions. The interests of the embryo or fetus are not completely ignored by the law, however. The general principle underpinning the law is to offer benefit to the embryo or fetus wherever possible (without, for example, breaching the rights of others). Once born alive, children are entitled to sue for damage they sustained prenatally (even pre-conception). This is based on the assumption that where a benefit should accrue, it is for the law to ensure that it does. But this is not to say that the law recognises the fetus as a rights holder before birth. Rather, it accepts that the injury arises at the moment the fetus becomes a child, and therefore is entitled to have rights attributed to it.

A BRIEF ANALYSIS OF CASE LAW

It is in the grey areas that problems have arisen, and an analysis of some of the leading cases will help to explore both the content of and the rationale for the law's attitude. Although the law is clear that the fetus has no rights, this does not mean that women's autonomous decisions about the management of their pregnancy and labour have always been respected. The first case to arise in the UK was that of *Re S*.⁴ In 1992. In this case, a woman refused a caesarean section on religious grounds. Her doctors believed that both her life and the life of her fetus were at risk and sought court authority to proceed with the caesarean section, even in the face of her objections. A judge heard the case as a matter of urgency (the hearing took about 20 minutes) and authorised the carrying out of the operation.

Perhaps unsurprisingly, this judgment was widely criticised for a number of reasons. First, the speed of the hearing was felt to prevent the nuances of the case being properly considered. Sir Stephen Brown's judgment, which is extremely brief, merely comments that:

*The consultant is emphatic. He says it is absolutely the case that the baby cannot be born alive if a caesarean operation is not carried out. He has described the medical condition. I am not going to go into it in detail because of the pressure of time.*⁵

Second, it is most unusual to interfere with people's religious commitments in this way and, given the passing of the Human Rights Act 1998, it is fairly certain that this judgment would not be compatible with the terms of the Act. Article 9 of the European Convention on Human Rights requires states to permit freedom of thought, conscience and religion, with the implication that this also includes the freedom to act on religious commitments. Manifestly, this right would be limited if, for example, X's freedom of religion threatened the life of Y. However, since the fetus – even at full term – is not a person for legal purposes, then this is not directly relevant. Equally, it is possible that Article 8 of the Convention – the right to respect for private and family life – could be called into play in such situations. This article of the Convention is generally described as being the one that most clearly supports autonomy.

Third, the woman was at no time represented at the hearing, which would also fall foul of Article 6 of the Convention on Human Rights: the right to a fair hearing. Finally, proceeding to surgery against the expressed wishes of a competent woman effectively means that she was the victim of an assault on her person (again in breach of the Convention, Article 5 – the right to liberty and security of the person) in the interests, in large part, of saving her fetus. Of course, the court was also concerned with the danger to the life of the woman, but, as courts have said on numerous occasions, a person is free to decline even life-saving treatment, no matter the reason for that choice, as long as they are competent.⁶

Subsequent cases, such as *St George's Healthcare NHS Trust v S*, *R v Collins and others, ex parte S*,⁷ showed the lengths to which doctors and the law were prepared to go in forcing women to accept medical treatment deemed to be essential to save the fetus. S was diagnosed as suffering from severe pre-eclampsia, and was advised that an early delivery would be needed. She understood that both she and the fetus might die if surgery was not undertaken, but none the less refused it. On 26 April 1997 an order had been made which dispensed with her consent to the treatment. She had also been made subject to an order under the Mental Health Act 1983 to be admitted for 'assessment'. No treatment for her alleged depression was offered. S continued to record her extreme objections to the caesarean section. During her time in hospital, '... it was still believed by the psychiatrist who had played a significant part in the decision to admit her to hospital under s 2 that her capacity to consent was intact'.⁸ It has already been indicated that a competent adult is free to refuse consent to life-saving treatment. As Lord Mustill said in the case of *Airedale NHS Trust v Bland*:⁹

*If the patient is capable of making a decision on whether to permit treatment and decides not to permit it his choice must be obeyed, even if on any objective view it is contrary to his best interests. A doctor has no right to proceed in the face of objection, even if it is plain to all, including the patient, that adverse consequences and even death will or may ensue.*¹⁰

Given that the psychiatrist was willing to state that her competence was not in issue, the decision of the lower court to authorise the section flies in the face of the general rule of law, and was ultimately criticised by the Court of Appeal. However, one earlier case had suggested that the only situation in which the law might be different was where '... the choice may lead to the death of a viable fetus',¹¹ although the jurisprudential basis for this exception is unclear. As the court in *St George's NHS Trust v S* noted, it is not sufficient simply to ignore the interests of the fetus. But as was also said, in this case there was no conflict between the interests of the mother and the fetus, because '... the procedures to be adopted to preserve the mother and her unborn child did not involve a preference for one rather than the other'.¹²

In addition, the court hazarded a look into the future, noting that it may soon be the case that relatively minor medical intervention on an adult might save the life of an unborn fetus. In contemplating a refusal of consent in such a case, the court said:

*The refusal would rightly be described as unreasonable, the benefit to another human life would be beyond value, and the motives of the doctor admirable. If, however, the adult were compelled to agree, or rendered helpless to resist, the principle of autonomy would be extinguished.*¹³

Finally, in the context of obstetrical intervention, it is worth restating the words of Butler-Sloss LJ in the case of *Re MB*.¹⁴

In this case she made an obiter explanation of the law as it currently stands:

*The fetus up to the moment of birth does not have any separate interests capable of being taken into account when a court has to consider an application for a declaration in respect of a caesarean section operation. The law does not have the jurisdiction to declare that such medical intervention is lawful to protect the interests of the unborn child even at the point of birth.*¹⁵

Thus, even if we disapprove of the decisions of a pregnant woman, it is essential to ensure that her autonomy is respected where she is legally competent. Legal competence (or its absence) is now statutorily defined by the Adults with Incapacity (Scotland) Act 2000 and the Mental Capacity Act 2005. The issue of competence is, of course, central to the management of any disputes that arise between pregnant women and those caring for them. The Royal College of Obstetricians and Gynaecologists' Ethics Committee (<https://www.rcog.org.uk>) advises healthcare professionals as follows:

If the patient's capacity is seriously in doubt, it should be assessed as a matter of priority by a medical practitioner experienced in such assessments (such as a consultant psychiatrist). If, following assessment, there remains a serious doubt about the patient's competence, legal advice should be sought.

One more recent case, widely reported in the media, further considers the question of the medical treatment of a non-competent pregnant woman. In August 2012, the Court of Protection considered the case of *Re AA*.¹⁶ In this case, the woman, who was 39 weeks' pregnant, had been compulsorily detained under the Mental Health Act 1983. She reportedly suffered from psychotic episodes and delusional beliefs. Mr Justice Mostyn also held that she was lacking in legal capacity in terms of the Mental Capacity Act 2005. Following the judgment in *Re MB*, he authorised a caesarean section to proceed, a procedure that he believed to be in the interests of the woman herself, and of the fetus. Psychiatric evidence as to her mental health was clear and evidence from the obstetrician indicated that, should she proceed with a natural birth, there was a significant (perhaps as high as 1%) risk of a ruptured womb. Mr Justice Mostyn was constrained to reach a decision that was in her best interests which, in his view, was that the section should go ahead even though she lacked capacity to consent to it. Interestingly, in light of what has already been said, he was at pains to make it clear that – although the section would probably also be in the interests of the fetus – it was the best interests of the woman over which he had jurisdiction.

It would seem, therefore, taking each of these cases into account, that the law is now clear that a competent refusal by a pregnant woman of treatment designed to save the life or preserve the health of her fetus (and/or herself) must be respected. This conclusion doubtless will sit uncomfortably with those whose mission is to save life, particularly given the tendency to

view the fetus as a separate entity from the woman. However, there are, as I have suggested, good reasons for the law to adopt this position, which – it should be noted – does not prevent those caring for pregnant women from using persuasion (not coercion) in advising women as to the clinically optimal path.

The principle of autonomy permeates our law and our ethics. It is a principle that can be freely exercised as part of our citizenship, subject only to the caveat that it may be restricted when its exercise threatens others. But as courts agreed in the case of *Paton v Trustees of BPAS*¹⁷ – a case in which a man attempted to prevent his wife from terminating a pregnancy – and in *Re F (in utero)*¹⁸ – a case in which an attempt was made to make a fetus a ward of court – the fetus does not have independent legal standing, and its interests cannot serve to outweigh the right of a woman to make autonomous decisions. This conclusion was further reinforced in the case of *Vo v France*.¹⁹ In the case of *Re F*, Balcombe LJ made it clear that it was not for the courts to make decisions that would fly in the face of this conclusion. As he said:

*If the law is to be extended in this manner, so as to impose control over the mother of an unborn child, where such control may be necessary for the benefit of that child, then under our system of parliamentary democracy it is for Parliament to decide whether such controls can be imposed and, if so, subject to what limitations or conditions.*²⁰

That Parliament has declined to do this is a reflection of the interest which we all have in protecting autonomy, even when to do so is emotionally difficult. Just as it is not for judges to change the law, neither is it for doctors to do so.

But it is not just the protection of the abstract concept of autonomy that mandates the current legal response. In jurisdictions beyond those of the United Kingdom, decisions – often generated by doctors and handed down by courts – have served to demonstrate clearly the dangers of attributing rights to fetuses either during pregnancy or at the point of delivery. Medical recognition of the potential harm that can be caused by pregnant women to developing embryos and fetuses in the course of the pregnancy has in some countries resulted in the aggressive 'policing' of pregnancy – an egregious invasion of liberty. All too often, it appears that fetal interests have relatively easily been taken to trump women's rights. In the USA, for example, Kolder *et al.*²¹ found that, of 21 applications for court orders by public hospitals, 86 per cent were successful. Interestingly – and arguably ominously – 81 per cent of the women affected were black, Hispanic or Asian, and 24 per cent did not have English as a first language. In addition, 46 per cent of heads of maternal medicine thought that women should be detained when they refused to follow medical advice and thereby endangered their fetuses.

In addition, as Sherman notes:

*Pregnant drug abusers have been jailed to keep them free of illegal substances that might harm fetuses. And laws have been expanded so that pregnant women who do ingest drugs harmful to the fetus can be charged with or investigated for child abuse.*²²

Whilst removing the availability of illicit substances might ultimately serve the long-term interests of the women (as well as benefiting the fetus), women in the USA have also been incarcerated because of their use of legal substances, such as alcohol. Moreover, those women addicted to illicit drugs are sometimes unable to gain access to programmes that might assist them in beating their addiction; locking them up or otherwise coercing them in the interests of their embryos/fetuses seems like a heavy-handed way of avoiding the need to address the fundamental problem head on.

In other cases, medical opinion that a natural delivery was too risky has been used to mandate coercion, but of course medical judgements can be wrong. In *Jefferson v Griffin Spaulding County Hosp. Auth.*,²³ for example, a court upheld an order for a forced caesarean section, although in fact the woman delivered naturally. Yet, at the time the order was sought, doctors had claimed that vaginal delivery carried a 99 per cent chance of fetal death and a 50 per cent chance of maternal death.

The consequences of coercion are perhaps most poignantly demonstrated by the US case of *In re AC*.²⁴ It was in fact on this case that the UK judge in *Re S*²⁵ depended for his authorisation of the forced intervention. Interestingly, he appeared to have failed to observe that *AC* had already been overturned on appeal.²⁶

The facts of the case make tragic reading. Angela Carder was a young woman who had suffered from leukaemia as a child. Her condition had gone into remission; she married and became pregnant, but in the course of the pregnancy the leukaemia returned aggressively. It was clear that Angela Carder would die. At about 26½ weeks into the pregnancy, her doctors summoned a judge to the hospital and sought authority to carry out a caesarean section on Mrs Carder, despite her clear refusal to consent. When the case was first heard, the order was granted and the operation proceeded in the face of Mrs Carder's objections. Neither she nor the child survived, and indeed the section was listed as a contributing cause of death on the death certificate. In a trenchant criticism of this judgment, the distinguished American academic George Annas described what had happened as follows:

*They [the judges] treated a live woman as though she were already dead, forced her to undergo an abortion and then justified their brutal and unprincipled opinion on the basis that she was almost dead and her fetus's interests in life outweighed any interest that she might have in her own life and health.*²⁷

Why not intervene?

Despite the temptations to manage pregnancy and childbirth with substantial, if not primary, concern for the welfare of the developing embryo or fetus, it should be clear from consideration of these cases that unthinkingly adopting such a position is potentially dangerous. In respect of intervening in lifestyle choices during pregnancy, it seems clear that the women in the

cases discussed were treated differently from other competent adults solely on the basis of their biological capacities. The fact that we generally wish to protect the fetus does not give us a right to do so at the expense of the woman. Equally, since many of the harms likely to be caused will occur in the early stages of pregnancy – when the woman may not even know that she is pregnant – the logical conclusion of this would be that every fertile, sexually active woman would need to behave at all times as if she were pregnant, or run the risk of being accused of harming her fetus and perhaps even – in the USA at least – of being deprived of her liberty. Equally, as Draper says, 'it is one thing to show what a woman ought to do in relation to her unborn child and quite another thing to say that this obligation ought to be enforced'.²⁸

Although some authors have suggested that the way forward is through a 'careful balancing of the offspring's welfare and the pregnant woman's interest in liberty and bodily integrity ...',²⁹ such a balancing act is arguably at best inappropriate and at worst doomed to failure. The very act of 'balancing' automatically implies that there are relevant things to be balanced. It has already been agreed that the embryo or fetus of the human species is worthy of some respect, but this is not equivalent to saying that such respect is capable of being weighed in the scales against an existing person. Even in cases where a born person's life is threatened by the failure of another to undergo medical treatment in their aid, the law is unable to compel submission to treatment. This was clearly seen in one US case. In this case, the defendant refused to consent to a treatment that could have saved the life of the plaintiff. As the judge in that case said:

*Morally, this decision rests with the defendant, and in the view of the court, the refusal of the defendant is morally indefensible. For our law to compel the defendant to submit to an intrusion of his body would change every concept and principle upon which our society is founded. To do so would defeat the sanctity of the individual ...*³⁰

MATERNAL/FETAL CONFLICT

As has been said, the circumstances described above have come to be called maternal/fetal conflict. I have argued elsewhere³¹ that this categorisation is inherently flawed, not least because it describes the pregnant woman as a 'mother' (which she is not yet) and assumes that conflict is possible. Arguably, conflict implies hostility and yet it is not obvious that a fetus can be hostile to the pregnant woman, nor that the pregnant woman's decisions are taken out of hostility for the fetus. None the less, this term has now become an accepted part of the language. Leaving aside these concerns, then, it is worth briefly analysing the implications of this purported conflict which is highly emotive because, as Lew says:

Conflicts between a woman's needs and those of her fetus are vexing because they pit powerful cultural norms against one another; the ideal of autonomy and the ideal

*of maternal self-sacrifice. Parents who make sacrifices for their children should be encouraged, even lauded, but the law should not require such sacrifices. Self-sacrifice is a gift. Forcing a pregnant woman to sacrifice her health for her fetus is simply slavery.*³²

Neither can it be presumed that it is always possible to measure the risk taken by the woman versus the risk to the fetus of non-intervention. A caesarean section carries risk (albeit that risk is lower given today's standards of medical treatment), but even if the risk is minimal, and the potential benefits to the fetus are considerable, we still do insult to the fundamental principles of law and ethics by compelling women to rescue their fetuses. No such ethical or legal principle is widely recognised and, as has been said, 'Even where there is a duty to rescue, the law never requires rescues which jeopardise life and limb'.³³

CONCLUSION

The developing capacities of modern medicine have served both to enhance the care of pregnant women and to confront women and those caring for them with new dilemmas. During pregnancy, the widespread use of prenatal screening makes the actualisation of reproductive choice both more complex and more intangible. At the point of labour and birth, the clinical ability to rescue poses real tensions in cases where competent women wish to assert their own autonomy at the potential expense of both themselves and their fetuses. The consequences, as Gregg has said, are that:

*Women's bodies increasingly have become medicalised as fertility testing, techniques of 'assisted conception', prenatal diagnosis, fetal monitoring, induced labour and caesarean sections have become normal, if not expected, interventions in women's procreative processes. Procreative technologies can enhance both the range of choices for women and the possibility of greater social control of women's choices.*³⁴

It is clear that, often encouraged by healthcare professionals, courts in particular have become increasingly intrusive into women's decision-making in the course of their pregnancy and at the point of birth. Medicine and the law make powerful allies in this venture, yet their collusion is a direct disavowal of the rights that we otherwise respect. The position in the UK now seems to have been clarified after a decade of highly dubious decisions, at least as far as forced caesarean sections are concerned, and the current legal position is endorsed by the Ethics Committee of the RCOG. It is to be hoped that, where the woman and physician share a relationship based on trust and the free exchange of relevant information, problematic cases will arise infrequently and, in the UK at least, this has proved to be the case. However, the impetus that triggered the call for courts to intervene in these decisions has not disappeared. The motivation of those caring for pregnant women is all too intelligible. However, no matter its source – religion,

professionalism or whatever – it does violence to other principles that have long been deemed essential to the proper functioning of society. All too often, the motivation for intervention is worthy, but it is no less a matter of concern for that. As Ikenotos has said:

*To the extent that the state invokes the parens patriae power to prevent harm to the fetus, the state subordinates the interests of the woman to those of the fetus. To the extent that the state regulates pregnant women to promote public health, safety, and morals – an exercise of the police power – it subordinates the interests of the woman to those of the rest of society. In either case, when the state regulates women as childbearers, it legislates the ideology of motherhood.*³⁵

It is not necessary to adopt a particular woman-centred philosophy, such as feminism, to understand the damage done to respect for persons by treating pregnant women without regard for their views. To be sure, the commitment to respecting autonomy does not prevent healthcare professionals from making an attempt to inform women as to the risks they run both for themselves and for their fetuses if certain decisions are made, and to persuade them to think again. However, attempts to enforce the 'right' decision (clinically at least) by resort to the law mark a departure, which should be resisted, from the traditional relationship between doctor and patient. Such a relationship is ideally based on trust, not coercion, on respect, not condemnation. The ability to visualise and assess the development of an embryo or fetus, and to visualise and monitor in the womb, while often immensely helpful to pregnant women, is a technical, not an ethical, issue, and provides insufficient justification to invade the rights of a live, competent individual, however painful that conclusion may be.

KEY POINTS

- The law is no longer simply a mechanism for judging allegations of negligence, but has taken on the role of standard setter.
- Modern fetal imaging technology has increased the temptation to treat the fetus as a separate patient with unique 'rights'.
- Although the human fetus is worthy of respect, it does not, in law, have rights.
- Occasionally, a woman's decision or behaviour may threaten the survival of an otherwise viable fetus. The law says that if the woman is otherwise legally competent, her wishes must be respected.
- Children are entitled to sue for damage that they sustained prenatally, but this is still not the same as saying that the fetus has rights before birth.
- There have been cases of legally enforced obstetric intervention in the UK but the law has now been made clear: a competent refusal by a pregnant woman of treatment

designed to save the life of her fetus (and/or herself) must be respected.

- In the USA, ominously, court-ordered treatment has mainly involved disadvantaged ethnic groups or women who did not have English as their first language.
- Pregnant women should not be treated differently from other competent adults.
- The concept of 'maternal/fetal conflict', in a legal context, is inherently flawed and is best avoided.
- The law and medicine make powerful allies. Attempts by the law to enforce the 'right' clinical decision are a departure from basic legal principles and should be resisted.

Chapter 5 Clinical risk

Sam Pretlove

INTRODUCTION

The vast majority of doctors subscribe to the basic principle of medicine, ‘to do no harm’, and very few clinicians ever want their patients to come to any harm. In contrast to this, however, when clinical risk and patient safety are discussed, clinicians can be suspicious, regarding the necessary processes as either meaningless tick-box exercises or something imposed by the financial or management team to reduce cost, rather than viewing clinical risk management as an opportunity to shape and improve healthcare and the systems around us. Rather than being a topic for a few medical managers, being able to understand and evaluate clinical risk enables us to give women and their babies the highest possible standard of care. The NHS Constitution¹ enshrines the principles that guide the NHS in all it does. Principle 3 states that ‘the NHS aspires to the highest standards of excellence and professionalism’ and principle 4 that ‘the NHS aspires to put patients at the heart of everything it does’. These principles cannot be put into practice without understanding the risks in clinical practice and the steps that are required to make the minimisation of risks a reality. When whole hospitals (and other organisations) become aware of this, it changes the culture so everyone understands and practises in a way that maximises patient safety.

The specialty of obstetrics and gynaecology is well known for high levels of litigation.² Therefore having a good understanding of clinical risk is particularly important for obstetricians and gynaecologists, and is not separate from clinical work. For example, health professionals working in a large tertiary referral maternity unit may consider that, as they are dealing with a complicated case mix of women, postpartum haemorrhages are an inevitable complication of childbirth.³ Obstetrics has particular challenges, as levels of risk can change very quickly. For example, a low-risk multiparous woman who has an abruption at 37 weeks’ gestation immediately changes to a high-risk delivery.

This chapter aims to cover the basic principles of risk management and patient safety and to discuss how they relate to clinical governance and the NHS complaints procedure.

HISTORY OF RISK MANAGEMENT

The Confidential Enquiry into Maternal Deaths (CEMD) is the classic example of risk management where a multidisciplinary team of obstetricians, midwives and anaesthetists formed an independent group to determine the causes of the rare event of maternal death and then disseminated the findings. Although the CEMD started in 1952, risk management as we know it has gradually evolved from a combination of audit, large-scale incidents and insights from industry applied to healthcare from the 1990s onwards. One of the most helpful ways to understand risk management is to look at key documents and events that changed how clinical risk was approached. Some of these occurred in the NHS whilst other initiatives were transferred from lessons learnt in industry.

The North Sea Piper Alpha disaster

On 6 July 1988 Piper Alpha, an offshore oil platform, exploded, killing 167 men. Piper Alpha was located 120 miles north of Aberdeen, off the coast of Scotland. A routine safety valve check for Pump A took place but the crew were unable to complete this in the usual time frame. The crew sealed off the pipe, with permission, with a plan to complete the work the next day. The permission paperwork was stored near the pipe, as was the usual practice. Later that evening, Pump B failed and the team on duty checked the central log to confirm Pump A could be started. There was no central record of a problem with Pump A and so it was switched on. Without the safety valve working correctly, the pump could not cope with the pressure generated and gas came out of the pump and ignited. A series of events due to the design of the platform meant that gas continued to pour into the fire for 22 minutes after the initial explosion.

The Piper Alpha disaster was the largest man-made disaster at the time, with damages costing US\$3.4 billion. The loss of life was so high that it ensured the practices on the platform were investigated and the disaster was not passed

off as a 'freak accident'. The Cullen enquiry took place in 1990 and made 106 recommendations regarding practice in the offshore oil industry. Many of the lessons learned have been transferable to other industries and organisations. These included: the design of the platform, expansion to cope with a larger amount of gas than was originally intended, communication and handover practices, inadequate training of staff in safety procedures, minimal response to inspection findings and overlooking small safety issues to maintain productivity.

Bristol heart scandal

In the 1990s an anaesthetist recognised that an excessive number of children were dying during open heart surgery at Bristol Royal Infirmary. The 'switch' operation for transposition of the great arteries (where both great arteries are disconnected, switched round and re-plumbed in) was stopped in 1995 after 9 of 13 babies who had the operation before 1993 had died in the previous 18 months. The Kennedy report in 2002 identified many concerns about the care in Bristol. The report identified poor teamwork, with the cardiologists and the cardiac surgeons based on different sites. There were difficulties inherent in the building, with the operating theatre and intensive care on different floors. In addition, the lift between the two departments was available for general use at all times. Although the mortality data had been collected and discussed, clinicians were reluctant to draw adverse conclusions from it, and speaking out about how the department was run was not encouraged or accepted.

'Bristol' is important as it changed attitudes to clinical governance and how incidents should be reported in a no-blame culture. It changed how organisations respond to concerns raised about services and whistleblowing. Risk management as we know it today started to be implemented in the 1990s, as incident reporting became established in hospitals and clinical governance was introduced as a statutory duty for NHS chief executives.

The document, 'An organisation with a memory' (OWAM)², published in 2000, was the report of an expert group, chaired by the Chief Medical Officer, on learning from adverse events in the NHS. This released the figures for known reported harm in the NHS. Key concepts brought out by the report were the similarities seen between many of the adverse events and 'learning the lessons of experience'. It became clear that if an adverse incident causing patient harm occurred in Hospital A there was no systematic mechanism to make Hospital B aware of any issues surrounding the incident. In practice this meant that, until the same adverse incident occurred in Hospital B, the system in Hospital B would not be changed, despite some staff in the NHS having the knowledge to prevent the adverse event occurring. The report called for systematic incident reporting and active implementation of lessons learned in organisations.

WHAT IS RISK MANAGEMENT?

Risk management has been defined by the RCOG as follows: 'Methods for early identification of adverse events, using either staff reports or systematic screening of records. This should be followed by creation of a database to identify common patterns and develop a system of accountability to prevent future incidents.'⁴ Risks are reduced by a process which includes risk identification, compiling a risk register, risk analysis and risk control.

Risk identification

Risks are identified by either internal or external sources. Internal sources reflect information gathered from events and situations in the organisation. External sources are risks that have often been identified nationally.

Systematic risk assessments should occur both in clinical areas (e.g. delivery suite, gynaecology theatres, gynaecology wards and outpatient departments) and in non-clinical areas (e.g. secretarial offices and canteen) to ensure areas are as safe as possible with minimal hazards. Staff should be encouraged to complete incident forms for specific triggers. A possible list of triggers is given in Table 5.1. An organisation needs to have a culture where the staff are able to report incidents and know they will be listened to, not blamed for the incident. Patient complaints and legal claims also provide insights into where problems may exist in systems in the hospital. Clinical audit can be a powerful tool for providing evidence of a clinical risk.

Patient safety indicators are inexpensive and readily available data-sets, such as return-to-theatre rates or number of cases of *Clostridium difficile* identified. Patient safety indicators can raise awareness in organisations of specific problems and how often they occur, without using large amounts of resources. Patient safety indicators do not distinguish between a true adverse event and medical error but can provide evidence of trends within an organisation.

Some risks are present in most hospitals, such as hospital-acquired infections, medication errors, thromboembolic disease and retained swabs. Other risks are specific to obstetrics and gynaecology and a suggested list of identified risks from the RCOG is shown in Tables 5.1 and 5.2⁴.

External sources that can demonstrate risk include the RCOG guidelines. For example, the guideline on small-for-gestational-age (SGA) explains how often women with risk factors or proven SGA should be scanned.⁵ This requires a significant resource involving sonographers, ultrasound machines and physical space. If the guideline cannot be implemented immediately, there is a risk of undetected SGA and the potential for an avoidable stillbirth to occur. NICE guidelines may also suggest changes to clinical care which require increased staff and resources. National confidential enquiries may highlight risks experienced in other organisations which need to be addressed. Alerts from the National

Table 5.1 Suggested trigger list for incident reporting in maternity

Maternal incident	Fetal/neonatal incident	Organisational incident
Maternal death	Stillbirth >500 g	Unavailability of health record
Undiagnosed breech	Neonatal death	Delay in responding to call for assistance
Shoulder dystocia	Apgar score <7 at 5 minutes	Unplanned home birth
Blood loss >1500 mL	Birth trauma	Faulty equipment
Return to theatre	Fetal laceration at caesarean section	Conflict over case management
Eclampsia	Cord pH <7.05 arterial or 7.01 venous	Potential service user complaint
Hysterectomy/laparotomy	Neonatal seizures	Medication error
Anaesthetic complications	Term baby admitted to the neonatal unit	Retained swab or instrument
Intensive care admission	Undiagnosed fetal anomaly	Hospital-acquired infection
Venous thromboembolism	European congenital anomalies and twins (Eurocat)	Violation of local protocol
Pulmonary embolism		
Third/fourth degree tears		
Unsuccessful Ventouse/forceps		
Uterine rupture		
Readmission of mother		

Table 5.2 Suggested trigger list for incident reporting in gynaecology

Clinical incident	Organisation incident
Damage to structures, e.g. bowel, bladder, vessel	Delay following call for assistance
Delayed or missed diagnosis, e.g. ectopic pregnancy	Faulty equipment
Anaesthetic complications	Conflict over case management
Venous thromboembolism	Potential service user complaint
Failed procedures, e.g. sterilisation, termination of pregnancy	Medication error
Unplanned intensive care admission	Retained swab or instrument
Omission of planned procedures (failure to insert intrauterine device after hysteroscopy)	Violation of local protocol
Unexpected blood loss >500mL	
Moderate/severe ovarian hyperstimulation (assisted conception)	
Procedure performed without consent (e.g. removal of ovaries at hysterectomy)	
Unplanned return to theatre	
Unplanned return to hospital within 30 days	

Patient Safety Agency (NPSA) can also identify areas where steps need to be taken to change practice. Information on risks can also be obtained from external visits such as those by the postgraduate dean or the Care Quality Commission (CQC). NHS England also describes ‘never events’ which are defined as ‘serious, largely preventable patient safety incidents that should not occur if the available preventative measures have been implemented’. These include incidents such as: wrong site surgery, retained instrument post-operation and wrong route administration of chemotherapy.⁶

Risk register

Once the risks have been identified, the next step is to quantify the level of risk. This is most commonly done using risk registers.

Divisions and departments identify their own risks, which are then graded with the standard matrix demonstrated in Table 5.3. Risk registers are not restricted to clinical issues. Problems with buildings, such as breakdown of the heating system on delivery suite causing issues with cold babies, or staffing shortages, can also be entered into the risk register.

Risks are scored between zero and five in two ways. First, how serious the risk is, from negligible to an event that results in multiple fatalities. The second score reflects how likely the event is to occur, from impossible to certain. The two scores are then multiplied together to give the risk score so the risks can be ordered and placed in a risk register.⁷

The most serious risks are collated and entered into the trust risk register where they should be reviewed regularly.

Table 5.3 Method for producing a risk matrix

Consequences	Probability					
	Impossible 0	Rare 1	Unlikely 2	Moderate 3	Likely 4	Certain 5
Negligible - 0	0	0	0	0	0	0
Minor - 1	0	1	2	3	4	5
Serious - 2	0	2	4	6	8	10
Major - 3	0	3	6	9	12	15
Fatality - 4	0	4	8	12	16	20
Multiple Fatalities - 5	0	5	10	15	20	25

Discussions should focus on how reduction could be achieved in either the severity of the risk or the frequency of it occurring. The impact of a risk register depends on how often and how effectively the risks are reviewed and whether subsequently situations are changed to reduce the risk. Having a risk register that is not reviewed or discussed will not reduce the risks in an organisation.

Risk analysis

Risk analysis involves identifying what went wrong after an incident has occurred. The incident should be investigated using Reason’s organisational accident model (Fig. 5.1).⁸ This places importance on the latent failures in a system and the pre-existing working conditions rather than just the active mistakes made at the time of the incident. Instead of asking ‘What went wrong?’, a better question is ‘Why didn’t the barriers put in place to stop errors work?’. This is important in preventing the same incidents happening again and again.

This model has been adapted by the NPSA to use as the ‘fishbone’ for root cause analyses (Fig. 5.2).

Below is a fictitious example of a scenario that could be examined in a root cause analysis. Although this is not a real incident, it is based on events that can happen in maternity units:

A woman who is 37 weeks’ pregnant with twins in her first pregnancy is admitted in labour at midnight with her cervix 4 cm dilated. Eight midwives were recorded on the rota to be on shift but three are sick. She is allocated a junior midwife who starts the cardiotocograph (CTG) but is unhappy with the trace of twin 2. She asks for the midwifery shift leader to review the CTG but the shift leader is looking after a woman who has pre-eclampsia and a previous caesarean section, and who is fully dilated and pushing. The shift leader advises calling the doctor as she cannot leave her woman. The junior midwife calls the doctor, an ST1 (specialist trainee year 1) who started his first Obs and Gynae job the week before. The doctor is unsure what to do and asks for the registrar to look at the CTG. The registrar is busy in theatre with a laparoscopic ectopic but says she will be finished soon. The junior midwife and the ST1 wait for the registrar to attend. When the registrar comes an hour later, she takes the woman to

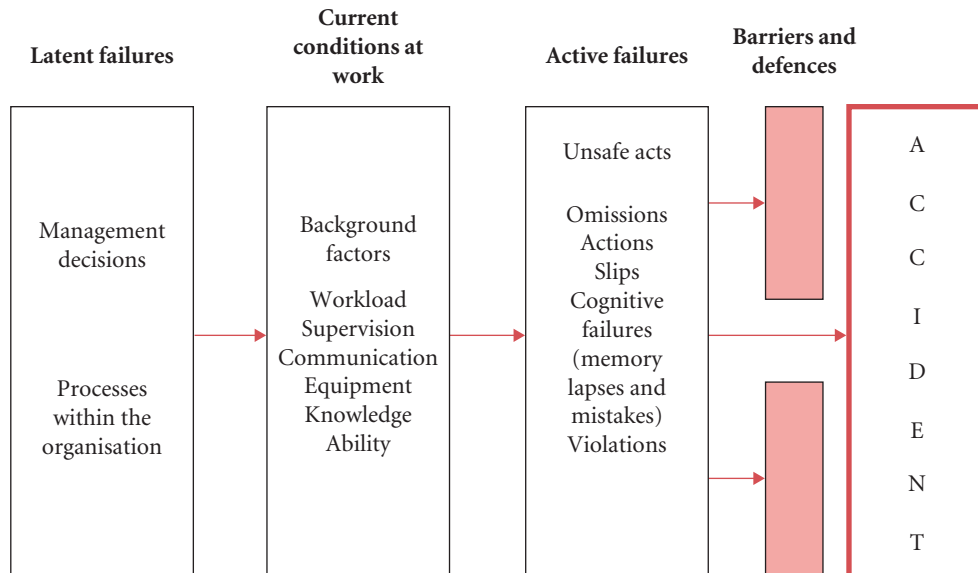

Fig. 5.1 Reason’s organisational accident model

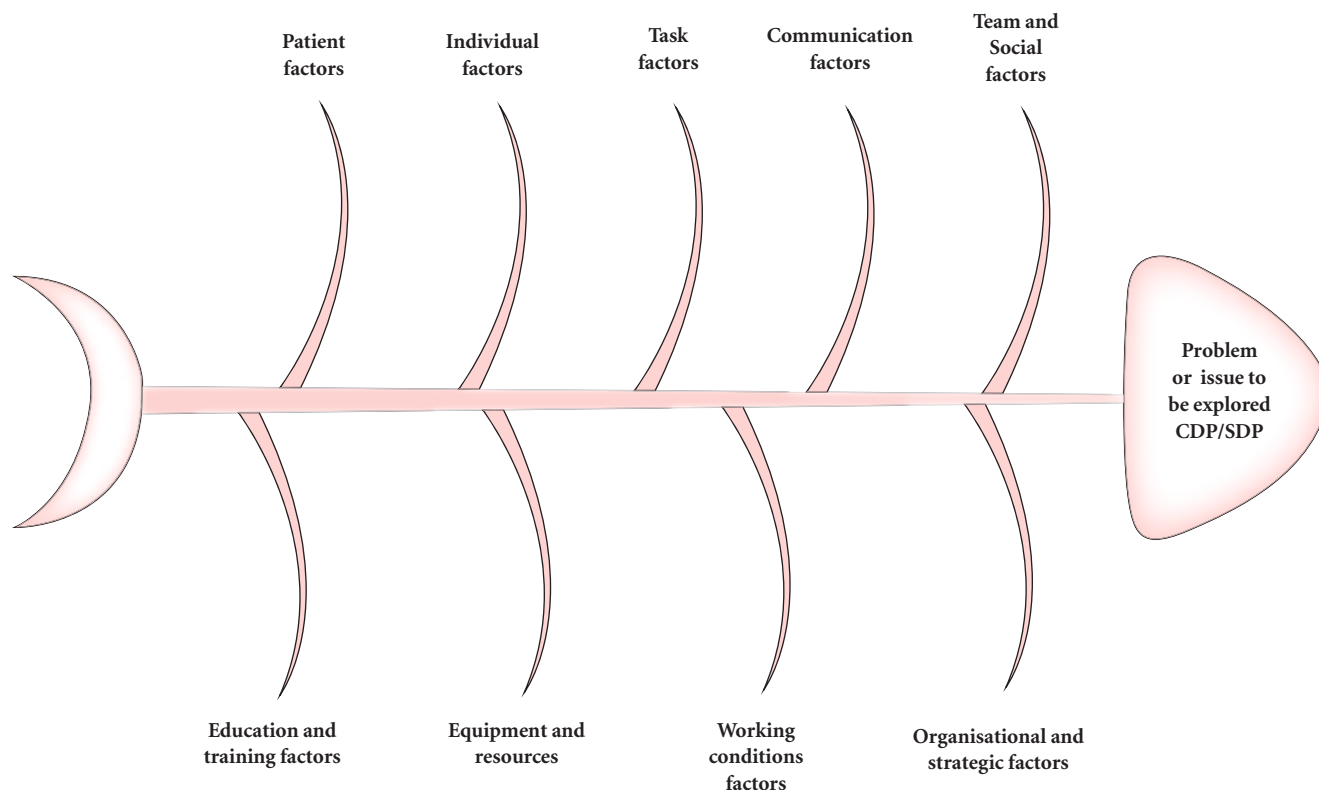

Fig. 5.2 The NPSA fishbone

theatre as a category 1 caesarean section and delivers the babies. Twin 2 suffers permanent hypoxic ischaemic brain damage.

The root cause analysis (RCA) is performed by staff who have undergone training in the process. Statements from those involved (the ST1, the registrar, the junior midwife and the shift leader) are collected and then the incident is presented. Instead of seeking to blame an individual for the events, the NPSA fishbone is used to systematically discuss where latent failures in the system occurred, the background to the incident and what, if any, part human error played. The staff are invited to attend and following the RCA are given individual feedback and support.

The incident is categorised according to whether or not sub-optimal care was provided and, if there was suboptimal care, whether this had an impact on the outcome for the patient.

In the RCA, the team find there are ongoing problems with the midwifery rota system and that two of the midwives off sick that night were on long-term sick leave and should not have been on the rota. They also found that the gynaecology department struggled to get slots in the emergency theatre for women who appeared well and so the majority of emergency gynaecology was being performed out of hours, leaving the delivery suite exposed.

Rather than blaming the staff who were working that night, the RCA helped demonstrate the events that led to the situation where a woman's care was compromised. The staff had the opportunity to debrief with their supervisors and reflect on the events that had taken place in a structured and supported way.

Root cause analyses can be difficult and stressful for staff. Giving feedback in a helpful and constructive way can be time-consuming but is vital. If staff do not receive appropriate feedback they may disengage from the risk analysis process, reducing the quality of information gained and potentially reducing the impact of change identified through RCAs.

Risk control

Measures should then be put in place to reduce the risks. This can be by avoiding the risk, by substitution of an alternative lower risk or by implementing change to reduce the likelihood of the incident happening again. Ideally, this should be part of a coordinated approach to risk management, rather than individuals making small changes in different parts of the organisation without considering the impact in other areas.

An important clinical example of risk reduction is the World Health Organization (WHO) surgical safety checklist,⁹ developed by Atul Gawande, an American endocrine surgeon:

Good checklists ... are precise. They are efficient, to the point, and easy to use even in the most difficult situations. They do not try to spell out everything – a checklist cannot fly a plane. Instead, they provide reminders of only the most critical and important steps – the ones that even the highly skilled professional using them

could miss. Good checklists are, above all, practical. Atul Gawande.¹¹

The checklist corresponds to the flow of work, with the sign-in check before anaesthesia is induced, the time-out check before the incision of the skin and the sign-out before the patient leaves the operating theatre. A large trial of its efficacy involved eight hospitals in eight different cities worldwide. This was not a randomised controlled trial but rather each site completed a baseline period followed by a second period where the checklist was introduced. Large numbers were recruited to the study ($n = 3733$ for the baseline period, and $n = 3955$ for second period). The trial demonstrated a significant reduction in death (from 1.5% to 0.8%, $P = 0.003$) during or after surgery. In addition the risk of any complication also dropped from 11.0% to 7.0%. Surgical site infection and unplanned return to theatre also dropped significantly. There was an increased adherence to appropriate antibiotic use from 56% to 83%.¹⁰

Inevitably there have been criticisms of the WHO surgical safety checklist, which have included concerns that it has less of an impact in high-income countries, that the success is dependent on the attitude of staff not the checklist itself, that implementation may result in unforeseen resource implications and that it can be difficult to administer in some settings (e.g. 'crash' caesarean section). Despite this the surgical checklist remains an important demonstration of how risk control can be effective clinically.

UNDERSTANDING THE COMPLAINTS PROCESS

Most complaints or issues can be resolved by talking directly to the complainant, acknowledging the situation and making a plan for the future. There are times when this does not resolve the complaint and a formal written complaint is made. Every NHS organisation has a complaints policy and process. Complaints can be made directly to the service provider but can also go to the Clinical Commissioning Group (CCG) or NHS England. If a complaint is made to a service provider and investigated, the same complaint cannot be taken to the CCG or NHS England. Usually complaints need to be made within 12 months of the incident to be valid.

If the matter cannot be resolved with the service provider, the complainant can refer to the Parliamentary and Health Service Ombudsman. Organisations are then obliged to put in place recommendations from the Ombudsman.

Complaints (and compliments) are an important source of patient feedback. Themes and recurring problems should be identified so that, where appropriate, changes can be made to the service provision to improve care. Complaints should be regularly audited to ensure that issues such as equality are considered. It could be presumed that not receiving complaints from some groups of the population means that they are happy with the service they receive. Alternatively, however,

this may mean that some groups are unable to represent their problems and difficulties with the service, and remain unhappy and disengaged.

SUMMARY

Delivering high-quality care is a fundamental challenge for obstetricians and gynaecologists as we work in a high-risk specialty often delivering complex care. Understanding how to identify risks and develop systems that prevent or significantly reduce adverse events can enable us to give women and their babies the safe, effective and high-quality care they deserve.

Chapter 6 Rationale for advanced skills training

Timothy Draycott and Islam Gamaleldin

MRCOG standard

Competence in the management of shoulder dystocia, eclampsia and obstetric collapse is essential for completion of core training.

INTRODUCTION

Maternity care could and should be safer.¹ Adverse outcomes in maternity care are frequently avoidable and the cost of litigation for maternity care is rising for many health services across the world.²⁻⁴ This is a tragedy for families for whom the injury was preventable, an enormous loss of resource to healthcare in general and possibly even a perverse incentive against best care.⁵

Poor care and avoidable harm are not confined to developing countries. In 2008, the UK-based King's Fund report, *Safe Births: Everybody's business*,¹ observed that, whilst the overwhelming majority of births in England are safe, some births are less safe than they could and should be. This observation may accurately describe obstetric care in the UK over the last century. There are similar problems with maternity care in France, Netherlands and the United States.⁴

Investigations of the root causes of maternal and perinatal mortality have consistently identified poor management of obstetric emergencies, including failure to recognise problems, failure to seek senior input, poor team working, poor communication and a need to improve these.⁶⁻⁸

Obstetric emergencies are rare, occurring rapidly and unpredictably. Their successful management requires a coordinated response by a multiprofessional team and although it is axiomatic that they should be managed by experienced staff – and indeed this is almost ubiquitously recommended – experience is difficult to acquire because of their rarity. This experience may be best gained in part through simulation.

This has led to repeated recommendations for obstetric emergency training, particularly simulation-based training, to prevent avoidable harm.

HARM AVOIDABLE WITH TRAINING

Poor team working, suboptimal communication and lack of effective training have been identified as possible contributors to preventable mortality and morbidity in maternity care.

Maternal mortality and morbidity

At least half of all maternal deaths are still considered avoidable. In the UK, the most recent Centre for Maternal and Child Enquiries (CMACE) report, *Saving Mothers' Lives*, published in 2011, identified substandard care in 70% of direct deaths and 55% of indirect deaths.⁹ Absent and poor team working were repeatedly identified as significant contributors to substandard care.¹⁰ Several other reports have demonstrated that accurate management of obstetric emergencies could have prevented significant maternal morbidities, including hysterectomy, multiple organ failure, shock, coma and admission to an intensive care unit.¹¹⁻¹⁴

Women's experience of labour and birth has significant implications for breastfeeding, bonding, expectations for future birth and sexual function.^{15,16} A unique challenge in obstetric emergencies is that mothers are most often awake with close relatives in attendance. A UK-based study demonstrated that over 25% of new mothers were not satisfied with communication by medical staff, which shows that training is needed to increase the overall satisfaction with care¹⁷ and to decrease the risk of litigation.

Systematic reviews have demonstrated that debriefing after the emergency may not be helpful to parents,^{18,19} and improved communication during the acute event is likely to be the most effective method of reducing the psychological morbidity. Therefore communication should be improved generally during the emergency, not just between other team members but also with the woman and her companions.

Perinatal mortality and morbidity

In 1917 the UK Medical Research Committee (MRC) reported that 52 per cent of infant deaths were avoidable, yet the 4th Confidential Enquiry into Stillbirth and Deaths in Infancy (CESDI) report, published 80 years later, in 1997, still identified that over 50% of intrapartum stillbirths were avoidable with better care.²⁰ Therefore although perinatal outcomes have improved significantly over the last century, the proportion of avoidable deaths has remained depressingly static.²⁰

Litigation and complaints

This avoidable harm is extraordinarily expensive and the expense is rising.^{2–4} Maternity claims represent the highest-value litigation claims reported to the NHS litigation authority (NHSLA). Substandard care and its sequelae cost the NHS £3.1 billion in the decade 2001–2010. Three (overlapping) categories accounted for 70% of the total value of claims: mistakes in fetal heart rate interpretation, mistakes in the management of labour and the development of cerebral palsy.⁴

Improved multiprofessional training appears to be one of the most promising strategies to improve perinatal outcomes across the world, localised for best fit, with a parallel evaluation of outcomes to ensure a positive effect.

SIMULATION TRAINING

The use of simulation in obstetrics is several centuries old. The earliest simulators were developed after 1600 and were known as ‘phantoms’. They were used to teach midwives how to manage complicated deliveries.²¹ This was followed by William Smellie, who developed a pelvis using human bones covered by leather, a fetus of wood and rubber, and a placenta also made of leather.²² As early as 1760 a French midwife, Madame du Coudray, recognised that poor training of midwives around France could directly cause harm, and that training on a life-sized and anatomically correct mannequin phantom called ‘The Machine’ could potentially reduce these harms.²³

More modern simulation models used for training in obstetrics range from very simple ones such as a bony pelvis with a baby, or trousers with red material to reproduce visual clues for postpartum haemorrhage,²⁴ through to complex, sophisticated simulators such as the SimMom, the NOELLE and the Practical Obstetric Multiprofessional Training (PROMPT) birth simulator. At one end of the spectrum, simple part-task trainers are less expensive and can be used alone to teach specific skills, for example instrumental deliveries or shoulder dystocia manoeuvres, or in combination with a simulated patient (hybrid simulation). At the other end of the

spectrum, computer-based virtual reality simulator models can provide both kinaesthetic and visual feedback to learners. Both have their place depending on the skills that need to be practised and on available resources.

Both simple and advanced simulation models can be used to teach obstetric skills within structured training programmes. Such structured simulation-based training courses in obstetric emergencies were developed and implemented in the 1990s. The ‘Advanced Life Support in Obstetrics’ (ALSO) course was introduced in 1991 in the United States,²⁵ followed by the ‘Managing Obstetric Emergencies and Trauma’ (MOET) course in 1998 to teach advanced skills to obstetricians and anaesthetists.²⁶ More recently, the PROMPT course was developed in the UK, as a training package for obstetricians, midwives and anaesthetists, allowing the implementation of local training in individual maternity units.²⁷

Since 2003, a nascent evidence base for intrapartum skills training has emerged and we shall review the current evidence for effective training for obstetric emergencies.

EVIDENCE OF EFFECTIVENESS

Intrapartum care demands sensitivity, clinical skill and acumen from a multi-professional team of carers. Training should address all these elements, and this is likely to require a broad range of training techniques and tools. The King’s Fund report¹ recognised that:

Maternity units could easily provide their own simulation-based training ... Any such training should include clinical skills, communication, team working, and awareness of roles within the team.

A systematic review of obstetric emergencies training published in 2003 concluded that there was minimal evidence to support obstetric skills training.²⁸ Since 2003, however, several studies have been published evaluating the effectiveness of skills training for obstetric emergencies, not all of them positive.

Training is not magic, nor is it automatically effective, and the current literature is conflicting. There are a number of studies where training either did not improve clinical outcomes^{29,30} or was associated with an increase in perinatal morbidity.³¹

We should demand the same robust research for training that we do for other obstetric interventions, to ensure that training passes the ‘Ronseal’ test. In 1975, Donald Kirkpatrick described the evaluation of training programmes using four interconnected levels³² (Table 6.1). Ideally, training programmes should aim to show effectiveness on all levels including up to level four – change in clinical outcome.

We have reviewed the current evidence for obstetric emergency training using the Kirkpatrick levels as a framework and hierarchical evidence of effect.

Table 6.1 Kirkpatrick's levels of programme evaluation

Level	Description	Expansion
K1	Reaction	How participants felt about the training, e.g. self-perceived changes in confidence
K2	Learning	Formally evaluated changes in knowledge and/or skills following training, e.g. post-course questionnaires
K3	Behaviour	Demonstrable improvement in skill levels of participants, persisting through to the workplace of participants (i.e. actual clinical care)
K4	Outcomes	Changes in clinical outcomes following implementation of training, e.g. improvement in morbidity or mortality statistics

Eclampsia

Eclampsia is a rare and catastrophic obstetric emergency. Its incidence in the UK has been falling, whilst substandard care for eclampsia has increased, accounting for over 90% of pre-eclampsia and eclampsia deaths.⁹ It appears that we have been getting better at preventing eclampsia after the publication of the Magpie trial,³³ but not getting better at managing eclampsia when it does happen, particularly now that it is even less common. This may be surprising given that one of the first reported obstetric drills was for the management of eclampsia,³⁴ and training has been recommended since at least 1996.³⁵ Moreover, a subsequent RCT³⁶ demonstrated marked improvement after training of maternity staff in interprofessional teams using realistic simulation. Following training there were significant increases in completion of basic tasks (including calling for help, stating the problem, calling for an anaesthetist, lowered head rest, recovery position and oxygen administration) (87% pre vs 100% post) and magnesium sulphate administration (61% pre vs 92% post) [K2].

There are data to inform best practice for women with eclampsia and these data have been used to produce a national guideline. There are also data that inform training for eclampsia, but clearly there has been a disconnection between the two. It is vital that we link these data to better understand the implementation of national guidance.

Shoulder dystocia

Training to manage shoulder dystocia is an excellent example of what can be achieved using simulation as both an implementation tool and a laboratory bench to understand and address the barriers preventing staff from providing best care.

There is wide variation in the reported incidence of shoulder dystocia³⁷ – from 0.58% to 3%.^{38–43} Shoulder dystocia is

rare, unpredictable and associated with significant perinatal morbidity (brachial plexus injury and hypoxic ischaemic encephalopathy) and mortality,⁴⁰ but it is probably the single most studied obstetric emergency, certainly in simulation research.

Practical shoulder dystocia training has been shown to improve knowledge,⁴⁴ confidence⁴⁵ and management of simulated shoulder dystocia.^{46–49} Training has also been shown to improve patient-actors' perception of their care during simulated shoulder dystocia.⁵⁰

Reports of the effect of training on perinatal outcomes, however, have been conflicting: an 8-year retrospective review of shoulder dystocia management before and after the introduction of annual shoulder dystocia training for all staff in one UK hospital demonstrated a significant reduction in neonatal injury at birth following shoulder dystocia: 9.3% pre-training, 2.3% post-training.⁵¹ There are other reports of improvements after training,^{52–54} but training has also been associated with no change in outcome⁵⁵ or even deterioration in neonatal outcome.⁵⁶

The RCOG has recognised in their national guideline that:

*Training associated with improvements in clinical management and neonatal outcome following shoulder dystocia was multiprofessional, with manoeuvres demonstrated and practised on a highfidelity mannequin.*⁵¹

*Teaching used the RCOG algorithm and staff were not taught mnemonics (e.g. HELPER – [H: call for help, E: evaluate for episiotomy, L: legs, McRoberts maneuver, P: suprapubic pressure, E: enter: rotational maneuvers, R: remove the posterior arm, R: roll the patient to hands and knees.]) or eponyms (e.g. Rubin's and Wood's screws).*⁵⁷

Postpartum haemorrhage

Postpartum haemorrhage (PPH) contributes to 140,000 deaths worldwide annually.⁵⁸ Although PPH is more common

in low-resource settings, it is still a significant problem for high-resource countries, complicating 4–6% of all deliveries,⁵⁹ and therefore both the Joint Commission on Accreditation of Healthcare and the UK CEMD have stressed the importance of simulation drills and regular training for all staff in reducing morbidity and mortality from PPH.^{11,60}

Once again the data for training efficacy are conflicting. There are reports of no effect of simulation-based training for PPH in both Denmark³⁰ and the UK.⁶¹ On the other hand, a group⁶² who provided lectures and simulation-based training for all high- and mid-level providers involved in childbirth at a hospital in Tanzania demonstrated a decrease in PPH rates following training (33% pre vs 18% post), in parallel with an increase in the proportion of women with active management of the third stage (25.1% post vs 0.6% pre), including uterine massage, bimanual compression and oxytocin infusion [K4].

Once again there is a requirement to investigate the effect of simulation-based training and to define the active ingredients of effective training.

Cord prolapse

Cord prolapse is a rare obstetric emergency complicating 1% of deliveries,⁶³ but it is associated with a very high fetal mortality rate of 10%.⁶⁴ Because of the rarity of the condition, a randomised trial to determine the effectiveness of training would be impossible, and therefore there are only observational studies available. Recently, a retrospective cohort study demonstrated a statistically significant reduction in median diagnosis–delivery interval (25 minutes pre vs 14.5 minutes post) for women after cord prolapse following simulation-based training.⁶⁵ This improvement was associated with a consistent reduction in the rates of infants born with both low Apgar score and neonatal intensive care unit (NICU) admission [4]. Crucially, the simulation training programme was interprofessional, covered teamwork in principle and in action, and included 100% of maternity staff.

Maternal collapse

Maternal cardiac arrest is a rare complication occurring in approximately 1:30,000 pregnancies in the UK.¹¹ The national Confidential Enquiry reported in 2007¹¹ that resuscitation skills were unacceptably poor in a high number of maternal deaths. It was therefore recommended that all clinical staff should have regular training to improve basic, intermediate and advanced life support.

Simulation provides an opportunity to practise skills for this very rare problem, and improved care after cardiac arrest has been described after simulation training in a general hospital setting.⁶⁶ A small US study also found improved outcome in an obstetric setting.⁶⁷

A retrospective cohort study evaluating the use of perimortem caesarean section (PMCS) in the Netherlands after the introduction of training showed that the utilisation rate of PMCS increased (12% pre vs 35% post).⁶⁸ The outcome, however, remained poor, possibly attributable to slow recognition, failure to initiate cardiopulmonary resuscitation (CPR), failure to display the uterus, poor communication, and delay in performing the procedure, as none was performed within 5 minutes of the arrest [K3]. Once again, it is not just individual decision-making and practical skills that make a difference to the clinical outcome of these rare situations, it is also the coordination and efficiency of the whole maternity team.

Instrumental delivery

The appropriate and safe use of forceps and vacuum instruments to assist vaginal birth should be one way to limit the ever-rising rate of caesarean section. This rise may be due to reduced senior supervision at night, leading most obstetric trainees to perform a caesarean section rather than attempt a difficult instrumental delivery. At the same time, UK obstetric trainees have identified that skills for operative birth, especially rotational operative births, are difficult to acquire and implement.⁶⁹ Simulation training may bridge the gap and help trainees build confidence and competence.

A high-fidelity model developed by Dupius *et al.* allows the trajectory of the application of forceps blades to be tracked using spatial sensors.⁷⁰ Following training, there was improvement in the abilities of junior doctors to perform instrumental deliveries.⁷⁰ Models have also been developed to train juniors in the appropriate traction. Both Moreau *et al.*⁷¹ and Leslie *et al.*⁷² found that correct forces and successful deliveries increased after simulating operative vaginal births [K3].

The RCOG has developed a new training course to meet the requirements for effective simulation-based training for operative vaginal birth: ROBUST (RCOG Operative Birth Simulation Training).

Communication and effect on patient perception

In obstetric care, complications commonly occur when the woman is conscious, and poor maternal experience is another significant complication of pregnancy and birth. UK-based research showed that over 25% of new mothers were not satisfied with communication by the medical staff, and there was a significant association between satisfaction with communication by medical staff and overall satisfaction with care.⁷³ Therefore training in communication with the women, their companions and among team members is crucial. This training can be delivered through simulation that can build confidence, which is then transmitted to the patient involved, creating a reciprocal feeling of safety and

assurance that the situation is being managed appropriately and efficiently.

Communication with patient actors was improved after simulation training using the actors,^{64,65} who reported improvement of safety perception with information about the cause of emergency, their baby's condition and the treatment plan [K3].

HOW SHOULD WE TRAIN?

It's not that practice makes perfect, but perfect practice leads to proficiency and perhaps perfection. Dr Andrew J Satin

Simulation-based training is a very promising intervention, but we should not overestimate the effect of simulation. A recent review of simulation-based medical education (SMBE) recognised that some but not all SMBE was associated with improvements in clinical outcome.⁷⁴

There is an important need to test whether obstetric simulation training programmes are effective, sustainable and cost-effective. A review of the obstetric programmes associated with improvement in clinical outcome in 2009⁷⁵ highlighted the common features of clinically effective training:

Multiprofessional training of all staff in an institution

Training should encourage active participation from all team members, including doctors, midwives, porters and health-care assistants⁷⁶ and should take place in a non-threatening environment,^{77,78} with everyone training in their professional role. Feedback should be given in a constructive way, stressing the positive attitudes of the participants, and possibly using a standardised checklist to be completed by peers, to reduce the authority gradient of facilitation by senior staff.

Training staff locally within their unit

Local (in-house) training can be less expensive than simulation centres; it helps units to recognise local safety issues and helps new staff members to familiarise themselves with their working environment.

In a previous study staff were able, after training, to identify and correct latent threats to patient safety in relation to emergency caesarean sections, peripartum hysterectomy and neonatal resuscitation.⁷⁹ Another study assessing local simulation demonstrated that the patient's bed could not pass through some labour ward rooms, resulting in unnecessary and potentially harmful delays. It appears to be the most effective way of improving outcome(s),⁸⁰ but it is not always feasible as small units will face problems in providing physical space and staff for training.

Realistic simulation

Environmental and training fidelity is important,⁵⁷ but high fidelity is not always synonymous with 'high technology'. There are a number of simulation-based courses that make use of simple, inexpensive tools to increase realism – e.g. trousers that 'bleed' red material and a perineum with prolapsed cord.²⁴

Institutional-level incentives for training

Implementing and subsequently running a training programme is demanding and can be costly through staff release, space for training and funding of training equipment. However, institutions can justify, or offset, the cost of running training directly from reduced insurance premiums^{4,63,75,81–83} and the insurers will recoup their investment downstream through better outcomes.

Interprofessional clinical training with integrated team work

Team training recognises that people make fewer errors when they work together. National bodies now recommend inter-professional training for the whole maternity team, comprising doctors, midwives and allied workers such as porters and healthcare assistants.⁷⁶

Studies analysing the behaviour of teams in simulated emergencies have highlighted that good situational awareness is essential for good teamwork,^{84,85} in particular three components of situational awareness for teams managing obstetric emergencies:

- 1 clinical situation awareness;
- 2 team awareness;
- 3 patient focus and involvement.⁸⁶

In addition the most effective maternity teams in one study used 'closed-loop communication', where team members clearly direct a message to intended recipients (by touching, naming and establishing eye contact with them), who acknowledge the information on task allocation verbally and then confirm that it has been correctly acted upon.⁸⁷ Such clear and directed communication is associated with fewer errors and repetitions⁸⁸ and a shorter time interval to administer important drugs such as magnesium sulphate for eclampsia⁸⁹ and Syntometrine for PPH.^{88,89}

Evidence-based training

Training should be based on, and implement, evidence-based practice.^{11,60} Training can also be used to give local impact to national guidance^{89–92} and develop implementation tools, e.g. CTG stickers, as mere availability of these guidelines is often not sufficient to change practice.

Evaluation of training

Ideally, training programmes should be formally evaluated, at least prior to distribution at scale. Moreover, it would be useful to understand implementation strategies and also the effect of the local context.

There is, however, minimal or no evidence that assessment of local practitioners is useful, or helpful.

Training in low-resource settings

The WHO Millennium Goals 4 and 5 aim to reduce infant mortality rates by two-thirds and maternal mortality rates by 75% by year 2015. Simulation will have a role in reaching these targets if it is not solely confined to the developed world. Training should be universal. Many candidates reading this book, particularly overseas candidates, will question the role of simulation training in obstetric emergencies. Even in busy units where emergencies such as eclampsia and shoulder dystocia are relatively more frequent, there is still an important role for simulation-based training. A recent WHO review of intrapartum training in low- and middle-income countries concluded that:

Where in-service training can be provided at a low cost, it may be worthwhile to do so, given that some improvements in the care process can be expected. However, in general, such training may be associated with high cost and therefore for most settings it is difficult to justify the conduct of routine in-service neonatal and paediatric training courses primarily based on models developed in high-income countries.⁹³

Care must be taken to avoid inappropriate 'square peg in a round hole' introduction of non-localised courses from high-income settings.

Once again the published data are conflicting: the introduction of training with the Essential Newborn Care course based in six countries (Argentina, Democratic Republic of Congo, Guatemala, India, Pakistan and Zambia) showed significant reduction in rate of stillbirths following training (23 per 1000 pre vs 15.9 per 1000 post),⁹⁴ whereas another study assessing the effect of training in improving outcomes done in a regional hospital in Tanzania showed that the introduction of ALSO training from the United States did not improve outcomes.⁶²

Success of training programmes in low-resource settings depends on many factors such as appropriately skilled instructors, locally adapted training materials and time for training. More work is required to understand the specific requirements for, and local adaptation of training in, developing world settings.

CONCLUSION

Reducing avoidable harm is a priority for midwives, women and families across the world. Simulation-based training for obstetric emergencies appears to offer a direct route to

improvement, but the effect of intrapartum training programmes has been inconsistent, if not conflicting.

Significant progress has been made at establishing an evidence base for training in obstetric emergencies since the publication of Black and Brocklehurst's paper in 2003.²⁸ However, those studies that demonstrate improvement in clinical outcomes are retrospective and only report neonatal outcome data, and there remains very little evidence for maternal outcomes. The next stage should be a well-designed RCT studying the effect of training on both maternal and neonatal outcomes across several hospitals while adjusting for baseline changes and temporal changes.

There is currently evidence of a positive impact of training on confidence, knowledge and skills, with emerging evidence of improvements for at least some perinatal outcomes. Therefore, based on the current available evidence, training for obstetric emergencies should be local, multiprofessional, mandatory for all staff and ideally supported by institutional incentives (most often insurance based) to train.

KEY POINTS

- Poor team working, suboptimal communication and lack of proper training can lead to preventable maternal and perinatal harm.
- Simulation-based training is one of the most promising strategies and can potentially reduce these avoidable complications by 50–70%.⁶
- Simulation-based training for maternity staff should be both effective and sustainable.
- Training programmes associated with improvements in perinatal outcome were all conducted 'in-house', trained 100% of staff, reported the introduction of system changes suggested by their staff after participating in the training, and trained all staff together, incorporating teamwork principles into clinical training scenarios.⁷⁶
- Training in low-resource settings may be different and local adaptation of training courses is crucial for locally sustainable training programmes.

Antenatal Obstetrics

This page intentionally left blank

Chapter 7 Routine antenatal care: an overview

Nina Johns

MRCOG standards

- Candidates should be able to recognise and manage pre-existing and developing problems from pre-conceptual period through to delivery.
- Candidates should be able to evaluate the clinical risk for patients and make the decision whether for Midwifery led or Obstetrician led antenatal care and set out frequency of appointments.
- Demonstrate skill in listening and conveying complex information (e.g. concerning risk) and be able to deal with the diversity of maternal choices in antenatal and intrapartum care.
- Show understanding of the roles of other professionals (within a multidisciplinary team) and demonstrate skills in liaison and empathetic teamwork.

Practical skills

- Undertake pregnant and non-pregnant abdominal examination.
- Take an obstetric history and make the relevant referral as a result of domestic violence.
- Conduct a booking visit and arrange (and counsel for) appropriate investigations.
- Conduct follow-up prenatal visits.
- Have the skills to liaise with midwives and other health professionals to optimise care of the woman (a holistic approach).
- Show awareness of the need to identify and deal appropriately with domestic violence and have a working knowledge of child protection issues.
- Demonstrate an ability to explain the detection rates and limitations of maternal and fetal screening programme (sensitivity and specificity).

Theoretical skills

- A revision of the knowledge and high level of understanding of normal antenatal processes and progress.

- An understanding and judgement of the different models of antenatal care.
- Be fully conversant with the principles of prenatal diagnosis and screening (in its widest sense).
- Have good knowledge of the use of ultrasound in antenatal care.
- Demonstrate the use of appropriate protocols and guidelines and knowledge of National Guidance on Routine Antenatal Care (NICE, 2008).¹

INTRODUCTION

Routine antenatal care describes the standard schedule of appointments, investigations and interventions offered to all pregnant women from healthcare services. It is perhaps important to emphasise here that in an ideal world all pregnant women and their partners would also have received pre-conceptual counselling and information, in either a primary care setting (low risk) or a secondary/tertiary care setting (complex-risk women, often with pre-existing medical problems). Pregnancy is a unique physiological state which may be associated with complications due to pre-existing medical conditions and gestation-specific conditions arising in otherwise healthy women. Antenatal care aims to identify risk factors for the development of complications in pregnancy and birth, prevent or treat these complications if they occur, and offer screening for specific pathologies in both the woman and the baby. The package of care also aims to provide the woman and her family with information to enable an improved experience of pregnancy, birth and early parenthood.

Evidence from observational studies has shown that women who receive antenatal care have lower maternal and perinatal mortality and better pregnancy outcomes. These studies appear to demonstrate that the number of antenatal appointments and the time of the initiation of care also affect pregnancy outcomes.² A systematic review by the WHO evaluated different models of antenatal care and found that a reduced number of antenatal visits could be as effective, in terms of preventing maternal and neonatal mortality and morbidity, as schemes with a higher number of visits. However, women were less satisfied with fewer antenatal visits.^{3,4}

The aims of antenatal care are to:

- provide high-quality information that can be easily understood;
- provide an informed choice about the pathways of antenatal care;
- offer evidence-based treatment options for medical conditions pre-existing or arising in pregnancy;
- identify and screen for maternal and fetal complications;
- assess maternal and fetal wellbeing throughout pregnancy;
- provide advice and education on the normal symptoms of pregnancy.

Historically, the current model of antenatal care began in the UK following a review of maternal health by the RCOG in 1944 and came into practice with the creation of the NHS in 1948. The pattern of care – with monthly visits to an antenatal clinic until 32 weeks' gestation, fortnightly until 36 weeks and weekly until birth – has changed only marginally to the current recommended schedule of appointments.

More recently, the *Changing Childbirth* report (1993) and *Maternity Matters* (2007) recommended that the focus of maternity care should be woman centred, with an emphasis on providing choice, easy access and continuity of care.^{5,6} These reports highlighted that care during pregnancy should enable women to make informed decisions and provide clear evidence-based information.

The management of antenatal care is subject to clear national and international guidance with NICE clinical guidelines¹ and WHO recommendations.⁷ Local pathways of care and clinical decisions should therefore reflect this guidance and be based on the evidence available.

The recommended NICE clinical antenatal care pathway can be found within the guidance and website link: <http://pathways.nice.org.uk/pathways/antenatal-care#content=view-index&path=view%3A/pathways/antenatal-care/routine-care-for-all-pregnant-women.xml> (Fig. 7.1).

PRINCIPLES OF RISK ASSESSMENT AND SCREENING

The basic principles of routine antenatal care are those of risk assessment and population screening.

Antenatal risk assessments aim to identify the level and frequency of care that the woman needs due to medical, obstetric or social risk factors in her previous or current pregnancy. This risk assessment should initially occur at the booking visit, and is repeated in the second and third trimesters, to ensure that the woman is receiving the appropriate care and to identify any need for changes in care when risks have been identified.

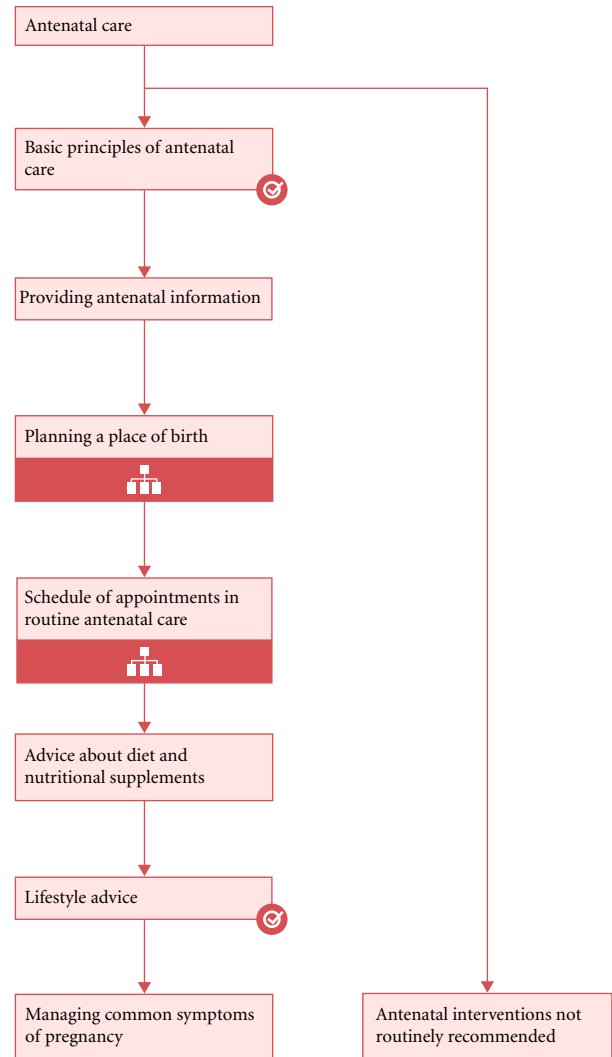

Fig. 7.1 NICE clinical antenatal care pathway

Potential risks in pregnancy include: significant pre-existing medical conditions, such as diabetes or hypertension; substantial obstetric factors, such as previous history of fetal growth restriction; or important social issues, such as domestic violence. The recognition of risk factors is empirical to the success of appropriate antenatal care and planning of multidisciplinary support and surveillance for the planning, birth and postnatal period.

Each part of antenatal care should also fulfil the criteria for effective screening programmes. These are that:

- 1 the condition being screened for is an important health problem;
- 2 the screening test (further diagnostic test and treatment) is safe and acceptable;
- 3 the natural history of the condition is understood;
- 4 early detection and treatment have benefit over later detection and treatment;
- 5 the screening test is valid and reliable;

- 6 treatments or interventions should be effective;
- 7 there are adequate facilities for confirming the test results and resources for treatment;
- 8 the objectives of screening justify the costs.

Maternal screening

Antenatal screening for pre-existing maternal conditions forms an essential part of the initial and on-going risk assessment and planning for care in pregnancy.

At the booking appointment women should be offered screening blood tests for anaemia, haematological conditions by electrophoresis (such as sickle cell diseases and thalassaemias), blood group and rhesus status testing, and red cell antibody screen. Screening for anaemia and red cell antibodies should also be repeated at 28 weeks' gestation.¹

It is likely that women with haematological diseases such as sickle cell and thalassaemias will be aware of their diagnosis prior to pregnancy and may have received preconception counselling (see Chapter 12). However, women may be unaware that they are carriers and, if identified as a carrier of a clinically significant haemoglobinopathy, then the father of the baby should be offered counselling and appropriate screening as soon as possible.¹

Anaemia in pregnancy is reviewed in detail in Chapter 21. Once identified by screening, it is recommended that routine antenatal anti-D prophylaxis is offered to all non-sensitised pregnant women who are rhesus D negative at 28 weeks.¹

Women with clinically significant atypical red cell alloantibodies should be offered referral to a specialist centre for further investigation and advice on subsequent antenatal management.¹

Screening for maternal infections enables potential intervention to reduce the risk to both mother and baby, and enables planning for appropriate specialist antenatal, intrapartum and postnatal care. Routine antenatal serological screening for hepatitis B, HIV, syphilis and rubella immunity are currently recommended.¹

Serological screening for hepatitis B virus should be offered to pregnant women at booking and has been part of the routine screening programme in the UK since 2000. Identification of active or carrier status will enable referral to secondary obstetric care and facilitate effective postnatal intervention to be offered to decrease the risk of mother-to-child transmission. Mother-to-child transmission is approximately 95% preventable through administration of vaccine and immunoglobulin to the baby at birth.¹

Routine screening for HIV infection in early pregnancy allows the identification of women with asymptomatic infection, referral to appropriate specialist services and treatment with antiretroviral therapy, and planning for labour and birth and treatment of the baby. In the UK, the mother-to-child transmission of HIV has dropped from 25.6% in 1993 to 0.57% in 2007–2011. In addition to this reduction in transmission the number of vaginal births has increased from 15% to 40%. (BHIVA paper 2014).⁸

Syphilis is a rare condition in the UK (but prevalence is increasing worldwide). The routine screening for syphilis should be offered to all pregnant women at booking as treatment is beneficial to the mother, and mother-to-child transmission of syphilis in pregnancy is associated with neonatal death and severe growth restriction, and is a cause of fetal hydrops fetalis. Congenital syphilis, which may cause long-term disability, is associated with stillbirth and preterm birth. In pregnant women with early untreated syphilis, 70–100% of infants will be infected and one-third will be stillborn.¹ Parenteral penicillin effectively prevents mother-to-child transmission of syphilis and is not associated with any difference in adverse pregnancy outcomes.

The national recommendation to screen for rubella susceptibility in antenatal care aims to identify women at risk of contracting rubella infection and to enable vaccination in the postnatal period for the protection of future pregnancies.¹

In addition to serological screening women should be offered routine screening for asymptomatic bacteriuria via midstream urine culture at the booking appointment.¹ Studies in the UK have shown that asymptomatic bacteriuria occurs in 2–5% of pregnant women and is associated with increased rates of maternal pyelonephritis and preterm birth. However, evidence from RCTs shows that antibiotic treatment is of benefit only to reduce the risk of pyelonephritis.¹

In addition to screening for those maternal conditions that are present prior to pregnancy, antenatal care also includes screening for those maternal medical conditions that develop without symptoms in pregnancy.

Screening for gestational diabetes should be targeted at women with risk factors such as: body mass index (BMI) >30 kg/m²; previous macrosomic baby weighing 4.5 kg or above; previous gestational diabetes; family history of diabetes (first-degree relative with diabetes); or family origin with a high prevalence of diabetes. Women with any one of these risk factors should be offered testing for gestational diabetes using an oral glucose tolerance at 26 weeks' gestation, or earlier at 16 weeks' gestation if there is a previous history of gestational diabetes.¹

At every antenatal appointment and contact with a healthcare professional, blood pressure measurement and urinalysis for protein should be carried out to screen for pre-eclampsia.¹ Additional risk factors for development of pre-eclampsia, such as age 40 years or older, first pregnancy, pregnancy interval of more than 10 years, family history of pre-eclampsia, previous history of pre-eclampsia, BMI 30 kg/m² or above, pre-existing vascular disease such as hypertension, pre-existing renal disease or multiple pregnancy, should be identified at the booking visit. At present, there is no predictive diagnostic test for pre-eclampsia or proven intervention; however, more frequent blood pressure measurements should be considered for pregnant women who have any of the above risk factors. In addition, all pregnant women should be made aware of the need to seek immediate advice if they experience symptoms of pre-eclampsia,

such as severe headache, problems with vision, vomiting, or swelling of face, hands or feet.¹

Fetal screening

Screening for fetal anomalies is discussed in detail in Chapters 29 and 30.

At the first contact in a pregnancy, women should be given information about the purpose and implications of fetal screening. Information given to women should include the screening pathway for both biochemical and ultrasound screening, the decisions that need to be made at each point along the pathway, the fact that screening does not provide a definitive diagnosis, and a full explanation of the risk score obtained following combined first trimester testing. Giving accurate information will enable women and families to make an informed choice as to whether to accept the offers of screening and the implications and limitations of the results provided.

The purpose of screening for fetal anomalies and identifying fetal anomalies is to enable women to make reproductive choices (which may include termination of pregnancy), assist parents to prepare (for any treatment/disability/palliative care/termination of pregnancy), facilitate birth in a

specialist centre if required, and allow intrauterine therapy if available.

The current antenatal and newborn screening opportunities are summarised in Fig. 7.2.

ANTENATAL INFORMATION

Routine antenatal appointments/visits also provide multiple opportunities for sharing information with women and their families. The majority of such visits in the UK are provided by midwives. However, worldwide other models of delivery exist. National guidance recommends that the information given is evidence based, easy to understand and accessible to women in different languages, and with additional sensory or learning requirements.¹ Some antenatal information is gestation specific and can be found in the relevant sections of this chapter. The following includes antenatal information that may be discussed at any time in the pregnancy.

Nutrition

Evidence from systematic review, RCTs and cohort studies has shown that antenatal advice on dietary intake can improve

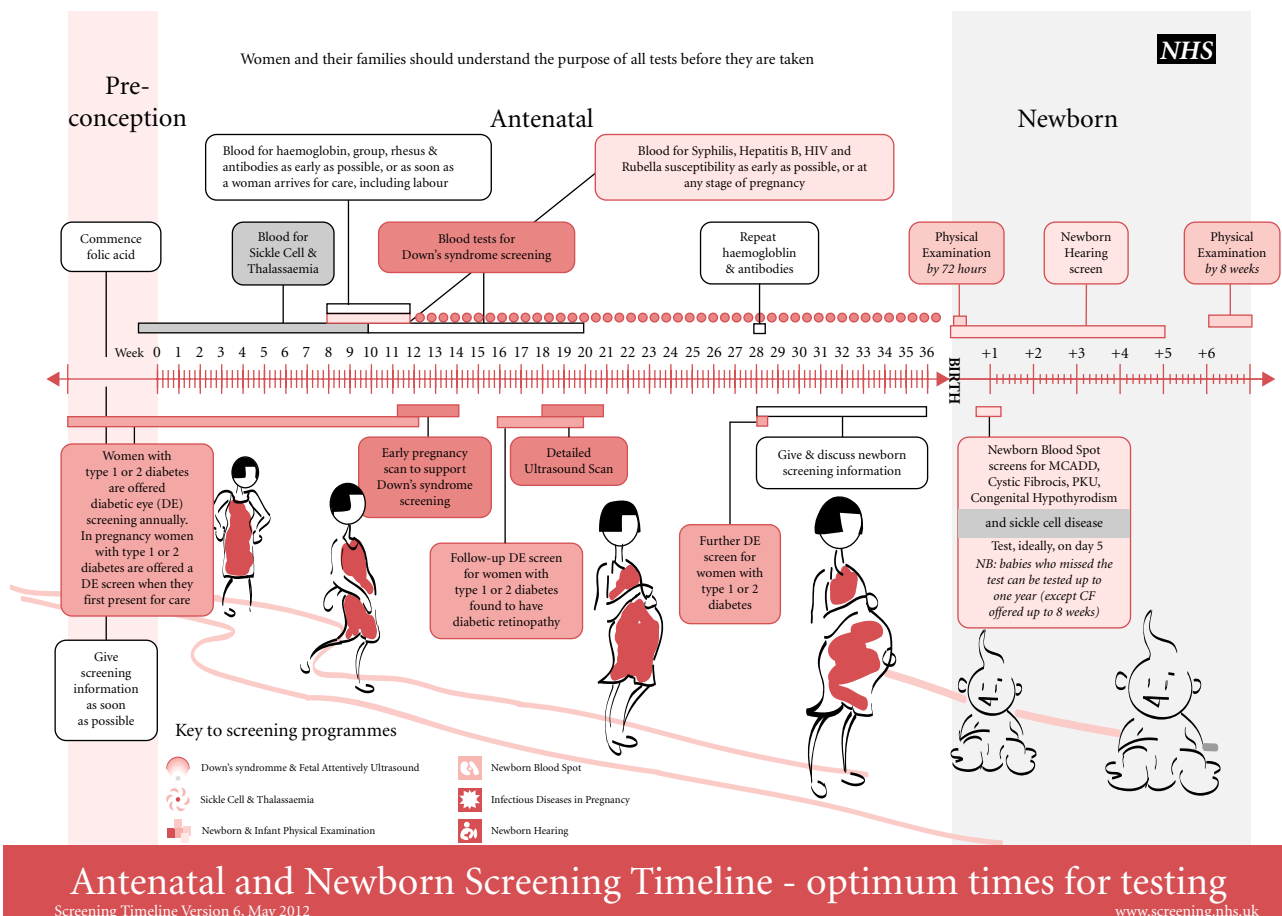

Fig. 7.2 The current antenatal and newborn screening opportunities summary: <http://cpd.screening.nhs.uk/timeline>

women's knowledge and healthy eating, but does not appear to affect pregnancy outcomes.¹ More recent reviews have confirmed that lower weight gain in pregnancy may be associated with less weight retention afterwards and that diet and exercise interventions may reduce the amount of weight gained in pregnancy.⁹

Smoking

Smoking in pregnancy is associated with increased risk of miscarriage, preterm premature rupture of membranes, preterm birth, small for gestational age (SGA), low birthweight, placental abruption, perinatal mortality and sudden infant death.

Systematic reviews show a reduction in smoking rates associated with structured cessation programmes, rewards and social support, and this was associated with lower rates of low birthweights and preterm birth.¹

Alcohol

RCOG guidance and patient information recommend that women should be informed that high intake of alcohol during the first trimester increases the risk of miscarriage and chronic use may lead to fetal alcohol spectrum disorder.¹⁰ It further recommends that women should avoid alcohol in pregnancy, but if they do drink alcohol they should limit intake to national recommendations (1–2 units, not more than twice a week) and avoid binge drinking. However a recent cohort study showed that women who drank regularly before pregnancy (more than weekly) continued to consume alcohol in the antenatal period, despite national guidelines recommending abstinence.¹¹

Working

National guidance recommends that most pregnant women can be reassured that it is safe to continue working during pregnancy and there is some evidence that employment is beneficial.¹ However, identification of potential occupational hazards (e.g. ionising radiation) for pregnancy need to be explored. There is some evidence that employment that involves heavy lifting or shift work may be associated with a small increased risk of preterm birth; however, the studies are small and systematic review showed no difference.¹²

Exercise

Systematic review of evidence confirms that, in the absence of any obstetric or medical complications, most women can begin or maintain a regular exercise regimen during pregnancy without complications. It is recommended that pregnant women should avoid exercise that involves the risk of abdominal trauma, falls or excessive joint stress, and also

scuba diving (increased incidence of fetal anomaly and risk of fetal decompression disease).¹

Travel

RCOG guidance on travel in pregnancy concentrates on air travel and the scientific impact paper concludes that there is no clear evidence that air travel increases the risk of pregnancy complications such as preterm labour, rupture of membranes or abruption. However, flights of more than 4 hours' duration are associated with a small increased risk of venous thrombosis, and the paper states that graduated elastic compression stockings for all women, and low-molecular-weight heparin (LMWH) for those with significant risk factors, are likely to be of benefit, but that low-dose aspirin should not be used for thromboprophylaxis.¹³ The guidance suggests avoidance of air travel from 37 weeks' gestation in a singleton pregnancy and from 32 weeks' gestation if there are significant risk factors for preterm birth.

Who provides antenatal care?

Midwives and GPs should provide care for women with an uncomplicated pregnancy. Care should be provided by small groups or teams of carers (usually midwives) and with continuity of care throughout the antenatal period. Systematic review of evidence shows that the routine involvement of obstetricians in the care of women with an uncomplicated pregnancy at scheduled times does not appear to improve perinatal outcomes compared with involving obstetricians when complications arise.¹ A system of clear referral paths should be established so that, if additional care is required, women can be seen and treated by the appropriate specialist teams. Obstetricians and specialist teams should be involved if pre-existing medical conditions are present, or when maternal or fetal complications arise.

National guidance recommends that antenatal appointments should take place in a location that women can easily access and that maternity records should be standardised, containing an agreed minimum data-set and held by the woman.¹

Schedule for appointments

The NICE recommendation for schedule of antenatal appointments can be found within the guidance and website link: <http://pathways.nice.org.uk/pathways/antenatal-care#path=view%3A/pathways/antenatal-care/schedule-of-appointments-in-routine-antenatal-care.xml&content=view-index> (Fig. 7.3).

Women in their first pregnancy, with no complications arising, should receive ten appointments and those in subsequent pregnancies require seven appointments.¹ An individualised schedule of appointments may need to include additional visits if complications arise within the pregnancy or other

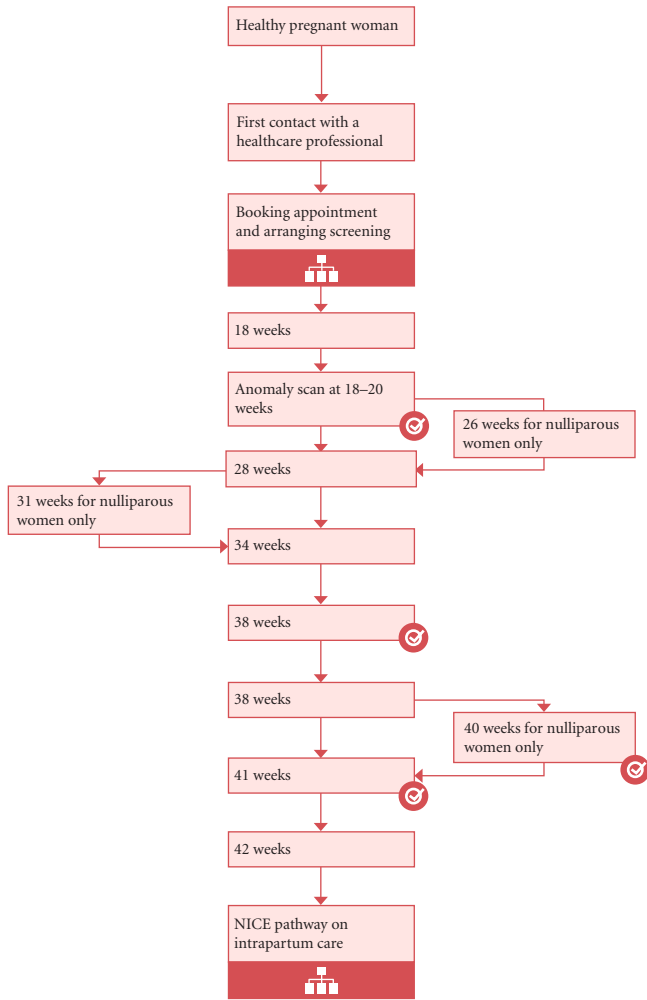

Fig. 7.3 NICE recommendation for schedule of antenatal appointments

risk factors are identified. Wherever possible, appointments should incorporate routine tests and investigations to minimise inconvenience to women.¹

First contact with healthcare professional

At their initial appointment with a healthcare professional, women should receive information regarding food hygiene and lifestyle advice, including smoking cessation, and the implications of recreational drug use and alcohol consumption in pregnancy. Women should also be advised to take folic acid supplementation and, if at increased risk (previous neural tube anomaly, maternal epilepsy or diabetes), offered a prescription for high-dose folic acid (5 mg). Information on the risks and benefits of antenatal screening tests and advice on who is likely to provide care and schedule of next appointments should also be given.

Booking visit

This antenatal appointment should occur ideally between 10 and 12 weeks' gestation and should include:

- Gestational age assessment with ultrasound scan offered between 11+0 weeks and 13+6 weeks, to determine gestational age, detect multiple pregnancies and offer nuchal translucency (NT) measurement for screening;
- Assessment of maternal and obstetric risk factors to identify women who may require additional antenatal care;
- Ask about any past or present severe mental illness or psychiatric treatment;
- Ask about the woman's occupation, to identify potential risks;
- Plan lead care professional (midwife or obstetrician);
- Plan pattern of care for pregnancy;
- Discussion on antenatal screening;
- Offer blood tests to check blood group and rhesus D status, and screening for anaemia, haemoglobinopathies, red-cell alloantibodies, hepatitis B virus, HIV, rubella susceptibility and syphilis;
- Measure height and weight and calculate BMI;
- Measure blood pressure and test urine for proteinuria;
- Offer screening for asymptomatic bacteriuria;
- Information on how the baby develops during pregnancy, nutrition, diet (including vitamin D supplements if necessary) and exercise;
- Monitor smoking status and offer smoking cessation advice and information on the specific risks of smoking during pregnancy (such as low birthweight and preterm birth);
- Information on pregnancy care pathway including parent education and infant feeding;
- Information on options for place of birth and different modes of birth.

First trimester

If the booking appointment occurs prior to 11 weeks' gestation, offer an additional appointment for ultrasound examination between 11+0 and 13+6 weeks to determine gestational age, detect multiple pregnancies and offer NT measurement for screening with the combined serum screening for Down's syndrome.

If ultrasound measurement of NT is not possible at ultrasound, or a woman presents after 13+6 weeks, then serum screening test (triple or quadruple test) between 15+0 and 20+0 weeks can be offered.

Second trimester

Routine antenatal appointment at 16 weeks' gestation for all women should include:

- Review, discuss and record the results of screening tests;
- Measure blood pressure and test urine for proteinuria;

- Investigate a haemoglobin level below 11 g/100 mL and consider iron supplements;
- Information on the routine anomaly scan.

An ultrasound scan should be offered to all women and, if accepted, be performed between 18+0 weeks and 20+6 weeks to detect structural anomalies. If structural differences are identified, appropriate information should be given and potential referral to a fetal medicine specialist considered. If ultrasound examination identifies a low-lying placenta, an additional scan at 32 weeks should be offered.

Routine appointment at 24–25 weeks' gestation is recommended only for women in their first pregnancy. This appointment should include:

- Measure blood pressure and test urine for proteinuria;
- Measure and plot symphysis–fundal height.

Third trimester

Routine antenatal appointment at 28 weeks' gestation for all women should include:

- Measure blood pressure and test urine for proteinuria;
- Offer blood tests to check for anaemia and atypical red-cell alloantibodies;
- Investigate a haemoglobin level below 10.5 g/100 mL and consider iron supplements;
- Offer anti-D prophylaxis to women who are rhesus D negative;
- Measure and plot symphysis–fundal height.

Routine appointment at 31 weeks' gestation is recommended only for women in their first pregnancy. This appointment should include:

- Review, discuss and record the results of blood tests undertaken at 28 weeks;
- Measure blood pressure and test urine for proteinuria;
- Measure and plot symphysis–fundal height.

Routine antenatal appointment at 34 weeks' gestation for all women should include:

- Review, discuss and record the results of blood tests undertaken at 28 weeks;
- Measure blood pressure and test urine for proteinuria;
- Measure and plot symphysis–fundal height;
- Give information on preparation for labour and birth, including the birth plan, recognising active labour and coping with pain.

Routine antenatal appointment at 36 weeks' gestation for all women should include:

- Measure blood pressure and test urine for proteinuria;
- Measure and plot symphysis–fundal height;
- Check the presentation of the baby (refer if breech presentation suspected);

- Give information on infant feeding, care of the new baby, vitamin K prophylaxis, newborn screening tests, and postnatal self-care.

Routine antenatal appointment at 38 weeks' gestation for all women should include:

- Measure blood pressure and test urine for proteinuria;
- Measure and plot symphysis–fundal height;
- Give information on options for management of prolonged pregnancy.

Routine antenatal appointment at 40 weeks' gestation is recommended only for women in their first pregnancy. This appointment should include:

- Measure blood pressure and test urine for proteinuria;
- Measure and plot symphysis–fundal height;
- Further discussion of management of prolonged pregnancy and offer membrane sweep.

Routine antenatal appointment at 41 weeks' gestation for all women should include:

- Measure blood pressure and test urine for proteinuria;
- Measure and plot symphysis–fundal height;
- Further discussion of management of prolonged pregnancy and offer membrane sweep and date for admission for induction of labour.

This plan of care relates to uncomplicated singleton pregnancies. In multiple pregnancy, NICE guidelines outline a regimen of care.

MANAGEMENT OF COMMON SYMPTOMS IN PREGNANCY

Multiple symptoms occur in a healthy uncomplicated pregnancy; most can be managed with conservative treatments and maternal reassurance. However, further investigation may be required to exclude unusual or insidious presentations of other pathologies.

Nausea and vomiting

It is estimated that nausea is experienced in 80–85% of all pregnancies and associated with vomiting in approximately 50%. The condition of hyperemesis gravidarum can be diagnosed if these symptoms lead to fluid, electrolyte or nutritional imbalance requiring hospital treatment.

For the majority of women symptoms of nausea and vomiting in pregnancy resolve spontaneously within 16 to 20 weeks of gestation and are not usually associated with a poor pregnancy outcome. Systematic review of evidence and RCT data show that dietary ginger, wrist acupuncture and prescribed antihistamines appear to be effective in reducing symptoms.¹

Heartburn

Symptoms of heartburn are caused by gastro-oesophageal acid reflux due to relaxation of the distal oesophageal sphincter and reduced gastric motility in pregnancy, and are not associated with any adverse outcomes in pregnancy, but generally worsen with gestation. Symptoms of heartburn should be differentiated from presenting epigastric pain in pre-eclampsia by checking maternal blood pressure and urinalysis.

Current guidance recommends that women should be offered information regarding lifestyle and diet modification (timing of meals, portion size and posture). If symptoms remain, RCT data show that antacids are safe and effective at relieving heartburn.¹

Constipation

Symptoms of constipation are due to reduced gastric motility and transit in pregnancy, and appear to improve with gestation. Systematic review of RCT data show that dietary changes with wheat or bran fibre supplements improve symptoms and, though laxative treatment is effective, it is associated with increased abdominal pain and diarrhoea.¹

Haemorrhoids

Observational studies estimate the incidence of haemorrhoids in the third trimester as 8%. There is currently no evidence for the safety or effectiveness of topical treatments in pregnancy. Women should be offered information concerning dietary changes (to increase fibre content) and advised that, if symptoms remain, standard haemorrhoid creams may be considered.¹

Varicose veins

Varicose veins are caused by the pooling of blood in the surface veins, commonly in the legs, due to inefficient valves and relative pelvic obstruction. RCT evidence shows that compression stockings do not prevent varicose veins occurring, but appear to improve leg symptoms for women in pregnancy.¹

Backache

Back pain affects 30–60% of pregnant women and worsen with gestation. A number of RCTs have investigated interventions such as shaped pillows, exercises in water, massage, back care classes and acupuncture with small numbers, but have failed to identify clear effectiveness or safety. Current guidance recommends that exercising in water, massage therapy and group or individual back care classes might help to ease backache during pregnancy.¹

Symphysis pubis dysfunction

Pelvis girdle pain is estimated to affect at least 20% of pregnant women.¹² Systematic review of the limited evidence available shows that normal activity, exercises to improve posture

and acupuncture may improve symptoms. Pharmacological pain-relief options have not been investigated for effectiveness, but guidance highlights that medications prescribed must be appropriate for pregnancy.^{1,14}

SUMMARY

Routine antenatal care describes the standard schedule of appointments, investigations and interventions offered to all pregnant women from healthcare services. Women who receive antenatal care have lower maternal and perinatal mortality and better pregnancy outcomes. Antenatal care aims to identify risk factors for the development of complications in pregnancy and birth, prevent or treat these complications if they occur, and offer screening for specific pathologies in both the woman and the baby. The package of care also aims to provide the woman and her family with information to enable an improved experience of pregnancy, birth and early parenthood.

KEY POINTS

The aims of antenatal care are to:

- Provide high-quality information that can be easily understood;
- Provide an informed choice about the pathways of antenatal care;
- Offered evidence-based treatment options for medical conditions pre-existing or arising in pregnancy;
- Identify and screen for maternal and fetal complications;
- Assess maternal and fetal wellbeing throughout pregnancy;
- Provide advice and education on the normal symptoms of pregnancy.

The recommended NICE clinical antenatal care pathway can be found within the guidance and website link: <http://pathways.nice.org.uk/pathways/antenatal-care#content=view-index&path=view%3A/pathways/antenatal-care/routine-care-for-all-pregnant-women.xml>.

Chapter 8 Chronic hypertension

Kate Bramham and Andrew Shennan

MRCOG standards

We would suggest the following:

Theoretical knowledge

Definition of chronic hypertension.

Describe the aetiology of chronic hypertension.

Relationship between chronic hypertension and pregnancy pathology.

Practical

Be able to recognise and diagnose secondary causes of hypertension.

Know how to manage moderate hypertension in pregnancy.

INTRODUCTION

Pre-existing or chronic hypertension is one of the most common conditions in women of child-bearing age, and is becoming more prevalent¹ due to trends of increasing maternal age² and obesity.³ Chronic hypertension is estimated to affect 1–5% of pregnant women,⁴ and is frequently diagnosed for the first time during antenatal care. Underlying pathology for secondary hypertension is identified in a small proportion of women, and should be sought in all women who are newly diagnosed during pregnancy. Similarly hypertension recognised postnatally should be monitored, and if persistent investigated appropriately.

Women with chronic hypertension have worse pregnancy outcomes than normotensive women, with both maternal and neonatal complications being reported. Pre-pregnancy counselling, increased antenatal surveillance and postpartum review are therefore recommended.

DEFINITION

Chronic hypertension is defined as:

- The presence of hypertension before 20 weeks' gestation (in the absence of a hydatiform mole)
- OR persistent hypertension beyond 6 weeks postpartum.

NICE guidelines also include threshold values of >140 mmHg systolic or 90 mmHg diastolic blood pressure;⁵ however, there is a linear relationship between blood pressure at first antenatal visit and frequency of adverse obstetric events.⁶

AETIOLOGY

The cause of primary hypertension is considered to be multifactorial, with both genetic and environmental contributions. Secondary hypertension is identified only in less than 5% of the general population but has been shown to be present in 14% of women of child-bearing age.¹ Renal disease is the most common cause of secondary hypertension in pregnancy. Chronic kidney disease affects up to 3% of women age 20–39 years⁷ and pregnancy may be the first time it is identified.

HISTORY AND EXAMINATION

The majority of women will be asymptomatic; however, a careful history for end-organ damage and potential underlying aetiology should be taken. Questioning about late enuresis and recurrent urinary tract infections in childhood may suggest reflux nephropathy, and a detailed family history may confirm a genetic basis for primary hypertension, or identify familial renal disease. Paroxysmal or severe hypertension associated with headache and sweating or palpitations may be indicative of a pheochromocytoma.

Examination should include fundoscopy to identify hypertensive retinopathy (mild vessel tortuosity, silver wiring and arteriovenous nicking), and assessment for radiofemoral delay (coarctation of the aorta). Other findings may include enlarged kidneys (polycystic kidneys), a renal bruit (renal artery stenosis) and clinical features of endocrine disease (e.g. hyperthyroidism – tachycardia, goitre, proptosis).

INVESTIGATIONS

Any woman of child-bearing age identified as having hypertension should have confirmation with 24-hour ambulatory monitoring,⁸ and be investigated for end-organ damage including an echocardiogram to assess for left ventricular hypertrophy and assessment of renal function and proteinuria. Referral for investigation for secondary causes should be made to an appropriate specialist depending on local expertise and interest (e.g. nephrology, clinical pharmacology, cardiology, endocrinology).

Investigations and causes for secondary hypertension are given in Table 8.1.

Chronic kidney disease

The most common causes of renal disease in women of child-bearing age are reflux nephropathy, lupus nephritis,

IgA nephropathy and autosomal dominant polycystic kidney disease (ADPKD), although hypertensive nephropathy and obesity-related focal segmental glomerulosclerosis are becoming increasingly common. Women with reflux nephropathy and ADPKD may have affected family members but both conditions can also occur spontaneously. The modified diet in renal disease formula (MDRD), which provides an estimate of glomerular filtration rate (eGFR), is not valid in pregnancy as it underestimates the GFR by approximately 20%.⁹

Endocrine disorders

Many endocrine disorders are associated with hypertension, the most common being hyperthyroidism in women of child-bearing age. A careful clinical history and examination may identify features of other conditions including primary hyperparathyroidism, pheochromocytoma, carcinoid and acromegaly.

Table 8.1 Causes and investigations of secondary hypertension (adapted from²⁰)

Cause of hypertension	Features	Investigations
Primary		
Essential hypertension	Family history of hypertension, raised BMI, >35 years, black ethnicity, maternal low birthweight, pre-eclampsia or hypertension Secondary causes must be excluded to make a diagnosis	Confirmation with 24-hour ambulatory monitoring
Secondary		
<i>Renal</i>		
Chronic kidney disease	Family history of renal disease Clinical features of autoimmune disease (e.g. rash, arthritis, mouth ulcers) History of recurrent UTIs in childhood or primary enuresis (reflux nephropathy); micturition difficulties including incomplete bladder emptying; renal calculi; episodes of haematuria (IgA nephropathy)	Creatinine Urinalysis Ultrasound of renal tract Immunoglobulins DMSA (^{99m} Tc-dimercaptosuccinic acid) to confirm scarring if clinically indicated Antinuclear antibodies/complement C3 and C4: if positive, extractable nuclear antigen/antiphospholipid screen
Renal artery stenosis (usually fibromuscular dysplasia)	Possible audible renal bruit	Renal artery Doppler
Renin-producing tumours		Plasma aldosterone:renin ratio
Drug induced or drug related	History of taking oral contraceptives, glucocorticoids, liquorice (mimics primary aldosteronism), cocaine or other illicit drugs, or history of taking nephrotoxic agents including non-prescribed over-the-counter medications, e.g. NSAIDs, calcineurin inhibitors	
<i>Endocrine</i>		

(continued)

Table 8.1 Causes and investigations of secondary hypertension (adapted from²⁰) (continued)

Cause of hypertension	Features	Investigations
Primary aldosteronism (Conn's syndrome) and other mineralocorticoid excess states	Myalgia, weakness and headaches, hypokalaemia	Plasma aldosterone:renin ratio Serum potassium (low)
Cushing's syndrome and other glucocorticoid excess states including chronic steroid therapy	History of steroid use or rapid weight gain, polyuria/polydipsia, skin changes including acne, skin thinning, telangiectasia	24-hour urine cortisol
Phaeochromocytoma	History of episodic headache, tachycardia and sweating	Plasma metanephrines 24-hour urine catecholamines
Thyroid or parathyroid disease	Clinical features of hyper- or hypothyroidism, or hyperparathyroidism (hypercalcaemia)	Thyroid function tests Parathyroid hormone, vitamin D and calcium
Acromegaly	Carpal tunnel syndrome, sweating, enlarged feet, hands, jaw, tongue, muscle weakness	IGF-1 Growth hormone suppression test
Carcinoid tumours	Diarrhoea, flushing, wheezing, weight loss	Chromogranin-A 24-hour urine 5-hydroxyindoleacetic acid
<i>Neurological disorders</i>		
Sleep apnoea	History of snoring and episodic apnoea and high BMI	Overnight oximetry
Increased intracranial pressure	Symptoms/signs of intracerebral tumours	Cerebral imaging
Spinal cord injury	Quadriplegia, paraplegia, Guillain-Barré syndrome	
Coarctation of the aorta	Radio-radial or radio-femoral pulse delay, differential blood pressure in arms	Echocardiogram CT/MR angiography Chest X-ray (rib notching)

TREATMENT

First-line treatment for non-pregnant women of African or Caribbean origin is a calcium channel blocker such as nifedipine, whereas angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) are the drugs of choice for other ethnicities.⁸ Modification of treatment may be required prior to, or at, conception. Medications which are considered safe in pregnancy are shown in Table 8.2. Currently there is no evidence that any agent is preferable during pregnancy and treatment should be chosen according to tolerability and dosing regimen. Single-agent dose should be maximised before a second agent is introduced.

ACEIs/ARBs

Women taking ACEIs or ARBs should be informed that these medications are contraindicated in pregnancy and should be stopped before or at conception. If they are being used to reduce proteinuria, for renal or cardiac protection it is

suggested that they are continued until a positive pregnancy test, provided that conception can be reliably identified. For women using these agents as antihypertensives alone, an alternative agent should be offered which is safe in pregnancy, e.g. amlodipine, nifedipine, labetalol.

ACEIs/ARBs are associated with a fetopathy when taken in the second trimester, and some reports suggest teratogenicity,^{10,11} although others suggest that these congenital abnormalities are associated with hypertension itself, rather than the ACEIs or ARBs.¹²

Beta blockers

Some beta blockers have been associated with intrauterine growth restriction and therefore are usually avoided in pregnancy.¹³ Labetolol is a combined alpha and beta blocker which has a good safety profile in pregnancy and breastfeeding, but may require three times daily dosing to achieve an adequate response. Women should be questioned about a history of asthma before prescribing, as it may exacerbate bronchoconstriction.

Table 8.2 Safety data for commonly used antihypertensives in pregnancy (adapted from NICE⁵)

Drug	Route	Safety data maternal	Safety data fetal/neonatal
Centrally acting			
Methyl-dopa	Oral	Fatigue, headache, transaminitis (rare)	Mild hypotension in babies in first 2 days of life No obvious association with congenital abnormalities
Beta blocker			
Labetolol	Oral/IV	Exacerbation of maternal asthma	No obvious association with congenital abnormalities Rare mild hypotension in first 24 hours in neonate
Very rare hypoglycaemia			
Atenolol	Oral	Exacerbation of maternal asthma	No obvious association with congenital abnormalities Low birthweight/placental weight Decreased fetal heart rate
Alpha blocker			
Prazocin	Oral		No obvious association with congenital abnormalities
Calcium channel blockers			
Nifedipine	Oral	Headache Ankle oedema	No obvious association with congenital abnormalities
Amlodipine	Oral	Headache Ankle oedema	No reports
Verapamil	Oral/IV	Headache Ankle oedema	No obvious association with congenital abnormalities
Diuretics			
Chlorothiazide	Oral	Possible electrolyte imbalance Hypovolaemia	Possible association with congenital abnormalities Possible neonatal thrombocytopenia Possible neonatal hypoglycaemia/hypovolaemia Possible electrolyte imbalance
Bendroflumethiazide	Oral	Possible electrolyte imbalance Hypovolaemia	No obvious adverse fetal effects
Furosemide	Oral/IV	Possible electrolyte imbalance Hypovolaemia	No obvious adverse fetal effects
Vasodilators			
Hydralazine	Oral/IV		No obvious association with congenital abnormalities
Diazoxide	IV	May inhibit uterine contractions Profound hypotension possible	Neonatal hypoglycaemia

α -Methyl-dopa

Methyl-dopa has an excellent safety profile, and has been used for decades. However, side effects are common and

include tiredness, headache and depression, and occasionally hepatitis. It is no longer recommended during breastfeeding in order to avoid exacerbation of postnatal depression.⁵

Vasodilators

Hydralazine crosses the placenta but has been shown to be safe in pregnancy. It can also be given intravenously for management of severe hypertension.

Diuretics

Very occasionally diuretics may be required for symptomatic relief of oedema in women with renal disease; however, their use for the treatment of hypertension is not recommended, as they reduce plasma volume. Chlorothiazide has recently been shown to be associated with increased risk of congenital abnormalities, and ideally should be switched before conception.⁵

PRE-PREGNANCY ASSESSMENT AND COUNSELLING

Pre-pregnancy counselling is essential for all women with chronic hypertension in order to optimise their hypertensive control, to plan switching of teratogenic medication to alternative agents, and to inform women about potential complications in the pregnancy. In addition, exacerbating factors can be addressed with lifestyle adaptation such as weight loss, reduced alcohol intake, a low-salt diet and exercise.⁸ Smoking cessation should be recommended for all women who continue to smoke.

MANAGEMENT OF HYPERTENSION IN PREGNANCY

If hypertension is diagnosed for the first time in pregnancy, secondary causes should be sought. The majority of investigations described in Table 8.1 are safe in pregnancy, but should be discussed with a specialist. Women should have increased frequency of antenatal contacts, but this should be tailored to individual requirements.

Target blood pressure in pregnancy for women with chronic hypertension is unknown, but NICE guidelines recommend that treatment is given to keep blood pressure lower than 150/100 mmHg, and lower than 140/90 mmHg if there is evidence of end-organ damage (e.g. left ventricular hypertrophy) or renal disease. Studies of blood pressure control in women with chronic or gestational hypertension have reported that individuals with 'tighter' control were less likely to develop severe hypertension or be admitted to hospital, and their babies were less likely to be born preterm.^{14,15} There is an association between low birth-weight and low diastolic blood pressure, therefore treatment should be reduced if diastolic blood pressure is persistently <80 mmHg.^{5,16}

Hypertension may improve in early pregnancy due to gestational physiological changes and some women may be able to stop their medication for several weeks. However, vigilance should be maintained, as the normal physiological rise in blood pressure with later gestation may require dose titration or the introduction of additional agents. In addition to antihypertensive therapy, lifestyle measures including a low-salt diet and weight loss, if necessary, should also be discussed.

MATERNAL COMPLICATIONS

The incidence of superimposed pre-eclampsia in women with chronic hypertension is approximately 1 in 5,¹⁷ and is higher in women with secondary hypertension.¹ All women should be advised to take aspirin 75 mg in order to reduce the risk of pre-eclampsia.⁵ It is recommended that aspirin should be offered from 12 weeks onwards, as this is the earliest gestational age for which evidence supporting benefit is available.¹⁸ Women with chronic hypertension may have undetectable renal damage which is revealed only by pregnancy, therefore a quantitative assessment of proteinuria should be performed at booking, for comparison in later pregnancy.

Evidence for uterine artery Doppler velocimetry in women with chronic hypertension is of poor quality and currently is insufficient to recommend any changes in antenatal care based on Doppler findings.⁵

Superimposed pre-eclampsia may be difficult to distinguish from physiological changes but the following features are suggestive of the condition:¹⁹

- A rapid rise in hypertension;
- New onset or doubling of proteinuria;
- Other laboratory parameters, e.g. low platelets, raised liver enzymes or creatinine.

Timing of delivery

Preterm delivery is more common in women with chronic hypertension compared with the general population.¹ Frequently this is iatrogenic for maternal and/or fetal indications. Timing of delivery should be guided by the severity of hypertension, the presence of proteinuria and fetal compromise. NICE guidelines suggest that delivery for women with chronic hypertension should be managed the same as for women with gestational hypertension, or if proteinuria is present as for pre-eclampsia.⁵ Additional recommendations are given below:

- Do not offer birth to women with chronic hypertension whose blood pressure is lower than 160/110 mmHg with or without antihypertensive treatment, before 37 weeks.
- For women with chronic hypertension whose blood pressure is lower than 160/110 mmHg after 37 weeks

with or without antihypertensive treatment, timing of birth, and maternal and fetal indications for birth, should be agreed between the woman and the senior obstetrician.

- Offer birth to women with refractory severe chronic hypertension, after a course of corticosteroids (if required) has been completed.

Neonatal complications

Neonatal complications are also more commonly reported for women with chronic hypertension than for normotensive women, including higher rates of perinatal mortality, fetal growth restriction and admission to neonatal special care.¹

POSTPARTUM MANAGEMENT

Peak postpartum blood pressure usually occurs at 3–5 days. It is recommended that women with chronic hypertension should have blood pressure measured at the following times postpartum, and treatment titrated to keep blood pressure lower than 140/90 mmHg:⁵

- Daily for the first 2 days postpartum;
- At least once between day 3 and day 5 postpartum;
- As clinically indicated if antihypertensive treatment is changed after delivery.

Women with previously diagnosed chronic hypertension can be discharged when their blood pressure is stable and <140/90 mmHg or <150/100 mmHg with treatment.²⁰ Medications that are safe for breastfeeding are listed in Table 8.3. Usually women can continue taking their antenatal antihypertensive agent. Enalapril is a good alternative for women with proteinuria associated with renal disease. It is the only ACEI/ARB that has been investigated for excretion into breast milk and is found in only small amounts.²¹

Hypertension may also be diagnosed postpartum, if blood pressure remains persistently elevated after 6 weeks. Community care should be alerted to the presence of unresolved hypertension and instructed to monitor and investigate appropriately.

All women with chronic hypertension should be offered a medical review at the postnatal review (6–8 weeks after delivery) for future pre-pregnancy counselling.⁵ Assessment of future cardiovascular risk should also be made including serum lipids, family history and smoking history. Each 2-mmHg rise in systolic blood pressure is associated with a 7% increased risk of mortality from ischaemic heart disease and a 10% increased risk of mortality from stroke.⁸ Women should be advised that statin and fibrate treatment should be stopped before or at conception.²²

It is recommended that oestrogen-containing contraceptives be avoided in women with hypertension, due to their potential to exacerbate sodium retention²³ and hypertension.²⁴

Table 8.3 Drugs safety in breastfeeding (adapted from Bramham *et al.*²⁰)

Drug	Dose	Comments
NICE recommendation and widely used in UK		
Alpha and/or beta blockers		
Labetalol	100–600 mg 2–3 times daily	Only small quantities detected in breast milk
Atenolol	25–100 mg once daily	Second-line use for women who require once-daily formulation
Calcium channel antagonists		
Nifedipine SR	10–20 mg twice daily	Amount in breast milk too small to be harmful; manufacturer suggests avoid but widely used without reports of neonatal side effects
Amlodipine	5–10 mg once daily	Second-line use for women who require once-daily formulation. Amount in breast milk too small to be harmful. Manufacturer suggests avoid but used in clinical practice without report of harm
Nifedipine MR	30–60 mg once daily	
Angiotensin-converting enzyme inhibitor (ACEI)		
Enalapril	5–20 mg twice daily	Can be used in breastfeeding when previously on ACEI; other first-choice agents cannot be used or cardiac/renal protection needed. Excreted into breast milk in low concentrations but amount probably too small to be harmful

(continued)

Table 8.3 Drugs safety in breastfeeding (adapted from *Bramham et al.*²⁰) (continued)

Drug	Dose	Comments
NICE recommendation and widely used in UK		
Contraindicated		
Other ACEIs and ARBs	Not recommended	Minimal data on use during lactation. Manufacturers suggest avoid
Diuretics	Not recommended	Excessive thirst in breastfeeding women; large doses may suppress lactation

CONCLUSION

Women with chronic hypertension in pregnancy have increased maternal and neonatal morbidity, and require pre-pregnancy counselling and heightened antenatal surveillance. Hypertension identified for the first time in pregnancy should be investigated for secondary causes and evidence of end-organ damage. All women should be offered low-dose aspirin, and lifestyle modifications advised to reduce risk of complications.

Chapter 9 Diabetes mellitus

Clare L Tower

MRCOG standards

Core curriculum, Module 9 (Maternal Medicine)

Knowledge criteria

Understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of disorders of carbohydrate metabolism:

- Type 1 and type 2 diabetes
- Maternal, fetal and neonatal hazards
- Diabetic ketoacidosis
- Diet
- Drugs (insulins and hypoglycaemic agents)

Clinical competency

Diagnose, investigate and manage, with direct supervision, type 1 diabetes and impaired glucose tolerance.

Be able to describe the natural history of diseases and illnesses that run a chronic course.

Have knowledge of long-term management plans for chronic conditions.

INTRODUCTION

Diabetes mellitus (DM) is a collection of metabolic disorders with hyperglycaemia as the common feature and is predominantly classified outside pregnancy into two major subtypes, type 1 and type 2. Type 1 is typically due to a deficiency of insulin and tends to present in a younger age group, whereas type 2 is considered to be a disease of insulin resistance presenting in an older age group. Persistent hyperglycaemia in both disorders causes organ damage affecting the eyes, kidneys, nerves and cardiovascular system. Pre-existing diabetes (type 1 or type 2) is associated with a higher risk of a poor obstetric outcome. In 1990, the St Vincent Declaration set a series of targets to improve the outcome of pregnant women with diabetes, with the aim that the risks should approximate those of the non-diabetic populations. Unfortunately, the 2007 CEMACH (Confidential Enquiry into Maternal and

Child Health) report on diabetes in pregnancy found that current care falls well short of this target.¹

PREVALENCE

Diabetes is the commonest medical condition encountered during pregnancy in the UK (and probably around the world), with up to 5% of pregnancies being complicated by either pre-existing or gestational diabetes. Overall, for adults in the UK with diabetes, 90% have type 2 diabetes and 10% type 1. However, in pregnant women, with diabetes this pattern is reversed, with 50% having type 2 diabetes, 7.5% having type 1 Diabetes, and the majority, 87.5% having Gestational diabetes.² Overall, 0.27% of births are affected by type 1 diabetes, and 0.1% are affected by type 2.²

EPIDEMIOLOGY

Type 2 diabetes is typically associated with advancing age, obesity and particular ethnic groups including those of African, black Caribbean, south Asian, Middle Eastern and Chinese origin. As such, the incidence of type 2 diabetes is increasing in the population as a whole, and also therefore in pregnant women. Type 1 diabetes is usually diagnosed before the age of 30 years and is also increasing in incidence at a rate of 4% per year, being commoner in Scandinavian countries (Finland has the highest incidence). In contrast to type 2 diabetes, type 1 is not thought to be associated with lifestyle factors, but is an autoimmune disorder. The reason for the increasing incidence is unclear.

CAUSES

Physiological changes in pregnancy

Pregnant women have considerably altered carbohydrate metabolism. There is hyperplasia of the pancreatic islet cells which leads to a doubling in insulin production between the first and the third trimesters. Although there is an initial increase in insulin sensitivity during the first trimester, the release of insulin-resistant hormones

(human placental lactogen, glucagons, progesterone and corticotrophin-releasing hormone) from the placenta results in progressive glucose intolerance (insulin resistance) with advancing gestation. In addition to the increased glucose uptake of the fetus, there is increased peripheral uptake, increased glycogenesis and reduced hepatic gluconeogenesis. The renal tubular threshold for glucose falls, such that glycosuria is common. Overall, fasting glucose levels fall by 10–20% and postprandial levels are higher.

Pathogenesis of type 1 diabetes

Type 1 DM (juvenile onset) is an autoimmune disease that usually presents in childhood or young adulthood. Autoimmune destruction of the pancreatic islet cells results in insulin deficiency and causes symptoms of thirst, polyuria, blurred vision, weight loss and, if untreated, progression to life-threatening diabetic ketoacidosis. There is a genetic component and it is associated with human leukocyte antigen (HLA)-DR3 and HLA-DR4. It is not associated with obesity. The baby of an affected mother has a 2% risk of developing diabetes, whilst the child of an affected father faces an 8% risk. If both parents have type 1 diabetes, there is a 30% risk to their offspring.

Pathogenesis of type 2 diabetes

Type 2 disease (maturity onset) is a disease of peripheral insulin resistance rather than deficiency. Although it more commonly occurs over the age of 40 years, it often occurs at a younger age (25 years and upwards) in those of south Asian and African Caribbean origin. The incidence increases with age and body-weight and there is a stronger genetic component than in type 1. Hyperglycaemia is commonly present for a prolonged period prior to diagnosis and, although these patients sometimes require insulin treatment, they do not become ketotic if it is withdrawn. The prevalence of type 2 diabetes is expected to rise with increasing maternal obesity, age and social deprivation.¹ The risks of affected offspring are higher than in type 1 diabetes. Offspring of an affected mother or father have a 15% risk, and if both parents are affected the risk is 75%.

Women with type 1 or type 2 diabetes are at risk of vascular complications (both macro- and microvascular), resulting in a reduced life expectancy. The CEMACH report confirmed that all women with pre-existing diabetes (type 1 and type 2) have uniformly poorer outcomes than women without diabetes.³

MANAGEMENT

Pre-conception

Optimising pre-conception care in women with diabetes has been shown to improve outcome. Despite this, the CEMACH report found that only 35% of pregnant women with diabetes received adequate pre-conceptual counselling and care.³ Studies have shown lower rates of congenital abnormalities

and pregnancy complications in women who received multidisciplinary preconception care^{4,5} [C].

Type 1 (Box 9.1)

The risk of major congenital malformations, in particular cardiac and neural tube defects, increases with poor control of blood glucose during the first 8 weeks of pregnancy. Levels of glycated haemoglobin, HbA1c, are used to reflect long-term glycaemic control, and in general, all congenital malformations are associated with poor control in the first trimester. If significantly raised, to greater than 69–80 mmol/mol (8.5–9.5%), malformation rates of around 20% have been reported, and these risks fall if levels of HbA1c can be reduced.^{1,6} Therefore, women should be advised that optimising diabetic control pre-pregnancy will improve outcome of pregnancy. Good glycaemic control will also reduce the risks of miscarriage, stillbirth and neonatal death. The NICE guidelines 2015 recommend that information about planning pregnancy and the importance of good control of blood glucose be explained at each contact with health professionals from adolescence and that this information be given in a supportive environment with other family members encouraged to attend.² Smoking and diet should also be discussed and women with a body mass index of greater than 27kg/m² be supported to lose weight. Risks of pregnancy should also be outlined, and the need for frequent and regular attendance at clinics during the antenatal period. Targets for self monitoring of blood glucose should be agreed with the woman, and these should consider individual risks of hypoglycaemia. These targets should be the same ranges as recommended for all people with type 1 diabetes. Monthly testing of HbA1c should be offered to women planning pregnancy and women advised to aim for an HbA1c of less than 48 mmol/mol (6.5% [C]) as long as this does not cause difficulties with hypoglycaemia.² Women with an HbA1c greater than 86 mmol/mol (10%) should be strongly advised to avoid pregnancy until better control is achieved.² The 2010 SIGN guidelines state that pre-pregnancy glycaemic control should be as close to the non-diabetic range as possible.⁵ Goals should be set with the woman, involving other members of the multidisciplinary team. More rigorous control will increase the risks of hypoglycaemia, so this should be discussed, and women and

Box 9.1 Pre-conceptual counselling

Multidisciplinary management
 Optimise glycaemic control – aim HbA1c 43 mmol/mol or less
 Discuss hypoglycaemia
 Review diet and weight loss
 Discuss complications of pregnancy
 Prescribe folic acid 5 mg
 Review renal function and blood pressure
 Retinal assessment
 Review other medications, e.g. ACE inhibitors, statins
 Smoking cessation

their families should be aware of the treatments for this (see below). Women planning pregnancy should also be offered ketone testing strips and a meter and be advised to self-monitor for ketonaemia if they become unwell or hyperglycaemic.² The opportunity should also be taken to counsel about diet, weight control and smoking cessation. Women should be prescribed 5 mg of folic acid to be taken pre-conception and for the first 12 weeks of pregnancy [D–E]. The risks of other complications of pregnancy, including pre-eclampsia, birth trauma, fetal macrosomia and the increased risk of caesarean section, should also be discussed.

Other aspects of the women's diabetes should also be reviewed, such as blood pressure, renal function and retinal assessment. Retinal assessment should be offered preconception unless this has been performed within the last 6 months. The use of any medications that are contraindicated in pregnancy should be assessed, and changed if a suitable alternative exists. Typical drugs falling into this category are statins, angiotensin II-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). ACE inhibitors, ARBs and statins should be discontinued prior to pregnancy, or as soon as pregnancy is confirmed and antihypertensive agents suitable for use in pregnancy be used. Renal function should be checked and women with creatinine levels greater than 120 µmol/L, a urinary albumin:creatinine ratio >30mg/mmol or a glomerular filtration rate of less than 45ml/min/1.73m² should be referred to a renal physician prior to stopping contraception use.

Women who have significant retinopathy or nephropathy should be advised that pregnancy may accelerate these pathological processes. Some women, with severe end-organ damage, such as diabetic nephropathy with glomerular filtration rate of <30%, severe cardiac damage or neuropathy, face significant maternal risk in pregnancy and may be better advised to avoid pregnancy.⁷ Due to the close association with other autoimmune disorders, some advocate screening for thyroid dysfunction.⁷

Type 2

It is estimated that there may be around half a million individuals in the UK with undiagnosed diabetes, usually type 2. Therefore, type 2 diabetes is often unrecognised prior to pregnancy and may be misdiagnosed as gestational diabetes during pregnancy. However, recent data suggest that women with type 2 diabetes have a similar increase in risk of congenital abnormality to those with type 1, at around double that of women without diabetes.⁶ Therefore, the pre-conception advice is the same as that for type 1 diabetes. This group of women is more likely to be overweight and should be helped to reduce their weight if their body mass index is greater than 27 kg/m². Women taking oral hypoglycaemic agents should have their medication reviewed. Metformin is safe to take in pregnancy so can be continued, but current advice is that other oral hypoglycaemics should be changed. Some women may achieve better control by converting to insulin, and this should be discussed with the woman.

Box 9.2 Complications of pregnancy associated with diabetes

Fetal risks

- Miscarriage
- Congenital anomaly
- Stillbirth
- Prematurity
- Macrosomia
- Shoulder dystocia and birth injury
- Respiratory distress
- Neonatal hypoglycaemia and poor feeding
- Risk of diabetes

Maternal risks

- Hypoglycaemia
- Diabetic ketoacidosis
- Operative delivery
- Worsening of retinal disease
- Worsening of pre-existing renal impairment
- Pre-eclampsia

Antenatal care

The risks and complications of pregnancy in a woman with diabetes are summarised in Box 9.2. The aim of antenatal care is to target and reduce these risks. There is no doubt that pregnant women with diabetes are best managed in a multi-disciplinary clinic involving diabetologists, obstetricians, dieticians, specialist midwives and nurses. Unfortunately, the CEMACH survey found that a third of maternity units in England, Northern Ireland and Wales did not provide such specialist services.¹ Women should be booked for care early in pregnancy, preferably before 10 weeks. An early ultrasound scan (7–9 weeks) will enable viability and dating to be confirmed. At this early appointment, a full clinical history and medication review should be conducted. If retinal or renal assessment has not occurred during the preceding 3 months, these should be arranged. NICE guidelines 2015 recommend digital imaging retinal assessment using tropicamide mydriasis both following booking and again at 28 weeks.² If there is any retinopathy present at booking, repeat assessment is recommended at 16–20 weeks. If the woman has a raised creatinine > 120mmol/l or proteinuria greater than 2g/day or a urinary albumin:creatinine ratio of >30mg/mmol then referral to a renal physician should be considered. Women with proteinuria >5g/day should be offered thromboprophylaxis. Due to the risk of pre-eclampsia, all women with diabetes should be offered 75 mg aspirin from the first trimester.⁸ The usual nutritional assessments offered to all pregnant women, including iron and vitamin D, should also be discussed.⁹

In common with all women, women with diabetes should be offered screening for Down's syndrome. The recommended first-trimester test which reaches the current required criteria of a detection rate of 75% and a false-positive rate of less than

3% is the combined test, consisting of nuchal translucency (NT), human β -chorionic gonadotrophin (β -hCG) and pregnancy-associated plasma protein A (PAPP-A). If women present too late, or the NT is unobtainable or not available, they should be offered the triple (β -hCG, unconjugated oestriol [uE_3], α -fetoprotein [AFP]) or quadruple test (triple + inhibin A) in the second trimester. The NT measurement is unaffected by diabetes. However, diabetes is associated with lower levels of AFP and uE_3 in the second trimester, hence risk adjustments need to be made. Recent data have also suggested that first trimester PAPP-A and β -hCG may be reduced, although the data are conflicting. Current practice is to reduce PAPP-A measurements in women with preexisting diabetes. Maternal weight and poor diabetic control are two factors that may also reduce the levels of these markers, thus explaining the differences between these studies.

Management of diabetic complications

The longer the duration of the diabetes, the higher the chance of a patient having pre-existing vasculopathy, renal dysfunction, neuropathy and diabetic retinopathy. The presence of these complications increases the risks of pre-eclampsia and fetal growth restriction. Pregnancy is associated with progression of pre-existing retinopathy, and this is more likely with increased severity of the pre-existing disease, duration of diabetes, poor glycaemic control and rapid improvements in control [C]. However, NICE considers that the benefits of improved glycaemic control overall outweigh the risks of progression of diabetic retinopathy² [E]. The presence of hypertension also worsens progression of retinopathy, thus it has been suggested that, in women with these complications, blood pressure should be kept at 120–130/70–80 mmHg. Beta blockers should be avoided as antihypertensives due to their possible adverse effects of glucose metabolism. There is evidence that some diabetic retinopathy may regress after delivery, but women with retinopathy should undergo further retinal assessment by 6 months postpartum.

Diabetic nephropathy is considered as a continuous spectrum from microalbuminuria, proteinuria and impaired renal function to end-stage renal disease in which there is increasing serum urea and creatinine. Overall, with the exception of women with pre-existing renal failure, nephropathy does not deteriorate with pregnancy. However, there is an increased risk of growth restriction, pre-eclampsia and preterm birth. Thus increased surveillance is required in these women.

Congenital anomalies

The CEMACH enquiry found the prevalence of confirmed major anomalies to be 41.8/1000 total births in pregnant women with diabetes.³ The commonest are cardiac abnormalities in which there is a 3 to 5-fold relative increased risk. Although caudal regression (sacral agenesis) is the most well-known associated abnormality (200-fold increased risk), the prevalence is low. Diabetes conveys a 2 to 10-fold increased risk

of neural tube defects. Thus, all women with diabetes should have a detailed fetal anatomy scan at 20 weeks, which should include the four-chamber cardiac view, 3 vessel view and the outflow tracts. NICE and SIGN currently do not recommend specialist fetal echocardiography for women with diabetes.^{2,5}

MEDICATIONS

Good glycaemic control is the key to improving the outcome of pregnancy in women with diabetes. This can be achieved using a combination of diet, insulin and oral hypoglycaemic agents.

Oral hypoglycaemic agents

The oral hypoglycaemic agents used in patients with type 2 diabetes are given in Box 9.3. With the exception of metformin and glibenclamide, there are few available data regarding the safety of most of these drugs in pregnancy, or whether they cross the placenta. Metformin is increasingly used in women with polycystic ovarian syndrome as it reduces the risk of first-trimester miscarriage and reduces the risk of developing gestational diabetes. Metformin is known to cross the placenta; use in early pregnancy does not increase the risk of congenital malformations.¹⁰ Glibenclamide may cross the placenta in small amounts and some small observational studies suggest that it may reduce morbidity and mortality in developing countries in which insulin use is impractical and expensive. Of the other sulfonylureas, chlorpropamide and tolbutamide, although probably not associated with congenital malformations, may be associated with prolonged neonatal hypoglycaemia and seizures. There are very

few data relating to the newer classes of drugs, and it is largely unknown whether drugs such as nateglinide are able to cross the placenta.

Current recommended practice is for women who conceive on oral hypoglycaemic agents to be switched to insulin therapy as soon as they are pregnant. However, there is growing interest in the use of metformin and glibenclamide in the management of type 2 diabetes or gestational diabetes. These drugs are cheaper, easier and more convenient, have less risk of hypoglycaemia and may have beneficial effects on long-term prognosis. An RCT of glibenclamide compared with insulin for the treatment of gestational diabetes found no significant differences in the major outcomes of macrosomia, blood glucose, neonatal hypoglycaemia or admissions to neonatal intensive care.¹¹ An RCT comparing metformin with insulin in gestational diabetes (MIG trial) has recently confirmed the safety and benefit of metformin treatment in women with gestational diabetes after 20 weeks' gestation.¹² Current NICE recommendations are that metformin may be considered as an alternative to insulin therapy in pregnant women with type 2 diabetes.² Individual risks and benefits should be considered and the patient should be involved in the decision. However, this remains the exception rather than the rule in current practice, with most women with pre-existing diabetes managed on insulin therapy.

Insulin

Insulin is the current recommended treatment for the majority of pregnant women with diabetes. Initially, insulin available for human use was cow or pig insulin. However, the majority of insulins in current use are recombinant insulins or their analogues. These analogues have a modified amino acid structure to improve absorption profile such that risks of hypoglycaemia are less and more stable blood glucose levels are achieved. There are four main types of insulin available for use, categorised by duration of action (summarised in Table 9.1). The newer long-acting insulin analogues may be associated with fewer hypoglycaemic episodes as they provide steady background levels without peaks. Some insulin preparations are described as biphasic as they contain a combination of

two types of insulin, for example Mixtard 30, which contains a short-acting insulin, together with intermediate insulin, given twice a day. Commonly, type 2 diabetics may be able to achieve good control following conversion from oral agents with these preparations. Insulin regimens vary with the individual, but will typically consist of a long-acting basal insulin, given once or twice a day, with additional boluses given via a pen to cover meal times. This is known as the multiple daily injection (MDI) regimen. The short acting insulins, aspart and lispro, have been associated with less hypoglycaemia, and better glycaemic control overall, therefore use of these preparations should be considered in pregnancy.²

Continuous subcutaneous insulin infusion (CSII) pumps were initially introduced in the 1970s, are growing in popularity. Regular and short-acting insulin can be delivered via a pump and the benefits include less risks of hyper- and hypoglycaemia and better compliance. Therefore, they are particularly useful in patients with unstable diabetes and troublesome hypoglycaemia. The pumps consist of a cannula that is inserted into the subcutaneous abdominal tissue (site changed every 3 days) through which a continuous basal level of fast-acting insulin is administered. Additional boluses are also given through the pump for meal times. Outside pregnancy, pumps are associated with better quality of life and better control of blood glucose. In general, studies have shown CSII is associated with improved HbA1c and lower hypoglycaemia rates, although to date minimal maternal and fetal benefits have been reported in studies of pregnancy.⁷ NICE (2015) recommends that CSII pumps be offered to pregnant women if their MDI regimen does not achieve adequate control without problematic hypoglycaemia.²

GLYCAEMIC CONTROL

Although good glycaemic control during pregnancy is likely to reduce the risks of macrosomia, stillbirth, neonatal hypoglycaemia and respiratory distress syndrome,⁵ the evidence for the timing and frequency of testing, or target blood glucose ranges, is of poor quality and at times conflicting. Although some data have suggested that obtaining good glycaemic

Table 9.1 Types of insulin

Type	Examples	Onset	Peak	Duration
Rapid acting	Lispro (Humalog) Aspart (NovoRapid) Glulisine (Apidra)	15 min	30-90 min	5 hours
Short acting	Regular	30 min	2-4 hours	4-8 hours
Intermediate acting	NPH (isophane), lente	2-6 hours	4-14 hours	14-20 hours
Long acting	Ultralente	6-14 hours	Small (or none) 10-16 hours	20-24 hours
	Glargine Detemir	1-2 hours	None	24 hours

control, as indicated by a satisfactory HbA1c level, does not reduce the risk of macrosomia,¹³ other observational studies have demonstrated that postprandial blood glucose measurements in the third trimester correlated with macrosomia [B]. The risks of respiratory distress and preterm labour also increase with worsening glycaemic control [C]. Women with diabetes also have an increased risk of stillbirth. The recent CEMACH report found that women whose babies had congenital malformations, or suffered a stillbirth or neonatal death, had worse glycaemic control (as monitored by higher HbA1c levels) throughout pregnancy³ [D]. Two small RCTs of preprandial and postprandial blood glucose monitoring have found improved outcomes in women in the postprandial group [B]. The HAPO study⁵ found that there was no threshold level of blood glucose which complications were increased and that there was a continuous linear association between blood glucose levels and complications such as macrosomia. With these reservations in mind, the NICE guidelines 2015 recommended that individualized targets for blood glucose measurements should be set with the woman, taking into account the risk of hypoglycaemia. Suggested targets for capillary plasma glucose are:

- Fasting less than 5.3mmol/l and
- 1 hour post meal less than 7.8mmol/l or 2 hours post meal less than 6.4mmol/l

Women taking insulin or glibenclamide should be advised to keep blood glucose greater than 4mmol/l.

Box 9.4 Glycaemic control – recommended levels²

Pre-conception

HbA1c <48 mmol/mol

Avoid pregnancy if HbA1c >86 mmol/mol

Aim for same capillary plasma blood glucose as recommended for all people with type 1 diabetes

Throughout pregnancy:

Fasting blood glucose <5.3 mmol/L

1 hour Postprandial blood glucose <7.8 mmol/L or

2 hour postprandial blood glucose <6.4mmol/L

Women on insulin or glibenclamide should aim to keep capillary plasma glucose level greater than 4mmol/L

Use of HbA1c not routinely recommended for monitoring

Monitoring

All women should test daily

Type 1 diabetes or those on multiple daily insulin doses:

Fasting levels

Pre meal and 1 hour after every meal

Bedtime

Those on diet, oral treatment or single insulin doses:

Fasting and 1 hour post meal

Women taking insulin should also test before bedtime

Women with type 1 diabetes should be offered ketone testing strips for use if they become hyperglycaemic or feel unwell.

Medical review on a regular basis (1–2 weekly)

Women with type 1 diabetes or those on an MDI regimen should be advised to test their fasting, pre-meal and 1 hour post meal and bedtime capillary blood glucose every day during pregnancy. Women receiving diet, oral hypoglycaemics or single daily dose insulin should also test a daily fasting glucose and 1 hour after meals.² SIGN guidelines suggest fasting levels of 4–6 mmol/L, <8 mmol/L 1 hour postprandially, <7 mmol/L 2 hours postprandially and >6 mmol/L before bed.⁵ The physiological adaptations of pregnancy result in increasing insulin requirements with gestation, and obtaining good control necessitates frequent review by a diabetic team at 1- to 2-weekly intervals.

HbA1c represents blood glucose levels in the preceding 4–12 weeks, and does not reflect subtle changes in blood glucose, in particular postprandial levels. Furthermore, it falls in response to the physiological changes in pregnancy, and the timescale may not be appropriate in pregnant women. Although American guidelines recommend monitoring HbA1c in type 1 diabetes,⁷ UK NICE guidelines (2015) and SIGN guidelines (2010) do not recommend it is used routinely to monitor blood glucose control in the the second and third trimesters. It is recommended at booking in order to determine the overall risk to the pregnancy from poor pre-existing control and can be considered for women with pre-existing diabetes to aid assessment of ongoing risk.² This is because risks increase when HbA1C is greater than 48nmol/l or 6.5%.

There is growing interest in the use of continuous blood glucose monitoring, using a subcutaneous sensor to measure interstitial blood glucose as frequently as every 10 seconds, with the aim of maintaining blood glucose within a physiological range, and avoiding the inevitable peaks and troughs that occur with intermittent monitoring. Although there is evidence for the benefit of such monitoring outside pregnancy, there are limited studies to support the use in pregnant women, although it offers a promising technology for the future.¹⁵ NICE guidelines currently do not recommend routine use of this technology, but it can be considered in women with problematic hypoglycaemia, unstable blood glucose levels or in order to gain information about blood glucose variability.²

Hypoglycaemia

Tighter glycaemic control in pregnancy is associated with an increase in the risk of hypoglycaemia. This is compounded by the fact that pregnant women also have an altered hormonal response to hypoglycaemia and reduced awareness, often worsened by pregnancy-related nausea and vomiting. Studies have shown that the highest risk time for hypoglycaemic episodes is between 8 and 16 weeks.⁷ The recent CEMACH report found that women with type 1 diabetes are much more likely to suffer recurrent hypoglycaemia (61%) than those with type 2 (21%).³ It is therefore vital that pregnant women who are taking insulin, and their families, are fully educated about the symptoms and treatment of hypoglycaemia. Women taking insulin should be advised to have a fast-acting form of glucose with them at all times and glucagon should also be provided to all pregnant women with type 1 diabetes, and the woman and her family should be educated in how to use it.² NICE

defines hypoglycaemia as a blood glucose of <3.5 mmol/L, and this level of blood glucose should be treated even if the patient is asymptomatic. If the patient is conscious, this should be by consuming 10–15 g of glucose (approximates to 4 teaspoons of sugar or half a can of juice or 3 glucose tablets). Alternatives include a glucose gel (2 tubes of HypoStop/Glucogel) which can be rubbed on the inside of the cheek. This should be followed by a slower-releasing carbohydrate such as bread or a sandwich. If unconscious, a family member can administer glucagon (0.5–1 mg) intramuscularly. This has a rapid onset and lasts approximately 90 minutes. For these reasons, it is recommended that patients carry information identifying them as having diabetes. Patients in hospital can be given 150 mL of 10% dextrose intravenously. Once a patient is conscious, they should be given oral therapy as above. If after 10 minutes the blood glucose remains less than 5 mmol/L, the treatment should be repeated. Insulin doses with the next meal should not be withheld but may require modification.

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) occurs when there is insufficient insulin to metabolise blood glucose. This can be caused by failure to appreciate the increasing insulin requirements in pregnancy, missed insulin doses or pump failure, concurrent illness such as infection, steroid therapy and stress, and is more common in pregnancy.¹⁶ It is defined as a plasma glucose over 12 mmol/L, an arterial pH of less than 7.3, with ketonuria or ketonaemia, and is associated with poor maternal and fetal outcome. CTG abnormalities are typical in the third trimester and resolve with treatment of the hyperglycaemia. Management should involve the diabetic teams and treatment of the precipitating cause, and will usually require intravenous insulin via a sliding scale. Volume replacement with careful monitoring and replacement of potassium are also needed. It is recommended that this therapy is administered within a level 2 critical care unit, where both medical and obstetric care is available. A continuous CTG may be necessary, but should be given careful consideration. CTG abnormalities are to be expected in a woman with DKA, and it would be unsafe to perform an emergency caesarean until the woman is stable from metabolic and haemodynamic perspectives. Severe hyperglycaemia requiring intensive treatment is defined as persistent pre-meal blood glucose values of greater than 12 mmol/L on 2 consecutive occasions, or a random level of more than 15 mmol/L. Involvement of diabetologists is recommended as it is important to ensure that the hyperglycaemia is at variance to the patients' usual level of control. Because of the dangers of DKA, NICE guidelines 2015 recommend that all pregnant women with type 1 diabetes should be given testing strips and a meter for blood ketones and instructed in their use. They should be advised to test if they become hyperglycaemic or feel unwell.² Similarly, a pregnant woman present with hyperglycaemia or feeling unwell should be tested for ketonaemia. Women with type 2 or gestational diabetes should be advised to seek medical advice urgently if they have hyperglycaemia or feel unwell.

Administration of corticosteroids

Corticosteroids, given to reduce neonatal morbidity and mortality associated with prematurity, almost always have an adverse effect on glucose tolerance, resulting in an increased insulin requirement in diabetic women. This can be managed by increasing subcutaneous doses, or by the use of intravenous insulin via a sliding scale.² The peaks in blood glucose usually occur between 9 and 15 hours after the first dose and 8–15 hours after the second dose. Diabetes should not be considered a contraindication to the use of antenatal steroids, but close monitoring and additional insulin will probably be needed, often requiring a sliding scale.

FETAL MONITORING

The aim of fetal monitoring is to detect the two extremes of fetal weight and to reduce the risk of stillbirth. Women, usually those with long-standing type 1 disease involving end-organ damage, are at risk of pre-eclampsia and fetal growth restriction. The CEMACH report found that the stillbirth rate after 24 weeks was 26.8 per 1000 live births and stillbirths, compared with the national background rate of 5.7 per 1000.³ The stillbirth rate varied with gestation, with 17.2% occurring at 24–27 weeks, 13.8% at 28–31, 41.4% at 32–36 weeks and 27.6% at 31–41 weeks [D]. More commonly, however, the risk is of fetal overgrowth and macrosomia.

RCOG guidelines list women with diabetes and vascular disease as having a major risk factor for the development of growth restriction.¹⁷ The odds ratio for a birthweight less than the 10th centile is 6 but with a wide 95% CI of 1.5–23.3 [D].¹⁸ This study also found a 3.5-fold (95% CI 1.28–9.53) increase in risk of pre-eclampsia. Although uterine artery Doppler at 20–22 weeks' gestation can be used to aid prediction of growth restriction, the negative likelihood ratio is not good enough to negate the risk or alter the management of regular growth scans starting from 26–28 weeks gestation. Therefore, the RCOG do not recommend uterine artery Doppler for these women.¹⁷

Fetal macrosomia, defined by either a birthweight greater than 4 kg or a birthweight centile greater than 90, is associated with increased rates of caesarean section, and birth injury such as shoulder dystocia, fractures and brachial plexus injury. Most macrosomic infants are uniformly or symmetrically large (70%), although asymmetrically large infants in whom the thoracic and abdominal circumference is greater than the head circumference are at greatest risk of shoulder dystocia.

Monitoring strategies aimed at reducing these risks consist of regular ultrasound scans and CTGs, but there is no good evidence for the use of any of these in the care of women with diabetes. CTG interpretation can be challenging as diabetes may reduce the variability and increase the baseline fetal heart rate. There may also be fewer movements and thus fewer accelerations. Therefore, patterns of change may be a better indicator of deterioration in fetal wellbeing.

NICE guidelines recommend regular ultrasound scans for growth, liquor volume and umbilical artery Doppler in women with diabetes at 4-weekly intervals, guided by findings and control of blood glucose between 28 and 36 weeks.² Ultrasound estimation of fetal weight to detect macrosomia is subject to inaccuracy, with sensitivities and positive predictive values 36–76% and 51–85% respectively, and there is evidence that this increases caesarean section rate without clinical benefit.⁵ The negative predictive value is better at 80–96%, hence there is probably a role for ultrasound in the exclusion of macrosomia. Overall, growth velocity and, in particular, crossing centiles are of use in identifying the development of macrosomia and growth restriction. Routine monitoring before 38 weeks of biophysical profile or CTG is not recommended unless there is a particular risk of growth restriction.²

MODE AND TIMING OF DELIVERY

The CEMACH enquiry found high rates of induction of labour and caesarean section in women with diabetes with

induction rates of 39% (background 21%), and a caesarean section rate of 67%³ [D]. There is evidence to suggest that induction of labour at 38 weeks may reduce the risk of shoulder dystocia in macrosomic infants of women with diabetes. An RCT compared induction with expectant management in women requiring insulin (most had gestational diabetes) and found that expectant management did not reduce caesarean section rates and increased the rates of large babies and shoulder dystocia¹⁹ [B]. A further case–control trial from Israel compared induction at 38–39 weeks with expectant management in type 1 diabetes. The rate of shoulder dystocia was lower in the induction group²⁰ [C]. Interestingly, there are also retrospective data suggesting that induction is associated with a reduction in caesarean section rates in women with diabetes [D]. Current NICE (2015) guidelines advise that timing and mode of delivery should be discussed with women with diabetes, and that women with any pre-existing diabetes without complications be offered an elective birth between 37+0 and 38+6 weeks gestation.² SIGN (2010) guidance is that women with diabetes and a normally grown baby should be offered delivery (induction or caesarean section if indicated)

Table 9.2 Example sliding scale for use during labour in pregnant women taking insulin

Hourly blood glucose (mmol/L)	Insulin rate (units per hour = mL per hour)	Other action
3.0 or less	0	Repeat glucose test, give glucose* If <3.1, check all lines and infusion pumps, call consultant
3.1–3.9	0.5	Repeat glucose test, give glucose if <4.0 and symptomatic* If hypo confirmed, check all lines and infusion pumps
4.0–6.9	1	
7.0–7.9	2	
8.0–8.9	3	
9.0–10.9	4	Call consultant
11.0–16	6	Stop dextrose, start 0.9% saline, call consultant
>16	8	Stop dextrose, start 0.9% saline, call consultant

*Treat hypoglycaemia with three glucose tablets, 60 ml lucozade or 150 ml of intravenous 10% dextrose.

- Serious clinical incidents including death have occurred with sliding-scale insulin regimens. Please follow protocol precisely.
- Setting up the insulin sliding scale should always be done in consultation with the consultant physician. Some patients required higher or lower insulin infusion rates especially if they are receiving high doses of insulin (>60 units/day).
- The insulin infusion rate should be reduced immediately after delivery – the consultant physician will advise.
- The aim is to keep blood glucose concentration between **4–7 mmol/L**.
- If blood glucose levels do not fall into the 4–7 mmol/L range after 3 hours of IV insulin contact the consultant physician, the diabetes specialist midwife or the on-call medical team.
- Set up the following infusions that can be given through the same Venflon using a Y-connector
 - IVAC Drip – 10% dextrose 500 ml at – 83 ml/h
 - Infusion syringe pump – 50 units Actrapid insulin in 50 ml 0.9% saline.
- It is very important that the lines and pumps are checked hourly, AND if there is unexplained hyper- or hypoglycaemia – failure of either IVAC pump or line can cause unexplained dangerous hyper- or hypoglycaemia.
- The rate of the insulin pump is adjusted based on hourly blood glucose measurements.

Taken from St Mary's Hospital guidelines, Central Manchester University Hospitals NHS Foundation Trust, Dr Martin Rutter and Dr Mike Maresh.

after 38 completed weeks, and certainly by 40 weeks. Women with pre-existing diabetes and any complications may need to be offered delivery before 37 weeks. Women with an ultrasound diagnosis of macrosomia should be informed of the risks and benefits of induction of labour, vaginal birth and caesarean section.² One retrospective case–control study suggested that caesarean section was safer with estimated fetal weights greater than 4.25 kg; thus some advocate this fetal weight as a cut-off, but this is poor quality data [D]. Diabetes is not a contraindication for attempting a vaginal birth after Caesarean section.

INTRAPARTUM CARE

Good control of maternal blood glucose during labour is important as maternal hyperglycaemia is associated with neonatal hypoglycaemia. Some infants produce high levels of insulin antenatally in response to high levels of glucose crossing the placenta. After delivery, there is withdrawal of the maternal glucose but a persistent high level of neonatal insulin production, resulting in neonatal hypoglycaemia. More recently, data have suggested that short-term control of maternal blood glucose, i.e. during labour, may impact on neonatal hypoglycaemia. A maternal blood glucose of greater than 7.1 mmol/L is associated with neonatal hypoglycaemia [C]. Furthermore, maternal hyperglycaemia is also associated with ‘perinatal asphyxia’ and ‘fetal distress’ [C]. Thus, current guidance is that maternal blood glucose should be kept between 4 and 7 mmol/L during labour and delivery.^{2,5} However, there are no studies investigating the best method of achieving this. Blood glucose should be tested hourly and women not maintaining their blood glucose within this range should be commenced on an intravenous insulin and dextrose infusion via a sliding scale. Sliding scales should be developed together with local diabetologists, but an example is given in Table 9.2. This may be considered at the onset of labour for women with type 1 diabetes, particularly if their oral intake is reduced. It will also be required for women delivered by elective caesarean section. However, some women, particularly those with a CSII pump, may manage the required level of control without the use of a sliding scale. Care should be taken with the use of sliding scales, and the intravenous infusions regularly checked (preferably hourly), as severe clinical incidents and death have occurred when infusions have become blocked or run too fast.

Induction of labour in women with diabetes is conducted in the same way as women without diabetes (Syntocinon infusions should be administered in saline), and NICE guidelines state that diabetes alone is not a contraindication to allowing a vaginal birth after a caesarean section.²

There are very few studies of the use of analgesia during labour and delivery. Thus NICE guidelines state that analgesia for women with diabetes should be managed in the usual way.² Diabetes may be associated with delayed gastric emptying, thus increasing risks for women requiring a general anaesthetic.

General anaesthesia also increases risks of hypoglycaemia and reduces awareness, thus these women should have blood glucose monitoring every 30 minutes until fully conscious. Since women with other co-morbidities such as autonomic neuropathy or obesity face additional risks, these women should be offered anaesthetic review during the third trimester.

POSTPARTUM CARE

With delivery of the placenta, insulin requirements dramatically decrease, thus all women will require a reduction in insulin dose. Consultant diabetologist involvement is very important at this time, and especially when the patient is converted back to pre-pregnancy insulin regimens. Advice varies regarding the subcutaneous insulin dose following delivery for women with pre-existing diabetes. Some suggest changing insulin regimens to the pre-pregnancy dosing, others suggest halving of insulin doses, and this should be carefully planned by the diabetic team. Careful capillary blood glucose monitoring is recommended to aid insulin dose adjustment for the first 2–3 days following delivery, aiming for values of 5–9 mmol/L. Hypoglycaemia is a major risk for women with type 1 diabetes at this time, especially in overweight or obese women who experience a large increase in their insulin requirements during pregnancy. Women who have undergone caesarean section will require continuation of the sliding scale until normal eating has been resumed. Women with type 2 diabetes can change from insulin back to their oral hypoglycaemic agents.

Breastfeeding

Glycaemic control is better in women who exclusively breastfeed than in those who bottlefeed [D], so overall breastfeeding should be supported.⁵ Small cohort studies have demonstrated that breastfeeding increases the frequency of hypoglycaemia in type 1 diabetics [C]. Thus women should be advised to have a snack before or during breastfeeding and be advised of this risk. Oral hypoglycaemic agents cross into breast milk in small quantities. NICE currently recommends that women with pre-existing type 2 diabetes can safely take metformin and glibenclamide while breastfeeding.²

Contraception and follow-up

Women with pre-existing diabetes should be referred back to their routine diabetic care team. Contraception should be discussed, and the need for planning of future pregnancies should be emphasised. The CEMACH report found that women with a poor obstetric outcome were less likely to receive such advice.³ UK Medical Eligibility Criteria (UKMEC) for contraceptive use should be followed and, for all hormonal methods, benefits usually outweigh risks for diabetic women in the absence of co-morbidity such as vascular disease or obesity.²¹

KEY POINTS

- Women with diabetes have poorer pregnancy outcomes than women without diabetes.
- Good glycaemic control pre-conception and in the first 8 weeks reduces the risk of congenital abnormalities.
- Pregnant women with diabetes should be managed in a joint obstetric/diabetic clinic involving the input of obstetricians, diabetologists, dieticians, specialist nurses and midwives.
- Insulin requirements usually increase during pregnancy.
- Fasting blood glucose should be less than 5.3 mmol/L.
- Postprandial levels at one hour should be less than 7.8 mmol/L.
- Tight glycaemic control results in a higher incidence of hypoglycaemia, hence education of the woman and her family about these risks is paramount.
- Diabetic ketoacidosis is associated with poor maternal and fetal outcome.
- Women with diabetes should be offered 4 weekly ultrasound monitoring of fetal growth and wellbeing, although there is no good evidence that these monitoring strategies reduce the risks of stillbirth and macrosomia.
- Women with pre-existing diabetes and no complications should be offered delivery after between 37+0 and 38+6 weeks.
- Women with macrosomia should have the risks and benefits of different modes of delivery discussed with them.
- Maternal blood glucose should be kept between 4 and 7 mmol/L during labour and delivery to reduce the risks of neonatal hypoglycaemia. This may require an insulin/dextrose infusion.
- Insulin requirements fall rapidly postnatally.
- Breastfeeding is associated with better glycaemic control and a risk of hypoglycaemia.
- All women should receive postnatal advice regarding contraception and planning of their next pregnancy.

CONCLUSIONS

Pregnancy represents a high-risk time for women with pre-existing diabetes. Management in a multidisciplinary team environment is imperative, with good glycaemic control being key to improving outcomes.

Chapter 10 Cardiac disease

Catherine Nelson-Piercy

MRCOG standards

Relevant standards

To understand and demonstrate appropriate knowledge skills and attitudes in relation to pregnant women with heart disease.

Theoretical skills

Understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of women with heart disease.

Practical skills

Be able to manage under direct supervision pregnant women with congenital, rheumatic or ischaemic heart disease, and those with:

- an artificial heart valve,
- arrhythmia,
- peripartum cardiomyopathy.

INTRODUCTION

Cardiac disease in pregnancy is rare in the UK, but common in developing countries. This chapter covers the most important conditions relevant to pregnancy, including arrhythmias, pulmonary hypertension, aortic dissection, myocardial infarction, mitral stenosis and mechanical heart valves. Peripartum cardiomyopathy is included as it is specific to the pregnant or postpartum state.

PHYSIOLOGICAL CHANGES IN PREGNANCY

Cardiac output increases by 40 per cent, reaching a maximum by the mid-second trimester. There is peripheral vasodilatation, an increase in heart rate, and a fall in systemic and pulmonary vascular resistance. Labour and delivery are associated with further increases in cardiac output. Palpitations, extrasystoles, sinus tachycardia and

ejection systolic murmurs are common in pregnancy but rarely represent underlying pathology. The ECG changes associated with normal pregnancy include atrial and ventricular extrasystoles, a 'left shift' in the QRS axis, a small Q wave and inverted T wave in lead III, and ST segment depression and T wave inversion in the inferior and lateral leads.

INCIDENCE

Although cardiac disease in pregnancy is rare (<1 per cent) in the UK, cardiac disease is the most common cause of maternal death.¹ Ischaemic heart disease is becoming more common in pregnancy, and deaths in pregnancy and the puerperium from myocardial infarction and ischaemic heart disease are increasing.¹

Congenital heart disease is encountered more frequently as those who have received corrective surgery as children reach child-bearing age. Rheumatic heart disease is less common in the UK, but is encountered increasingly in migrant women from developing countries.

AETIOLOGY

The aetiology of heart disease may be divided into congenital and acquired causes. The most common congenital heart diseases encountered in pregnancy are ventricular and atrial septal defects (VSD, ASD), patent ductus arteriosus (PDA) and aortic coarctation. These are mostly diagnosed before pregnancy and septal defects and PDA are usually either haemodynamically insignificant or corrected. Acquired causes of cardiac disease include ischaemic heart disease, rheumatic heart disease, cardiomyopathies, and aneurysms and dissection of the aorta or its branches.

GENERAL PRINCIPLES

In pregnant women with heart disease, it is important to remember that the outcome and safety of pregnancy

Table 10.1 New York Heart Association (NYHA) functional classification

NYHA	Symptoms
I	No symptoms and no limitation in ordinary physical activity
II	Mild symptoms and slight limitation during ordinary activity
III	Marked limitation in activity due to symptoms, even during less than ordinary activity. Only comfortable at rest
IV	Severe limitations. Experiences symptoms even at rest

are related to the presence and severity of pulmonary hypertension, the presence of cyanosis, the haemodynamic significance of the lesion and the functional class [D]. The functional class is determined by the level of activity that leads to dyspnoea (Table 10.1). In addition, women with previous cardiac events including transient ischaemic attacks, arrhythmia, pulmonary oedema or heart failure, and those with left-sided lesions (e.g. aortic or mitral stenosis) or myocardial dysfunction, are at risk in pregnancy.³ Women with congenital heart disease are at increased risk of having a baby with congenital heart disease, and should therefore be offered detailed fetal scanning for cardiac anomalies. During pregnancy, women with heart disease require multidisciplinary team care,² with regular antenatal visits and judicious monitoring to avoid or treat expediently any anaemia, infection or hypertension. There should be early involvement of obstetric anaesthetists and a carefully documented plan for delivery.²

PULMONARY HYPERTENSION

The most common forms of pulmonary hypertension encountered in women of child-bearing age are idiopathic pulmonary arterial hypertension, Eisenmenger's syndrome (when pulmonary hypertension develops secondary to a large left-to-right shunt such as a VSD, and the shunt is reversed to become right to left, with consequent cyanosis), secondary to chronic pulmonary thromboembolic disease, secondary to connective tissue disorders particularly scleroderma and sickle cell disease, and secondary to cardiac lesions causing raised pulmonary capillary wedge pressure such as mitral stenosis. Pulmonary hypertension from any cause is dangerous and maternal mortality is 25 to 40 per cent [D],^{4,5} although this may be decreasing.⁶ The danger relates to fixed pulmonary vascular resistance and an inability to increase pulmonary blood flow, with refractory hypoxaemia. Most pregnancy-associated deaths can be attributed to thromboembolism, hypovolaemia or pre-eclampsia.

Management

Women with pulmonary hypertension should be advised to avoid pregnancy or, in the event of unplanned pregnancy, to have a therapeutic termination [D].^{5,7} If such advice is declined, multidisciplinary care in a pulmonary hypertension centre is recommended [D].⁴ Vasodilatation therapies such as sildenafil, nebulised or intravenous prostacyclin should be continued or instituted in pregnancy as indicated. Endothelin antagonists (e.g. Bosentan) are usually avoided as they are teratogenic in rats, although it is not known whether there are similar risks in humans.

EBM

- Most published evidence relating to pulmonary hypertension comes from retrospective cohorts and case series.
- All the literature supports a high risk of maternal death sufficient to make this condition one of the absolute contraindications to pregnancy.
- There is no evidence that monitoring the pulmonary artery pressure prepartum or intrapartum improves outcome.

AORTIC DISSECTION

Aortic dissection is a common cause of cardiac death in pregnancy,¹ and pregnancy increases the risk of aortic dissection. Most cases occur in late pregnancy at or near term or in the early puerperium. Certain conditions predispose to aortic dissection. These include bicuspid aortic valve, aortic coarctation, Turner's syndrome, Ehlers–Danlos syndrome (vascular type IV) and Marfan's syndrome.⁸

Marfan's syndrome is an autosomal dominant condition with typical skeletal and other features including tall stature, a high arched palate, scoliosis and lens dislocation. Progressive aortic root dilatation and an aortic root dimension >4 cm are associated with increased risk [D].⁹ Conversely, in women with minimal cardiac involvement and an aortic root <4 cm, pregnancy outcome is good [C]. Overall, pregnancy is associated with a 5-fold increased risk of aortic complications in women with Marfan's syndrome.¹⁰

Management

Acute aortic dissection should be suspected if a woman in late pregnancy presents with severe chest or interscapular pain, particularly if associated with systolic hypertension, different blood pressures in each arm or an early diastolic murmur, especially if she has predisposing risk factors. Urgent imaging with CT, MRI or echocardiography is essential, as well as rapid and effective control of blood pressure. Women with aortic roots >4.5 cm should be advised to delay pregnancy. Management in women with Marfan's syndrome

or dilated aortic roots from other causes should include serial echocardiograms and beta-blockers. Vaginal delivery is appropriate for those with stable aortic root measurements <4.5 cm, but elective caesarean section with epidural is usually recommended if there is an enlarged (>4.5 cm) or dilating aortic root [D].⁹

EBM

- Most published evidence relating to Marfan's syndrome comes from retrospective cohorts and case series.
- The literature supports a higher risk of aortic rupture and maternal death if the aortic root is >4 cm.

MITRAL STENOSIS

Mitral stenosis is increasingly encountered in migrant women, who may or may not have had the diagnosis made prior to pregnancy.¹¹ A history of previous mitral valvotomy does not preclude restenosis. Mitral stenosis is the most common rheumatic heart disease and is important in pregnancy because women may deteriorate secondary to tachycardia, arrhythmias or the increased cardiac output. The commonest complication is pulmonary oedema secondary to increased left atrial pressure and precipitated by increased heart rate or increased volume (such as occurs during the third stage of labour) [C].¹¹ The risk is increased with severe mitral stenosis, moderate or severe symptoms prior to pregnancy, and in those diagnosed late in pregnancy [C].¹²

Management

Women with severe mitral stenosis should be advised to delay pregnancy until after balloon, open or closed mitral valvotomy or mitral valve replacement. Beta-blockers decrease heart rate and the risk of pulmonary oedema [D],¹¹ but if medical therapy fails or for those with severe mitral stenosis, balloon mitral valvotomy may be safely and successfully used in pregnancy [D].¹¹

Women with mitral stenosis should avoid the supine and lithotomy positions as much as possible for labour and delivery. Fluid overload must be avoided [E]. Pulmonary oedema should be treated in the usual way with oxygen and diuretics.

EBM

- Most published evidence relating to mitral stenosis comes from retrospective cohorts and case series.
- The literature supports a higher risk of pulmonary oedema in severe mitral stenosis.
- Beta-blockers, diuretics and balloon valvotomy are safe in pregnancy.

MECHANICAL HEART VALVES

Women with mechanical heart valves require lifelong anticoagulation, and this is the reason they have such high-risk pregnancies. Pregnancy itself increases the risk of thrombosis. Warfarin is associated with warfarin embryopathy¹³ and increased risks of miscarriage, stillbirth and fetal intracerebral haemorrhage.¹⁴ Heparin, even in full anticoagulant doses, is associated with increased risks of valve thrombosis and embolic events [C].^{13,14}

Management

The safest option for some mothers is to continue warfarin throughout pregnancy [C].^{13,14} Other management strategies include replacing the warfarin with high-dose low-molecular-weight heparin (LMWH), either from 6 to 12 weeks' gestation to avoid warfarin embryopathy or throughout pregnancy.¹⁵ Since the risk of thrombosis is less with the newer bileaflet valves (e.g. Carbomedics), and valves in the aortic position, it may be that high doses of LMWH throughout pregnancy are appropriate in women with these valves [E]. If LMWH is used, doses should be adjusted according to anti-factor Xa levels and low-dose aspirin is usually also given.¹⁵ Both strategies carry risk; with warfarin the risk is predominantly fetal and with LMWH the risk is of maternal valve thrombosis or stroke. Whichever management option is chosen, warfarin should be discontinued and substituted with LMWH for 10 days prior to delivery to allow clearance of warfarin from the fetal circulation. For delivery itself, heparin therapy is interrupted, but restarted postpartum. Warfarin is recommenced 5–7 days postpartum [E]. In the event of bleeding or the need for urgent delivery in a fully anticoagulated patient, warfarin may be reversed with prothrombinase complex and vitamin K, and heparin with protamine sulphate. If heparin is used, this should be in full anticoagulant doses, adjusted according to regular monitoring.

EBM

- Most published evidence relating to mechanical heart valves comes from retrospective cohorts and case series of women.
- The literature supports a lower risk of thromboembolic events if warfarin is continued throughout pregnancy, and a lower risk of fetal loss, fetal haemorrhage and anomalies if LMWH is used.

ISCHAEMIC HEART DISEASE/ MYOCARDIAL INFARCTION

Ischaemic heart disease in pregnancy is becoming more common as maternal age and obesity increase.^{1,16} The risk

of myocardial infarction (MI) is increased in women over 35 years old, multigravid women, those who smoke, and women with diabetes, obesity, hypertension and hypercholesterolaemia [C].¹⁶ Acute coronary syndromes may be diagnosed as in the non-pregnant patient with raised troponin levels, which are not altered by pregnancy, and ECG changes. Infarction most commonly occurs in the postpartum period. The maternal death rate is about 10 per cent.¹⁶ In pregnancy, other underlying aetiologies for MI, such as coronary artery thrombosis or dissection, are more common than outside pregnancy and should be considered [C].¹

Management

Management of acute MI is as for the non-pregnant woman [D]. Coronary angiography should not be withheld in pregnant patients. Percutaneous coronary intervention may provide a better alternative to thrombolysis in pregnancy as it is associated with less bleeding risk and also allows management of spontaneous dissections with coronary artery stents. However, stent implantation may be associated with an increased risk of coronary dissection in a vulnerable vessel [D]. For secondary prevention in women with known ischaemic heart disease, both aspirin and beta-blockers are safe in pregnancy [A]. Statins should be discontinued prior to and for the duration of pregnancy [E].

ENDOCARDITIS PROPHYLAXIS

The current UK recommendations from NICE (2008) are that antibiotic prophylaxis against infective endocarditis (IE) is not required for childbirth. The British Society for Antimicrobial Chemotherapy (BSAC 2006) and the American Heart Association (AHA) have recommended cover only for patients deemed to be at high risk of developing IE (such as women with previous IE) and for those who have the poorest outcome if they develop IE (such as those with cyanotic congenital heart disease) (see below under Published guidelines). If antibiotic prophylaxis is used, it should be with amoxicillin 2 g IV plus gentamicin 120 mg IV at the onset of labour or ruptured membranes or prior to caesarean section, followed by amoxicillin 500 mg orally (or intramuscular [IM]/IV depending on the patient's condition) 6 hours later. For women who are penicillin allergic, vancomycin 1 g IV or teicoplanin 400 mg IV may be used instead of amoxicillin.¹⁷

HYPERTROPHIC CARDIOMYOPATHY

Most cases of hypertrophic cardiomyopathy (HCM) are familial, inherited as autosomal dominant. Women may be asymptomatic, especially if diagnosed because of family screening, or may experience syncope or 'angina-like' chest pain. The danger relates to left ventricular outflow tract obstruction which may be precipitated by hypotension or

hypovolaemia. Provided that these are avoided, pregnancy is usually well tolerated. Risk factors for sudden cardiac death (SCD) are non-sustained ventricular tachycardia (VT), failure of the systolic blood pressure to rise during exercise and a family history of SCD. Beta-blockers should be continued in pregnancy or initiated for symptomatic women [D].¹⁸

PERIPARTUM CARDIOMYOPATHY

This pregnancy-specific condition is defined as heart failure secondary to left ventricular (LV) systolic dysfunction towards the end of pregnancy or in the months following delivery, where no other cause of heart failure is found. It is a diagnosis of exclusion. The left ventricle may not be dilated but the ejection fraction is always reduced below 45% [C].¹⁸ Risk factors include multiple pregnancy, hypertension, multiparity, increased age and African–Caribbean race [D].²

Diagnosis should be suspected in puerperal women or those in late pregnancy with breathlessness and signs of heart failure. It is confirmed with echocardiography showing LV dysfunction and often dilatation of all four chambers of the heart. Treatment is as for other causes of heart failure, with oxygen, diuretics, vasodilators, ACE inhibitors if postpartum and inotropes if required. Prognosis and recurrence depend on the normalisation of LV size and function within 6 months of delivery [C].^{2,18}

ARRYTHMIAS

A sinus tachycardia requires investigation for possible underlying pathology such as blood loss, infection, heart failure, thyrotoxicosis or pulmonary embolus, but no treatment is required if such causes are excluded. The most common arrhythmia encountered in pregnancy is supraventricular tachycardia (SVT). An SVT that does not respond to vagal manoeuvres may be safely terminated in pregnancy with adenosine [D] or intravenous verapamil or beta blockers.

KEY POINTS

- Heart disease is the commonest cause of maternal mortality in the UK.
- Eisenmenger's syndrome, other causes of pulmonary hypertension, severe mitral stenosis, Marfan's syndrome with marked or increasing aortic root dilatation and severe cardiomyopathy are contraindications to pregnancy.
- The safest option for some women with mechanical heart valves is to continue warfarin in pregnancy, notwithstanding the associated fetal risks.
- Antibiotic prophylaxis against endocarditis is no longer recommended peripartum in women with heart disease.

Chapter 11 Thyroid disease

Andrew Shennan and Joanna Girling

MRCOG standards

Relevant standards

- Conduct pre-pregnancy counselling to a level expected in independent primary care.
- Be able to 'recognise and manage' thyroid disease in pregnancy.

In addition, we would suggest the following.

Theoretical skills

- Understand the physiological and biochemical changes in thyroid function in pregnancy.
- Understand the fetal and neonatal implications of maternal thyrotoxicosis.

Practical skills

- Be able to recognise and diagnose hyperthyroidism in pregnancy.
- Be able to recognise and diagnose hypothyroidism in pregnancy.
- Understand the treatment options for hypothyroidism in pregnancy.
- Be aware of the fetal issues involved.

INTRODUCTION: PHYSIOLOGY OF THYROID FUNCTION

Maternal physiology

Thyroid disease occurs in more than 1 per cent of the population and is the most common pre-existing endocrine disorder in pregnant women. A fundamental understanding of thyroid function in pregnancy is essential.

Thyroid-stimulating hormone (TSH) is released from the anterior pituitary in 1 to 2-hourly cycles. It increases both the synthesis and release of thyroxine (T_4) and triiodothyronine (T_3) by the thyroid gland. The T_3 and T_4 are mostly protein bound – to thyroid-binding globulin (TBG), albumin and

transthyretin. Although the concentration of TBG is low, the binding affinity is high, and TBG binds more than 75 per cent of thyroid hormones. The unbound thyroid hormones have biological activity; only 0.04 per cent of T_4 and 0.05 per cent of T_3 are free; the bound thyroid hormones do not have biological activity.

Iodide is essential for the synthesis of thyroid hormones, and the thyroid gland actively traps iodine, which is then bound to a tyrosine molecule on a thyroglobulin molecule. Each molecule carries three or, more commonly, four molecules of iodine, making T_3 or T_4 respectively. Most circulating T_3 is produced by peripheral deiodination of T_4 , by deiodinase enzyme, and is three times more potent than T_4 . Although the production of T_3 is lower than that of T_4 , more T_3 is available as a free, inactive compound.

In pregnancy, there is altered TBG production as a result of increased oestrogen synthesis. Levels of TBG increase in the first 2 weeks of pregnancy, and triple to reach a plateau by 20 weeks, due to glycosylation that is oestrogen driven. The half-life extends from 15 minutes to 3 days in this time. The increase in TBG leads to an increase in the serum concentrations of total T_4 and T_3 , but there are no major changes in the amount of free circulating (unbound) thyroid hormones, although these must be interpreted within pregnancy-specific reference ranges.

There is relative iodine deficiency in pregnancy as a result of loss through increased glomerular filtration and increased maternal production of T_4 and T_3 . This results in increased uptake by the thyroid gland, which can result in enlargement and the appearance of a goitre. Fetal thyroid activity also depletes the maternal iodide pool from the second trimester, probably via diffusion along a concentration gradient.

As human chorionic gonadotrophin (hCG) and TSH share a common alpha subunit and have similar beta subunits, TSH receptors are prone to stimulation by hCG. In conditions such as molar pregnancy, hyperemesis gravidarum and multiple pregnancy, increased thyroid activity has been noted, associated with high levels of hCG. Even in normal pregnancy, a fall in TSH levels is associated with peak hCG concentrations, and there is a correlation between levels of T_4 and hCG. In pregnancy, there is also placental conversion of T_4 to T_3 . Low levels of T_4 will increase this activity, producing more active

thyroid hormone. Deiodination also occurs in trophoblasts, preventing excess thyroid hormone exposure to the baby and perhaps explaining the fall in T_4 found in the mother in later pregnancy.¹

Fetal thyroid function

During the first trimester, the fetus requires maternal T_4 for normal fetal brain development. It is likely that T_4 crosses the placenta in small amounts before 12 weeks' gestation to facilitate this (otherwise, T_3 , T_4 and TSH do not cross the placenta). From 10 weeks' gestation, the fetal thyroid gland produces both T_4 and T_3 . From this point onwards, the fetal thyroid axis is independent of the mother, and requires only transplacental iodine; there is little relationship between maternal and fetal thyroid hormone levels. Fetal levels reach those of the adult by 36 weeks' gestation. Although fetal TSH concentrations are greater than maternal TSH levels, T_3 is lower in the fetus, probably as a result of little peripheral conversion and a good placental barrier. Both thyrotrophin-releasing hormone (TRH) and iodine freely cross the placenta. (TRH has unsuccessfully been investigated as a method of stimulating thyroid function to enhance fetal lung maturity.)

Congenital hyperthyroidism can occur when TSH receptor-stimulating antibodies cross the placenta (see below). Very rarely, mutations of the TSH receptor result in either congenital hyperthyroidism or hypothyroidism.

Thyroid function tests in pregnancy

In pregnancy, it is important to measure free T_4 and T_3 and to base management decisions principally on these levels [C]; TSH is often suppressed, especially in the first trimester, and then can only be detected with new, ultrasensitive assays.

Pregnancy-specific reference ranges should be used: as T_4 levels fall slightly during pregnancy, the lower limit of normal for free T_4 is below that of non-pregnant women. As there is more conversion of T_4 to T_3 , low levels of T_4 are not necessarily indicative of hypothyroidism.²

Thyroid hormones are involved in the metabolism of alpha-fetoprotein (AFP), and there has been some concern that AFP measurements may be unreliable. However, in women suspected of having thyroid disease, the available evidence suggests AFP measurements can still be used if required for the quadruple Down's serum screening test [D].

AETIOLOGY AND MANAGEMENT OF THYROID DISEASE

Iodine

Women in areas of iodine deficiency may have goitres and reduced reproductive success.³ In iodine deficiency, the maternal thyroid gland has a greater affinity for iodine than

the placenta and the fetuses are thus prone to cretinism – the leading preventable cause of learning disability worldwide.

The fetal cochlea, cerebral neocortex and basal ganglia are particularly sensitive to iodine deficiency.⁴ Iodine administration prior to conception and up to the second trimester will improve neurological outcome by allowing normal thyroid hormone production by the fetus, therefore protecting the fetal brain. Iodination of water, salt or flour, or even annual injections for reproductive-age women, can easily achieve this.

The introduction of iodine supplementation in certain areas of the developing world has also reduced both the miscarriage and the stillbirth rates. However, high levels of iodine intake can cause fetal hyperthyroidism. Therefore, some cough medicines and eye drops containing iodine should be avoided, as should radiological procedures utilising iodinated contrast dyes. Similarly, amiodarone, which is rich in iodine, should be avoided in pregnancy unless absolutely necessary for life-threatening arrhythmias. In these cases, neonatal assessment must be made regarding thyroid function. Radioactive iodine, which destroys the fetal thyroid, must never be used, even in early pregnancy, as damage can occur before there is active fetal tissue.

Hyperemesis gravidarum

In women with hyperemesis, T_4 levels may be elevated with suppression of TSH. These changes probably result from high levels of hCG, particularly if there are higher levels of subtypes of hCG which have a greater affinity for the thyroid gland TSH receptor: these stimulate the TSH receptors⁵ and occur in approximately 40 per cent of hyperemesis cases (particularly in those with more severe disease). This usually resolves by 20 weeks' gestation. The clinical signs of thyrotoxicosis are generally absent and, as the condition improves, T_4 levels only remain elevated if true hyperthyroidism ensues.

Antithyroid medication should not be used in hyperemesis as the thyroid abnormality is biochemical and self-limiting and is not related to an overactive thyroid [D]. When used, this type of medication is generally ineffective or required in unusually high doses.

Hyperthyroidism

Hyperthyroidism occurs in approximately 1 in 500 pregnancies and is usually diagnosed and treated prior to the pregnancy, since untreated thyrotoxicosis is associated with reduced fertility. It is usually due to Graves' disease (autoimmune thyrotoxicosis). Less than 5 per cent of cases result from a toxic nodule, thyroiditis or a carcinoma. If pregnant women present with hyperthyroidism, hyperemesis or a molar pregnancy must be considered.

Graves' disease is associated with a hyperplastic goitre and often with exophthalmos. Disease activity and severity are correlated to immunoglobulin G (IgG) thyrotrophin (TSH) receptor-stimulating antibody titres. The immunosuppressive effect of pregnancy means that the disease typically remits in

the last two trimesters,⁶ and doses of antithyroid medication should be reduced accordingly, to minimise the likelihood of either maternal or fetal side effects; in approximately one-third of women treatment may be discontinued. Postnatally the TSH-receptor-stimulating antibody titre usually returns to its pre-pregnancy value, and so treatment needs to be restarted or the dose increased for most women.

Typical symptoms and signs of hyperthyroidism are difficult to separate from those of normal pregnancy, but poor weight gain in the presence of a good appetite or a tachycardia >100 beats per minute that is unresponsive to a Valsalva manoeuvre may indicate the disease. Onycholysis does reflect disease activity, unlike the eye signs and pretibial myxoedema, which may persist after Graves' disease has resolved. Unfortunately, many other symptoms, such as fatigue, warm peripheries, amenorrhoea, hair thinning and heat intolerance, are common in pregnancy and are not useful.

It is essential to maintain euthyroidism in pregnancy, as uncontrolled disease is associated with maternal and fetal complications, including thyroid storm, heart failure and maternal hypertension. Observational studies have reported increased rates of premature labour, growth restriction and stillbirth. Treatment is similar to that for non-pregnant women, although radioactive iodine must not be given [D]. Surgery may be considered if medical treatment fails or there is a clinical suspicion of cancer or compressive symptoms due to a goitre. With well-controlled disease, normal pregnancy outcomes can be expected.

Medical treatment involves blocking thyroid hormone synthesis. Propylthiouracil (PTU) and carbimazole both reduce the titre of TSH-receptor antibodies, directly influencing the aetiology of Graves' disease. PTU was previously the preferred therapy, as it not only inhibits T_4 synthesis by blocking the incorporation of iodine into tyrosine, but also inhibits the peripheral conversion of T_4 to T_3 . However, both drugs probably cross the placenta in the same proportion and there is no need to change from carbimazole to PTU [D]. Both drugs are equally beneficial and the dose of either can be titrated against maternal wellbeing and biochemical status [D].⁷ Neither PTU nor carbimazole is thought to be teratogenic, and indeed studies have shown that pregnancies conceived with pharmacologically achieved biochemical control have a better outcome than those that are not controlled; the relationship previously found between aplasia cutis of the scalp and these drugs is unlikely to exist. Antithyroid drugs can cause agranulocytosis and so a sore throat should prompt a full blood count.

It is recommended that thyroid function tests be performed every 4–6 weeks during pregnancy. When Graves' disease is unstable, beta blockers can be used to control the symptoms of tachycardia or tremor, and propranolol is the recommended therapy [D].

As both PTU and carbimazole cross the placenta, both may make the fetus hypothyroid.⁸ The minimal dose required in the mother should therefore be used, and it is usual to aim for free T_4 levels at the upper limit of normal [E]. Even if the

fetus does become hypothyroid, neurodevelopmental status is preserved, although careful control can still lead to neonatal hypothyroidism and even neonatal goitre. The goitres are generally small, clinically unimportant and tend to resolve within 2 weeks. No long-term fetal side effects of antithyroid drugs have been demonstrated, although the studies performed have been small and retrospective.

Both drugs are expressed in breast milk, but have little effect on thyroid function.

Fetal and neonatal hyperthyroidism

When maternal TSH-receptor-stimulating antibodies cross the placenta, they can cause fetal thyrotoxicosis, although, as many women are taking antithyroid medication which also crosses the placenta, this is relatively uncommon. Women who had their Graves' disease treated by radioactive iodine or surgery may still have TSH-receptor antibodies, but will no longer be taking antithyroid medication (and in fact are likely to be taking thyroxine), and they have a greater likelihood of developing fetal hyperthyroidism. The fetal thyroid is capable of responding to these antibodies after 20 weeks' gestation, and potential effects should be monitored in the second half of pregnancy. Assessment should include maternal perception of fetal movements, standard growth assessments (symphyseal–fundal height) and measurement of the fetal heart rate, which, if sustained above 160 beats/min, may be indicative of fetal thyrotoxicosis.

An ultrasound scan can be used to exclude a fetal goitre or clinically undetected fetal growth restriction. In suspected cases, the diagnosis can be made clinically or cordocentesis for free T_4 and TSH determination can be performed and is preferable to amniocentesis [D].

Fetal hyperthyroidism is associated with premature delivery. Fetal cardiac failure can result, leading to hydrops fetalis and death; fetal goitre can cause polyhydramnios or an obstructed delivery. The condition is also associated with craniosynostosis and intellectual impairment. The fetus can be effectively treated in one of two ways, either by maternal administration of antithyroid agents, which cross the placenta, or by delivery. The fetal heart rate can be used to titrate the dose of antithyroid drugs. The mother can be treated with T_4 to offset any hypothyroid effects, as T_4 will not cross the placenta [C]. As thyroid TSH receptor stimulating antibodies have a long half-life (3 weeks), which exceeds that of placentally transferred antithyroid medication, they can also cause neonatal hyperthyroidism. The symptoms may therefore present in the baby only after a week and tend to be non-specific, such as poor weight gain, feeding and sleeping.

A goitre may also cause problems with breathing and feeding. Untreated fetal/neonatal hyperthyroidism is responsible for substantial mortality.

TSH-receptor-stimulating antibody titres should be measured in women with active Graves' disease, as well as those whose disease was cured by surgery or radioactive iodine. As long as antibody levels are low, involvement of the fetus

is unlikely. If antibody levels are high, fetal/neonatal thyroid function should be checked, both in cord samples and in peripheral samples taken approximately a week after delivery.

Hypothyroidism

Hypothyroidism occurs in nearly 1 per cent of pregnant women and is usually due to autoimmune Hashimoto's thyroiditis or idiopathic myxoedema; the condition can also occur following treatment of hyperthyroidism. Direct pituitary causes are rare.

In pregnancies complicated by hypothyroidism, babies are normally grown and do not seem to have an increased risk of congenital anomalies. Large studies have not yet confirmed this apparent lack of adverse events. Aberrant thyroid function has been implicated in the aetiology of recurrent miscarriage, but the evidence for this is weak, and the current RCOG guidelines suggest against routine testing of thyroid function in the investigation of recurrent miscarriage.

There is a reduced intelligence quotient (IQ) in babies of women with profound hypothyroidism that is not adequately treated, or that goes unrecognised. The insult is likely to occur in the first trimester, and therefore pre-conceptual optimisation of T₄ therapy is important [D];^{9,10} ideally contraception should be used until euthyroidism is achieved. Referral to a physician or obstetrician interested in the field would seem prudent.

As hypothyroidism is associated with subfertility, it is rare to make a new diagnosis in pregnancy. The classic symptoms of hypothyroidism, such as tiredness, constipation, anaemia, weight gain, carpal tunnel syndrome and hair changes, are common in pregnancy and cannot be relied upon to discriminate onset or worsening of the disease. Treatment is with thyroxine, which is safe in pregnancy and lactation [C]. Thyroxine dose is titrated against biochemical results.

As long as the patient is clinically euthyroid, thyroid function tests should be performed every few months, such as at booking and at 28 weeks. More frequent measurements are made if the clinical or biochemical condition is deranged [E]. Most pregnant women do not need any increase in therapy [C].¹¹ Some authors have advocated a routine increase in the first trimester, but, as there have been some reports of adverse events with thyroxine therapy, such as miscarriage, it would seem prudent to titrate therapy to biochemistry.¹² A low free T₄ level indicates a need for increased therapy, rather than a raised TSH [D].¹³ Beyond the end of the first trimester, placental pharmacokinetics prevent transfer of maternal T₄, whether endogenous or exogenous, to the fetus, and therefore at this stage treatment is aimed only at normalising the biochemical picture and minimising maternal symptoms; it does not have a direct action on the fetus.

Fetal hypothyroidism

Although in Hashimoto's hypothyroidism autoantibodies cross the placenta, these do not affect fetal thyroid development. However, very rarely, TSH-receptor-blocking

antibodies can cause a transient hypothyroidism in either a fetus or a baby.

Postpartum thyroiditis

Postpartum thyroiditis (PPT) can occur up to a year following delivery and can manifest as hyper- or hypothyroidism. The incidence varies widely and, when diagnosed biochemically, has been reported to be as low as 2 per cent in New York and as high as 17 per cent in Wales. Most women will not have clinically apparent disease, and may present with depression or be diagnosed as having Hashimoto's hypothyroidism as they tend to present to general practitioners, who may be unaware of PPT. Women on long-term T₄ treatment following an onset soon after pregnancy should have this diagnosis considered.

The condition is thought to be autoimmune and presents postpartum following a return to normal immunity after delivery. Ninety per cent of women will have thyroid antiperoxidase antibodies (compared with 10 per cent of the normal population). Histology from thyroid biopsies suggests a chronic thyroiditis with lymphocytic infiltration but not fibrosis (which is a typical feature of Hashimoto's thyroiditis).

The disease may present initially between 1 and 3 months postpartum with thyrotoxicosis and later with hypothyroidism. Radioactive iodine or technetium uptake tests can help distinguish between postpartum thyroiditis (low uptake) and Graves' disease (high uptake), but lactation should not continue during testing [D]. If symptomatic with hyperthyroidism, beta blockers can be used; antithyroid drugs are inappropriate, as T₄ production is not increased [D]. Hyperthyroidism is due to destruction of thyroid follicles and the release of pre-formed hormones. The destruction of thyroid follicles ultimately leads to the hypothyroid phase, which is more likely to be associated with symptoms such as tiredness and cold intolerance, and even a goitre. At this stage, the differential diagnosis includes Hashimoto's thyroiditis and Sheehan's syndrome. A course of T₄ may be necessary. If the symptoms of hypothyroidism are due to Hashimoto's thyroiditis, withdrawing treatment will result in relapse, but cessation of T₄ is probably the only way to avoid unnecessary long-term treatment.

The period of hypothyroid state is variable, and permanent hypothyroidism can result (approximately 5 per cent of antibody-positive postpartum thyroiditis sufferers). The condition will recur in 70 per cent of future pregnancies and women with postpartum thyroiditis should be followed up to ensure that permanent hypothyroidism does not occur [E]. This would usually involve annual TSH and T₄ measurement.

THYROID CANCER IN PREGNANCY

Thyroid cancer is two to three times more common in women than men, and 50 per cent of cases occur within the reproductive age group. Pregnancy itself does not appear to influence the survival rates of women diagnosed with thyroid cancer. It is recommended that pregnancy should be delayed after treatment with radioactive iodine, probably for a period of a year

[D], in view of the higher incidence of congenital anomalies that follow this treatment.

If a pregnant woman presents with a thyroid nodule, thyroid function tests and an ultrasound are indicated. Thyrotoxicosis occurring with cystic nodules is unlikely to be malignant, but other nodules should be investigated with a fine-needle aspirate. Cellular cytology from a fine-needle aspirate may suggest an underlying malignancy, and serial ultrasound should be performed. Removal of nodules that are increasing in size should be considered. A thyroidectomy can be performed, usually in the second trimester of pregnancy. If radioactive iodine is required, this should not be administered during pregnancy or breastfeeding [D].

Thyroid globulin concentration cannot be used to detect a relapse of thyroid cancer in pregnancy, as it is already elevated. Women on suppressive doses of T_4 may continue this therapy, with the usual aim of reducing TSH to undetectable levels.

KEY POINTS

- Management decisions should be based on free T_4 and T_3 measurements in pregnancy; T_4 is found at the lower limits of normal in pregnancy and trimester-specific reference ranges should be used for all assessments of thyroid function in pregnancy.
- Management of hypothyroidism should be optimised prior to conception, and pregnant women may need to alter their dose of thyroxine from early pregnancy.
- Forty per cent of women with hyperemesis gravidarum have elevated T_4 (and suppressed TSH); they do not require antithyroid treatment. This will usually resolve by 20 weeks' gestation.
- Graves' disease is the most common cause of hyperthyroidism, and euthyroidism should be maintained in pregnancy with antithyroid drugs. Thyroid status should be checked every 4–6 weeks. Treatment can be reduced in the third trimester to prevent fetal hyperthyroidism, then restored postnatally.
- Women with hypothyroidism should be euthyroid prior to conception to avoid intellectual impairment in the baby. The fetus requires maternal thyroxine in early pregnancy.

Chapter 12 Haematological conditions

Sarah Wharin and Sue Pavord

MRCOG Standards

Knowledge: Understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of haemoglobinopathies. Understand genetic modes of inheritance, common genetic conditions, the importance of screening and the diagnosis thereof.

Clinical competency: Diagnose, investigate and manage, with direct supervision, maternal haemoglobinopathies.

Professional skills and attitudes: Demonstrate an ability to explain correctly and place in context for the woman principles of screening for haemoglobinopathies.

INTRODUCTION

Over the last two decades there has been increasing recognition of the impact of haematological conditions on pregnancy, delivery and the puerperium. However in many areas there is a lack of evidence to guide practice. Established standards for haematological conditions relate mainly to haemoglobinopathies. For the other topics, we have suggested points for guidance and identified key areas of knowledge and technique.

NORMAL HAEMATOLOGICAL CHANGES IN PREGNANCY

Red cells

During pregnancy, blood volume increases by around 1500 mL. Plasma volume expands by 25–80%, approximately twice the simultaneous expansion in the red cell mass. This results in a net reduction in haemoglobin (Hb) concentration, despite the 10–15% rise in Hb mass. There is a small physiological rise in the mean cell volume (MCV) due to increased red cell production and a higher proportion of larger immature erythrocytes.

Increased leukocyte production in pregnancy is manifest by a 'left shift', with increased band forms and the occasional presence of more immature neutrophil precursors. This is most marked in the third trimester and peaks at delivery. Lymphocytes are

slightly reduced in number and monocytes increase, whilst the eosinophil and basophil counts remain the same.

Platelets

The platelet count usually remains constant but around 6% of women develop a gestational thrombocytopenia in the second half of pregnancy, related to increased peripheral clearance of platelets and a shorter platelet lifespan. The investigation and management of thrombocytopenia in pregnancy are covered later in the chapter.

Haemostasis

Pregnancy confers a hypercoagulable state which persists for up to 12 weeks postpartum. This is secondary to physiological changes in all elements of the haemostatic system, preparing the body for delivery. The haemostatic system is a fine balance between mechanisms to form a platelet-fibrin plug, mechanisms to control and localise its formation, and mechanisms to break it down. The main changes in the coagulation factors, natural anticoagulants and fibrinolytic system are outlined below in the Key Points.

KEY POINTS: NORMAL CHANGES TO HAEMATOLOGICAL PARAMETERS IN PREGNANCY

Red cells: \uparrow plasma volume $>$ \uparrow red cell mass = \downarrow Hb
 \downarrow haematocrit \uparrow MCV

White cells: \uparrow white cell count: \uparrow neutrophils, \uparrow monocytes \downarrow lymphocytes

Platelets: \downarrow platelet count in around 6% of women

Routine coagulation tests: \downarrow PT, \downarrow APTT

Coagulation factors: \uparrow factors VII, VIII, fX, fibrinogen and von Willebrand's factor. Possible rise in fII and fIV

Anticoagulants: \downarrow protein S, activated protein C resistance
 \uparrow fibrin but \downarrow fibrinolytic activity \uparrow D-dimers

Whilst these normal physiological changes provide some protection against haemorrhage at delivery, they can have a detrimental effect for some women if they result in venous thromboembolism. The risk is particularly high around the time of delivery and persists for a number of weeks after.

HAEMOGLOBINOPATHIES

Background

The haemoglobinopathies are inherited disorders of Hb synthesis and are largely classified into those that display a qualitative defect in the globin chains, namely sickle cell disease, or those with reduced synthesis of globin chains, thalassaemia.

Epidemiology

Haemoglobinopathies are most common in people whose family origins are in Africa, the Caribbean, the Middle East and Mediterranean areas, and hence are becoming more prevalent in the UK as the world's population becomes more mobile. It is estimated that sickle cell diseases affect one in every 200 births in the UK and 240,000 people are carriers. Beta-thalassaemia affects more than 700 people in the UK and the carrier rate is around 214,000.¹

Normal Hb structure

Haemoglobin A (HbA) consists of 2 alpha chains and 2 beta chains ($\alpha_2\beta_2$). In the adult, HbA makes up 95% of red cell haemoglobin. Up to 3% is HbA2 ($\alpha_2\delta_2$), and a small amount of fetal Hb ($\alpha_2\gamma_2$) persists into adulthood. HbA is the predominant haemoglobin by 3 months of age and reaches adult levels by 9 months of age. Alpha-chains are coded for by a total of four genes, i.e. two from each parent. These are found on chromosome 16. The beta-chain is encoded for by two genes, one from each parent, found on chromosome 11.

Thalassaemia pathophysiology and clinical features

Thalassaemia is a quantitative defect in Hb production and includes alpha-thalassaemia and beta-thalassaemia. Some mutations cause complete absence of globin chain synthesis, denoted α^0 or β^0 , whilst others produce chains at a reduced rate, α^+ or β^+ .

Alpha-thalassaemia

If four affected alpha genes are inherited, no alpha chain is produced and Hb Barts, with four gamma chains, accumulates in red blood cells. The extremely high affinity for oxygen makes it incompatible with life, and death from hydrops fetalis occurs shortly before or after delivery. Conversely inheritance of only one abnormal gene is not associated with morbidity and the blood count may be completely normal. Two affected genes gives rise to alpha-thalassaemia trait, with hypochromic, microcytic anaemia. Three affected genes (two from one parent, one from the other) lead to an accumulation of beta- globin chains known as HbH bodies. This results in chronic haemolysis, anaemia and splenomegaly. Patients are usually transfusion dependent and susceptible to haemolytic crises, often triggered by infection.

Beta-thalassaemia

One abnormal beta gene gives rise to an asymptomatic carrier state: β -thalassaemia trait. Two defective genes results in clinical disease, with varying phenotype depending on the underlying mutations. This ranges from mild anaemia requiring only occasional blood transfusion (β -thalassaemia intermedia) to transfusion dependence (β -thalassaemia major) and the consequent iron accumulation in the heart, liver and endocrine system. Iron chelation therapy is necessary to prevent death from cardiac failure.

Management of pregnant women with thalassaemia

Physiological haemodilution of pregnancy exacerbates the anaemia of thalassaemia but women with thalassaemia trait usually remain asymptomatic. A serum ferritin is required to exclude coexisting iron deficiency, which should be treated with iron supplements. Iron should not be given to women with HbH disease who are at risk of iron overload, particularly if receiving blood transfusion. The chronic haemolysis renders them folate depleted and folate supplements should be routine. Pregnancy is uncommon in transfusion-dependent thalassaemia major and there are few data to guide management. However, with advances in iron chelation, fertility and life expectancy have improved over recent years and successful pregnancy outcomes are possible if women are adequately transfused and chelated prior to conception.² Complications predominantly relate to iron overload, particularly cardiomyopathy, and transfusion-related issues. Risks to the fetus include an increased incidence of intrauterine growth restriction (IUGR) and early and late pregnancy loss.^{3,4}

Prior to pregnancy in women with β -thalassaemia major, iron chelation therapy should be optimised, to minimise organ dysfunction. Assessment of hepatic and cardiac function should be performed, the latter with T2-weighted magnetic resonance imaging (MRI). Iron chelation is potentially teratogenic and should be discontinued.

Blood count, serum ferritin and liver function tests should be monitored regularly throughout pregnancy, as well as serial growth scans. Transfusion regimens may need

KEY POINTS: MANAGEMENT OF THALASSAEMIA IN PREGNANCY

- Partner testing and prenatal diagnosis
- Echocardiogram to assess ventricular function
- Monitor full blood count (FBC) and ferritin. Transfuse as required
- Serial growth scans
- Give extended phenotype blood due to the risk of alloimmunisation
- Monitor liver function tests (LFTs).

altering to minimise large fluid shifts and iron chelation therapy may be necessary at delivery to reduce the toxic effect of free iron on the fetus.

Sickle cell disease pathophysiology and clinical features

Sickle cell disease (SCD) is caused by the production of defective beta chains due to a single amino acid shift in the beta-globin gene from glutamine to valine. Sickle cell anaemia (HbSS) is the most common of the sickling disorders. However SCD is also caused by a combination of sickle haemoglobin in the heterozygous state with a thalassaemia or another haemoglobin variant. Significant sickling syndromes occur with HbSC, HbS β -Thal, HbSD^{Punjab}, HbSLepore, HbSE and HbSO^{Arab}. The prevalence of SCD varies geographically and is classically associated with areas where malaria is endemic. Highly prevalent areas include West and Central Africa, Asia, the Caribbean and northern Greece.

When Haemoglobin Sickle [HbS] is in a deoxygenated state, it forms large polymers with other Hb tetramers. This leads to 'sickling' of the red cells which are more rigid and less 'deformable' in the circulation. The consequences of this are vaso-occlusion and a state of chronic haemolysis. Patients encounter 'crises' which can be vaso-occlusive (painful), aplastic (characteristically triggered by parvovirus B19 infection), acute chest syndrome and splenic sequestration (predominantly in children). Situations in which sickling increases include hypoxia, hypothermia and acidosis. The clinical manifestations of SCD are vast and are largely the consequence of vaso-occlusive disease. Heterozygous HbS carriers are usually asymptomatic.

Fig. 12.1 Blood film of a patient with HbSS during a sickle crisis. Note the presence of numerous sickle cells, polychromasia and nucleated red cells

KEY POINTS: SICKLE CELL DISEASE

Chronic complications

- Haemolytic anaemia
- Hyposplenism and increased risk of infection
- Bone disease
- Renal disease
- Retinopathy
- Neurological
- Thromboembolic disease
- Pulmonary hypertension
- Hepatobiliary disease

Acute crises

- Painful (vaso-occlusive)
- Chest syndrome
- Splenic sequestration (infants)
- Aplastic crisis

Prenatal diagnosis and counselling

Any woman who has a haemoglobinopathy or is a known carrier should ideally undergo prenatal counselling in a specialist centre. Possible risks of pregnancy to the mother and the fetus should be outlined and the option of pre-implantation genetic diagnosis discussed.

Screening

Due to the increasing incidence of haemoglobinopathies in the UK population and the resulting morbidity, a screening programme was initiated in 2005 and updated in 2011.⁵ The aim of the programme is to detect women who are carriers of a thalassaemia or Hb variant and thereby assess their risk of having an affected child. Mother and partner testing should be completed before 12 weeks' gestation, to allow the parents enough time to make a decision regarding prenatal diagnosis. Antenatal screening is offered to all women; the exact method varies depending on whether the area has a high or low prevalence of haemoglobinopathies. In high-prevalence areas, FBC and haemoglobin analysis via high pressure liquid chromatography (HPLC) are performed on all women in conjunction with a family origin questionnaire. In low-prevalence areas, FBC is performed initially, with a family origin questionnaire and HPLC undertaken if the fetus is deemed to be at risk. β -thalassaemia is suspected if red cell indices are hypochromic (mean corpuscular Hb [MCH] <27) and microcytic (MCV <75 fL) in conjunction with a raised HbA₂. Alpha-thalassaemia trait results in similar red cell indices but a normal HbA₂. A family origin questionnaire

will identify if the woman is from a high-risk population group for alpha-thalassaemia. Haemoglobin variants, such as HbS, HbE or HbD Lepore, will be detected by HPLC. Any abnormal results should prompt partner testing to assess potential risk to the fetus. If the child is at risk, prenatal testing should be offered; the usual method of choice is chorionic villous sampling in the first trimester.

Sickle cell disease in pregnancy

There are 150–250 deliveries each year in women with sickle cell disease.⁶ SCD in pregnancy has consequences for both the mother and the fetus; maternal morbidity and mortality are significantly higher than those for healthy women. Painful episodes may become more common, particularly in the third trimester, and the risk of infections and thromboembolic disease is amplified. A recent nationwide surveillance study of pregnant women with SCD in the UK over a 12-month period found that 52% suffered a painful crisis, with 25% requiring admission to hospital (Fig. 12.1).⁶

Anaemia is exacerbated by physiological changes and increased maternal demands, and cardiac complications are increased by pulmonary hypertension and iron overload. Specific obstetric complications include an increased risk of pre-eclampsia and antepartum haemorrhage, and the rate of miscarriage, intrauterine growth restriction and neonatal death is substantially increased.⁷ These complications are less apparent in HbSC disease.⁸

Management in pregnancy

Health should be optimised before pregnancy and iron overload aggressively treated with chelation prior to conception. An up-to-date echocardiogram should be performed to look for evidence of pulmonary hypertension. Vaccinations must be up to date. Hydroxycarbamide should be discontinued at least 3 months prior to conception and ACE inhibitors or ARBs should be stopped.

Routine antenatal care

During pregnancy, women should be cared for by a specialist obstetric haematology team, where available. The increased incidence of infections, painful crises and acute chest syndrome should be discussed, highlighting the need to avoid triggering factors such as cold, exertion and dehydration, and to seek medical attention early if pain is not relieved by simple analgesia or vomiting occurs, increasing the risk of dehydration and subsequent crisis. Three litres of oral fluid is needed daily, due to the reduced ability of the kidneys to concentrate urine.

Full blood count, renal and liver function tests, and serum ferritin should be performed at booking, with urine dipstick

for blood and protein. These should be repeated regularly throughout the course of the pregnancy. Blood group and antibody screen are important to exclude alloimmune antibodies caused by blood transfusion. Continued folic acid 5 mg daily and phenoxymethylpenicillin prophylaxis should be ensured.

Sickle cell disease is a risk factor for pre-eclampsia and women should receive aspirin prophylaxis.⁹ A large study of 18,000 deliveries to SCD mothers in the USA showed that these women had a six-fold increased risk of venous thromboembolic disease.¹⁰ It is therefore recommended that these women receive graded compression stockings and thromboprophylaxis during hospital admissions and the postpartum period.¹¹

KEY POINTS: SICKLE CELL DISEASE IN PREGNANCY

- Pre-conception counselling
- Partner testing and prenatal diagnosis
- Folic acid, phenoxymethylpenicillin for all women
- Avoidance of triggers
- Treat infections early
- Consider aspirin and LMWH
- Monitor FBC, ferritin, urea & electrolytes (U&Es), urine dip
- 4-weekly growth scans after 20/40

Women should be offered a viability scan at 7–9 weeks, routine first-trimester scan at 11–14 weeks and a detailed anomaly scan at 20 weeks. Thereafter, 4-weekly growth scans should be performed.¹¹

Blood transfusions

There is little evidence to support prophylactic blood transfusions, with no apparent improvement in morbidity in mother or fetus.¹² If blood is transfused it should be matched according to an extended phenotype, and should be cytomegalovirus (CMV) negative and sickle negative.

Management of acute painful crisis (Box 12.1)

Women need to be admitted and assessed immediately and managed by obstetric and haematology teams. They should be offered adequate analgesia, working up the analgesia ladder. NSAIDs can be given between weeks 12 and 28. Pethidine should be avoided due to the risk of seizure but other strong opioids such as morphine may be given. Particular attention needs to be paid to treatment of infection, prevention of dehydration with intravenous fluids and early detection of acute chest syndrome. Supplemental oxygen should be given to treat

Box 12.1 Management of an acute crisis

- Early and frequent analgesia
- Maintain good hydration and oxygenation
- Treat any underlying infection
- Monitor Hb; top-up transfusion may be required
- Early recognition of chest syndrome
- Thromboprophylaxis during inpatient stay

hypoxia and close liaison with critical care teams should be maintained. Top-up transfusions and possibly exchange transfusion may be required. Consideration should be given to early delivery at 38–40 weeks. Mode of delivery should be decided by obstetric factors. Women need to be closely monitored with pulse oximetry and kept well hydrated. Thromboprophylaxis is essential postnatally.

PLATELET DISORDERS IN PREGNANCY

Platelets are formed from megakaryocytes, which are large multinucleate cells found in the bone marrow. Their differentiation and proliferation is under the control of

Box 12.2 Causes of thrombocytopenia in pregnancy

- Gestational thrombocytopenia
- Isoimmune (idiopathic) thrombocytopenic purpura (ITP)
- Pre-eclampsia
- Haemolysis, increased liver enzymes and low platelets (HELLP) syndrome
- Disseminated intravascular coagulation
- Thrombotic thrombocytopenic purpura
- Haemolytic uraemic syndrome
- Antiphospholipid syndrome (APLS)

Box 12.3 Investigation of thrombocytopenia in pregnancy

- Full history and examination
- Blood film
- Prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen
- Liver function tests
- Reticulocyte count
- Haptoglobin, lactate dehydrogenase (LDH)
- Consider systemic lupus erythematosus (SLE) serology
- Consider APLS screen
- Hepatitis/HIV serology

thrombopoietin. Each megakaryocyte can generate 2000–3000 platelets. Thrombocytopenia in pregnancy is relatively common and there are a number of possible causes. Platelet function disorders are less common but do occur so will be covered briefly.

Thrombocytopenia in pregnancy

Thrombocytopenia affects 6–10% of all pregnant women and after anaemia is the most frequent haematological disorder in pregnancy. There are many possible causes, some specific to pregnancy and others that can also occur in the non-pregnant population (Boxes 12.2 and 12.3).

Gestational thrombocytopenia

Gestational thrombocytopenia (GT) is the most common cause of thrombocytopenia and accounts for 75% of the cases.¹³ The fall in platelet count is secondary to haemodilution and increased platelet activation and clearance. Inevitably, as the platelet count falls in pregnancy, some will fall into the thrombocytopenic range. In these patients, the platelet count outside pregnancy is normal and it usually resolves 1–2 months postnatally. The platelet count usually remains above $70 \times 10^9/L$ and it is diagnosed after other causes of thrombocytopenia have been considered. It is often not possible to distinguish between GT and mild ITP and the platelet count should be monitored 4 weekly throughout pregnancy. Affected women do not suffer with bleeding symptoms, there is no associated morbidity in the fetus and the risk of neonatal thrombocytopenia is not increased.

Fig. 12.2 ITP; note normal red cell morphology

Immune thrombocytopenia

Immune thrombocytopenia (ITP, Fig. 12.2) affects 1 in 1000–10,000 pregnancies.¹⁴ It occurs as a first presentation in a third of cases and as a relapse in women with pre-existing disease in the other two-thirds. Unlike GT, the platelet count can fall significantly and these women may suffer associated symptoms of mucosal bleeding. It may present at any point in pregnancy and, unlike gestational thrombocytopenia, may present in the first trimester. Investigations may be necessary to exclude alternative diagnoses or associated conditions.

The aim of management in ITP in pregnancy is to control bleeding symptoms and to allow for a safe delivery. Bleeding symptoms rarely occur with a platelet count $>20 \times 10^9/L$ and therefore asymptomatic women with platelet counts above this threshold are unlikely to require treatment in the first two trimesters. Treatment should be initiated if bleeding or excessive bruising occurs or the platelet count falls $<20 \times 10^9/L$. Around the time of delivery, the platelet count needs to be raised to a threshold to ensure minimal haemorrhagic complications. There should be close collaboration of the obstetricians, the haematologist and the obstetric anaesthetist. A platelet count of $>50 \times 10^9/L$ is acceptable for a vaginal delivery or caesarean section; however, whilst there is no evidence base, it is recommended that the platelet count should be $>75 \times 10^9/L$ for spinal anaesthesia.¹⁵

First-line treatment of ITP in pregnancy is corticosteroids, which achieve good response in 70–80% of women. Side effects include increased risk of gestational diabetes, pregnancy-induced hypertension and postpartum psychiatric disorders. Steroids are not teratogenic but may be associated with premature rupture of membranes and placental abruption. To avoid unnecessary adverse effects, the minimal therapeutic dose possible should be used, with dose escalation if response is poor. An appropriate starting dose of prednisolone is 20 mg daily.¹⁵

For refractory cases, or where a rapid increase in platelet count is required, intravenous immunoglobulin (IVIg) can be given (1 g/kg). Women often report headaches and more serious complications, such as aseptic meningitis and renal impairment, have been known. Although vigorous viral safety measures are ensured, women should be counselled about the use of blood products. The rise in platelets lasts around 6 weeks but this can become shorter as pregnancy advances. The cost is high and shortage of supply not infrequent.

There is some experience of using anti-D but higher doses are needed than for prevention of rhesus D (RhD) alloimmunisation and there is concern about theoretical risk of fetal haemolysis. It does not appear to add any advantages over IVIg except perhaps the lower volume. Azathioprine appears to be safe in pregnancy (teratology information service) and can be helpful for persistent or refractory disease; however, full effect takes 3 months, limiting its value if started late in gestation. Platelet transfusions are reserved for emergency bleeding or for delivery of women with platelet counts $<50 \times 10^9/L$. The response is brief due to clearance by the circulating antibody.

Transplacental transfer of maternal antiplatelet antibodies may cause thrombocytopenia in the infant. The incidence is around 25%;¹⁶ however, severe thrombocytopenia is uncommon. Approximately 15% of neonates will have platelet counts of <100 , $<10\%$ have platelet counts $<50 \times 10^9/L$ and the incidence of neonatal intracranial haemorrhage or other haemorrhagic complications is $<1\%$. There are no reliable factors that predict the risk to the baby other than the occurrence in an older sibling,¹⁷ where the ability for transplacental passage of the antibody has clearly been demonstrated. Other alarm bells are a history of splenectomy and severe and/or refractory ITP.

Cordocentesis is not recommended as the risks outweigh the benefits, given that the random platelets transfused will be rapidly destroyed by antibody (in contrast to fetal alloimmune thrombocytopenia, where compatible platelets can be used). The mode of delivery should be determined by obstetric indications. However to minimise trauma, fetal scalp electrodes, blood sampling and use of Ventouse or rotational forceps should be avoided. Lift-out forceps can be used.

A cord platelet count should be taken and intramuscular vitamin K withheld until the count is known, or given orally. A count $<70 \times 10^9/L$ necessitates a repeat sample at day 5, when the nadir is reached due to splenic development. Babies with a platelet count of $<30 \times 10^9/L$ require platelet transfusion and intracranial ultrasound performed.

KEY POINTS: MANAGEMENT OF ITP IN PREGNANCY

Should be managed in collaboration with obstetrician, haematologist and anaesthetist.

Desired platelet counts

First and second trimester: Treatment only required if platelet count is $<20 \times 10^9/L$ or patient is symptomatic.

36 weeks onwards: Treatment required if platelets $<50 \times 10^9/L$.

Vaginal delivery: Platelet count $>50 \times 10^9/L$.

Caesarean section: Platelet count $>50 \times 10^9/L$.

Spinal anaesthesia: Platelet count $>75 \times 10^9/L$.

Maternal treatment strategies

First-line treatment: Corticosteroids.

Second-line treatment: Intravenous immunoglobulin.

Emergency/rapid response required: Platelet transfusion + IVIg + IV methylprednisolone.

Management of fetus

Routine cordocentesis not recommended.

Avoid fetal scalp sampling.

Avoid Ventouse and rotational forceps.

Check FBC from cord sample.

Intracranial Doppler in the neonate if platelet count $<30 \times 10^9/L$.

Fig. 12.3 TTP; schistocytes (red cell fragments), polychromasia and spherocytes

Pre-eclampsia and HELLP

Consumptive thrombocytopenia occurs in around 30% of women with pre-eclampsia and may precede other signs and symptoms. HELLP is the combination of thrombocytopenia with microangiopathic haemolytic anaemia and elevated liver enzymes. These disorders are discussed in detail in other chapters.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP, Fig. 12.3) is a relatively rare but important cause of thrombocytopenia in pregnancy as it carries a high mortality and morbidity rate which can be avoided if treatment is started early. It is defined by the combination of microangiopathic haemolytic anaemia and thrombocytopenia, usually accompanied by neurological symptoms and sometimes fever. Renal impairment can also occur. In the acute setting, TTP can be difficult to distinguish from severe pre-eclampsia and HELLP and, like these disorders, the main therapeutic manoeuvre is to deliver the baby.

TTP is caused by reduced levels of ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13), a metalloprotease required for the cleavage of ultra-large von Willebrand's factor (vWF) multimers. This leads to the formation of platelet aggregates in the microvasculature, leading to tissue ischaemia and sometimes infarction. This process particularly affects the lung, renal and cerebral vasculature. Most cases are acquired, with an auto-immune antibody to ADAMTS-13; however, some cases are familial and may present for the first time in pregnancy.

The mortality rate of untreated TTP is 80% which reduces to around 10% with plasma exchange, with intracerebral and cardiac events being the main cause of death. A high index of suspicion is crucial to ensure rapid diagnosis and treatment. If

KEY POINTS: TTP IN PREGNANCY

Clinical:	<p>Typical 'pentad' of fever, renal impairment, neurological symptoms, thrombocytopenia and microangiopathic haemolytic anaemia.</p> <p>May be difficult to distinguish from pre-eclampsia and HELLP.</p> <p>Obstetric emergency: up to 90% mortality rate if left untreated.</p>
Investigations:	<p>FBC and film: schistocytes (fragments), polychromasia, thrombocytopenia.</p> <p>U&Es, LFT (↑ bilirubin), LDH (↑), reticulocytes (↑), haptoglobin (↓).</p> <p>Clotting (will be normal in TTP).</p> <p>The Direct Antiglobulin Test (DAT) (will be negative in TTP).</p> <p>ADAMTS-13 level and ADAMTS-13 antibody (ADAMTS-13 level may be low in HELLP but with no antibody detected).</p>

Continuing:	<p>Start folic acid 5 mg once daily.</p> <p>Start aspirin and LMWH when platelets are >50.</p> <p>Continue plasma exchange until platelet count is normal.</p> <p>If fetus not delivered immediately, serial growth scans with uterine artery Doppler.</p>
Future:	<p>Warn about risk of recurrence in future pregnancies.</p> <p>Avoid oral contraceptive pill.</p>

any doubt remains regarding the diagnosis, an ADAMTS level should be taken and plasma exchange initiated until the diagnosis can be definitively confirmed or refuted. If there is likely to be a delay in starting plasma exchange, solvent-treated fresh frozen plasma (FFP) should be infused, to provide the missing protease.

Plasma exchange needs to continue daily, in addition to corticosteroids. Folic acid supplements are necessary to support erythropoiesis and thromboprophylaxis with LMWH and aspirin should be started as soon as the platelet count is $>50 \times 10^9/L$. Serial growth scans with uterine artery Doppler will be required to monitor placental function and the fetus should be delivered as early as possible. Recovery after delivery

of the baby is not necessarily prompt and repeated plasma exchanges are necessary until the platelet count normalises. Women should be counselled about the risk of recurrence in further pregnancies and should be advised to avoid the oral contraceptive pill.

Platelet function disorders

Congenital platelet function disorders reflect the inability of platelets to aggregate under normal conditions, or the defective release of platelet granule constituents. Pre-conception counselling is necessary to explain the risks of inheritance where these are known and the management for pregnancy. The clinical picture in these disorders is very variable and ranges from asymptomatic mild mucosal-type bleeding to a severe bleeding phenotype. The description of the individual disorders is beyond the scope of this chapter; however patients should be managed in close liaison with a haematologist. Desmopressin (trade name DDAVP) is usually the agent of choice and, as these are heritable conditions, care should be taken in the delivery of the baby.

Alloimmune conditions in pregnancy

Blood group antigens are found on the red cell surface. The ABO and Rh groups of antigens are the most clinically significant in clinical transfusion practice. There are numerous other red cell antigens and these can become more significant in multiply transfused patients and during pregnancy. Platelets also have antigens on their cell surface and both red cell and platelet antigens are inherited in a mendelian fashion. Fetal red cells and platelets therefore express both maternal and paternal antigens. As maternal circulation is in contact with fetal cells, maternal antibodies can be formed against the paternally derived antigens, if they are not present on maternal cells. Red cell alloimmunisation can result in fetal or neonatal haemolytic disease. Alloimmunisation against fetal platelet antigens can cause fetal or neonatal alloimmune thrombocytopenia.

Red cell alloimmunisation and haemolytic disease of the fetus and newborn (HDFN)

Maternal antibodies to paternally derived fetal red cell antigens may cross the placenta and coat fetal red cells, leading to their destruction. If this process exceeds the rate at which erythropoiesis occurs in the fetus, anaemia ensues. This can lead to heart failure, oedema and, in the most severe cases, hydrops fetalis and fetal death. Severe haemolysis can occur in neonates, with a risk of kernicterus as the immature liver is unable to process the unconjugated bilirubin.

The most significant antibodies are anti-D, anti-C and anti-K, of which anti-D is the most common and will be the

Box 12.4 Antenatal 'sensitising' events with risk of isoimmunisation

- Miscarriage or threatened miscarriage >12 weeks' gestation
- Medical or surgical termination of pregnancy at any gestation
- Ectopic pregnancy
- Hydatidiform mole
- Prenatal diagnostic procedures: chorionic villous sampling (CVS) or amniocentesis
- Abdominal trauma
- External cephalic version
- Antepartum haemorrhage
- Stillbirth
- Traumatic delivery including caesarean section
- Manual removal of placenta

focus of this text. The D antigen is one of the Rh group of antigens, formally known as rhesus antigens. Most RhD-negative women have a complete absence of the RhD antigen whilst a small minority have a qualitative or quantitative deficiency of the D antigen, known as partial D or weak D respectively. In the UK, 10% of deliveries are RhD-positive babies born to RhD-negative women. In one in six RhD-negative women, isoimmunisation will occur after delivery of an RhD-positive baby.

Isoimmunisation is precipitated by fetomaternal haemorrhage (FMH). Most commonly this is at delivery and, in the majority of cases, HDFN does not affect the first pregnancy but is a risk for subsequent pregnancies. However, as little as 0.25 mL of fetal blood can be sufficient to cause isoimmunisation and, in order to prevent this, anti-D should be given to the mother after all potentially sensitising events (Box 12.4).

Anti-D is a virally inactivated, plasma-derived product from US donors. A dose of 500 units of anti-D will neutralise an FMH of up to 4 mL. For women with sensitising events before 20 weeks' gestation 250 IU is sufficient. For events after 20 weeks' gestation 500 IU should be administered immediately, within 72 hours,¹⁸ with further doses depending on estimation of the size of the FMH.

Estimation of fetomaternal haemorrhage

Estimation of FMH should be undertaken:

- in an RhD-negative woman following delivery of an RhD-positive baby;
- following any sensitising events after 20 weeks' gestation.

estimation for FMH is not required when:

- events occur before 20 weeks' gestation;
- the fetus is known to be RhD negative;
- the mother is RhD positive;
- the mother is known to have immune anti-D.

Two main methods exist for estimating FMH.

Kleihauer (acid elution method). Fetal haemoglobin (HbF) is more resistant than adult haemoglobin (HbA) to acid and alkali conditions. Dried maternal blood is fixed and exposed to acid; the HbA is denatured and eluted leaving 'red cell ghosts'. The HbF remains and can be stained, allowing estimation of the fetal red cell volume. This method detects the presence of fetal cells but does not distinguish between RhD-positive and RhD-negative cells.

Flow cytometry method. This test is performed after Kleihauer, to confirm the volume of FMH and determine whether the fetal cells are RhD positive or negative. A fluorochrome is conjugated to an IgG antibody which recognises the RhD antigen. If flow cytometry is negative when a Kleihauer test is positive, it suggests that the fetus is RhD negative. Unfortunately this test is not readily available in all centres.

If the FMH is estimated to be <2 mL by Kleihauer test, 500 IU anti-D is sufficient and no further action is required. If the FMH is >2 mL, the volume should be confirmed by flow cytometry. If the FMH is >4 mL, a further dose should be calculated on the basis that 125 IU anti-D will neutralise 1 mL of FMH. Follow-up testing should be performed after 72 hours to confirm that the fetal cells have been cleared.

Postnatal anti-D

The guideline published by the British Committee for Standards in Haematology (BCSH)¹⁹ states that every RhD-negative woman should receive at least 500 IU of anti-D within 72 hours of delivery of an RhD-positive baby. However 1% of women will have an FMH of >4 mL and therefore it is important to be able to accurately estimate the FMH volume and a maternal blood sample for FMH estimation should be sent within 2 hours.¹⁸ Some centres give a single anti-D 1500 IU dose postnatally, which is adequate to neutralise a 15 mL bleed; however, some FMH are >15 mL.

A fetal cord blood sample should also be sent to confirm the infant's blood group and Rh status. If the pregnancy is non-viable and fetal blood sampling is not possible, anti-D should be given to an Rh-negative non-sensitised mother within 72 hours of the diagnosis of fetal death, regardless of the timing of delivery.¹⁹ If the Kleihauer test estimates an FMH of >2 mL, this should be confirmed by flow cytometry and additional anti-D should be administered if required. Follow-up testing should be performed 72 hours after the dose.

If intraoperative cell salvage (ICS) is used during caesarean section, a dose of at least 1500 IU of anti-D should be given. This is to allow for the fact that, during ICS, fetal cells can be re-infused into the maternal circulation and a dose of up to 20 mL has been reported. Estimation of FMH should then occur 35–40 minutes after re-infusion of red cells to establish whether any further anti-D is required.¹⁹

Sensitising events prior to 20 weeks' gestation

Prior to 12 weeks' gestation anti-D is required after surgical evacuation of the uterus, termination and ectopic pregnancy. Spontaneous miscarriage does not require anti-D

prophylaxis if there is no instrumentation of the uterus and if there is only mild painless bleeding. However, a recent update of the BCSH guidelines state that anti-D should also be given before 12 weeks if there is prolonged heavy bleeding or bleeding accompanied by abdominal pain.¹⁹ Anti-D is required following a spontaneous miscarriage after 12 weeks' gestation.

KEY POINTS: MANAGEMENT OF SENSITISING EVENTS IN RHD-NEGATIVE WOMEN

- <20 weeks' gestation: administer 250 IU anti-D within 72 hours.
- >20 weeks' gestation: administer 500 IU anti-D and perform estimation of FMH.
- If FMH >4 mL, administer 125 IU for each additional 1 mL.
- Re-check FMH estimation after 72 hours to ensure neutralisation of fetal red cells.

Sensitising event after 20 weeks' gestation

Prophylaxis should be given for any sensitising event after 20 weeks' gestation at a dose of 500 IU. FMH should then be estimated. For recurrent intrauterine bleeding after 20 weeks' gestation, women should receive anti-D at least 6 weekly. An FMH sample should be tested 2 weekly and, if positive, extra anti-D should be given.¹⁹

Routine antenatal anti-D prophylaxis (RAADP)

In addition to overt clinical events, it became clear that isoimmunisation can result from occult, low-volume FMH occurring in normal pregnancy. RAADP has been shown to significantly reduce rates of sensitisation²⁰ and NICE now recommend RAADP for all RhD-negative women.

Anti-D prophylaxis can either be given as a single dose of 1500 IU at 28 weeks or as two separate doses of 500 IU at 28 and 34 weeks' gestation with no evidence of difference in efficacy.¹⁸ RAADP should still be offered if prophylactic anti-D was administered earlier in pregnancy after a sensitising event and, conversely, prophylactic anti-D still needs to be administered after sensitising events even if RAADP has been given previously.

It is important to note that passive anti-D can be detected up to 8 weeks post-prophylaxis and laboratory tests are unable to distinguish between passive and immune anti-D. Therefore if anti-D has been given early in pregnancy, anti-D antibodies may be detected at the 28-week routine screen. Passive anti-D is usually <1 IU/mL. If there is doubt, the woman should be treated as non-immune and RAADP should continue.

Management of alloimmunisation

Despite efforts with prophylaxis, isoimmunisation may still occur. This is usually because guidelines for RAADP have not been followed, women fail to attend in a timely manner after sensitising events, 'silent' FMH occurs before 28 weeks' gestation or a woman has been exposed to Rh antigens during transfusion. If immune anti-D is detected, close monitoring in a fetomaternal medicine unit is needed. Investigations should be undertaken to try to determine the cause of the immune anti-D and to assess the risk of haemolytic disease of the newborn (HDFN) in the current pregnancy. This involves a full history of previous pregnancies, transfusion history and testing of the partner to determine heterozygosity or homozygosity for the RhD antigen. The level of the anti-D antibody at booking can give valuable information regarding the risk of HDFN. If it <4 IU/mL, HDFN is unlikely; if >15 IU/mL, there is a high risk of hydrops. The antibody level should be monitored closely throughout pregnancy: 4 weekly to 28 weeks' gestation then 2 weekly thereafter.

The Rh status of the fetus should be determined if the father is heterozygous or if he is not available for testing. This is achieved by testing for free fetal DNA in maternal blood. This can be done from the first trimester but testing is more sensitive and therefore usually performed after 16 weeks' gestation.

Fetal anaemia can be predicted by measuring fetal blood flow velocity in the middle cerebral artery (MCA) by Doppler. It is a non-invasive yet accurate and sensitive test which detects fetal anaemia in the early stages. If there is evidence of anaemia, fetal blood sampling is undertaken and an intrauterine transfusion (IUT) programme initiated. IUT is particularly hazardous prior to 20 weeks' gestation and carries a mortality rate of around 10%. After 20 weeks' gestation the risk of fetal loss, membrane rupture, fetal bleeding or bradycardia is around 2–4%. Blood used for IUT should be cross-matched against the maternal blood and should be CMV negative, irradiated and less than 5 days old. The transfused blood should have a haematocrit of >75–80% to reduce the volume of transfusion and should be given at a rate of <5 mL/min. The mother is usually sedated for the procedure. Transfusions may need to be repeated every 2–3 weeks until 34–36 weeks' gestation, at which point delivery should be arranged. Close communication should be maintained with the neonatology team.

After delivery, the infant should have cord blood sent for grouping, direct coombs' test (DCT) and bilirubin level. Phototherapy may be required and, in severe cases, exchange transfusion may be necessary. Exchange transfusions can be very hazardous for the baby and should be avoided if possible. IVIg may reduce the need for exchange transfusion.²¹ The baby may need repeated transfusions over the first 4–6 months of life as maternal antibodies circulate for 4–6 months and normal erythropoiesis may be suppressed by the newborn and intrauterine transfusions. Parents should be carefully counselled about the risk of recurrence in subsequent pregnancies.

KEY POINTS: MANAGEMENT OF ANTI-D DURING PREGNANCY

- Management by fetal–maternal medicine unit.
- Quantify anti-D level at booking.
- Establish RhD status of father with full genotype.
- If father is heterozygous for RhD, establish RhD status of the fetus by testing free fetal DNA in the maternal blood after 16 weeks' gestation.
- If the fetus is RhD positive, monitor anti-D levels at 4-weekly intervals until 28 weeks' gestation then 2 weekly thereafter.
- Perform MCA Doppler ultrasound at 20 weeks' gestation.
- If evidence of anaemia arrange fetal blood sampling and IUT programme.

Other clinically significant red cell antigens causing haemolytic disease of fetus and newborn (HDFN)

Anti-C antibodies and anti-K antibodies can also cause significant HDFN, with the latter suppressing erythropoiesis as well as causing increased haemolysis. If detected at booking, a similar approach should be taken as with detection of anti-D antibodies. The father should be typed and, if heterozygous or not available, the fetal red cells should be typed from a maternal blood sample. Presence of fetal anaemia should be monitored with MCA Doppler ultrasound from 20 weeks' gestation and an IUT programme initiated if necessary. Other antibodies at high titre of more than 1:32 dilution may result in neonatal anaemia.

Fetal maternal alloimmune thrombocytopenia

Fetal maternal alloimmune thrombocytopenia (FMAIT) is the most common cause of severe fetal and neonatal thrombocytopenia and of intracranial haemorrhage in term neonates. It results from the formation of maternal antibodies against the fetal platelet alloantigens that are paternally derived. Transplacental passage of the maternal IgG antibody can cause thrombocytopenia in the fetus or neonate. It is thought to affect 1:1000 pregnancies. The most common platelet antigens implicated in FMAIT are HPA-1a, which accounts for 80% of cases, and HPA-5b, which accounts for 15% of cases. Two per cent of mothers are homozygous for HPA-1b and therefore lack the HPA-1a antigen. Only 10% of these will form anti-HPA-1a antibodies. Unlike HDFN, approximately 50% of cases of FMAIT occur in the first pregnancy.

The most severe complication of FMAIT is intracranial bleeding which may occur *in utero* or after birth. This complicates 10% of cases and often results in death or long-term neurological damage. In most other cases, there is a finding of severe thrombocytopenia in an otherwise well baby with

Table 12.1 Clinical and laboratory diagnosis of FMAIT

FMAIT diagnosis	
When to suspect FMAIT in the fetus	When to suspect FMAIT in the newborn
Previous history of neonatal thrombocytopenia	Incidental finding of neonatal thrombocytopenia
Fetal intracranial haemorrhage, hydrocephalus or ventriculomegaly	If there are signs or symptoms of bruising, bleeding or unexplained intracerebral haemorrhage
Family history of FMAIT	Platelets $<50 \times 10^9/L$ with otherwise normal counts and absence of other causes of neonatal thrombocytopenia – sepsis, DIC, maternal ITP
Unexplained late fetal loss	
Samples required for diagnosis	
Maternal	6 mL EDTA blood for analysis of platelet antigens + 6 mL clotted blood for antibody detection
Paternal	6 mL EDTA blood for platelet antigen analysis
Neonate	1 mL EDTA for analysis of platelet antigens

- DIC, disseminated intravascular coagulation; EDTA, Ethylenediaminetetraacetic acid .

purpura or bruising. The platelet nadir is usually around day 3–4. The condition is self-limiting and usually resolves within 2–8 weeks. The presence of anti HPA-1a antibodies results in a more severe clinical picture than HPA-5b antibodies.

Investigation and management of FMAIT

Diagnosis (Table 12.1) requires the demonstration of maternal platelet antibodies that react against platelet-specific antigens present in the father and neonate but not in the mother. Samples therefore need to be sent from both parents and the neonate to the transfusion laboratory.

In a term healthy infant platelet transfusions should be given to maintain the platelet count $>30 \times 10^9/L$. The platelets should be kept higher at $50 \times 10^9/L$ in the presence of bleeding

Table 12.2 Risk of FMAIT in subsequent pregnancies

Risk to fetus	History of older sibling
Standard	Neonatal thrombocytopenia with no ICH
High	ICH occurring in third trimester
Very high	ICH occurring before 28 weeks' gestation

or in preterm infants. HPA-1a- and -5b- negative platelets will be compatible with 90–95% of cases of FMAIT and should be used in preference to random platelets, which would be destroyed by maternal antibody in the neonate. Platelets should also be irradiated and CMV negative.

Information must be given to the parents about FMAIT, in particular the risk of recurrence in future pregnancies and the antenatal management options. It should be suggested that female relatives of the mother are also tested. Paternal testing for the HPA antigen should be performed to see if the father is homozygous or heterozygous for the causative HPA antigen.

Management of subsequent pregnancies

The rate of recurrence in subsequent pregnancies is 75–90% and, with each subsequent affected pregnancy, the thrombocytopenia usually occurs earlier in gestation and unfortunately tends to be more severe. The risk of intracranial haemorrhage (ICH) following a previous pregnancy of FMAIT with ICH is estimated to be around 70%. Women should be managed in a hospital with a dedicated fetomaternal medicine unit and in collaboration with a haematologist.

Fetal blood sampling (FBS) and intrauterine platelet transfusions used to be the mainstay of treatment but, given the associated morbidity and fetal mortality, focus has diverted to maternal treatment early in gestation, to control antibody production. There is much debate regarding the agents given, the exact timing of treatment and whether or not FBS should be performed. Practice varies between centres but, as there is good correlation between the severity of FMAIT in siblings, most stratify risk according to the history of the older sibling, as shown in Table 12.2.²²

Treatment comprises IVIg with or without steroids. Berkowitz *et al.* randomised high-risk women to receive IVIg alone or combined with prednisolone 1 mg/kg per day and found a satisfactory increase in platelet count, by 20 weeks, in 89% on combined therapy compared with 35% with IVIg alone ($P=<0.05$).²³ No differences were seen in responses of standard-risk women. A management model that avoids fetal blood sampling has been proposed by Pachecho *et al.*²² (Fig. 12.4).

Intrapartum management

There is debate regarding the optimal route of delivery, however, vaginal delivery is considered safe if the fetal platelet count is $>100 \times 10^9/L$. In cases where the fetal platelet count is $<50 \times 10^9/L$, the options are to perform a caesarean section or allow normal vaginal delivery within 5 days of an intrauterine platelet transfusion. If the fetus is to be delivered vaginally, trauma should be minimised with avoidance of Ventouse, rotational forceps, scalp monitoring and fetal blood sampling.

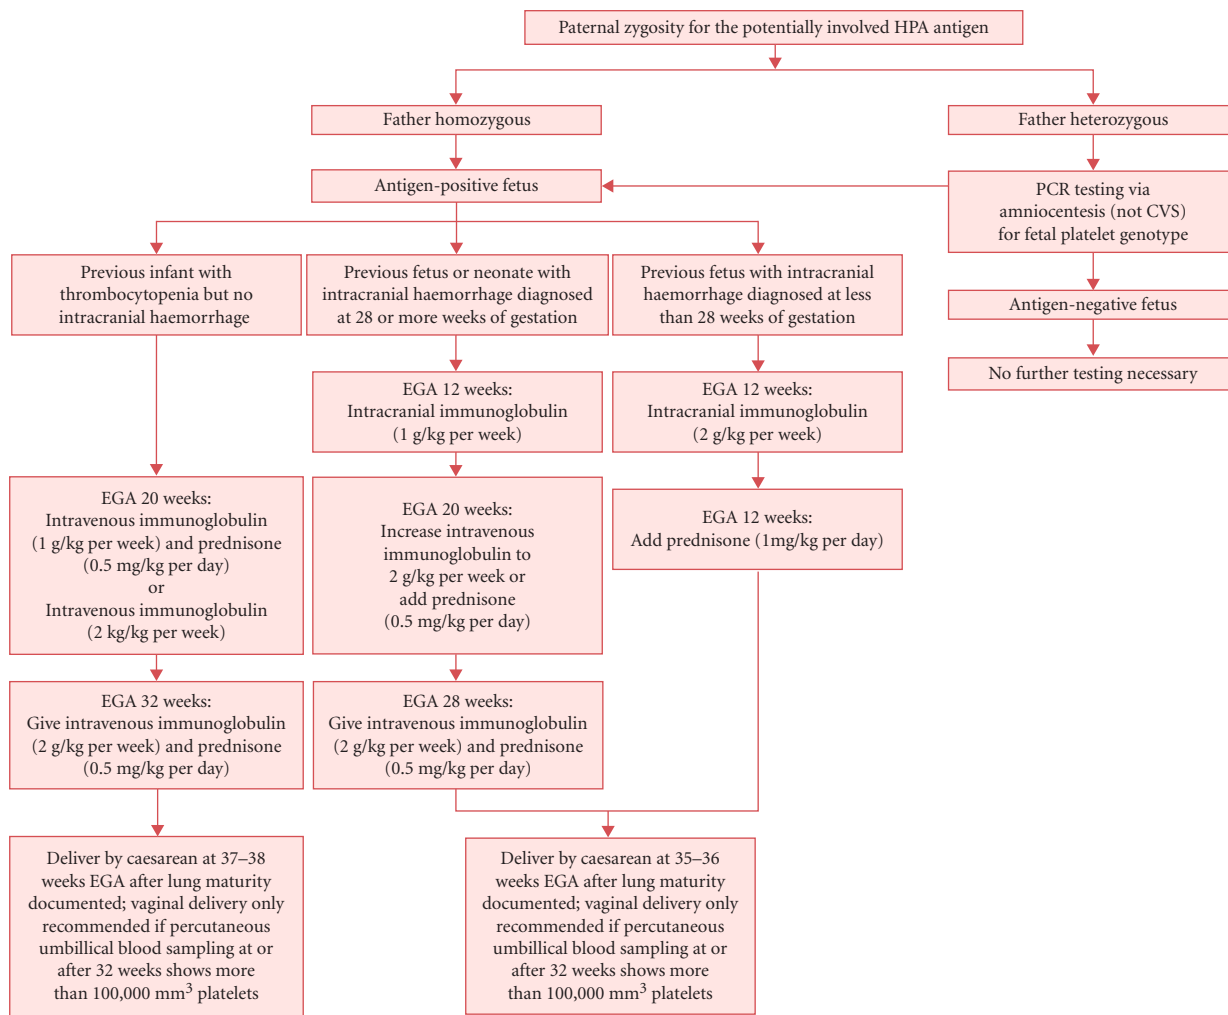

Fig. 12.4 Algorithm for antenatal management of FMAIT.²²

INHERITED BLEEDING DISORDERS IN PREGNANCY

Managing women with bleeding disorders in pregnancy is challenging. Attention must be given to prevention of bleeding complications in the mother as well as considering the risk of inheritance and bleeding for the baby. Conditions that are considered here are disorders of primary haemostasis including

von Willebrand’s disease and platelet function disorders, and inherited coagulation defects, including haemophilia A and B and the rare coagulopathies.

Von Willebrand’s disease

Von Willebrand’s disease (vWD) is the most common inherited bleeding disorder, with an incidence of around 1% of the population. VWF is a large multimeric glycoprotein required for platelet adhesion. It also acts as a carrier for factor VIII, maintaining its stability in the circulation. There are three main types of vWD: type 1 is due to a quantitative reduction in vWF levels and accounts for around 80% of cases of vWD; type 2 is due to a functional deficiency in vWF and is subdivided by the particular defect. These types have autosomal dominant inheritance but clinical penetrance is variable and the severity of bleeding problems is not consistent in family members. Type 3 vWD is characterised by complete absence of vWF, due to autosomal recessive homozygosity or compound heterozygosity.

KEY POINTS: VON WILLEBRAND’S DISEASE

- Type 1:** Quantitative deficiency of vWF
- Type 2:** Qualitative deficiency of vWF
- Type 3:** Complete absence of vWF
- Laboratory diagnosis:** APTT may be normal.
Test for vWF:Ag, factor VIII, vWF:RCO, vWF:CBA.

Symptoms consist of mucosal bleeding and bleeding after surgery or trauma associated with failure of primary plug formation. Most affected individuals will be diagnosed in childhood, but in some women, childbirth may present the first significant haemostatic challenge.

Laboratory tests show reduced vWF antigen (vWF:Ag), with or without accompanying low factor VIII levels and reduced functional ability of vWF with ristocetin (vWF:RCo) and collagen-binding activity (vWF:CBA). In type 1 disease, both the vWF level and function are reduced in parallel. In type 2 disease the vWF:RCo is disproportionately reduced.

Management of von Willebrand's disease in pregnancy

Patients should be managed in conjunction with a haemophilia centre. VWF and fVIII levels rise from 6 weeks' gestation and often reach three times their baseline level by delivery. For most patients with type 1 disease, this rise is significant, enough to bring their vWF levels into the normal range, so that no special precautions are required for delivery.

Pre-pregnancy care

Management should begin with pre-pregnancy counselling of the couple, outlining the inheritance patterns and potential risks to the mother and fetus. Individual bleeding risk and response to treatment should be assessed. Women should be warned about the potential need for plasma products during delivery and consented appropriately. Antenatal diagnosis is not usually offered owing to the mild bleeding phenotype in these disorders, except where both parents have the condition and the baby is at risk of type 3 vWD.²⁴ Women should be vaccinated against hepatitis A and B if this has not already been done.

Antenatal care

Given the physiological rise in vWF in pregnancy, many women with type 1 disease will achieve levels of above 50 IU/dL, which is the lower limit of normal. vWF levels, including vWF:Ag, factor VIII and ristocetin cofactor activity (RiCof) should be performed at booking, at 28 weeks' gestation and prior to any invasive procedures. If the levels have risen adequately, no further testing is required. However, if levels are below 50 IU/dL, testing should be repeated at 34 weeks.

Treatment options for vWD in pregnancy

Treatment options include DDAVP or plasma concentrates. DDAVP is a synthetic vasopressin (antidiuretic hormone) analogue and stimulates the release of vWF multimers from endothelial cells. It can be given intravenously or subcutaneously. A trial of DDAVP should be done before pregnancy to assess its utility in each individual case. It is particularly useful in patients with type 1 vWD, but may also be beneficial in some patients with type 2 disease, although the release of abnormal vWF means that the functional deficit may not be

overcome. It should not be used in type 2B, which is associated with increased platelet binding, as it may exacerbate the thrombocytopenia. It is of no use in type 3 vWD. It is also contraindicated in patients with arterial disease or pre-eclampsia as there are reports of myocardial and cerebral infarction. Due to the antidiuretic effect, DDAVP will cause fluid retention and women should be advised to restrict their fluid intake to only quenching thirst, for 24 hours.

In cases where DDAVP is contraindicated, or does not produce significant improvement in vWF levels or where the response is unknown, factor concentrates will be required. There are a number of virally inactivated plasma-derived vWF/FVIII concentrates available. Treatment should be given 1 hour preoperatively or at the onset of established labour.²⁴

KEY POINTS: MANAGEMENT OF PREGNANCY IN WOMEN WITH vWD

Pre-pregnancy:	Pre-conceptual counselling with inheritance risk. Discuss prenatal diagnosis in severe cases. Assess maternal bleeding risk and treatment options. Perform DDAVP trial in type 1 and type 2 disease. Consent for use of plasma products. Ensure immunity against hepatitis A and B.
Antenatal:	Check vWF levels at booking, 28 weeks and 34 weeks if low. Cover procedures with DDAVP or factor concentrates if vWF or vWF:RCo <50 IU/dL. Form an intrapartum care plan.
Intrapartum:	Maintain levels >50 IU/dL. Avoid fetal scalp monitoring, Ventouse, rotational forceps.
Postnatal:	Risk of delayed PPH so monitor bleeding symptoms and Hb in all cases and vWF levels in severe cases. Tranexamic acid 1 g three times daily for 2 weeks.
Neonate:	Minimise trauma at birth. Avoid intramuscular vitamin K. Test cord blood for vWF:Ag and vWF:RCo. Consider cranial ultrasound scan in affected infants.

Intrapartum management

Particular risks for the mother in the intrapartum period include postpartum haemorrhage (PPH) and perineal haematoma. The consensus expert opinion is that both vWF:Ag

and vWF:RCo should be above 50 IU/dL for safe vaginal delivery or caesarean section.²⁵ Due to the risk of intracranial bleeding in the fetus, traumatic delivery should be avoided as far as possible. Prolonged labour, fetal scalp monitoring and vacuum extraction or rotational forceps should be avoided.

Postpartum management

Factor VIII and vWF levels can fall rapidly postpartum, occurring between 24 hours and 2 weeks. Women with vWD are therefore at risk of delayed postpartum haemorrhage and this occurs in 20–25% of cases. The average time of presentation of PPH in women with vWD is 10–20 days. The risk of PPH can be reduced by active management of the third stage of labour and by minimising perineal trauma. Women should be warned of the risk of delayed bleeding and advised to seek help early. Hb should be monitored and oral tranexamic acid given for 2 weeks. Those with type 2 and type 3 disease will need close observation with measurement of vWF levels. Women with type 3 disease or those who have a caesarean section should continue to receive treatment for 7 days after delivery.

Diagnosis of vWD in the neonate

A cord blood sample should be tested for vWF:RCo and oral vitamin K should be given in place of intramuscular vitamin K while the result is awaited.

Haemophilia

Haemophilia is the clinical syndrome produced by the deficiency of either factor VIII (haemophilia A), or factor IX (haemophilia B or Christmas disease). The genes for both factor VIII and IX are found on the X chromosome and the disorders are X-linked recessive. Therefore males are clinically affected and females are carriers. Females may have reduced factor levels due to a skew in the X-chromosome inactivation (unbalanced lyonisation). The incidence of haemophilia A is 1:5000 male births and 1:30,000 for haemophilia B.

Haemophilias can be classified according to the residual activity of the coagulation factor in question, which is also predictive of their bleeding symptoms:

Mild: >5%

Moderate: 1–5%

Severe: <1%

Patients with mild haemophilia are likely to bleed in response to trauma or other haemostatic challenges but spontaneous bleeding is rare. In contrast, boys with severe

haemophilia suffer with spontaneous major bleeding events affecting joints and muscles, resulting in chronic joint arthropathy, if attention is not given to effective prophylaxis.

Haemophilia in pregnancy

Pregnancy should be managed in a comprehensive care centre by a team of obstetricians, haematologists and anaesthetists who are experienced in managing patients with haemophilia and where there is 24-hour access to suitable laboratory facilities. Good communication between these teams and the neonatologist is paramount. There should be a written intrapartum care plan accessible to all staff involved with the patient's care.

Levels of factor VIII rise steadily in pregnancy from 6 weeks, therefore most women with low factor VIII will have achieved normal levels by delivery. Factor IX levels remain unchanged and women with low levels are likely to need treatment around the time of delivery.

Pre-pregnancy management

The risk of inheritance should be discussed with the parents prior to conception. Female carriers of the haemophilia gene have a 50% chance of having an affected male and a 50% chance of having a daughter who is a carrier. Sons born to affected males are not affected but daughters are obligate carriers. The severity of the bleeding pattern tends to follow in family lines and therefore it can be predicted whether the child will be mildly, moderately or severely affected. The role of prenatal diagnosis should be discussed. Fetal sex can be determined by maternal blood sampling, testing circulating fetal DNA for Y-chromosome-specific sequences.²⁶ This can be done from 7 weeks' gestation and will obviate the need for further investigations in female fetuses.

If prenatal diagnosis is not wanted, fetal sex should be determined at the anomaly scan as this information is vital for the intrapartum care plan. For male fetuses some centres also perform third-trimester amniocentesis to determine the presence of haemophilia.²⁴

Antenatal management

The mother should have her factor VIII levels checked at booking then again at 28 weeks' gestation. If levels are still low, they should be re-checked at 34 weeks' gestation. Factor IX levels do not change and therefore need to be checked only at booking. Factor levels should also be checked before invasive procedures such as amniocentesis or CVS or if there is spontaneous abortion or termination of the pregnancy.

Treatment options

DDAVP will usually give a significant rise in factor VIII levels, unless baseline levels are <15 IU/dL, in which case factor VIII concentrates may be required. DDAVP does not affect factor IX levels and women with low factor IX levels will need

KEY POINTS: HAEMOPHILIA

Genetics: X-linked recessive, males are affected, females are carriers.

Clinical: Classified as mild, moderate or severe. Muscle and joint bleeds, bleeding after trauma.

Haemophilia A: Deficiency in factor VIII.

Haemophilia B: Deficiency in factor IX.

treatment with factor IX concentrates. Recombinant factor concentrates are the treatment of choice.

Intrapartum management

Expert consensus opinion is that factor levels should be >50 IU/dL for vaginal delivery and caesarean section. The level should be brought to >100 U/dL pre-delivery and maintained at >50 U/dL for 3–5 days post-partum. If the fetus is considered to be at risk, fetal trauma should be minimised by avoiding fetal blood sampling, fetal scalp electrodes, Ventouse delivery and the use of mid-cavity and rotational forceps.²⁷

The use of spinal anaesthesia is controversial in women with bleeding disorders due to the risk of spinal haematoma; however, if the factor level is >50 U/dL, it is not contraindicated.

It is equally important for factor levels to be sufficient when removing a spinal catheter, therefore levels should be rechecked prior to removal.

Postnatal management

The risk of PPH can be reduced by active management of the third stage of labour. One study of female haemophilia carriers found the rate of primary and secondary PPH to be 19% and 2% respectively.²⁸ Factor levels should be maintained for 3 days postpartum and for 5 days in women who have had a caesarean section. Tranexamic acid may be useful to reduce bleeding symptoms. Care must be taken to maintain levels <100 U/dL as there is an increased thrombotic risk with levels above this threshold.

KEY POINTS: MANAGEMENT OF HAEMOPHILIA CARRIERS IN PREGNANCY

Pre-pregnancy:	Pre-conception counselling. Bleeding risk in mother and fetus. Offer pre-implantation or antenatal genetic diagnosis. Check baseline factor levels and consent for products. Ensure hepatitis immunity.
Antenatal:	Determine fetal sex at anomaly scan or by Y-chromosome testing after 10 weeks. Check factor VIII/factor IX levels at booking. Factor VIII levels rise in pregnancy therefore repeat at 28 weeks' gestation and 34 weeks' gestation. Factor levels need to be >50 U/dL for procedures. DDAVP can be used to increase factor VIII levels. Recombinant factor concentrates will be required for factor IX deficiency or with very low factor VIII levels.
Intrapartum:	Maintain levels >50 U/dL for vaginal delivery, caesarean section and spinal anaesthesia. Avoid fetal scalp monitoring, prolonged labour, Ventouse or forceps delivery.
Postpartum:	Maintain factor levels for 3–5 days. Consider the use of tranexamic acid.
Neonate:	Cord blood at delivery for factor levels. Avoid intramuscular vitamin K until results known. Cranial ultrasound (USS) for moderate or severe haemophilia.

Diagnosis of haemophilia in the neonate

Cord blood should be sent immediately after birth to test for factor VIII or factor IX levels. Oral vitamin K should be given in place of intramuscular vitamin K where the child is known to be affected or if the results are awaited. Cranial ultrasound should be undertaken in all infants with moderate or severe haemophilia prior to discharge.²⁷

THROMBOEMBOLIC DISEASE AND PREGNANCY

Venous thromboembolic disease in pregnancy

Despite the risk of venous thromboembolism (VTE) being significantly increased by pregnancy and particularly the postpartum period, the absolute risk remains low, at around 1:1000. However pulmonary embolism is one of the leading causes of maternal mortality and deaths occur where management has been tardy or sub-standard (MMBRACE). Detection of VTE in pregnancy is particularly problematic and, whilst a high index of suspicion must be maintained, it is important not to undertake unnecessary investigations.

Deep vein thrombosis (DVT)

The three elements of Virchow's triad are alterations in blood flow (stasis), alterations in blood coagulability and damage to the vascular endothelium. Venous stasis occurs in pregnancy with a reduction of up to 50% in venous flow by 29 weeks' gestation. Hypercoagulability results from a rise in procoagulant factors, a fall in anticoagulant factors and a reduction in fibrinolytic activity. Vascular endothelial damage occurs at the time of delivery, contributing to the higher risk of VTE in the puerperium.

Almost 90% of DVTs occurring in advanced pregnancy develop in the left leg, with 70% involving the iliofemoral veins. These carry a significantly higher risk of embolisation

to the pulmonary circulation than distal DVTs. The signs and symptoms of DVT are outlined in Table 12.3.

Diagnosis can be particularly difficult in pregnancy as the methods that would be relied upon in non-pregnant women are often inadequate. Clinical probability scores have not been adequately validated, although the LEFt rule shows promise. This combines three variables: symptoms in the left leg (L), calf circumference difference of 2 cm or more (E for oedema) and first-trimester presentation (Ft). Two studies with a combined total of 135 patients found that no one with a negative LEFt rule had DVT and propose its usefulness as a negative predictive test when used in conjunction with other tools, such as D-dimers and/or ultrasound.^{29,30}

The value of negative D-dimers in excluding VTE in non-pregnant patients with a low clinical probability score has been well demonstrated. However, they rise progressively in pregnancy and by delivery are elevated to approximately three times normal. They are therefore less likely to be helpful in excluding VTE in pregnant patients. Thus professional bodies differ in their recommendations, but a pragmatic approach

would be to consider their use for women presenting in the first and possibly second trimesters.

Compression duplex ultrasonography of the lower limb is both sensitive and specific for DVT. However, the calf veins may be difficult to visualise and, if it is negative but a high index of suspicion remains, anticoagulation should be continued and the scan repeated in a week (Green top, Grade C). If the repeat scan is negative, a DVT can be excluded and anticoagulation stopped.

Iliac vein thrombosis may not be detected by ultrasound scan and if there is entire leg swelling or unexplained back pain, magnetic resonance venography or contrast venography should be considered.

Pulmonary embolism

Signs and symptoms of PE are outlined in Table 12.3. The high frequency of non-specific chest pain and breathlessness in pregnancy leads to many women being scanned for PE, with a positive detection rate of only around 2%. Therefore non-invasive tests should be used wherever possible (Box 12.5).

A chest X-ray should be performed initially to exclude other pathology such as infection. This will be normal in about 50% of cases but changes associated with a PE may be seen, including atelectasis, effusion, focal opacities or pulmonary

Table 12.3 Signs and symptoms of venous thromboembolism

Symptoms and signs of venous thromboembolism	
DVT	Leg pain and swelling, (usually unilateral) Erythema Tenderness over the affected area
Pelvic vein thrombosis	Lower abdominal pain Back pain
PE	Shortness of breath, Chest pain, usually pleuritic Haemoptysis
Submassive/ massive PE	Collapse Cyanosis Pain and breathlessness
Non-specific features	Low-grade temperature Leukocytosis

- PE, pulmonary embolism.

Box 12.5 Non-invasive tests that may be helpful in the diagnosis of suspect PE

ECG: can show classic S1,Q3,T3 appearance or signs of right heart strain such as P pulmonale, right bundle-branch block or right axis deviation.

Pulse oximeter: although patients are rarely hypoxic.

D-dimers: may be helpful in first and second trimesters.

Leg ultrasound: should be done if there are signs and symptoms of DVT, as PE can be assumed without confirmation if DVT is detected.

Bilateral leg ultrasound: may be considered in women without signs and symptoms of DVT, as a positive result would obviate the need for lung scanning.

Table 12.4 Diagnostic imaging in suspected pulmonary embolism

	Advantages	Disadvantages
CTPA	Lower dose of radiation to fetus Better sensitivity and specificity to \dot{V}/\dot{Q} scan Can detect other pathology e.g. aortic dissection Readily available	Higher dose of radiation to the breast tissue with a 13.6% increased lifetime risk of developing breast cancer May miss small peripheral PEs
\dot{V}/\dot{Q} scan	Lower dose of radiation to the breast tissue The ventilation scan can often be omitted, further lowering the radiation dose High negative predictive value	10 × higher dose of radiation to the fetus Scan may be delayed because of the availability of isotope

oedema. If any of these abnormalities are seen and/or there is a high clinical suspicion of PE, definitive imaging should be arranged. If the chest X-ray is normal, a bilateral Doppler ultrasound scan of the legs may be considered, which may indirectly confirm the presence of a PE without the need for further radiation exposure.

More definitive imaging requires computed tomography pulmonary angiogram (CTPA) or Ventilation–Perfusion (\dot{V}/\dot{Q}) scan. There are small radiation risks associated with both, which need to be discussed with the patient (Table 12.4); however, ultimately the choice of scan usually depends on availability and local protocols.

Initial treatment of acute VTE in pregnancy

Prior to starting anticoagulation, samples should be sent for full blood count, urea and electrolytes, liver function tests and coagulation screen. Thrombophilia testing is not recommended in the acute setting (see below for discussion of thrombophilia testing in pregnancy).

If there is likely to be a significant delay before investigations are complete or the index of suspicion is high, anticoagulation should be started until the diagnosis is confirmed or refuted. The anticoagulant of choice is LMWH.^{31,32} Meta-analyses have shown that, in comparison with unfractionated heparin (UFH), LMWH is equally efficacious and has a reduced risk of haemorrhagic complications³³ and lower overall mortality. The risk of heparin-induced thrombocytopenia and osteoporosis is also significantly less. Vitamin K antagonists should not be used in pregnancy, as they are teratogenic in the first trimester and associated with haemorrhagic complications and central nervous system (CNS) anomalies at all stages of pregnancy.

The LMWHs commonly used in the UK include enoxaparin, dalteparin or tinzaparin. Due to altered pharmacokinetics in pregnancy, both enoxaparin and dalteparin are usually given as a twice-daily dose to begin with, with some centres reducing to a once-daily intermediate dose after 2–4 weeks, if symptoms and signs are resolving. Tinzaparin is given once daily. LMWH therapy does not require monitoring with anti-factor Xa levels, except for extremes of weight, renal disease or if VTE has occurred while on LMWH, when they may be helpful to guide dosing. Although the test is limited by lack of standardisation and wide inter-laboratory variation, in-house experience allows reasonable interpretation of the assay result and the activity level is considered therapeutic at 0.5–1.2 U/mL 3 hours after injection. Unfractionated heparin may be preferred if the acute thrombotic event occurs near term, as the half-life is short and it can be continued for longer before delivery. It is also more easily monitored, readily reversed and not a concern in renal impairment.

Duration of anticoagulation will be determined by the circumstances of the VTE but should continue throughout pregnancy and until at least 6 weeks postpartum.³² A total of at least 3 months' therapy should be given and in the absence of any other provoking factors this should be extended to 6 months.

Heparin-induced thrombocytopenia is very rare in pregnant women on LMWH and routine platelet monitoring is not recommended. However, the risk is higher with UFH and, if patients are being treated with UFH or have received UFH prior to LMWH, the platelet count should be monitored every 3–4 days until 2 weeks.

Women should be advised to wear a class II graduated compression stocking on the affected leg for at least 2 years after the acute event. This reduces pain and swelling and lowers the risk of post-thrombotic syndrome. Knee-length stockings have been shown to be just as effective as thigh length and are easier to manage. Contrary to previous advice, once anticoagulation has been started, women should be encouraged to mobilise while wearing their compression hosiery.

Massive PE in pregnancy

There are a number of case reports regarding the successful use of thrombolytic therapy for acute massive PE in pregnancy. RCTs outside pregnancy show that, if restricted to massive PE, there is a lower rate of recurrent PE or death, compared with using heparin alone. However, maternal haemorrhage and/or fetal loss may occur in approximately 1–3%. As data are minimal, thrombolysis should be reserved for those women with life-threatening PE.³¹

Inferior vena caval filters

Inferior vena caval filters are rarely required but can be helpful if the thrombotic event has occurred within a week of delivery, or if PE has developed despite anticoagulation or where anticoagulation is contraindicated. Potential complications include migration, infection and an increased risk of DVT. Occasionally temporary filters cannot be retrieved and long-term anticoagulation is necessary to reduce the DVT risk.

Management at the time of delivery

The delivery should be planned by induction of labour or elective caesarean section. This minimises the risk of delivery while fully anticoagulated and allows the option of spinal anaesthesia.

An intraoperative care plan should be generated and coordination between obstetricians and anaesthetists is essential. The dose of LMWH should be reduced to once daily the day before procedure. If a spontaneous presentation occurs, the woman should be advised not to inject herself with LMWH once there are any signs of labour. To avoid the risk of spinal haematoma, neuraxial anaesthesia is contraindicated within 24 hours of a therapeutic dose of LMWH and LMWH should not be given within 4 hours of catheter removal. The risk of wound haematoma and postpartum haemorrhage is increased and women should be monitored for 1–2 days after delivery.

Postnatally, the patient should be given the choice of continuing on LMWH or switching to an oral anticoagulant. Neither warfarin nor LMWH is contraindicated in breastfeeding. The new oral anticoagulants should be avoided in pregnancy and breastfeeding. The ongoing risk of thrombosis and requirement

for anticoagulation should be discussed postnatally, taking into account the circumstances surrounding the acute event, family history and ongoing risk factors. A thrombophilia screen should be performed if deemed appropriate.

Thrombophilia and antiphospholipid syndrome in pregnancy

The presence of a heritable or acquired thrombophilia increases the relative risk of VTE in pregnancy. A systematic review studied the increased risk associated with all the thrombophilias; homozygosity for factor V Leiden (FVL) was the most prothrombotic, with a 34-fold increase in the relative risk of thrombosis. Tests for inherited thrombophilia include measurement of protein C, protein S and antithrombin levels, and genotyping for FVL and prothrombin G20210A mutations. Antiphospholipid syndrome is an acquired thrombophilia and requires testing for anticardiolipin antibodies and lupus anticoagulant.

Thrombophilia testing

A thrombophilia screen should not be performed during an acute event as it may give misleading results. It may, however, have a role after a period of anticoagulation to determine management in a future pregnancy, although this is largely based on the clinical circumstances surrounding the initial thrombotic event and the presence of transient provoking factors. It is important to note that the protein S levels may not return to normal baseline for a number of weeks and therefore testing should be delayed until at least 12 weeks postpartum. The limitations of thrombophilia testing should be understood, as negative results do not guarantee the absence of an inherited factor and positive results may be given too much importance. Guidelines from the BCSH state that thrombophilia testing need not be performed in women who suffer an unprovoked VTE as in future pregnancies they will qualify for thromboprophylaxis on clinical grounds alone.³⁴ Conversely, if there was a clear provoking factor at the time of VTE, for example a lower-limb plaster cast, antenatal thromboprophylaxis is unlikely to be required in a future pregnancy. The difficulty lies with those patients in whom there was a weak provoking factor and it is in these cases that a thrombophilia screen may be most valuable in determining future risk.

Antiphospholipid syndrome

Antiphospholipid syndrome (APLS) is an autoimmune disorder that is characterised by vascular thrombi and/or pregnancy morbidity in the presence of persistent antiphospholipid (aPL) antibodies, specifically anticardiolipin antibodies (aCL), β_2 -glycoprotein 1 antibodies or a lupus anticoagulant (LAC). It may be a primary disease or occur in association with other autoimmune disease as secondary APLS. It is not completely understood why the presence of anticardiolipin antibodies

results in a prothrombotic syndrome but it is thought that antibodies against a particular domain of β_2 -glycoprotein 1 play a major role. β_2 -glycoprotein is an apolipoprotein that has a role in the regulation of haemostasis as well as many other physiological functions. It has been shown that the presence of LAC is most predictive of thrombosis.³⁵ Conversely, the sole presence of ACL antibodies does not appear to be associated with an increased thrombotic risk but is associated with increased pregnancy morbidity.³⁶

Obstetric complications include early miscarriage, late pregnancy loss, premature delivery and early onset pre-eclampsia. Thrombosis may occur in the placental bed, inflammatory cell infiltrate results from activation of complement and aPL may cause direct damage to the trophoblasts, affecting invasive ability.³⁷

Epidemiology

Antiphospholipid antibodies are found in 3–5% of healthy individuals and in up to 30% of individuals with SLE. Among patients suffering recurrent pregnancy loss, 10–20% have detectable aPL antibodies and up to 90% will have further fetal loss if left untreated.

Diagnosis requires the presence of one clinical criterion and one laboratory criterion; it therefore follows that testing should be performed in the clinical situations described (Box 12.6).

Box 12.6 Diagnostic criteria for antiphospholipid syndrome (Sapporo's criteria)

Clinical criteria

- Vascular thrombosis: one or more episodes of arterial, venous or small-vessel thrombosis.
- Pregnancy morbidity:
 - (a) One or more unexplained deaths of a morphologically normal fetus at or beyond week 10 of gestation.
 - (b) One or more preterm births of a morphologically normal neonate before week 34 of gestation because of (i) eclampsia or severe pre-eclampsia or (ii) recognised features of placental insufficiency.
 - (c) Three or more unexplained consecutive spontaneous miscarriages before week 10 of gestation, with maternal anatomical or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory criteria

- The LAC present in plasma, on two or more occasions at least 12 weeks apart.
- The aCL antibody of IgG and/or IgM isotype in serum or plasma, on two or more occasions, at least 12 weeks apart.
- Anti- β_2 -glycoprotein 1 antibody of IgG and/or IgM isotype in serum or plasma, present on two or more occasions at least 12 weeks apart.

Management of APLS and pregnancy

APLS associated with VTE

These women should be managed as other women who have previously suffered an unprovoked VTE. They may well be on long-term oral anticoagulation and should be advised to stop this and start taking LMWH as soon as they have confirmation of pregnancy. This should be at a high or an intermediate dose. If the previous thrombotic event was associated with a clear provoking factor then prophylactic LMWH may be sufficient. Each case should be considered individually to assess current risk factors for thromboembolic disease. Aspirin 75 mg daily should also be given from 12 weeks' gestation. The patient should be regularly reviewed to assess ongoing thrombotic risk and should be offered serial growth scans with uterine artery Doppler to ensure adequate placental function.

APLS associated with pregnancy morbidity

A Cochrane review of 13 studies found that aspirin and unfractionated heparin are superior to aspirin alone in preventing miscarriage.³⁸ Smaller studies have shown the benefit of LMWH and aspirin and there is now vast experience of using LMWH, which remains the agent of choice³⁹ due to its ease of use and more favourable safety profile. There is less evidence to confirm its benefit in reducing late-pregnancy morbidity, pre-eclampsia, preterm birth and IUGR associated with APLS but aspirin is proven to improve outcomes in these conditions.

Thromboprophylaxis

Whilst VTE remains one of the leading causes of maternal death, the fact is that many of these cases could have been avoided. Several CEMACH/national audit reports have highlighted the need to identify those women who are at risk and ensure that adequate thromboprophylactic measures are taken. In 2008, a case-control study undertaken by the UK Obstetric Surveillance System (UKOSS) revealed that, of 143 cases of pulmonary embolism, only 9 should have received thromboprophylaxis on risk assessment criteria of the time, and only 3 of these had actually done so. Also six women had a PE whilst on thromboprophylaxis, three of whom were on an inadequate dose. The risk is greatest postnatally with studies showing as high as a 60-fold increase compared with the non-pregnant population.⁴⁰ Whilst risk increases as pregnancy advances, many studies have shown that the incidence of VTE in the first trimester is also significantly increased compared with the non-pregnant state, with one American study revealing 44% of DVTs occurring in the first trimester.⁴¹

Reducing risk of VTE

All women should undergo a VTE risk assessment early on in pregnancy which should be reassessed if the woman is admitted to hospital or if her clinical situation changes in any way.

The 2009 Green-top guideline, which is due to be updated shortly, defines the approach to risk assessment and thromboprophylaxis in pregnant women. Education of midwives and pregnant women plays a significant part in reducing the occurrence and early identification of VTE in pregnancy.

General antithrombotic advice should be given to all women – the importance of maintaining good hydration and mobility and, in times of unavoidable immobility, for example travel situations or illness, to regularly perform feet and ankle

Table 12.5 Adapted from Robertson *et al.* Risk of VTE with associated thrombophilias⁴⁴

Thrombophilic defect	Adjusted OR for risk of VTE
AT deficiency	4.7
Protein C deficiency	4.8
Protein S deficiency	3.2
FVL heterozygous	8.3
Prothrombin G20210A heterozygous	6.8
FVL homozygous	34.4
Prothrombin G20210A homozygous	26.4

- OR, odds ratio.

Table 12.6 Additional risk factors for VTE in pregnancy and the puerperium

Pre-existing	New onset or transient	Specific to postpartum
Age >35 years	Ovarian hyperstimulation syndrome	Caesarean section (especially emergency)
Obesity (BMI >30 kg/m ²)	Hyperemesis	Prolonged labour
Parity >3	Dehydration	Mid-cavity instrumental delivery
Gross varicose veins	Severe infection	Postpartum haemorrhage
Sickle cell disease	Long-distance travel	Immobility after delivery
Smoking	Immobility	
Paraplegia	Pre-eclampsia	
Inflammatory bowel disease	Hospital admission/surgical procedure	
Medical disorders: pre-existing diabetes		
Family history in first-degree relative especially in presence of thrombophilia		

exercises. The signs and symptoms of a DVT or PE should be outlined to all women to increase the chance of early diagnosis and treatment.

Assessing individual risk (Table 12.5)

Early identification of those women at risk of VTE can allow counselling and commencement of thromboprophylaxis. The single greatest risk factor for VTE in pregnancy is a previous thrombotic event. One retrospective study of 1104 pregnant women with previous VTE found an incidence of recurrent VTE of 5.8%. This was increased if the first event was unprovoked, or related to pregnancy or hormonal therapy. The rate of recurrence in the puerperium was 15% if the first VTE was pregnancy related.⁴² Conversely, there was no increased risk of recurrence if the previous event was provoked by a transient risk factor. For women with a weak provoking factor, the risk of recurrence is less clear and a thrombophilia screen may be helpful in guiding the use of thromboprophylaxis.

Up to 50% of women who suffer a VTE in pregnancy will have an underlying thrombophilia; however, some thrombophilias confer a greater risk than others; homozygotes for FVL or prothrombin gene mutation, compound heterozygotes and women with antithrombin deficiency have the highest risks and intermediate to high doses of LMWH are required throughout pregnancy and for at least 6 weeks postnatally.⁴³

A number of other factors have been shown to significantly increase the risk of VTE in pregnancy and are listed in Table 12.6. In reality the individual risk is an interplay of many factors: the more factors present, the higher the risk of VTE. Some risk factors carry more weight than others and it is therefore difficult to validate a scoring system that is appropriately weighted. For simplicity and applicability, RCOG suggest adding the number of risk factors with the recognition that coexistent risk factors have an additive effect.

A large Norwegian case–control study of over 600,000 pregnancies showed that the overall incidence of VTE was 1:1000 and antenatal risk factors associated with increased risk were assisted reproduction, gestational diabetes, age older than 35 years and multiple pregnancies. Postnatal risk factors were caesarean section, pre-eclampsia, assisted reproduction, placental abruption and placenta previa.⁴⁵ The UKOSS 2008 study also showed that the strongest risk factors for VTE were multiparity and obesity.⁴⁶ A recently published UK cohort study of >300,000 deliveries⁴⁷ suggested that the risk factors traditionally associated with increased VTE risk in pregnancy and postnatally were associated only with moderately increased risk. However, during the antepartum period, varicose veins, inflammatory bowel disease, urinary tract infection and pre-existing diabetes were associated with a significant increased risk for VTE. Postpartum the strongest risk factor was stillbirth; however, medical co-morbidities, including varicose veins, inflammatory bowel disease (IBD) and cardiac disease, a BMI of 30 kg/m² or higher, obstetric haemorrhage, preterm delivery, and caesarean section were

Table 12.7 Prophylactic dosing schedules for LMWH in pregnancy

Dose	Enoxaparin	Dalteparin	Tinzaparin
Standard prophylactic			
<50 kg	20 mg OD	2500 units OD	3500 units OD
50–90 kg	40 mg OD	5000 units OD	4500 units OD
91–130 kg	60 mg OD or 40 mg BD	7500 units OD or 5000 units BD	7000 units OD
131–170 kg	80 mg OD or 40 mg BD	10,000 units OD or 5000 units BD	
High prophylactic			
	40 mg BD	5000 units BD	4500 units BD
Treatment/therapeutic			
	1 mg/kg BD	100 units/ kg BD	175 units/ kg OD

- BD, twice daily; OD, once daily.

also all associated with increased risk. The same group also confirmed the significant risk associated with hospital admission, increased by 17.5 times.⁴⁸

Management

All women should undergo risk assessment for VTE in early pregnancy or pre-pregnancy. The history and circumstances of any previous events should be assessed, along with family history and any known thrombophilic defects. Risk assessment should be repeated if the situation changes to take account of additional transient risk factors. A thrombophilia screen may help to determine risk in cases where there is a personal history of VTE with a weak provoking factor, or if there is no personal history but a strong family history of unprovoked VTE.

Pharmacological

LMWHs are the agent of choice due to ease of use and a large body of experience supporting their safety and efficacy. Dalteparin, enoxaparin or tinzaparin is the LMWH used in the UK. The dose should take account of the patient's early pregnancy weight; patients <50 kg will require a reduced dose whilst those >90 kg will require a higher dose (Table 12.7).

Duration, dose and timing of LMWH will depend on the risk group. The RCOG have divided women with a previous history of VTE into three risk groups:

- Very high risk: recurrent VTE, or VTE associated with a high-risk thrombophilia. These women should receive an intermediate to high dose of LMWH.

- High risk: previous unprovoked or hormone-related VTE or a previous VTE with other risk factors or a family history suggesting thrombophilia. These women should be considered for standard-dose LMWH antenatally and for 6 weeks postpartum.
- Intermediate risk: previous VTE was provoked by a major risk factor which is no longer present. These women may not need LMWH but should be reassessed regularly through pregnancy and LMWH should be given if any additional risk factor arises. They should receive LMWH for 6 weeks postpartum.

For those without a previous history of VTE but with a thrombophilia, or a family history, thromboprophylaxis is likely to be required postnatally and should be considered antenatally if other risk factors are present. For women with multiple risk factors as outlined above, thromboprophylaxis should be given postnatally for 6 weeks and should be considered antenatally. Table 12.8 shows indications for postpartum thromboprophylaxis.

Table 12.8 Indications for postpartum thromboprophylaxis

Indication	Usual duration of LMWH (weeks)
Received antenatal prophylaxis	6
Previous VTE	6
Class III obesity	1
Emergency caesarian section	1
Elective caesarian section with one or more additional risk factors	1
Presence of some thrombophilias without personal history of VTE	1

Aspirin

The role of aspirin in preventing VTE in pregnancy has not been validated and there are no recommendations for its use or otherwise for thromboprophylaxis in pregnant women. Outside pregnancy it has been shown to reduce the risk of recurrent VTE by 40% compared with placebo, with no increase in major bleeding.⁴⁹

Graduated elastic compression stockings

If correctly applied, anti-embolic stockings may reduce the occurrence of VTE. They are advised for women with previous VTE, those undertaking long journeys and hospitalised women in whom LMWH is contraindicated. They are also recommended in addition to LMWH for women post-caesarean section with multiple additional risk factors.

Management of labour

Women should be advised to withhold any further doses of LMWH as soon as there are signs of labour or if they have any vaginal bleeding. Regional anaesthesia should not be used for

12 hours after a prophylactic dose of LMWH. Women should be encouraged to stay hydrated and to remain as mobile as possible.

Chapter 13 Renal disease

Catherine Nelson-Piercy

MRCOG standards

Relevant standards

To understand and demonstrate appropriate knowledge, skills and attitudes in relation to pregnant women with kidney disease.

Theoretical skills

Understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of women with kidney disease.

Practical skills

Be able to manage independently:

- urinary tract infection,
- pyelonephritis.

Be able to manage under direct supervision pregnant women with:

- chronic kidney disease,
- a renal transplant,
- acute kidney injury.

INTRODUCTION

Urinary tract infection (UTI) is a common cause of maternal morbidity and a potential cause of perinatal morbidity and mortality via preterm delivery. Renal disease is an important predisposing factor for pre-eclampsia and fetal growth restriction (FGR). The combination of hypertension and proteinuria at booking (provided that this is in the first or early second trimester) suggests pre-existing renal disease and should prompt further investigation. A serum creatinine is mandatory in such cases to exclude pre-existing chronic kidney disease (CKD).

The number of women with renal transplants considering pregnancy is increasing and success rates are high, but case selection is required. Acute kidney injury in pregnancy is most commonly due to obstetric conditions, particularly haemorrhage and pre-eclampsia.

PHYSIOLOGICAL CHANGES IN PREGNANCY

There is dilatation of the ureters and renal calyces in pregnancy. This must be remembered when interpreting ultrasound scans of the renal and urinary tract systems in pregnancy. Both renal plasma flow and glomerular filtration increase dramatically in pregnancy.¹ This results in an increased urinary protein excretion and increased creatinine clearance.¹ Thus, in the second trimester, the upper limit of normal for serum creatinine falls to around 65 $\mu\text{mol/L}$ with a mean of 54 $\mu\text{mol/L}$,¹ and throughout pregnancy the upper limit of normal for proteinuria is taken as 300 mg/24 hours or a protein:creatinine ratio less than 30 mg/mmol.

URINARY TRACT INFECTION

Incidence

Urinary tract infection is more common in pregnancy because of the physiological dilatation of the upper renal tract. The incidence of asymptomatic bacteriuria in pregnancy ranges from 4 to 7 per cent, and up to 40 per cent of the women affected will develop symptomatic UTI in pregnancy. Cystitis complicates about 1 per cent of pregnancies, and 1–2 per cent of pregnant women develop pyelonephritis. Women who have a history of previous UTIs are at increased risk of a UTI in pregnancy, as are those with diabetes, receiving steroids or immunosuppression, or with polycystic kidneys, reflux nephropathy, congenital abnormalities of the renal tract (e.g. duplex kidney or ureter), neuropathic bladder (e.g. spina bifida or multiple sclerosis) or urinary tract calculi.

Presentation

A midstream urine (MSU) specimen performed as part of routine antenatal screening may reveal asymptomatic bacteriuria. Additional MSUs are indicated in pregnancy in those women at increased risk as described above, and those with symptoms of UTIs. Typical clinical features are urinary frequency, dysuria, suprapubic pain, haematuria, proteinuria

and nitrites on urinalysis. Fever, loin and/or abdominal pain, vomiting and rigors suggest pyelonephritis.

Diagnosis

Much dipstick proteinuria in pregnancy is erroneously attributed to UTIs. Indeed, a diagnosis of pre-eclampsia may not be considered if it is assumed that proteinuria is due to UTI (see Chapter 26). Dipsticks for nitrites and leukocyte esterase may be used to help exclude UTIs, but their positive predictive value is low and therefore any positive dipstick should be followed up with an MSU. A clinical diagnosis should always be confirmed with culture of an MSU sample. Bacteriuria is considered significant if there are more than 100,000 organisms per millilitre of urine. Urine culture resulting in a non-significant or mixed growth should be repeated on a fresh MSU specimen.

Management

All bacteriuria in pregnancy requires treatment to prevent pyelonephritis and preterm delivery (Cochrane guideline A) (Box 13.1). Treatment for 3 days is sufficient for asymptomatic bacteriuria [E].² Regular urine cultures should be taken following treatment to ensure eradication of the organism. About 15 per cent of women will have recurrent bacteriuria during the pregnancy and will require a second course of antibiotics. The choice of antibiotic depends on the sensitivities of the causative organism, but, in suspected pyelonephritis, treatment should begin before the results of culture are available. Penicillins (amoxicillin) and cephalosporins are safe and appropriate antibiotics in pregnancy. Augmentin (co-amoxiclav) increases the risk of necrotising enterocolitis in the neonate. Cefadroxil 500 mg twice daily is effective against the majority of urinary pathogens. Nitrofurantoin should be avoided in the third trimester as it may cause haemolytic anaemia in the neonate and trimethoprim should be avoided in the first trimester because of its antifolate action. For acute cystitis, a 7-day course of antibiotics is recommended and antibiotics should be continued for 10–14 days for pyelonephritis [E].²

In pyelonephritis with vomiting or pyrexia, antibiotics should be given intravenously until the pyrexia settles; intravenous fluids may also be required. Renal function should be checked. Ultrasound examination of the renal tract is indicated in those with pyelonephritis or two or more proven UTIs. This is to exclude hydronephrosis, congenital abnormalities and renal calculi. Continuous prophylactic antibiotics are usually recommended only for those with two or more confirmed (with a positive culture) UTIs and either one of the above risk factors or in those with renal transplants.

Box 13.1 Suggested treatment regimens for urinary tract infection (UTI) in pregnancy

Oral antibiotics

Amoxicillin 500 mg three times daily

Cefadroxil 500 mg twice daily

Cephalexin 250 mg three times daily

Nitrofurantoin 100 mg three times daily (not third trimester)

Trimethoprim 200 mg twice daily (not first trimester)

Intravenous antibiotics for pyelonephritis

Cefuroxime 750 mg to 1.5 g three times daily

Amoxicillin 1 g three times daily

Gentamicin 5–7 mg/kg daily as one dose and then further doses as determined by serum gentamicin concentrations (for organisms resistant to, or women allergic to, penicillins and cephalosporins)

Duration of treatment

Asymptomatic bacteriuria: 3 days

Acute cystitis: 7 days

Pyelonephritis: 10–14 days

Prophylaxis of UTI

Cephalexin 250 mg once daily

Amoxicillin 250 mg once daily

CHRONIC KIDNEY DISEASE

Aetiology

In women of child-bearing age, the most common causes of CKD are reflux nephropathy, diabetes, SLE, other forms of glomerulonephritis and adult polycystic kidney disease. Conventionally, CKD is classified as CKD 1–5 depending on the degree of renal impairment¹ (Table 13.1). However, it must be remembered that the eGFR is not validated for use in pregnancy, so the serum creatinine level should be used. However, the serum creatinine is also dependent on the muscle mass, so a figure that represents moderate impairment in an 85-kg woman may represent severe impairment for a 50-kg

Table 13.1 Stages of chronic kidney disease

Stage	GFR (mL/min per 1.73 m ²)
1	>90
2	60–89
3	30–59
4	15–29
5	<15 or dialysis

woman. It has been estimated that around 1 in 750 pregnancies is complicated by CKD stages 3–5.

Presentation

If renal disease is not diagnosed pre-pregnancy, it is usually first recognised because of hypertension and proteinuria and/or haematuria in early pregnancy, prompting blood tests for urea and creatinine. However, a common caveat is to attribute hypertension and proteinuria to underlying renal disease rather than to the much more common pre-eclampsia, which may rarely present before 20 weeks' gestation. If there is no record of blood pressure or urinalysis in the first trimester to allow the hypertension and proteinuria to be designated 'new onset', a differentiation between pre-eclampsia and renal disease is more difficult.

Effect of pregnancy on renal impairment

In general, those with mild impairment (creatinine <125 µmol/L; CKD 1–2) tolerate pregnancy well and do not usually suffer deterioration in renal function as a result of the pregnancy. The serum creatinine will follow a trend similar to that in normal pregnancy, i.e. it will fall to a nadir in the second trimester and then rise again but remain below non-pregnant levels in the third trimester. Conversely, those with severe impairment of renal function (creatinine >180 µmol/L; CKD 3b–5) are at increased risk of permanent loss of function during and after the pregnancy (50 per cent will have a permanent decline in function) and even end-stage renal failure (35 per cent within 1 year) [C].¹

Effect of CKD on pregnancy outcome

All women with renal impairment are at increased risk of pre-eclampsia, FGR, and spontaneous and iatrogenic preterm delivery [C].^{1,3} Again, outcome depends on the level of impairment and the level of any pre-existing hypertension [C].^{3–6} Those with severe renal impairment (creatinine >250 µmol/L) and hypertension have a less than 50 per cent chance of successful pregnancy, often developing severe, early-onset pre-eclampsia with marked FGR. Even in the absence of pre-eclampsia or uteroplacental dysfunction, one may be faced with the need to deliver a woman with rapidly worsening renal function (or to institute dialysis), resulting in a pre-viable or extremely preterm infant. For these reasons, it is usual to counsel women with severe renal impairment against pregnancy [C].^{3–5} Women with severe renal impairment may also develop polyhydramnios and the risk of cord prolapse. This is probably the result of fetal polyuria in response to the high osmotic load from increased maternal urea. Those with nephrotic syndrome and heavy proteinuria also develop worsening hypoalbuminaemia in pregnancy, with the associated risks of pulmonary oedema and venous thrombosis.

Management

This should begin with pre-pregnancy counselling and should involve multidisciplinary care by clinicians with expertise in the management of these high-risk pregnancies.³

It is important to document baseline (pre-pregnancy and early pregnancy) values for creatinine, albumin and protein excretion. Some increase in proteinuria is inevitable in pregnancy and does not necessarily indicate superimposed pre-eclampsia or worsening renal disease. Deterioration in renal function at any stage in pregnancy should prompt a search for reversible causes such as UTI, obstruction or dehydration.

Tight control of any hypertension is important to minimise the risk of deterioration in renal function. Blood pressure should be maintained below 140/90 mmHg.³ The choice of antihypertensive agents is no different in women with renal disease [E]. Many renal patients, especially those with significant proteinuria, are treated with ACEIs or ARBs. These should be discontinued prior to or in early pregnancy as they are teratogenic [C].⁷ Diuretics are also usually discontinued and their use restricted to severe hypoalbuminaemia with fluid overload and incipient pulmonary oedema [D].

Not only are women with renal disease at high risk of pre-eclampsia, but it is also often difficult to diagnose in the presence of pre-existing hypertension and proteinuria. Admission should be considered with worsening hypertension, increasing serum creatinine, and large increases in proteinuria. Useful additional features to support a diagnosis of pre-eclampsia include FGR, thrombocytopenia and abnormal liver function. The use of prophylactic low-dose (75 mg/day) aspirin is appropriate to decrease the risk of pre-eclampsia in all those with CKD [A].⁸ Serial scans for fetal growth and liquor volume, and serial haematology and biochemistry are essential in the monitoring of these pregnancies [D].^{3,9}

If CKD is discovered for the first time in pregnancy, and the hypertension and proteinuria are not readily attributable to pre-eclampsia, investigation should include blood glucose (for diabetes), serum calcium, antinuclear antibodies (for SLE),⁹ immunoglobulins (for IgA) and a renal tract ultrasound (e.g. for polycystic kidneys, reflux nephropathy with scarring or to demonstrate small kidneys suggestive of chronic renal failure) [D].

EBM

- The risks of obstetric complications such as pre-eclampsia, FGR and iatrogenic preterm delivery increase with increasing baseline serum creatinine.
- The chances of successful pregnancy decrease with increasing baseline serum creatinine.
- The risks of temporary and permanent deterioration in renal function increase with increased baseline serum creatinine.
- Women with severe renal impairment (creatinine >250 µmol/L; CKD 4–5) are usually advised against pregnancy.

Postpartum, continued close monitoring is necessary to ensure the renal function returns to pre-pregnancy levels. ACEIs may be safely used in breastfeeding women. Those with newly suspected underlying renal disease should be referred to a nephrologist.

RENAL TRANSPLANTS

The rates of successful pregnancy outcome in women with well-functioning renal transplants are similar to those of the general population. However, a recent UK-wide study of 105 renal transplant recipients found that 24% developed pre-eclampsia and the same percentage had an SGA baby; over 50% delivered before 37 weeks' gestation. Women are usually advised to delay pregnancy for a year after transplantation to allow graft function to stabilise and immunosuppression to reach maintenance levels [E]. The risks of adverse outcome in pregnancy relate to the pre-pregnancy level of function of the allograft and the presence of hypertension (C).^{10,11}

In addition, these women are immunosuppressed and therefore more prone to infection. There are substantial data regarding the safety of immunosuppressive drugs in pregnancy. Prednisolone [C], azathioprine [C], ciclosporin¹⁰ [C] and tacrolimus [C] are all considered safe. Recent data suggest that tacrolimus is not transferred to breast milk in significant quantities and women should be encouraged to breast-feed¹² [E]. Mycophenolate mofetil (MMF) is teratogenic in humans.¹⁰ Women can usually be switched from MMF to azathioprine prior to pregnancy.

DIALYSIS

Because women with end-stage renal failure have markedly reduced fertility, pregnancy on dialysis is unusual. The chances of a successful pregnancy outcome are sufficiently low, and the attendant risks sufficiently high, to counsel women on dialysis against pregnancy [E].³ Anaemia and haemorrhage are common, and the risks of miscarriage, fetal death, pre-eclampsia, preterm labour, preterm rupture of the membranes, polyhydramnios and placental abruption are increased [C].¹³ Pregnancy outcome in CKD has improved with modern dialysis techniques and livebirth rates are up to 80 per cent,¹⁴ but pregnancy is not advised in women on dialysis. Women who decide to continue with pregnancy require increasing frequency of dialysis in order to maintain the pre-dialysis urea, 15–20 mmol/L [C].^{3,11} The incidence of poor obstetric outcome is similar with both haemodialysis and peritoneal dialysis.

ACUTE KIDNEY INJURY IN PREGNANCY

Acute kidney injury (AKI) is rare in pregnancy, the most common causes being pre-eclampsia and related syndromes, haemorrhage, infections, drugs, particularly NSAIDs, and obstruction due to a gravid uterus or ureteric damage or stones. Mild degrees of renal impairment are more common, and again are usually related to pre-eclampsia or blood loss. AKI most commonly complicates the early postpartum period. It is characterised by oliguria, a rising urea and creatinine, a metabolic acidosis and hyperkalaemia. In the obstetric situation, there may be an associated coagulopathy. An isolated rise in urea (without concomitant rise in creatinine) is often observed following antenatal corticosteroid administration. A rare cause of AKI that is most commonly encountered postpartum is haemolytic uraemic syndrome (HUS). The hallmark of this condition is a microangiopathic haemolytic anaemia (diagnosed with a blood film) associated with renal failure and thrombocytopenia.

Pre-eclampsia and renal failure

Oliguria is an almost universal finding in pre-eclampsia and is exacerbated by Syntocinon and caesarean section. It does not alone indicate AKI, but should prompt measurement of serum urea and creatinine. AKI is more common in acute fatty liver of pregnancy¹⁵ (see Chapter 15), HELLP syndrome (7 per cent) [C]¹⁶ and eclampsia (6 per cent) than in 'straightforward' pre-eclampsia. HELLP syndrome is the most common cause (50 per cent) of AKI in the context of pre-eclampsia.

The management of AKI depends on the cause: blood volume replacement for haemorrhage, delivery for pre-eclampsia, cessation of nephrotoxic drugs. Postpartum management is largely conservative and supportive. Accurate assessment of fluid balance with the use of a central venous pressure (CVP) line is important. Provided that blood loss and volume depletion have been excluded as causes (CVP high or normal), fluids are given only to replace insensible losses and the previous hour's urine output. Iatrogenic fluid overload must be avoided in pre-eclampsia because these women are often hypoalbuminaemic and particularly susceptible to pulmonary oedema. Overzealous fluid administration is far more dangerous than oliguria. Dialysis may rarely become necessary, but a need for long-term renal replacement therapy is extremely unusual.

KEY POINTS

- UTIs are common in pregnancy, and bacteriuria requires treatment to prevent pyelonephritis and preterm labour.
- The risks of complications, such as pre-eclampsia and FGR, and deterioration in renal function are high, and the chances of successful pregnancy lower in women with severe renal impairment (CKD 4–5).
- Women with well-functioning renal allografts generally have successful pregnancies, but should be advised to delay pregnancy until a year after transplantation.
- Women on dialysis should be advised to delay pregnancy until they have received a renal transplant.
- Acute kidney injury is rare, but may complicate haemorrhage and pre-eclampsia.

Chapter 14 Autoimmune conditions

Catherine Nelson-Piercy

MRCOG standards

Relevant standard

To understand and demonstrate appropriate knowledge, skills and attitudes in relation to pregnant women with connective tissue disease.

Theoretical skills

To understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of women with connective tissue disease. To understand the use of immunosuppressant drugs in pregnancy.

Practical skills

Be able to manage under direct supervision pregnant women with:

- SLE,
- rheumatoid arthritis,
- antiphospholipid syndrome.

INTRODUCTION

This chapter covers the autoimmune connective tissue diseases, including rheumatoid arthritis (RA), systemic lupus erythematosus (SLE) and antiphospholipid syndrome (APS), Sjögren's syndrome and scleroderma. Autoimmune thrombocytopenia is discussed in Chapter 12; myasthenia gravis in Chapter 17; and autoimmune thyroid disease in Chapter 11.

Changes in the immune system in pregnancy result in relatively suppressed cell-mediated immunity and enhanced humoral immunity. These changes revert postpartum when there is a sudden reduction of oestrogen, progesterone and cortisol levels. The postpartum period is therefore a time of theoretical susceptibility to autoimmune disorders. This means that some autoimmune conditions such as RA often improve in pregnancy and may flare, worsen or present anew

in the postpartum period. In pregnancy, many of the issues for women with connective tissue disease relate to the safety of the drugs used to control their disease and to the degree of any systemic involvement of their disease.

RHEUMATOID ARTHRITIS

This is a chronic, inflammatory, symmetrical arthritis causing joint pain, stiffness and deformity. Systemic features include rheumatoid nodules, pulmonary granulomas, vasculitis, Sjögren's syndrome (see below) and scleritis. Haematological abnormalities include a normocytic anaemia and raised erythrocyte sedimentation rate (ESR). Rheumatoid arthritis is usually associated with positive rheumatoid factor and anti-cyclic citrullinated peptide (anti-CCP). Thirty per cent of cases are antinuclear antibody (ANA) positive. Up to 20–30 per cent are Ro/La positive (see below) and 5–10 per cent are antiphospholipid (aPL) antibody positive (see below), although APS is rare. Pregnancy is associated with a decrease in T-cell immunity that is reversed postpartum.¹ This may explain why 48–66 per cent of women with RA experience improvement in their symptoms during pregnancy and why those who improve usually flare postpartum.²

Rheumatoid arthritis has no adverse effect upon pregnancy outcome. Limitation of hip abduction is rarely severe enough to preclude vaginal delivery, and atlantoaxial subluxation is a rare complication of general anaesthesia for caesarean section. Severe joint deformity and disability may rarely necessitate the need for help with care of the infant.

Management

Assessment of disease activity is usually clinical. The ESR is raised in normal pregnancy and does not therefore provide a reliable marker of disease activity. As arthritis often improves in pregnancy, some reduction in analgesia may be possible.

DRUGS FOR AUTOIMMUNE CONDITIONS

Paracetamol is safe in pregnancy and may be instituted or continued in maximal doses if required. The commonly used drugs for connective tissue disease are summarised in Table 14.1.³

NSAIDs, such as ibuprofen and diclofenac, are often used in women with RA and SLE. They are normally avoided in pregnancy because they are detrimental to the fetal kidney, causing oligohydramnios, and they may cause premature closure of the ductus arteriosus, leading to pulmonary hypertension and fetal haemorrhage, in large doses. Neither aspirin nor the other NSAIDs are teratogenic, so it is not necessary to discontinue these drugs prior to conception [C]. However, there is an association between NSAIDs and infertility due to luteinized unruptured follicle syndrome.⁴ They should therefore be withdrawn if there is a history of infertility [D]. Occasionally, they are used in pregnancy when alternatives, such as paracetamol, codeine and corticosteroids, are inadequate or inappropriate. In such cases, they should be discontinued by 32 weeks' gestation, as at later gestations the effects on the fetal renal function and the ductus are irreversible.³ The selective cyclooxygenase-2 (COX-2) inhibitors are also contraindicated in pregnancy.

Corticosteroids are the first-line anti-inflammatory drugs in pregnancy.³ They are used for many connective tissue diseases, not only for the arthritis manifestations, but also to treat vasculitis, skin involvement, renal lupus and thrombocytopenia. There is no evidence to support the premise that steroids will prevent flare, either antenatal or postnatal, but they remain the mainstay of management for these disorders in pregnancy. They must never be withheld because of erroneous fears concerning their effects on the fetus. Many women are understandably reluctant to use any drugs, but particularly steroids, in pregnancy and therefore, if they are used, this must be with adequate counselling regarding their safety in pregnancy to ensure concordance with therapy [E].

Table 14.1 Safety in pregnancy of drugs used for autoimmune conditions

Safe to continue or start in pregnancy	Discontinue or avoid in pregnancy
Paracetamol	NSAIDs
Hydroxychloroquine	Cyclophosphamide
Sulfasalazine	Gold
Corticosteroids	Penicillamine
Azathioprine	Methotrexate
	Chlorambucil
	Leflunamide
	Mycophenolate mofetil

Any possible small risk of teratogenesis (there are some data suggesting a small increased risk of oral clefting with first trimester exposure⁵) is dwarfed by the beneficial effects to the fetus of controlling the maternal disease process [C]. Caution is needed because the use of steroids in pregnancy is associated with an increased risk of infections and gestational diabetes. Large doses of steroids are associated with an increased risk of preterm rupture of the membranes.

Azathioprine is also safe in pregnancy. The fetal liver lacks the enzyme that converts azathioprine to its active metabolites. Azathioprine is used as a 'steroid-sparing' agent and there are reassuring data regarding a lack of adverse effects on babies born to mothers receiving this drug for renal transplants, inflammatory bowel disease⁶ and connective tissue diseases [C].³ A study has shown that there are no detectable levels of the metabolites of azathioprine in the blood of neonates who were fully breastfed by women receiving azathioprine [D].⁷

Antimalarials such as hydroxychloroquine are safe in pregnancy [C].³ Discontinuation of this drug is associated with a risk of SLE flare.

Sulfasalazine is safe in pregnancy and breastfeeding. It is a dihydrofolate reductase inhibitor and therefore associated with an increased risk of neural tube, oral cleft and cardiovascular defects. Folate supplementation (5 mg/day) is advised [B].

Gold and D-penicillamine used in RA are usually avoided in pregnancy, although the risk of abnormalities is probably low. Cytotoxic drugs, such as cyclophosphamide, methotrexate and chlorambucil, are all highly teratogenic and must be discontinued prior to pregnancy.³ Mycophenolate mofetil, used in lupus nephritis, is teratogenic and women should be changed to azathioprine prior to pregnancy.⁸

The anti-tumour necrosis factor (TNF) biologic agents (etanercept, adalimumab and infliximab) are used increasingly in inflammatory arthritis. Available data suggest that these agents are safe in pregnancy but that they should ideally be discontinued by about 28-30 weeks' gestation depending on the individual drug [D].^{8,9} It is important that live vaccines are avoided in the child for 6 months after birth.⁹

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a relapsing and remitting multisystem connective tissue disorder that predominantly affects women of child-bearing age. The diagnostic criteria are shown in Table 14.2. It most commonly affects the joints (symmetrical non-erosive peripheral arthritis and arthralgia), the skin (malar rash, photosensitivity, discoid lupus, alopecia, vasculitis, Raynaud's phenomenon) and the kidneys (glomerulonephritis). There may be anaemia, lymphopenia, thrombocytopenia, hypocomplementaemia and a raised ESR. The C-reactive protein (CRP) is not raised.

SLE is associated with ANA and anti-double-stranded DNA (dsDNA) antibodies. There may be antibodies to extractable nuclear antigens (ENAs) including Ro and La, or aPL antibodies with or without APS.

Table 14.2 American College of Rheumatology criteria for SLE

Malar rash	Renal disorder
Discoid rash	Neurological disorder
Photosensitivity	Haematological disorder
Oral ulcers	Immunological disorder
Arthritis	Antinuclear antibody
Serositis (e.g. pleurisy, pericarditis)	

- For a diagnosis of SLE, four of these criteria are required simultaneously or serially.

Effect of pregnancy on SLE

Pregnancy is associated with an increased risk of SLE flare, which may occur at any stage of the pregnancy or postpartum. Neither the severity nor the type (e.g. renal or skin) of flare is altered by pregnancy. Flares may be harder to diagnose in pregnancy because many features, such as fatigue, erythema, anaemia and hair loss, are common to both.¹⁰

Pregnancy does not alter the antibody profile but increases the ESR and may exacerbate thrombocytopenia.

Effect of SLE on pregnancy outcome

In women who have quiescent SLE, have no renal involvement and are Ro/La and aPL negative, there is no adverse effect of their disease on pregnancy.¹⁰ Active disease at conception, renal involvement and APS increase the risks of miscarriage, pre-eclampsia, FGR, preterm delivery and stillbirth.

Management

This should begin with pre-pregnancy counselling enabling an accurate risk assessment for individual women. Women should be advised to conceive during periods of disease remission. Once pregnancy is confirmed (or pre-pregnancy if there is a delay in conception), NSAIDs are discontinued. Hydroxychloroquine is continued because it is safe, withdrawal may precipitate flare and it has a very long half-life such that the fetus remains exposed for up to 3 months after the mother discontinues the drug.¹⁰ Prednisolone and azathioprine are also continued. During pregnancy, SLE flares are treated with new or increased doses of steroids [C].^{10,11}

Not only are women with renal lupus at increased risk of pre-eclampsia, but also pre-eclampsia may be harder to diagnose in such women, who already have hypertension and proteinuria. Low platelets, renal impairment, oedema, worsening hypertension and proteinuria may be attributable to either. Pointers to a renal lupus flare include red cells or red cell casts in the urine, hypocomplementaemia (falling levels of C3 and C4) and a rising anti-DNA titre. Pointers to a diagnosis of pre-eclampsia include raised transaminases and absence of other features of SLE flare. Those at high risk of pre-eclampsia and

FGR should be offered serial growth scans and tests of fetal wellbeing as indicated. Regular visits to a joint obstetric/rheumatology clinic are important to screen for pre-eclampsia and SLE flare.

NEONATAL LUPUS SYNDROMES

These are caused by anti-Ro or anti-La antibodies and manifest as cutaneous neonatal lupus, affecting 5 per cent of babies of Ro-positive women, and congenital heart block, affecting 2 per cent of babies of Ro-positive women. If the first child is affected, the risk to the second child is 10-fold higher, and once two children are affected the risk rises to about 50 per cent. Neonatal cutaneous lupus develops in the first 2 weeks of life and is a geographical skin lesion of the face or scalp. It may be precipitated by exposure to ultraviolet light and usually regresses spontaneously without scarring within 6 months. Congenital heart block develops *in utero* at 18–30 weeks' gestation. There is no treatment, and one in five affected babies dies *in utero* or as a neonate. About half of those surviving require pacemakers in early infancy and the rest by their teens.¹⁰ Ro-positive women should be offered fetal cardiology screening [C]. Retrospective data suggest hydroxychloroquine may reduce the risk of congenital heart block.

ANTIPHOSPHOLIPID SYNDROME

This describes the association of aPLs (either aCL antibodies or lupus anticoagulant) with the clinical features shown in Table 14.3.¹²

Additional clinical features include thrombocytopenia, livedo reticularis, epilepsy, migraine, heart valve disease and

Table 14.3 Classification criteria for antiphospholipid syndrome

Clinical criteria	
Thrombosis	Venous
	Arterial
	Small vessel
Pregnancy morbidity	Three or more consecutive miscarriages (<10 weeks)
	One or more fetal death (>10 weeks)
	One or more premature birth (<35 weeks) due to severe pre-eclampsia or placental insufficiency
Laboratory criteria	
Anticardiolipin antibody	IgG or IgM
	Medium/high titre
	Two or more occasions >12 weeks apart
Lupus anticoagulant	Two or more occasions >12 weeks apart

pulmonary hypertension. APS may be primary or found in association with SLE, RA or other connective tissue disease. Therefore women with primary APS, even if based on a positive lupus anticoagulant, do not have 'lupus' unless there are features of SLE (see Table 14.1).

The pathogenesis of APS involves a co-factor, beta-2 glycoprotein. Antiphospholipid antibodies reduce hCG release and inhibit trophoblast invasion in vitro – a potential explanation for the association with miscarriage. However, the 'typical APS' fetal loss occurs in the second trimester and is associated with severe FGR, oligohydramnios and early onset pre-eclampsia.¹³

The common feature is defective or abnormal placentation, possibly related to thrombosis.

Pregnancy in women with APS is associated with an increased risk of thrombosis. This is particularly so for women with previous thrombosis. APS is an acquired thrombophilia and may therefore affect unusual sites such as the axillary or retinal veins. What makes APS particularly dangerous is the fact that thrombosis may also affect arterial and small vessels, causing, for example, stroke or renal disease. In general, those women who have had a previous venous thrombosis are at risk of recurrent venous thromboses, and those with previous arterial thrombosis at risk of recurrent arterial events. Pregnancy also increases the risk of, or may exacerbate, pre-existing thrombocytopenia.

The effect of APS on pregnancy is to increase the risk of early and late miscarriage, stillbirth, placental abruption, FGR and pre-eclampsia.¹³

Management

APS should be managed in pregnancy by multidisciplinary teams with expertise in caring for these high-risk pregnancies. Those women with a previous history of arterial or venous thrombosis will usually be on long-term treatment with warfarin or other oral anticoagulants. This should be converted to aspirin and high prophylactic or treatment doses of LMWH as soon as pregnancy is confirmed and at least before 6 weeks' gestation to avoid warfarin embryopathy (see Chapter 27). LMWH is continued in high prophylactic doses throughout pregnancy and postpartum for 6 weeks or until warfarin is recommenced.

For women without a previous history of thrombosis, there is agreement that low-dose aspirin (75 mg/day) is beneficial, although supportive evidence is mostly from retrospective, non-randomised studies. Indeed, randomised studies do not support a beneficial effect of aspirin, but this is because such studies have included very-low-risk groups of women, some without any previous history of adverse pregnancy outcome. Low-dose aspirin is safe and all centres with an interest in APS use aspirin sometimes from pre-conception [D].¹³ The role of LMWH in addition to aspirin is more controversial.¹⁴ Two prospective studies of women with aPLs and recurrent miscarriage demonstrated significantly increased livebirth rates in

groups allocated to aspirin and LMWH versus those receiving aspirin alone, and current RCOG guidelines advocate the use of LMWH in addition to aspirin for women with recurrent miscarriage and aPLs (see Published guidelines at the end of this chapter). However, both these studies had an unusually low livebirth rate in the aspirin-alone groups. Two more recent randomised studies failed to show any increased benefit of LMWH over and above aspirin alone in women with APS and recurrent pregnancy loss.¹⁴ That said, in women who have suffered late fetal losses or neonatal deaths attributable to APS, the risk of adverse pregnancy outcomes is higher and it is common to recommend LMWH in these situations [D].^{13,15}

EBM

- Evidence supports the use of high prophylactic doses of LMWH throughout pregnancy in women with APS who have had previous thromboses.
- Evidence from retrospective and cohort studies supports a role for low-dose aspirin for fetal indications.
- There is growing evidence that the use of LMWH in addition to aspirin for recurrent miscarriage provides no additional benefit.

A suggested management plan is given in Table 14.4. The risk of pre-eclampsia, abruption, FGR and preterm delivery is less for women with APS diagnosed as a result of recurrent early miscarriage compared with those women with APS diagnosed as a result of later pregnancy adverse outcome.^{13,15} Past obstetric history is the best predictor of risk, although success rates for women diagnosed and treated for APS are about 70–80 per cent.^{13–15} All women require careful and regular monitoring for pre-eclampsia, and serial growth scans and tests of fetal wellbeing as appropriate [D].¹³ Liaison with obstetric anaesthetists is vital prior to delivery in women receiving LMWH for any indication. In those who have had previous thromboses, discontinuation of LMWH peripartum should be minimal, but, for those receiving LMWH for purely fetal indications, it may simplify the management of analgesia and anaesthesia for labour and delivery if the LMWH is discontinued prior to delivery.

Table 14.4 Management recommendations for APS pregnancies

aPL antibodies; no thrombosis or pregnancy loss	Aspirin 75 mg or nothing
Previous thrombosis	LMWH and aspirin
Previous recurrent (>3) miscarriages (<10 weeks)	Aspirin +/- LMWH (? stop LMWH at 13–20 weeks)
Fetal loss or severe pre-eclampsia/FGR/NND	Aspirin + LMWH

- NND, neonatal death.

SJÖGREN'S SYNDROME

This typically causes dry eyes and a dry mouth. The dry eyes may be confirmed objectively with Schirmer's tear test. Similar to APS, Sjögren's syndrome may be primary or associated with SLE, RA or other connective tissue disease. This syndrome is typically associated with positivity for Ro and La antibodies, and therefore the risk of neonatal lupus and congenital heart block (see above). Primary Sjögren's syndrome is associated with the finding of positive rheumatoid factor and positive ANA, and hypergammaglobulinaemia.

SCLERODERMA

Scleroderma may occur as a localised cutaneous form, as systemic sclerosis, or as part of the CREST syndrome (calcinosis, Raynaud's phenomenon, (o)esophageal involvement, sclerodactyly and telangiectasia). Skin involvement produces characteristic facies with a beaked nose and limited mouth opening, limiting facial expression. Systemic fibrosis involves the oesophagus, the lungs, the heart and the kidneys. There is no effective definitive treatment for scleroderma, although symptoms may be controlled with calcium antagonists, procyclin and specific treatments for renal involvement (ACEIs) and pulmonary hypertension (sildenafil, bosentan).

Adverse effects on pregnancy relate to the degree of any renal, lung or cardiac involvement. Women with early diffuse disease are at increased risk in pregnancy and therefore women should be advised to postpone pregnancy until the disease has stabilised.¹⁶ Those with severe pulmonary fibrosis or pulmonary hypertension should be advised against pregnancy [E]. Those with renal involvement and hypertension are at increased risk of pre-eclampsia and FGR. Oesophageal symptoms often increase in pregnancy, but those of Raynaud's phenomenon may improve secondary to vasodilatation.

Management

Pre-pregnancy counselling is vital to inform women accurately about the potential risks of pregnancy. Formal lung function and echocardiography to assess the extent of systemic involvement are recommended. During pregnancy, regular multidisciplinary assessment is required, with screens of blood pressure, urinalysis, renal function and maternal symptoms. Scleroderma renal crises are extremely dangerous and ACEIs should not be stopped in pregnancy or withheld [E]. Raynaud's phenomenon may be ameliorated with heated gloves and calcium antagonists. High-dose corticosteroids, such as used to induce fetal lung maturation, should be avoided because they may precipitate a renal crisis. Assessment by an obstetric anaesthetist prior to delivery is essential. In women with scleroderma, there are often problems with blood pressure measurement, venous access, capillary oxygen saturation monitoring and difficult airways.

KEY POINTS

- RA commonly improves in pregnancy and deteriorates postpartum.
- SLE is more likely to flare in pregnancy.
- Adverse pregnancy outcome in SLE is related to the presence of APS, renal involvement, disease activity and the presence of anti-Ro and -La antibodies.
- Ro and La antibodies are associated with Sjögren's syndrome and may cause congenital heart block and neonatal lupus.
- APS may cause arterial, venous or capillary thrombosis, miscarriage, late fetal loss, early onset pre-eclampsia and severe FGR.
- APS is treated in pregnancy with low-dose aspirin and LMWH.
- Steroids are safe to treat connective tissue disease in pregnancy and are used in preference to NSAIDs.

Chapter 15 Liver and gastrointestinal disease

Catherine Nelson-Piercy

MRCOG standards

Theoretical skills

Understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of women with liver and gastrointestinal disease.

Practical skills

Be able to manage independently:

- irritable bowel syndrome,
- reflux oesophagitis,
- hyperemesis,
- obstetric cholestasis.

Be able to manage under direct supervision pregnant women with:

- Crohn's disease and ulcerative colitis,
- acute fatty liver of pregnancy,
- hepatitis.

to pregnancy – obstetric cholestasis and acute fatty liver of pregnancy – and those that pre-date or coincide with pregnancy – viral hepatitis and chronic liver disease. HELLP syndrome is discussed in Chapter 26. Gastrointestinal diseases usually pre-date the pregnancy; inflammatory bowel disease (IBD) and irritable bowel syndrome are the most common. Gastrointestinal problems exacerbated or brought on by pregnancy, such as gastro-oesophageal reflux and hyperemesis, are also discussed.

PHYSIOLOGICAL CHANGES IN PREGNANCY

Pregnancy causes decreased lower oesophageal pressure, decreased gastric peristalsis and delayed gastric emptying. Gastrointestinal motility is reduced, with increased small-bowel and large-bowel transit times. There is a 20–40 per cent fall in serum albumin concentration, partly due to dilution resulting from the increase in total blood volume. Total serum protein concentration also decreases. The alkaline phosphatase concentration more than doubles due to production by the placenta, which increases with gestation. Levels of alanine transaminase (ALT), serum glutamic-pyruvic transaminase (SGPT), aspartate transaminase (AST) and serum glutamic-oxaloacetic transaminase (SGOT) fall, and there is a fall in the upper limit of the normal ranges for these enzymes (Table 15.1).¹ Thus a mildly abnormal level for transaminases that may be significant in the diagnosis of obstetric cholestasis

INTRODUCTION

Liver disease in pregnancy is encountered relatively rarely, but gastrointestinal problems, including nausea, vomiting, oesophageal reflux and constipation, are almost universal. Liver disease can be dangerous for both the mother and the fetus. This chapter considers the liver conditions specific

Table 15.1 Normal ranges for liver enzymes in non-pregnant and pregnant women

Liver enzyme	Non-pregnant	First trimester	Second trimester	Third trimester
AST (IU/L)	7–40	10–28	10–29	11–30
ALT (IU/L)	0–40	6–32	6–32	6–32
Bilirubin (µmol/L)	0–17	4–16	3–13	3–14
γ-Glutamyl transferase (γ GT) (IU/L)	11–50	5–37	5–43	3–41
Alkaline phosphatase (IU/L)	30–130	32–100	43–135	133–418

or in the assessment of pre-eclampsia may be overlooked unless pregnancy-specific ranges are used. The concentrations of other liver enzymes are not substantially altered and there is no significant change in bilirubin concentration during normal pregnancy.

NAUSEA, VOMITING AND HYPEREMESIS

Nausea and vomiting are common symptoms in early pregnancy, affecting over half of pregnant women. The onset of symptoms is usually early in the first trimester at around 5–6 weeks' gestation. Hyperemesis is less common, but causes much morbidity and repeated hospital admissions and can be dangerous if inadequately or inappropriately treated. Nausea and vomiting in pregnancy become hyperemesis if the woman is unable to maintain adequate hydration and nutrition, because of either severity or duration of symptoms. This is associated with marked weight loss, muscle wasting, ketonuria, dehydration and electrolyte disturbance, including hypokalaemia and a metabolic hypochloreaemic alkalosis. A common associated symptom is ptyalism – the inability to swallow saliva. The risks associated with hyperemesis include FGR, maternal hyponatraemia leading to central pontine myelinolysis, and thiamine deficiency leading to Wernicke's encephalopathy.² Markers of severity include weight loss >10 per cent, abnormal thyroid function tests with raised free T₄ and suppressed TSH, and abnormal liver function tests with raised transaminases.

Management

Other possible causes of nausea and vomiting should be considered, especially UTI (which often coincides with hyperemesis), hypercalcaemia, Addison's disease and thyrotoxicosis (weight loss, heat intolerance and tachycardia precede the pregnancy), and cholecystitis. An ultrasound scan of the uterus is important to exclude multiple pregnancy and hydatidiform mole, both of which increase the risk of hyperemesis. The most important component of management (Table 15.2) is to ensure adequate rehydration. This should be with 0.9% saline with added potassium chloride sufficient to correct tachycardia, hypotension and ketonuria, and return electrolyte levels to normal. Dextrose-containing fluids are avoided except in women with diabetes. High concentrations of dextrose in particular may precipitate Wernicke's encephalopathy. This is prevented by routine administration of oral or intravenous thiamine. Antiemetics may be liberally and safely used in pregnancy [A, C].²⁻⁴ Women with severe hyperemesis may require regular parenteral doses of more than one antiemetic to control their symptoms. Even for women with nausea and vomiting in pregnancy that do not require hospital admissions

Table 15.2 Protocol for the management of hyperemesis

Investigations	U&Es, FBC, LFTs, TFTs
MSU	US scan of the uterus
Fluid therapy	0.9% saline 1 L + 20–40 mmol KCl 8-hourly
Vitamin therapy	Thiamine orally 25–50 mg t.d.s. <i>or</i> thiamine intravenously 100 mg in 100 mL 0.9% saline weekly
Antiemetic therapy	Possible regimens include: <ul style="list-style-type: none"> ● Cyclizine 50 mg p.o./i.m./i.v. t.d.s. ● Promethazine 25 mg p.o. nocte ● Stemetil 5 mg p.o. t.d.s.; 12.5 mg i.m./i.v. t.d.s. ● Metoclopramide 10 mg p.o./i.m./i.v. t.d.s. ● Domperidone 10 mg p.o. q.d.s.; 30–60 mg p.r. t.d.s. ● Chlorpromazine 10–25 mg p.o.; 25 mg i.m. t.d.s. ● Ondansetron 4–8mg p.o./i.v.

- i.m., intramuscularly; i.v., intravenously; p.o., orally; p.r., as required; q.d.s., four times daily; t.d.s., three times daily; US, ultrasound.

but interfere with work and home life, antiemetics may be appropriate. For women with severe hyperemesis who do not improve despite conventional treatment with IV fluids and electrolytes and regular antiemetics, a trial of ondansetron or corticosteroids may be considered [B].^{2,5,6} Iron supplements may induce nausea and vomiting, and should be withheld until symptoms resolve.

EBM

- There are substantial data from systematic reviews³ and cohort studies² to support the safety of conventional antiemetics in pregnancy, including the first trimester.
- Several RCTs⁵ support a beneficial effect of corticosteroids for severe disease.

GASTRO-OESOPHAGEAL REFLUX

About two-thirds of women experience heartburn in pregnancy, commonly in the third trimester. This is partly because of increased reflux due to the decreased lower oesophageal pressure, decreased gastric peristalsis and delayed gastric

emptying, and partly due to the enlarging uterus. Reflux of acid or alkaline gastric contents into the oesophagus causes inflammation of the oesophageal mucosa, leading to pain, waterbrash and dyspepsia.

Management

Postural changes, such as sleeping in a semi-recumbent position, may help, especially in late pregnancy. Avoiding food or fluid intake immediately before retiring may also prevent symptoms. Antacids are safe in pregnancy and may be used liberally. Liquid preparations are more effective and should be given to prevent and treat symptoms. Aluminium-containing antacids may cause constipation, and magnesium-containing antacids may cause diarrhoea. Metoclopramide increases lower oesophageal pressure and speeds gastric emptying, and may help relieve reflux. Sucralfate and histamine H₂-receptor blockers (e.g. ranitidine) are both safe throughout pregnancy. Proton-pump inhibitors (PPIs) such as omeprazole are more powerful suppressors of gastric acid secretion, and are also safe.⁴ It should be reserved for reflux oesophagitis when H₂-receptor blockers have failed.

PEPTIC ULCER

Peptic ulceration is rare in pregnancy. Presentation is usually with epigastric pain rather than with complications such as haemorrhage or perforation. Prostaglandins induced by pregnancy have a protective effect on the gastric mucosa, thus explaining the reduced incidence compared with non-pregnant women. Gastrointestinal endoscopy (including the sedation used for the procedure) is safe in pregnancy and should be used to investigate all but minor haematemesis.

Management

Antacids, sucralfate and H₂-receptor blockers and PPIs are all safe in pregnancy. *Helicobacter pylori* has a causal role in peptic ulceration, but eradication therapy is usually deferred until after delivery. Misoprostol, a prostaglandin analogue, protects the gastric mucosa but is contraindicated during pregnancy because of the risk of miscarriage.

CONSTIPATION

This is another common symptom of normal pregnancy, probably due to reduced colonic motility. Poor dietary intake associated with nausea and vomiting, dehydration, opiate analgesia and iron supplements exacerbates constipation. Management includes advice regarding increased fluid intake and dietary fibre. Temporary cessation of oral iron supplements may help, and laxatives should be used only if the

EBM Gastro-oesophageal reflux, dyspepsia, constipation

- There are substantial data from systematic reviews³ to support the safety of antacids, anti-emetics, sucralfate, H₂-receptor blockers and PPIs in pregnancy.
- Misoprostol should be avoided.
- Osmotic and stimulant laxatives are safe to use in pregnancy.

above measures fail. Osmotic laxatives, such as lactulose and magnesium hydrochloride, are safe. Stimulant laxatives, such as glycerol suppositories, and senna (Senokot®) tablets are also safe in pregnancy.

INFLAMMATORY BOWEL DISEASE

Both Crohn's disease and ulcerative colitis tend to present in young adulthood. Ulcerative colitis is more common in women and is encountered more commonly in pregnancy. The course of IBD is not usually affected by pregnancy. The risk of flare in pregnancy is reduced if the colitis is quiescent at the time of conception. Most exacerbations occur early in pregnancy and cause abdominal pain, diarrhoea, and passage of rectal mucus and blood. Women with Crohn's disease may experience postpartum flare. Pregnancy outcome is usually good in women with IBD, although active disease at the time of conception is associated with an increased risk of miscarriage, and active disease later in pregnancy may adversely affect pregnancy outcome, with an increased rate of pre-term delivery.^{7,8} Prior surgery, including ileostomy, proctocolectomy and pouch surgery, does not preclude successful pregnancy.

Management

Women with IBD should be encouraged to conceive during periods of disease remission. Management is not substantially affected by pregnancy. Oral or rectal sulfasalazine (Salazopyrin), mesalazine (Asacol) and other 5-aminosalicylic acid drugs may be safely used throughout pregnancy and breastfeeding, although, as sulfasalazine is a dihydrofolate reductase inhibitor, 5 mg daily folic acid should be used pre-conception and in pregnancy to reduce the increased risk of neural tube defects, cardiovascular defects, oral clefts and folate deficiency. Oral and rectal preparations of corticosteroids may be required for acute treatment or maintenance and are safe in pregnancy. Azathioprine may be needed to maintain remission and this should be continued in pregnancy (see Chapter 14).⁸ Biologic therapies such as the anti-TNF agents (infliximab and adalimumab) are used

increasingly in IBD. Available data suggest that these agents are safe in pregnancy but should ideally be discontinued by 30 weeks' gestation [D].^{9,10}

Clinicians must remain alert to the possible dangerous surgical complications of IBD, including intestinal obstruction, haemorrhage, perforation or toxic megacolon. Caesarean section may be indicated in the presence of severe perianal Crohn's disease with a deformed, inelastic or scarred rectum and perineum. Active perianal Crohn's may prevent healing of an episiotomy.

EBM Inflammatory bowel disease

- Evidence from systematic review⁷ supports an association between conception during periods of active disease and adverse pregnancy outcome.
- Sulfasalazine and related drugs are safe in pregnancy, but folic acid 5 mg/day should be given concomitantly.
- Corticosteroids and azathioprine may safely be used for maintenance or acute management of disease flares.^{7,8}

ACUTE AND CHRONIC VIRAL HEPATITIS

The course of most viral hepatitis is not altered by pregnancy. Pregnant women may contract acute hepatitis in the same way and with the same clinical features as non-pregnant women. Thus fever, malaise, anorexia, jaundice and possible recent exposure should alert the clinician to the diagnosis. The implications of acute hepatitis infection in pregnancy are discussed in Chapter 24. As with acute hepatitis B infections, neonates born to women with chronic hepatitis B virus (HBV) should be given hepatitis B immune globulin and HBV vaccine within 24 hours of birth. Immunisation is 85–95 per cent effective at preventing both HBV infection and the chronic carrier state. There is a significant risk (60–80 per cent) of hepatitis C infection progressing to chronic infection, and about 20 per cent of those with chronic infection develop slowly progressive cirrhosis over a period of 10–30 years. Detection of hepatitis C virus (HCV) antibody implies persistent infection rather than immunity. The risk of progressive liver disease with hepatitis C is lower in women and in those aged <40 years who do not abuse alcohol. Women with hepatitis C are at increased risk of obstetric cholestasis (see below).¹¹

CHRONIC LIVER DISEASE

Severe hepatic impairment is associated with infertility. Liver disease may decompensate during pregnancy, and pregnancy should be discouraged in women with severe impairment of

hepatic function. Those with portal hypertension and oesophageal varices are at risk from variceal bleeding, especially in the second and third trimesters.

OBSTETRIC CHOLESTASIS

This is a liver disease specific to pregnancy, characterised by pruritus affecting the whole body but particularly the palms and soles, and abnormal liver function tests. It is more common in women from South America, the Indian subcontinent and Scandinavia. The prevalence in the UK is about 0.7 per cent.¹² The aetiology is unknown, but relates to a genetic predisposition (one-third of patients have a positive family history) to the cholestatic effect of oestrogens.

Obstetric cholestasis most commonly presents in the third trimester at around 30–32 weeks' gestation.¹² Women with pruritus but without a rash, other than excoriations, should have liver function tests. These must be interpreted with reference to the normal ranges for pregnancy¹ since often in obstetric cholestasis the hepatic transaminases are only mildly elevated. The most usual abnormality is raised ALT or AST, although a small proportion of women have only a raised gamma GT or raised bile acids.¹³ Although raised bile acids are not necessary to confirm the diagnosis, they are useful, especially in those women with typical clinical features but normal standard liver function tests.¹³ There may be associated dark urine, pale stools, steatorrhoea and malaise. Obstetric cholestasis is a diagnosis of exclusion, and the differential diagnosis includes extrahepatic obstruction with gallstones, acute or chronic viral hepatitis, primary biliary cirrhosis (PBC) and chronic active hepatitis (CAH). Investigations should therefore include a liver ultrasound, serology for hepatitis A, B and C, and liver autoantibodies (anti-mitochondrial antibodies to exclude PBC and anti-smooth muscle antibodies to exclude CAH).

The risks with obstetric cholestasis include postpartum haemorrhage (related to vitamin K deficiency secondary to malabsorption of fat), preterm labour, meconium-stained liquor, fetal distress (CTG abnormalities) in labour and, rarely, intrauterine death (IUD).^{14,15} The cause of the adverse effects on the fetus is unknown. The risk of IUD increases towards

EBM Obstetric cholestasis

- Evidence from prospective studies,^{12,13} supports the need for a high index of clinical suspicion, and therefore serial measurement of liver function tests, in women with onset of pruritus affecting predominantly the palms and soles in the third trimester.
- The evidence also highlights significant increased risks of adverse perinatal outcomes in women with severe cholestasis.

and beyond term but does not correlate with either symptoms or transaminases. There is a correlation with bile acid levels.^{14,15}

Management

This should involve counselling the woman regarding the above risks. Liver function tests and clotting times should be monitored regularly. Current guidelines suggest that there is insufficient evidence to support the common practice of expediting delivery at 37–38 weeks unless the bile acids exceed 40 µmol/l. Vitamin K should be given to the mother (10 mg orally daily) if the clotting is deranged to reduce the risk of postpartum haemorrhage. No specific method of fetal surveillance can be recommended to predict fetal complications in mothers with obstetric cholestasis. Although such monitoring may serve to reassure the mother and her carers, delivery is rarely indicated earlier than 37 weeks on the basis of such monitoring. Management strategies that involve elective early (by 38 weeks) delivery and fetal surveillance have shown a decreased risk of IUD compared with earlier studies, but also result in increased rates of caesarean section, prematurity and admissions to neonatal intensive care units.¹²

Control of symptoms may be achieved with a combination of antihistamines and emollients or, if these are insufficient, ursodeoxycholic acid (UDCA). This drug usually leads to rapid reduction in liver function tests and pruritus, but there is as yet no evidence for a reduction in fetal risk. A pilot RCT showed that UDCA significantly reduced pruritus and that early term delivery did not increase the caesarean section rate. A larger trial is planned.¹⁶

Following delivery, liver function tests return to normal and there is no permanent detrimental effect on maternal liver function. Symptoms may recur with menstruation (cyclical itching) or with oestrogen-containing oral contraceptives, which should therefore be avoided. Recurrence of obstetric cholestasis in subsequent pregnancies exceeds 90 per cent.

KEY POINTS

Obstetric cholestasis

- Liver function tests should be requested in any pregnant woman with pruritus without obvious rash.
- Liver function tests should be repeated serially if the itching involves the palms and soles.
- Other causes of pruritus and abnormal liver function tests, including viral hepatitis and gallstones causing extrahepatic obstruction, should be excluded.
- Severe cholestasis is associated with a significantly increased risk of preterm delivery and stillbirth.
- Fetal risks increase with increasing bile acid levels.
- UDCA improves symptoms and liver function tests

ACUTE FATTY LIVER OF PREGNANCY

This is another pregnancy-specific liver disease. It is rare and a recent UK-wide study found a prevalence of 5 per 100 000.¹⁴

Acute fatty liver of pregnancy (AFLP) is closely related to, and shares many features and probably pathophysiology with, pre-eclampsia. It usually presents in the third trimester with abdominal pain, nausea, vomiting, anorexia and sometimes jaundice. It is associated with markedly deranged liver function tests, renal impairment, a markedly elevated uric acid, a raised white cell count, hypoglycaemia and coagulopathy.¹⁴

Clinical features of pre-eclampsia may be mild or absent. It is more common in twin pregnancies. It may come to light only after delivery when coagulation is checked because of excessive bleeding. It is also associated with diabetes insipidus and may present with polyuria and polydipsia. Perinatal and maternal mortality and morbidity rates are increased (10 and 1.8 per cent, respectively).¹⁴

Management

This should involve a high-dependency or intensive care unit and a multidisciplinary team. Delivery should be expedited following adequate correction of any hypoglycaemia or coagulopathy with 50 per cent dextrose, intravenous vitamin K and fresh frozen plasma. Management after delivery is conservative, although early referral to a liver unit should be considered if liver function does not improve or if there are any features of hepatic encephalopathy.

Chapter 16 Respiratory conditions

Louise Kenny

MRCOG standards

Taken from Core Curriculum Module 9: Maternal Medicine, <http://www.rcog.org.uk/files/rcog-corp/uploaded-files/ED-CORE-9.pdf>

Theoretical skills

- Understand the epidemiology, aetiology, pathophysiology, clinical characteristics and prognostic features of pulmonary diseases in pregnancy.
- Understand the impact that pregnancy may have on pre-existing pulmonary disease and the influence the illness may have on pregnancy.
- Specific mention is made of asthma, infection, embolism and aspiration syndrome. However, venobolism and aspiration syndrome are dealt with elsewhere within this text. Pre-existing common pulmonary disease and infection are discussed here in detail.

Practical skills

- Diagnose, investigate and manage pulmonary disease in pregnancy with specific reference to asthma, infection, embolism and aspiration syndrome.
- Manage a pregnancy complicated by pre-existing pulmonary disease.
- Request and interpret pulmonary investigations with reference to pregnancy.

INTRODUCTION: PULMONARY DISEASE IN PREGNANCY

The physiological changes occurring within the respiratory system are summarised in Tables 16.1 and 16.2. Symptomatically, pregnant women may complain of new-onset rhinitis, which

may result from oestrogen-induced oedema, hyperaemia and hypersecretion of the upper airways. Although mostly harmless, this contributes to the greater difficulties encountered during intubation of pregnant women. Much more common is the complaint of shortness of breath or 'air hunger'. This dyspnoea is experienced by approximately half of all pregnant women by 20 weeks' gestation and by three-quarters by 30 weeks. It rarely occurs at rest and does not significantly impair normal activities. The postulated mechanism is high

Table 16.1 Normal arterial blood gas values and the effect of pregnancy

	Pre-pregnancy	By term
PaO ₂	11–13 kPa (83–98 mmHg)	13 kPa (98 mmHg)
PaCO ₂	4.8–6.0 kPa (36–45 mmHg)	3.7–4.2 kPa (28–32 mmHg)
HCO ₃ ⁻	24–30 mmol/L	18–21 mmol/L
pH	7.35–7.45	7.4–7.45

Table 16.2 The effect of pregnancy on lung function

Lung function	Change by term	Actual volume change
Total lung capacity	4% decrease	200–400 mL
Functional residual	10–20% decrease	300–500 mL capacity
Expiratory reserve	15–20% decrease	100–300 mL volume
Tidal volume	30–50% increase	200 mL
Minute (or expired volume in 1 min) ventilation	30–50% increase	3 L/min
Residual volume	20–25% decrease	200–300 mL
Respiratory rate	No change	
Vital capacity	No change	
Peak flow	No change	
Metabolic rate	15% increase	
Oxygen consumption (V _{O₂})	20–33% increase	

progesterone levels acting via the hypothalamus to increase respiratory drive.

Anatomically, the lower chest wall circumference increases by 5–7 cm, the diaphragm is elevated 4–5 cm by term and the costal angle widens. These changes occur due to pressure from the expanding uterus and the relaxation of thoracic ligaments. Diaphragmatic excursion is not reduced; however, the accessory muscles contribute proportionally more than the diaphragm to the increase in tidal volume found in pregnancy.

The metabolic rate becomes elevated in pregnancy, as demonstrated by a rise in resting oxygen uptake and carbon dioxide output. This extra oxygen turnover is of course necessary for the fetoplacental unit and the extra demands made by maternal physiology. Minute ventilation (or volume expired in a minute) and alveolar ventilation are both increased to meet this demand by an increase in tidal volume rather than by a change in respiratory rate, which remains constant. This state of relative hyperventilation causes a fall in PaCO_2 , which results in a chronic respiratory alkalosis. Blood pH is kept within the normal range by a reactionary increase in renal bicarbonate excretion.

Airway function is maintained and peak expiratory flow rate (PEFR) and forced expiratory volume in 1 second (FEV_1) measurements are not affected by pregnancy.

Investigating pulmonary disease in pregnancy

The physiological changes occurring in pregnancy must also be considered when interpreting the results of investigations. The effect on arterial blood gas analysis is clear from Table 16.1. The chest X-ray must also be interpreted with caution. The cardiothoracic ratio is elevated, vascular markings may become more prominent, and small pleural effusions are even possible in normal pregnancy. Peak flow and spirometry tests can be interpreted in the usual manner.

Concern is often raised about the safety of various radiological examinations during pregnancy. For a fuller description of risks to the fetus, see Chapter 23. The maximum safe exposure for the fetus is often considered to be 5 cGy, although this is gestation dependent [D]. Chest X-ray, venography, pulmonary angiography and ventilation–perfusion (V/Q) scanning all expose the fetus to significantly lower levels than this, and the potential benefits of all these investigations are usually thought to outweigh the risks. However, exposure should be minimised where possible. For example:

- lateral chest X-rays are often unnecessary and carry a greater exposure risk than an anteroposterior (AP) erect chest film; they can mostly be avoided;
- a mobile chest X-ray carries greater exposure than a departmental film, so the patient should be moved where possible;
- the ‘ventilation’ component of V/Q scanning can be omitted in women with no previous history of chest disease;
- pulmonary angiography carries less fetal risk if a brachial route is used in preference to the femoral.

Shielding of the fetus should be used where the situation allows. CT scanning utilises much higher energy levels, and safer alternatives are usually available. However, if the indication is strong enough, even CT has its place. Spiral and non-contiguous axial imaging are techniques that may reduce exposure without compromising diagnostic accuracy. MRI involves no irradiation and is also considered safe.

ASTHMA

The incidence of asthma appears to be increasing globally. There is some geographical variation, with reported prevalence in pregnancy ranging from 4 per cent to 12 per cent. Consequently, asthma is the respiratory illness most likely to be encountered during pregnancy and up to 6 per cent of women are hospitalised on at least one occasion for asthma during pregnancy.

The effect of pregnancy on asthma

The true effect of pregnancy on asthma severity has been addressed by a number of prospective case-controlled studies which suggest that asthma will deteriorate, stay the same and improve in equal measure.¹ The potential benefits of pregnancy-induced immune system alterations and progesterone-mediated bronchodilatation may be opposed by the reluctance of patients and physicians to treat asthma appropriately for fear of harming the fetus through drug exposure. Women with severe asthma seem more likely to deteriorate, whilst those showing improvement during pregnancy are more likely to suffer postpartum relapse.² Approximately 1 in 10 women with asthma will suffer an acute attack in labour [C].

The effect of asthma on pregnancy

The precise effect that the asthma has on the pregnancy is unclear. Almost every conceivable obstetric complication has been found to be more common in pregnant women with asthma by one case–control study or another. However, the pattern of antenatal complications varies greatly among studies and this lack of consistency has cast doubt over the findings. Poor controls, varied case mixes and different treatment regimens make resolution of the data very difficult.

Several studies have reported an association with asthma and an elevated risk of hypertension in pregnancy. Recent evidence suggests that this risk is confined to women with pre-existing severe asthma and points to a mechanistic common pathway of mast cell–airway smooth muscle cell interactions.³

Moderate-to-severe asthma and poorly controlled asthma with frequent exacerbations are associated with other adverse

outcomes including intrauterine growth restriction and preterm rupture of membranes/labour so increased surveillance is justified [E].

Management of asthma in pregnancy

In the recent Eighth Report of the CEMD in the UK, there were five indirect deaths due to asthma (mortality of 0.22 per 100,000 maternities), a similar number to those in the two previous reports.⁴ None of the five women who died had received specialist care in pregnancy even though three of them had many hospital admissions or a history of asthma that was particularly difficult to treat. This highlights the need for specialist input in pregnant women with severe asthma.

Asthma will usually have been diagnosed prior to pregnancy and treatment already instituted. However, this is not always the case, and the initial presenting signs and symptoms of asthma are the same as those of asthma that is inadequately treated:

- chest tightness and wheeziness;
- cough;
- breathlessness, especially in the early hours of the morning.

The management of asthma in pregnancy is essentially the same as in the non-pregnant patient and should be in line with current guidelines from British Thoracic Society/SIGN.⁵

Prevention is the key, and known triggers of exacerbations should be eliminated or avoided in the home and at work (Table 16.3).

Pharmacological treatment of asthma

This follows a step-by-step approach, more clearly outlined in the current guidelines from British Thoracic Society/SIGN. In general, the medicines used to treat asthma are safe in pregnancy. A large UK population-based case-control study found no increased risk of major congenital malformations in children of women receiving asthma treatment in the year before or during pregnancy. The risk of harm to the

Table 16.3 Triggers and provocative stimuli for exacerbations of asthma

Allergens	Pollen (seasonal)
	Dust mites, animal danders, moulds (non-seasonal)
Occupational	Industrial chemicals, metal salts, wood and vegetable dust
Infection	Viral and/or bacterial
Environmental pollution	Tobacco smoke, ozone
Pharmacological	Aspirin and NSAIDs, beta blockers
Emotional stress	
Exercise and cold air	

EBM

Counsel women with asthma regarding the importance and safety of continuing their asthma medications during pregnancy to ensure good asthma control [B]

fetus from severe or chronically under-treated asthma outweighs any small risk from the medications used to control asthma.

No significant association has been demonstrated between major congenital malformations or adverse perinatal outcome and exposure to short-acting or long-acting β_2 agonists, and these can be used with confidence in pregnancy.

A meta-analysis of four studies of inhaled corticosteroid use in pregnancy showed no increase in the rate of major malformations, preterm delivery, low birthweight or pregnancy-induced hypertension, and therefore inhaled steroids should be used as normal during pregnancy.

No significant association has been demonstrated between major congenital malformations or adverse perinatal outcome and exposure to methylxanthines.

Neonatal irritability and apnoea have been reported with theophylline; however, this uncommon side effect should not prohibit use of the drug if indication exists. For women requiring theophylline to maintain asthma control, measurement of theophylline levels is recommended. As protein binding decreases in pregnancy, resulting in increased free drug levels, a lower therapeutic range is probably appropriate.

No significant association has been demonstrated between major congenital malformations or adverse perinatal outcome and exposure to chromones, and these should therefore be used as normal during pregnancy.

Prednisolone is the oral steroid of choice for pregnancy, as 88 per cent of it is metabolised by the placenta, limiting fetal exposure. The teratogenic risk and possible harmful fetal effects of maternal steroid treatment remain an area of controversy. Initial worries about an association with isolated cleft lip have been allayed by a recent case-control study which did not support the original animal experimental work [B].⁶ However, a subsequent meta-analysis has once again confused the debate with a statistically significant three-fold increase in oral clefting risk for steroid use in the first trimester [A].⁶ Newer anxieties have arisen about associations with intrauterine growth restriction, neuronal development, long-term hypertension and preterm labour.

These associations are therefore not definite and, even if real, the benefit to the mother and the fetus of steroids for treating a life-threatening disease justifies the use of steroids in pregnancy.

Data regarding the safety of leukotriene receptor antagonists in pregnancy are limited but so far reassuring. Leukotriene antagonists may therefore be continued in women who have demonstrated significant improvement in asthma control with these agents prior to pregnancy not achievable with other medications.

There are as yet no clinical data on the use of immunomodulation therapies such as omalizumab for moderate-to-severe allergic asthma in pregnancy. There are some reassuring animal studies on teratogenicity (classified as FDA category B). A registry of pregnancy exposures is being undertaken.

Specific guidelines also exist for the management of acute asthma attacks and these should also be adhered to in pregnancy.⁷ The severity of acute exacerbations is divided into three groups.

- 1 **Uncontrolled asthma in adults.** Speech must be normal, with a pulse of <110 beats/min and respiratory rate of <25/min. Peak flow should be >50 per cent of predicted or personal best. Treatment involves nebulised salbutamol or terbutaline. Failure to respond should prompt referral to hospital. Otherwise, normal treatment can be stepped up and a course of oral steroids may be prescribed.
- 2 **Acute severe attack.** These patients will not be able to complete sentences, will have a pulse >110 beats/min, a respiratory rate of >25/min and a peak flow of <50 per cent predicted or personal best. Acute treatment involves oxygen, nebulisers and oral prednisolone. Those not responding well should be transferred to hospital with an aminophylline infusion.
- 3 **Life-threatening asthma.** This most serious of asthma exacerbations is characterised by a 'silent chest', cyanosis, bradycardia or a peak flow of <33 per cent of predicted or personal best. Immediate hospital treatment is necessary with oxygen, nebulisers, intravenous aminophylline, oral steroids or intravenous hydrocortisone.

It is useful for all clinicians to remember these guidelines. However, there should be a low threshold for the involvement of appropriate physicians in cases of deteriorating asthma in pregnancy. Possible precipitating factors should be addressed with all acute exacerbations. For example, antibiotics are often prescribed for presumed chest infection.

Managing pregnancy in asthmatic patients

- Patients with well-controlled mild or moderate asthma will have a normal outcome with standard antenatal care [B]. For those with poorly controlled or severe asthma, care should be multidisciplinary, preferably through a high-risk antenatal clinic with general medical input [E].
- Baseline investigations, such as peak flow measurements, should be obtained at booking [E].
- Medical treatment should be optimised by following the above protocol, with repeated reassurance about the use of these drugs in pregnancy. A recent study has demonstrated that physicians are still reluctant to prescribe oral steroids during pregnancy.²
- In view of the uncertainty over the true impact of severe asthma on pregnancy outcome, the maternity team should remain vigilant for signs of preterm labour and follow fetal growth and wellbeing with ultrasound [E].

- Induction of labour and caesarean section will mostly be reserved for obstetric indications, although delivery may need to be expedited in the most severe cases [D].
- No form of analgesia is contraindicated, although regional anaesthesia is preferable rather than general for major operative procedures.
- Women taking prednisolone should be screened for glucose intolerance and measures taken to control this if it is found. Those taking prednisolone at the onset of labour should be given supplementary doses of 100 mg hydrocortisone 6–8 hourly until oral intake is resumed [B].
- Prostaglandin E₂ may safely be used for labour inductions [E].
- Prostaglandin F₂α(carboprost/hemabate®) used to treat postpartum haemorrhage due to uterine atony may cause bronchospasm and should be avoided if possible [E].
- Although ergometrine may cause bronchospasm, particularly in association with general anaesthesia, this is not a problem encountered when syntometrine (Syntocinon/ergometrine) is used for postpartum haemorrhage prophylaxis [E].
- The risk of postnatal deterioration should be discussed with the woman.
- Breastfeeding is not contraindicated with any of the medications used.

CYSTIC FIBROSIS

The reporting of pregnancies in women with cystic fibrosis (CF) began in the 1960s and the initial outcomes seemed unfavourable. However, with improvements in the care of both individuals with CF and high-risk pregnancies in general, the outlook is more favourable. Although men with CF are usually infertile, this is not the case for women. Menarche is delayed by an average of 2 years and the incidence of anovulatory cycles and secondary amenorrhoea is indeed higher. Cervical mucus may be more tenacious. However, fertility is the general rule rather than the exception. Average life expectancy for those with CF continues to lengthen. According to the 2011 Annual Data Report from the Cystic Fibrosis Patient Registry, the median predicted age of survival is approaching 40 years. Consequently many women are now choosing to start a family and employing specialist assistance where sub-fertility exists.

The North American Cystic Fibrosis Foundation Patient Registry has reported approximately 140 pregnancies per annum since 1991, equating to 3–4 per cent of women aged over 17 becoming pregnant each year. Thus, pregnancy in women with CF is increasingly common and most adult CF centres and many paediatric centres will have had to care for a woman with CF and her pregnancy.

The spectrum of disease phenotype and severity is highly varied and only loosely correlated to genotype. Individual counselling, preferably prior to conception, is vital and it

must be clearly understood that outcome predictors are imprecise.

Outcomes

Outcomes needing consideration are both the effect of the pregnancy on the CF and, conversely, the effect of the CF on the pregnancy.

A recent case–control study of women with CF compared 22 pregnant women with matched non-pregnant women and an average follow-up of 4.5 years. Nutritional outcomes, changes in lung function and exacerbation rates were compared. Pregnancy was not associated with immediate or medium-term adverse effects for CF patients.⁹ This is broadly in line with two large previously reported case series from Toronto ($n=92$ pregnancies in 54 women)¹⁰ and the UK ($n=22$ pregnancies in 20 women).¹¹

A number of different markers of disease severity have been proposed as predictors of maternal and fetal outcome (Box 16.1) but the evidence base to support each of these markers is weak and in the recent case–control study the only significant predictors of decline were higher lung function at the beginning of the study and pancreatic insufficiency.

Effect of pregnancy on cystic fibrosis

No women in these three studies died during or within 6 weeks of pregnancy. However, only 79 per cent of the Canadian women were still alive 10 years after the delivery, the earliest death occurring 3 years after the birth. Only three-quarters were still alive 4 years after delivery in the UK study, the earliest death occurring only 6 months postpartum. These mortality rates are, however, no different from those for non-pregnant individuals with CF.

Death is a very crude measure of the effect of pregnancy on CF. Decline in lung function has also been examined. Edenborough found a 13 per cent loss in %FEV₁ during pregnancy, although this was mostly regained in the following year, and a net loss of 5 per cent in FEV₁ overall at 1 year following delivery. Gilljam's prediction of 3 per cent is similar; neither deterioration is significantly greater than that expected for the

normal CF population [B]. However, caution must be exercised in women with poor pre-pregnancy lung function (<50 per cent predicted %FEV₁). There is evidence suggesting that they do suffer a permanent pregnancy-associated decline in lung function,¹⁰ although this, too, is disputed.⁸

The anatomical and physiological changes in cardiorespiratory function during pregnancy might be thought to impair mucus clearance, increase atelectasis and predispose to pulmonary infections. However, serious medical events would appear to be no more common in pregnancy than would be expected from the pre-pregnancy lung function tests.

Effect of cystic fibrosis on pregnancy

Studies have not shown an increase in miscarriage or anomaly risk over the general obstetric population,^{8–12} although CF was diagnosed in two of the Canadian offspring. In one case, the diagnosis of maternal CF was not made until after the child was born, and, in the second, prenatal screening had indicated that there was only a very low risk that the child would be affected (see below). The mean gestation at delivery was >37 weeks in both studies, although one in three babies was born preterm in the UK study. The prematurity rate was no higher than for the general population in the Canadian group (8 per cent). Intrauterine growth restriction was not encountered more frequently than would normally be expected. Only one neonate died, sepsis being the cause following delivery at 31 weeks' gestation.

The average maternal weight gain of 10–12 kg during pregnancy demands an extra 300 kcal/day. Pancreatic insufficiency is very common in CF, and enzyme supplements are usually needed to aid digestion. Increasing nutritional intake during pregnancy may be very difficult, especially with confounding factors such as nausea, hyperemesis and indigestion. It is hardly surprising that average maternal weight gain is reduced by approximately half. Furthermore, a compromised pancreas may fail to fulfil its added endocrine responsibilities: gestational diabetes occurred in 8 per cent of those women in the Canadian group who did not have pre-existing diabetes.

Caesarean section is normally employed only for obstetric reasons in women with mild-to-moderate CF. However, one in three women was delivered by preterm section in the UK group, the most common indication being deteriorating lung function. Instrumental delivery rates do not appear to be increased.

The more recent retrospective reviews do suggest a generally good outcome for mother and baby. Problems such as prematurity and maternal death within 5 years of delivery are mostly confined to cases with poor pre-pregnancy lung function, pancreatic insufficiency (especially glucose intolerance) and lung colonisation with *Burkholderia cepacia*. A %FEV₁ of <50 per cent is often considered a relative contraindication to pregnancy. Good outcomes with prolonged maternal survival afterwards are nevertheless possible, even with values below this. The presence of pulmonary hypertension causes grave concern. Serious consideration should be given

Box 16.1 Predictors of maternal and fetal outcome in pregnancies complicated by cystic fibrosis

- Absolute pre-pregnancy pulmonary function
- Stability of pre-pregnancy pulmonary function
- Colonisation with *Burkholderia cepacia*
- Presence of pulmonary hypertension
- Degree of pancreatic insufficiency
- Glucose intolerance/diabetes (pre-dating pregnancy or gestational)
- BMI
- Maternal weight gain during pregnancy
- Presence of liver disease and portal hypertension

to termination of the pregnancy to prevent right-sided heart failure.

Management of cystic fibrosis during pregnancy

A recent and comprehensive guideline has been commissioned by the European Cystic Fibrosis Society, based on review of the literature and experience of paediatricians, adult and transplant physicians, nurses, physiotherapists, dieticians, pharmacists and psychologists experienced in CF, and anaesthetists and obstetricians with experience of CF in pregnancy.¹³ This makes broad-based multidisciplinary recommendations for the management of pregnancy in CF, which should be undertaken in specialist centres.

- Ideally, a full discussion should take place prior to conception. Treatment can be optimised and the risks discussed. Patients with poor lung function or pulmonary hypertension may be advised to avoid pregnancy altogether.
- The average age of survival for women with CF in the UK is approximately 28 years. The effect on a child of losing a parent should be considered before conception.
- The issue of prenatal screening should be raised, although this must be done diplomatically, as the condition being screened for is, after all, present in the mother. As CF is an autosomal recessive condition, the offspring will either be all obligate carriers, if the partner is free of mutations, or one in two will be affected if he is a carrier himself. Approximately 1 in 25 individuals is a CF carrier in the UK. $\Delta F508$ is the most common CF mutation in the UK, accounting for 80 per cent of the total. A 'rare' mutation screen may test for as many as 30 different mutations; however, this will still only detect approximately 90 per cent of all mutations. Hence, even when the partner of the woman with CF has a 'negative' mutation screen, there is still a 1 in 250 chance that he is a carrier ($1/25 \times 1/10$) and therefore a 1 in 500 chance that the baby will have cystic fibrosis ($1/250 \times 1/2$).
- Vigilance must be maintained for the complications of CF: haemoptysis, pneumothorax, atelectasis, respiratory failure and cor pulmonale.
- There should be no hesitation in performing chest X-rays where these are deemed necessary.
- Chest physiotherapy and bronchial drainage should continue.
- Serial lung function tests, e.g. spirometry and arterial blood gases, should be performed at regular intervals throughout pregnancy.
- Careful surveillance for signs of chest infection becomes even more important due to the complications of pneumonia in pregnancy (see below). *Pseudomonas aeruginosa* is the most common cause of chest infection in CF. Penicillins, cephalosporins and aminoglycosides are the most commonly used antibiotics (intravenously, orally or inhaled). All are considered safe in pregnancy, even gentamicin (the risk of fetal ototoxicity can be minimised

by ensuring maternal serum levels do not exceed recommended levels). The risks to the mother and fetus of withholding appropriate antibiotics are greater. Some antibiotic-dosing schedules will need to be adjusted due to the larger volume distribution and enhanced renal elimination found in pregnancy.

- Cardiovascular status should be observed during pregnancy, preferably by echocardiography.
- Pancreatic enzymes should be continued and insulin levels adjusted appropriately.
- Termination of pregnancy should be considered by women with very unfavourable features.
- Advice from dieticians will be essential to maintain caloric intake. Rarely, enteral (and even parenteral) feeding is necessary.
- Regular fetal monitoring with growth scans is advisable, especially in more severe cases of lung disease or poor maternal weight gain.
- Ideally, induction of labour and caesarean section are performed only for obstetric reasons. However, deterioration in lung function may prompt intervention. General anaesthesia should be avoided where possible.
- Facial oxygen may be required in labour, and exhaustion should be prevented by instrumental delivery if necessary. Prolonged Valsalva manoeuvres may predispose to pneumothoraces.

EBM

Retrospective studies suggest that pregnancy accelerates the loss of respiratory function only in 'severe' cases of cystic fibrosis.

TUBERCULOSIS

Infection with *Mycobacterium tuberculosis* most commonly presents in African and Indian ethnic groups, new immigrant populations, refugees and asylum seekers. HIV positivity is another well-recognised risk factor and this is one reason cited for the increasing incidence of tuberculosis (TB) since the 1980s. As deaths from TB appear to be increasing a prospective national study of TB in pregnancy was undertaken by UKOSS from February 2005 to August 2006.¹⁴ Over this period, there were 52 confirmed cases, representing an incidence rate of 4.6 per 100,000 maternities with a 95% CI of 3.4–8.0. From these figures the estimated total number of cases of TB in the 2006–8 triennium was 266 (95% CI 184–374). In this same period, the Confidential Enquiry reported that two pregnant women died from TB, giving an estimated case fatality rate of TB in pregnancy in 2006–8 of 1:133 known cases (95% CI 1:92 to 1:187).

Treatment can be safe and effective in pregnancy and the outcome is normally good. Failure to diagnose the condition

EBM

There is no good evidence to suggest that pregnancy is an independent risk factor for infection with *Mycobacterium tuberculosis* or that the course and outcome of TB are altered by pregnancy.

and patient non-compliance with medication regimens put the mother and newborn at increased risk.

Primary infection is usually asymptomatic, although fever, cough, conjunctivitis and erythema nodosum may all occur. A cellular immune response can be detected 3–8 weeks later by a positive tuberculin test.

Any further clinical manifestations are known as 'post-primary tuberculosis' and include pulmonary disease (apical lung cavitation, pneumonia, pleural effusion), miliary TB (widespread disseminated TB), pericarditis, peritonitis, meningitis, bone and genitourinary TB. These may occur months or years after the primary infection following a period of 'latency'.

Public health policies towards TB prevention and detection have differed on each side of the Atlantic. In the USA, tuberculin testing (the Mantoux test) is used to screen high-risk groups during pregnancy. A positive result combined with specific risk factors may prompt a screening chest X-ray and sputum testing for mycobacteria. Based on the results of these, the patient is either treated for active TB or given prophylaxis with isoniazid, on the assumption that latent infection is present and could reactivate at any time. In the UK, widespread vaccination of schoolchildren with bacille Calmette–Guérin (BCG – said to prevent 70 per cent of infections) reduces the value of routine tuberculin testing, which will be positive in those who have been vaccinated. There is no screening programme for TB in pregnancy in the UK and clinicians must remain hypervigilant for signs and symptoms suggestive of the disease.

Pulmonary manifestations are the most common presenting features of TB, and a chest X-ray may show upper-lobe densities and cavitation, fibrosis, pleural effusion, empyema or calcifications. Sputum is examined for acid-fast bacilli using a Ziehl–Neelsen stain and subsequently cultured for antibiotic sensitivity testing. Bronchoscopic washings must be obtained if there is no sputum. Extrapulmonary TB is diagnosed using tissue biopsies in a similar way. Although the Mantoux test is considered safe in pregnancy, it is unable to distinguish active disease from previous disease and BCG vaccination.

Active TB infections are treated with a combination of antibiotics, determined by the results of the culture sensitivities. Although regimens vary, treatment usually includes therapy with rifampicin, isoniazid, pyrazinamide and sometimes ethambutol. Less well-known drugs may be necessary in cases of multi-drug resistance including amikacin, kanamycin and ethionamide.

The relationship between pregnancy and TB

It is generally agreed that pregnancy has no impact on the course of TB and that TB, if diagnosed and treated expeditiously, has no significant impact on the pregnancy [D]. Delayed or inadequate therapy would appear to be detrimental to both maternal and fetal outcomes; however, increasing the risks of prematurity and intrauterine growth restriction [D].

Presentation and diagnosis are unaffected by pregnancy, although misguided reluctance in performing chest X-rays may lead to further diagnostic delay.

Vertical transmission (congenital TB) is extremely rare and usually occurs only where maternal disease has gone untreated. Fewer than 300 cases have been reported, although placental infection is somewhat more common. Lateral transmission from the mother or other close contacts, occurring after delivery, is a much more likely cause of infant infection. Therefore strict criteria exist for the diagnosis of congenital TB. One of the following is necessary:

- lesions in the first week of life;
- a primary hepatic complex or caseating granuloma;
- histological evidence of placental or endometrial involvement;
- absence of TB in other carers of the child.

Congenital TB usually presents with fever, lymphadenopathy, hepatosplenomegaly and respiratory distress. It is fatal in one in five cases. In only half of all cases has the diagnosis of maternal TB already been made.

Treatment of TB during pregnancy

TB is most likely to be diagnosed by physicians, even during pregnancy, and the specialist advice of a respiratory consultant is essential along with close involvement by microbiologists [E].

Isoniazid, rifampicin and ethambutol are used initially. The ethambutol can be stopped when sensitivities show that the other two drugs are adequate. These are then continued for 9 months in total. The most significant toxic side effect of isoniazid in animal and human studies is demyelination (causing a peripheral neuropathy). This can be prevented by supplementation with pyridoxine (vitamin B₆). Hepatotoxicity may be more common in pregnancy, and liver function tests should be performed monthly [D]. Most studies do not show a significant elevation in the anomaly rate above the background 2–3 per cent in users of rifampicin in pregnancy [B]. Liver enzyme induction, with theoretical vitamin K deficiency, should prompt maternal oral vitamin K supplements in the third trimester to prevent haemorrhagic disease of the newborn. The theoretical risks of fetal ocular toxicity with ethambutol have not been borne out in practice. Although pyrazinamide is usually avoided in pregnancy, there are no data to suggest a harmful effect and it should be used if needed

as a second-line agent. Streptomycin, a previous favourite in TB treatment, has well-recognised fetal ototoxicity. Safer alternatives are available.

Non-compliance with drug regimens outside pregnancy is a major problem. There is no reason to think that it is any less so during pregnancy. Supervision, encouragement and incentive schemes may be necessary to encourage proper use of the prescribed medications.

All the anti-tuberculous drugs mentioned in this section are compatible with breastfeeding [D].

There is often concern over the infectious nature of TB in a maternity setting. Provided that the prescribed drugs have been taken properly, an active TB sufferer will become non-infectious within 2 weeks of commencing treatment. If the mother is still sputum positive, specialist infection control nursing will be necessary. The newborn should be immunised with BCG and also given prophylactic antibiotics (usually isoniazid). Separation of the infant from its mother is not necessary unless she is non-compliant or another carer or family member is highly infectious.

It would seem prudent to send the placenta for microbiological investigation. Evidence of acid-fast bacilli should increase surveillance of the newborn.

PNEUMONIA

Pneumonia in otherwise healthy individuals is no more common in pregnancy than in an age-matched population as a whole, and the maternal outcome, in the main, is no better or worse. The incidence of pneumonia in pregnancy would appear to be on the rise, but this may be accounted for by an increase in the number of pregnancies in women with coexisting problems such as HIV and CF. Four women died in the 2006–2008 CEMD, most of whom had underlying social factors such as severe deprivation. Generally prompt diagnosis and treatment avoid poor maternal outcomes. In addition, fetal outcome may be affected, and prompt recognition and treatment of pneumonia in pregnancy are essential if this is to be avoided. The main risk would appear to be preterm labour, although growth restriction has also been reported (Box 16.2).

Box 16.2 Risk factors for pneumonia

- History of recent upper respiratory tract infection
- Chronic respiratory disease (e.g. asthma, cystic fibrosis)
- Smoking
- Immunocompromise (HIV, substance abuse, alcoholism, recurrent courses of antenatal steroids)
- Anaemia
- Farm workers (*Coxiella burnetii*)
- General anaesthesia (aspiration pneumonitis)
- HIV

Diagnosis of pneumonia in pregnancy

The symptoms and signs of pneumonia are not altered by pregnancy, but may be confused with physiological changes common to pregnancy. Reluctance to perform a chest X-ray may further delay the diagnosis. Obstetricians have a responsibility in educating other physicians that the fetal radiation exposure with appropriate shielding is minimal and that this examination is safe. This message is even more important if risk factors for pneumonia are present.

Sputum should be sent for microbiological examination and culture. Blood can be taken for serological testing for *Mycoplasma* and viral antibodies.

Treatment of pneumonia in pregnancy

Common organisms

Frequently, no infectious agent is found and the pneumonia is treated empirically. The most common bacteria causing community-acquired pneumonia are *Streptococcus pneumoniae* and *Haemophilus influenzae*, often occurring after a viral infection. Atypical pneumonias caused by *Mycoplasma* and, less commonly, *Legionella* must also be considered. Penicillins, macrolides and cephalosporins are the treatments of choice and none is contraindicated in pregnancy. Higher doses of amoxicillin should be used to counteract the increased renal clearance found in pregnancy. Erythromycin or clarithromycin should be added if there is suspicion of an atypical pneumonia, and cephalosporins used for penicillin-allergic individuals or hospital-acquired infections. Pneumonias requiring hospitalisation are usually treated with a third-generation cephalosporin (e.g. ceftriaxone) with erythromycin.

Common viral causes of pneumonia include the three subtypes of influenza myxovirus. Although amantadine and ribavirin antiviral agents have been used in pregnancy with no obvious harmful effects, their use is not recommended. The generally good outcome of viral pneumonia in pregnancy would support this.

Less common causes of pneumonia in pregnancy

More unusual pneumonias occur when there are underlying risk factors. *Klebsiella* is said to be typical of alcoholics, often associated with abscess formation. *Coxiella burnetii* is found in the aerosols produced by farm animals. Q fever, the pneumonia caused by this organism, is said to cause miscarriage, intrauterine death and stillbirth. *Staphylococcus aureus* is significantly more likely after influenza infections and may have a sudden and rapid course. Pneumonia following aspiration of stomach contents is rare, but carries a significant mortality, with anaerobic and Gram-negative organisms being the most common infectious agents.

S. pneumoniae and *Pseudomonas aeruginosa* are common causes of pneumonia in HIV-positive individuals. *Pneumocystis jirovecii* is an acquired immune deficiency syndrome (AIDS)-defining illness that carries a high mortality

rate, whether or not it occurs in pregnancy. The theoretical risks of using Septrin (trimethoprim–sulfamethoxazole) in pregnancy include folate antagonism, and kernicterus or haemolysis in the newborn. The latter is extremely uncommon, and folate supplementation minimises the risks associated with trimethoprim. Pentamidine can be used as an alternative in pregnancy. Other unusual organisms to be considered in HIV-positive women, or those with other causes of significant immunocompromise, include atypical mycobacteria and cryptococci.

The true incidence of pneumonia in adult chickenpox infections is unclear, but mortality from varicella pneumonitis has been quoted as 11 per cent. Whether the depressed cell-mediated immunity of pregnancy truly influences the incidence and mortality of varicella pneumonia in pregnancy is unclear, although many reports suggest that it worsens outcome, with mortality quoted as being as high as 1 in 3. Varicella-zoster virus infections in pregnancy are discussed further in Chapter 24.

Chapter 17 Neurological conditions

Louise Kenny

MRCOG standards

Theoretical skills

- Understand the epidemiology, aetiology, pathophysiology, clinical characteristics and prognostic features of common neurological diseases.
- Understand the impact that pregnancy may have on pre-existing neurological disease and the influence the illness may have on pregnancy.
- Specific mention is made of epilepsy, cerebrovascular disease, multiple sclerosis, migraine, neuropathies, myasthenia gravis and paraplegia.

Practical skills

- Be able to manage, in broad terms, a pregnancy complicated by neurological disease.
- Conduct a differential diagnosis for the causes of headache and seizures during pregnancy.
- Be able to recognise risk factors for stroke during pregnancy.
- Understand the role of genetic diagnosis and prenatal counselling and testing.
- Be able to liaise with other healthcare professionals to optimise standards of care.

INTRODUCTION

The focus of this section is mostly on pre-existing medical conditions and how they interact with pregnancy. Neurological disease is fortunately rare. The details of each and every neurological condition are well beyond the bounds of this textbook, and also of the MRCOG. Candidates sitting this examination are not expected to be obstetric physicians. However, competence is demanded in the management of several neurological conditions commonly encountered in the antenatal clinic. Epilepsy is common in women of

reproductive age and the use of anticonvulsant drugs in pregnancy represents a model example of how benefits of treatment to the fetus and mother must be weighed against the risks. Multiple sclerosis demonstrates clearly how pregnancy can alter the clinical course of a disease. Myasthenia gravis illustrates how maternal conditions can continue to cause harm, even after delivery, and the 'triplet repeat diseases' highlight the need for specialised pre-pregnancy counselling and prenatal diagnostic services.

Strictly speaking, stroke need not be included here as it tends to feature more as a problem arising during pregnancy. However, in other respects it fits well with this discussion and it is important to recognise those women presenting with risk factors for stroke at booking, when the possibility of prevention exists.

EPILEPSY

Approximately 6 in every 1000 pregnancies are complicated by a past or current history of epilepsy, making it the most common pre-existing neurological condition complicating antenatal care. However, on occasion epilepsy can present for the first time during pregnancy and every obstetrician must have a working differential for the causes of seizure during pregnancy (Box 17.1). Familial, cryptogenic and trauma-related epilepsies account for the vast majority of cases with an established diagnosis at the onset of pregnancy. A minority of cases are caused by brain tumours, congenital abnormalities and vascular problems, and these may require even more specialised care during the pregnancy. Seizure frequency may increase, decrease or stay the same in pregnancy (37 per cent, 13 per cent and 50 per cent, respectively),¹ with labour being a particularly high-risk time for convulsions. A recent prospective study in the UK demonstrated no major differences in obstetric outcomes (excluding fetal abnormalities); however, an Icelandic retrospective study found a caesarean section rate almost double that of the control population.² A proportion of emergency caesarean sections were performed for seizures occurring during labour.

Box 17.1 A differential diagnosis of seizures during pregnancy and the postpartum period

Idiopathic epilepsy
 Epilepsy secondary to a specific cause
 Previous trauma
 Antiphospholipid syndrome
 Intracranial mass lesions
 Gestational epilepsy (seizures secondary to pregnancy)
 Intracranial infection
 Meningitis
 Encephalitis
 Brain abscess/subdural empyema
 Cerebral malaria
 Vascular disease
 Cerebral infarction
 Subarachnoid and cerebral haemorrhage
 Hypertensive encephalopathy
 Eclampsia
 Cerebral vein thrombosis
 Thrombotic thrombocytopenic purpura
 Metabolic
 Hyponatraemia/hypoglycaemia/hypocalcaemia
 Liver and renal failure
 Anoxia
 Alcohol withdrawal
 Drug toxicity
 Local anaesthetics, e.g. lidocaine
 Tricyclic antidepressants
 Amphetamines
 Lithium
 Pseudoepilepsy (factitious)

Therapeutic aspects

Antiepileptic drugs (AEDs) may affect the fetus and newborn in a number of ways (Box 17.2).

The evidence is confusing and often contradictory. There are no RCTs and studies are mostly retrospective with ascertainment bias. This makes patient counselling very difficult. However, a number of points are generally accepted.

- The incidence of congenital anomalies is increased significantly among the offspring of epileptic mothers [B].
- AEDs are responsible for most or all of this increase [B].
- The benefits of seizure control during pregnancy outweigh the risks [E].
- Polytherapy with more than one AED carries greater risks to the fetus than monotherapy [B].

Box 17.2 Effects of antiepileptic drugs on the fetus and newborn

Teratogenicity
 Major and minor congenital malformations
 Characteristic dysmorphic syndrome
 Neonatal withdrawal effects
 Vitamin K deficiency with haemorrhagic disease of the newborn
 Developmental delay or behavioural difficulties

- Although certain AEDs are more strongly linked to particular congenital abnormalities, there is significant overlap, and the first-line agents can all cause the fetal anticonvulsant syndrome [B].

Other points are more controversial. No evidence grade is given for these points in view of this uncertainty.

- Women with a history of seizures who are not taking AEDs have a higher risk of congenital anomalies in their offspring than those with no history.
- Women with regular and severe seizure activity during pregnancy carry a higher congenital abnormality risk.
- Lower doses of AEDs carry a lower risk.
- The use of high-dose folic acid reduces the congenital anomaly risk.
- AED levels should be checked during each trimester as altered pharmacokinetics may disrupt seizure control.

Congenital abnormalities

The reported incidence of congenital abnormalities among the offspring of epileptic women varies among studies, mainly due to variations in case ascertainment and definition. Major abnormalities (which are less likely to go unreported) are found in 5–10 per cent of women who have taken AEDs [C].^{2–4} The incidence of anomalies may actually be determined by a number of different factors:

- an inherent added risk associated with epilepsy, independent of AEDs;
- genetically inherited tendencies;
- the number and severity of seizures during pregnancy;
- the use of AEDs during pregnancy.

Until recently, it was generally agreed that, whether treated or not, women with a history of seizures had a higher fetal anomaly rate than those without such a history. A recent prospective study from Newcastle has supported this assertion, finding *major* abnormality rates among treated epileptics, untreated epileptics and controls to be 4.6 per cent, 8 per cent and 2.4 per cent respectively.³ However, equivalent figures from the USA published in 2001 have suggested differently (5.7 per cent, 0 per cent and 1.8 per cent, respectively),⁴ as did a study from Milan, which found severe structural anomalies in 5.3 per cent of AED-exposed pregnancies and none in the 25 pregnancies with a history of seizure but no treatment.⁵

There is similar disagreement over the impact that first- and second-trimester seizure activity has on congenital anomaly rates. These studies found no evidence of increased congenital anomaly rates in the offspring of women with higher-level seizure activity.

The medications themselves undoubtedly carry the greatest risk [B]. Non-epileptic women using these drugs for other reasons demonstrate similar anomaly rates.⁴ The 'fetal hydantoin syndrome' described by Hanson and Smith in 1975 has been renamed the 'fetal anticonvulsant syndrome' after the realisation that AEDs other than phenytoin (carbamazepine, valproate, phenobarbital, benzodiazepines) could also cause a similar array of abnormalities (Table 17.1).

The incidence of this syndrome in AED-exposed pregnancies is two to three times higher than in controls [B]. Behavioural problems, learning difficulties, speech and gross motor delay, and features of autism were found in more than 50 per cent of children diagnosed with this syndrome when studied retrospectively [D].⁶

Despite this generic effect seen with most anticonvulsants, certain drugs are more closely associated with particular groups of anomalies. Valproate and, to a lesser extent, carbamazepine are thought to increase the risk of neural tube defects to between 1 and 2 per cent [B]. Doses >1000 mg/day of valproate seem more likely to be associated with this outcome [C]. Valproate may likewise increase the incidence of genitourinary anomalies and, along with phenytoin, cardiac abnormalities. Prospective studies have estimated a risk as high as one in five of developmental delay with phenytoin and carbamazepine therapy, although this is disputed.

The various studies do agree on one point: polytherapy carries greater risk than treatment with one drug alone [B].^{4,5} Holmes and colleagues, for example, found the incidence of major malformations to be 5.7 per cent in the offspring of women using monotherapy but 8.6 per cent in those using two or more AEDs.⁴

The question is often asked: which anticonvulsant carries least risk of fetal harm? A recent systematic review⁷ highlighted that women presenting already pregnant on AEDs should probably remain on their current regimen, as any teratogenic harm is likely to have occurred already. If a pregnancy is being planned, some have the opinion that valproate

should be avoided, as it would appear to carry the greatest teratogenic risk and more recent reports suggest that it may also cause developmental delay. Newer drugs such as lamotrigine, gabapentin and tiagabine so far have a good record in animal studies, but experience in human pregnancies is still too limited to assess their safety confidently [E].

Other important drug effects

For reasons that are not entirely clear, carbamazepine, phenytoin, phenobarbital (and even valproate) cause vitamin K deficiency, perhaps by inducing liver enzymes responsible for its oxidative degradation. Vitamin K is required for the carboxylation of factors II (prothrombin), VII, IX and X, and deficiency in the neonate may cause haemorrhagic disease of the newborn, with catastrophic intracranial and gastrointestinal bleeding occurring in a few. Owing to the extremely low levels of vitamin K in a healthy neonate, deficiency must be measured indirectly by studying 'prothrombin induced by vitamin K absence' (PIVKA) levels. Use of these anticonvulsants has been shown to increase PIVKA levels [B]. This increase can be prevented by maternal therapy with vitamin K supplements in the third trimester [B]. Indeed, some have even postulated that vitamin K deficiency may contribute to some of the structural abnormalities found in the fetal anticonvulsant syndrome, raising the possibility that vitamin K supplements earlier in pregnancy might be warranted.

Neonatal withdrawal effects have been noted with maternal use of phenobarbital, carbamazepine and valproate, and range from poor feeding to jitteriness and convulsions. Such effects are uncommon now that phenobarbital is used less frequently.

Phenytoin and carbamazepine *may* also cause an increase in childhood cancers such as neuroblastoma, although the rarity of these makes statistical certainty difficult [C].

Drug pharmacokinetics

A number of factors during pregnancy serve to reduce effective serum concentrations of various AEDs:

- the increased volume distribution of pregnancy;
- the increased renal clearance;
- induction of hepatic enzyme metabolism by pregnancy and high folate levels;
- vomiting and delayed malabsorption.

The reduction in serum protein concentration during pregnancy means that a greater proportion of the drug is found in the free (active) state. This is especially true for those AEDs exhibiting strong protein-binding characteristics (Table 17.2).

Serum levels of AEDs include both the free and the protein-bound components. Keeping the total level in the low 'normal' range is therefore advised during pregnancy to limit the chances of maternal toxic side effects and fetal complications [E]. In reality, even free levels do not correlate

Table 17.1 The fetal anticonvulsant syndrome(s)

Major abnormalities	Minor abnormalities
Microcephaly	Hypertelorism
Cleft lip and palate	Distal digital and nail hypoplasia
Neural tube defects	Flat nasal bridge
Congenital heart defects	Low-set abnormal ears
Intrauterine growth restriction	Epicanthic folds
Developmental delay	Long philtrum

Table 17.2 Protein binding of anti-epileptic drugs

50% protein bound	50% protein bound
Clonazepam	Carbamazepine
Gabapentin	Phenytoin
Valproate	Lamotrigine
	Phenobarbital
	Vigabatrin

well with seizure control [D] and some authorities disagree with routine testing of serum levels.

However, testing should be performed in a number of special cases [E]:

- suspected non-compliance (60 per cent of pregnancies in a recent survey);
- increasing seizure activity;
- concerns over toxic side effects;
- polypharmacy with drug interactions.

The enzyme-inducing AEDs may enhance their own metabolism and that of other agents (Table 17.3). Valproate may inhibit the enzyme epoxide hydrolase, which metabolises phenytoin and carbamazepine.

Managing epilepsy and pregnancy

There are no RCTs pertinent to the management of epilepsy in pregnancy. Guidelines such as the ones given below are based on evidence of grades C, D and E.^{8,9} Retrospective studies highlight how poorly such guidelines are adhered to.

Pre-pregnancy counselling

As with diabetes, there is much to be gained by planning pregnancy carefully following detailed counselling from a joint team including obstetricians and neurologists [D].

- The diagnosis should be reviewed by a neurologist – this is dubious in a proportion of women using AEDs.
- Consideration should be given to stopping AEDs in those who have been seizure free for more than 2 years. The risk of relapse is 20–50 per cent, being higher for some forms of epilepsy (e.g. juvenile myoclonic epilepsy) than others (e.g. absence or tonic-clonic seizures) [C]. Serious health and social consequences may result from a recurrence of seizures (e.g. driving prohibition). If withdrawal is to be attempted, it should occur in small increments over a prolonged period, supervised by a specialist. The patient should not drive during this period.
- Where possible, treatment regimens should be simplified to a single AED and the lowest effective dose used to minimise the risk of congenital abnormalities [E].
- The risks to the mother and the fetus of non-compliance with prescribed medications, especially status epilepticus, must be discussed along with the AED-associated fetal risks [E].

Table 17.3 Enzyme-inducing ability of antiepileptic drugs

Enzyme-inducing AEDs	Non-enzyme-inducing AEDs
Phenobarbital	Valproate
Phenytoin	Lamotrigine
Carbamazepine	Gabapentin
	Ethosuximide
	Clonazepam

- Folic acid 5 mg should be taken each day periconceptually. This is most important for women taking valproate and carbamazepine, although it is still unclear whether this reduces the risk of neural tube defects in this group [E].
- The risk to the offspring of epilepsy should also be discussed. Few cases of epilepsy exhibit autosomal dominant inheritance. However, having one parent with idiopathic epilepsy confers a 4 per cent risk of epilepsy in the offspring, increasing to 10 per cent when a parent and a sibling are affected, and to 15 per cent when both parents have epilepsy [C].

Antenatal management

- Care should be carried out by an obstetrician with a special interest in epilepsy, jointly with a neurologist [E].
- All pregnancies occurring in women on anticonvulsant drugs should be notified to the UK Register of Anti-epileptic Drugs in Pregnancy [E].
- Screening for fetal anomalies should be offered to all women with epilepsy, with particular attention paid to those anomalies more commonly found in this group. A fetal cardiac scan may be warranted at 22 weeks' gestation [E].
- Drug level monitoring may not need to be carried out as a routine but many clinicians like a 'starting' value and there are other situations that may prompt testing (see above) [E].
- Oral vitamin K supplements should be taken from 36 weeks onwards (10 mg per day) to prevent haemorrhagic disease of the newborn [C].
- If steroids are to be given for the usual obstetric indications, women using enzyme-inducing AEDs should be given 48 mg in total (two lots of 24 mg dexamethasone 24 hours apart) [E].

Intrapartum care

- Induction of labour and caesarean section are indicated for the usual obstetric indications. Vaginal delivery should otherwise be the aim [E].
- Labour carries a higher risk of seizure due to sleep disruption, reduced intake and absorption of AEDs, and hyperventilation, which may alter free levels of AEDs. Every effort must be made to administer anticonvulsants as usual. Intravenous phenytoin can be used if necessary, although it may cause arrhythmias.

- Seizures during labour are best controlled with IV benzodiazepines (e.g. clonazepam or diazepam). Rectal diazepam can be used in the absence of intravenous access. Provided that the fetal heart rate tracing remains reactive, this is not usually considered an indication for emergency caesarean section. However, status epilepticus or recurrent seizures in labour may warrant abdominal delivery for fetal reasons [E].

Postpartum care

- The serum levels of AEDs may rise in the postpartum period and monitoring may be necessary to prevent maternal toxic side effects. However, sleep deprivation may lower the normal threshold for seizure activity. If doses have been raised during pregnancy, a reduction in the immediate postpartum period may be necessary [E].
- All anticonvulsants reach breast milk. Neonatal side effects are rare, but sedation and withdrawal effects must be watched for, in particular where phenobarbital and benzodiazepines have been used. Breastfeeding is to be encouraged [C].
- A single 1 mg intramuscular vitamin K neonatal supplement is advised in order to prevent haemorrhagic disease of the newborn [C].
- Contraceptive advice should be given before discharge home. The enzyme inducers will reduce the contraceptive efficacy of the combined pill, minipill and Depo-Provera injections. A combined oral contraceptive pill containing 50 mg of oestrogen should be used, preferably with a shorter pill-free interval (5–6 days instead of 7). ‘Tricycling’ will further reduce the chances of ovulation. Depo-Provera should be given every 10 weeks instead of every 12. The Mirena intrauterine system is ideal, as the locally administered progestogen will not be affected by induced liver enzymes [C].
- Special advice should be given to new mothers who also have epilepsy [C].
 - Ask for extra help if you are not getting enough sleep.
 - Ensure that someone else is present when you bath your baby.
 - Surround yourself with cushions and pillows when you are holding your baby.
 - Feed and change your baby on the floor while leaning against a wall to prevent you falling on to the baby in the event of a seizure.

Unfortunately, a recent UK prospective study³ has shown how poorly such recommendations are being followed. Less than 50 per cent of pregnancies were planned and only 1 in 10 epileptic women took folic acid appropriately. Most did not have pre-pregnancy counselling and 1 in 5 was using AEDs despite a fit-free interval of more than 2 years prior to the pregnancy. Sixty per cent were looked after solely by general practitioners, and vitamin K was given to only a third of those who should have received supplements in the third trimester.

Sudden unexpected death in epilepsy

Sudden unexpected death in epilepsy (SUDEP) is an uncommon and non-traumatic death that occurs suddenly and unexpectedly in a patient with epilepsy who was otherwise previously healthy. Deaths from SUDEP are usually not witnessed and may or may not occur during a seizure. It is without any obvious clinical or pathological explanations. SUDEPs account for 10% of all epilepsy-related deaths; 85% of these fatalities occur between the ages of 20 and 50 years. The incidence of SUDEP stands at approximately 1 in 1000 people with epilepsy per year, which is at least 10 times the sudden death rate found in the general population.

The latest Confidential Enquiry *Saving Mothers’ Lives* investigated 14 deaths of women with epilepsy in the 2006–8 triennium – the highest number from any neurological disease and three times the number of deaths from asthma. The actual cause of death in 11 of the 14 women with epilepsy was categorised as SUDEP. The other three deaths were seizure-related deaths, one from status epilepticus, one from a fall and one death while bathing.

It is not clear whether pregnancy is an independent risk factor for SUDEP; it will, however, be an indirect risk factor since SUDEP is known to be more common in patients who do not take prescribed anticonvulsants and many women are reluctant to take anticonvulsants when pregnant or breastfeeding for fear of harming their babies.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a multifocal autoimmune disease of the CNS. Infiltrating lymphocytes and macrophages bring about inflammation, demyelination and axonal damage while further activating inherent CNS immune cells such as astrocytes and microglia. Optic nerve, brain and spinal cord may all be affected and this may manifest as almost any neurological deficit, symptom or sign. Most cases are characterised by a ‘relapsing and remitting’ natural history, with slow gradual decline. Less commonly, the MS follows a more rapidly progressive pattern. Diagnoses of MS are either ‘probable’ or ‘definite’, depending on whether the clinical features (probable) have been supported by the results of specialised investigations (oligoclonal abnormalities in cerebrospinal fluid, white matter lesions on MRI or prolonged latency of evoked potentials on neurophysiological testing). An inheritable genetic element to the disease does exist, but very rarely is a true mendelian pattern of autosomal dominance seen. Overall, the risk of the offspring developing MS with one affected parent appears to be approximately 4 per cent. The rate can, however, be as high as 30 per cent if both parents are affected [D]. Viral infection is likely to be a more important aetiological factor and indeed relapses are more common following non-specific viral illness [D].

Effect of pregnancy on MS

Various studies, both prospective and retrospective, suggest that pregnancy does not accelerate the course of MS, but relapses are more common in the puerperium. Pregnancy may have a protective effect.

The key part that the immune system plays in MS disease activity is highlighted by the effects of pregnancy on this condition. Pregnancy is characterised by a shift from type 1 (pro-inflammatory) to type 2 (anti-inflammatory) T-cell activity. Although various studies have reached slightly different conclusions, the combined evidence suggests that pregnancy itself is associated with a reduction in the number of relapses [C]¹⁰ and that this may even reduce the overall progression of the disease in the long term [D].¹¹ Also, the incidence of MS may be lower in multiparous women than in women who have never been pregnant [D].¹¹ As with rheumatoid arthritis, however, relapses in the puerperium are more common [C],¹⁰ although this is not influenced by breastfeeding and one recent study has even reported a possible protective effect.¹⁰ It is important to be aware of potential bias in such studies; women with more active disease are less likely to become pregnant for many reasons. However, the most recent reports have tried to avoid such bias and the above effects remain. Confavreux and colleagues¹⁰ found a relapse rate of 0.2 per woman per year during the third trimester, compared with 0.7 in the year before pregnancy. In the first 3 months postpartum this rate increased to 1.2. The overall progression in disability scores was not altered by pregnancy over a 3-year time period. The effect of pregnancy on the course of the chronic progressive variant of MS is less clear.

Management of MS during pregnancy

Multiple sclerosis sufferers experience a wide variety of neurological symptoms and treatment should be tailored to the individual. Non-pharmacological therapy may be sufficient in some cases, but expert help should be requested from a neurologist.

A recent expert consensus report made several recommendations regarding pharmacological treatment of MS in pregnancy.¹²

Immunomodulator therapy such as beta-interferon (B-IFN) or glatiramer acetate (a synthetic amino acid polymer) has not been shown to be harmful to the fetus and can be safely continued until pregnancy is confirmed. In case of very active disease, continuation of immunomodulator therapy throughout the entire pregnancy may also be considered on a case-by-case basis, as there is a lack of evidence of toxicity from studies and pharmacovigilance registries.

There is a paucity of data in pregnancy for newer agents such as natalizumab and fingolimod. Natalizumab is a humanised monoclonal antibody against the cell adhesion molecule 4-integrin. Given the current absence of sufficient

safety data in pregnancy the current recommendation is to discontinue this drug 3 months before conception.

Fingolimod is a sphingosine 1-phosphate receptor modulator, which sequesters lymphocytes in lymph nodes, preventing them from contributing to an autoimmune reaction. This drug should be discontinued at least 2 months before conception due to a presumed teratogenic risk shown in animals.

Urinary urgency may be treated with tricyclic antidepressants such as imipramine and this is safe to continue. Spasticity and paroxysmal pain may be treated with baclofen (probably safe in pregnancy) and anticonvulsant drugs (see Epilepsy). Mood alterations are also common in MS. Depression and hopelessness are just as typical as the frequently mentioned 'euphoria'. Treatment with tricyclic antidepressants is not contraindicated in pregnancy. Prophylaxis for MS remains an area of controversy.

Induction of labour and caesarean section are mostly reserved for obstetric indications [E], although serious disability may make vaginal delivery impractical and an exacerbation of urinary symptoms and limb spasm may warrant earlier planned delivery. The use of epidural anaesthesia is not contraindicated and does not cause an increased rate of disease progression [C].

Breastfeeding is not advised while using b-IFN, although harmful effects have not been noted.

MYASTHENIA GRAVIS

This relatively rare neurological condition deserves mention as it is more common in women of child-bearing years and illustrates well how maternal disease can interact with pregnancy in ways not yet covered in this chapter.

Myasthenia gravis (MG) is caused by autoimmune disruption at the nicotinic neuromuscular junction. It may present with double vision, difficulty swallowing, ptosis and respiratory muscle failure. Anti-acetylcholine receptor autoantibodies can be found in 85–90 per cent of patients, and thymic abnormalities (hyperplasia or thymoma) in somewhat fewer. However, these autoantibodies can also be found in women who do not have the disease, and the diagnosis instead is usually made by administration of edrophonium chloride (a short-acting anticholinesterase), which transiently improves symptoms, notably muscle strength, in those with MG (the Tensilon test). Longer-acting acetylcholinesterase inhibitors are the mainstay of treatment (neostigmine and pyridostigmine), but immunosuppressive therapy with corticosteroids, azathioprine, ciclosporin and methotrexate is a second-line option. Plasmapheresis and IV immunoglobulin infusions are used for serious exacerbations. Undertreatment and overtreatment both carry their own risks. 'Myasthenic crises' can be precipitated by infection, aminoglycosides, magnesium sulphate, local anaesthetics, beta blockers, beta-receptor agonists, narcotics and neuromuscular blockers (Table 17.4).

Table 17.4 Emergencies in myasthenia gravis

Myasthenic crisis	Cholinergic crisis
Nasal regurgitation	Abdominal 'colicky' pain
Dysphagia	Diarrhoea
Respiratory impairment	Excess salivation and sweating
	Severe weakness (depolarising block)
	Bradycardia

Interaction between myasthenia and pregnancy

The effect of pregnancy on MG is unpredictable and varies considerably among women and even between pregnancies in the same woman.

A recent retrospective review found deterioration in 19 per cent, improvement in 22 per cent and no change in 59 per cent.¹³ Myasthenic symptoms worsened postpartum in approximately a third of the women in this study [D]. The severity of the pre-pregnancy disease did not predict well what would occur during the confinement, although women who have previously undergone thymectomy have been noted in other studies to be less likely to have an exacerbation [D].

The risk of maternal mortality is highest during the first year after diagnosis of MG, with the risk being minimal 7 years after diagnosis. Thus, women with MG should delay pregnancy for at least 2 years after disease onset. Despite these considerations, pregnancy has not been shown to adversely affect MG in the long term.

A recent study of 163 pregnant women with MG reported no statistically significant increase in preterm delivery, low birthweight of SGA infants and caesarean delivery, suggesting that MG does not adversely affect pregnancy outcome.

Anticholinesterases are considered safe in pregnancy, although neonatal intestinal tube muscular hypertrophy has been reported following a pregnancy exposed to very high doses. Although there have been concerns regarding the teratogenicity and fetal effects of corticosteroids and azathioprine, their use is not contraindicated [E] and most clinicians will continue to use them through pregnancy if an indication exists. Experience with ciclosporin in pregnancy is growing, although there remains an added possible risk of intrauterine growth restriction. Methotrexate should be avoided before and during pregnancy due to its teratogenic effects. The theoretical reduction in serum hormone levels brought about by plasmapheresis has not caused preterm labour in practice. Miscarriage rates and preterm delivery rates are not significantly different from those of a control population [C].

Due to the change in volume distribution of pregnancy, the dose of anticholinesterase inhibitors needed to control

symptoms usually increases in pregnancy. Increasing the dosage frequency has been found to be more effective in some cases. Persistent vomiting in the first trimester will necessitate intravenous administration of anticholinesterases. Prolonged labour (associated with delayed gastric emptying and malabsorption) may also be an indication for parenteral drug delivery.

Transplacental passage of the IgG autoantibodies may cause two distinct fetal/neonatal problems:

- 1 Women with anticholinergic receptor antibodies occasionally deliver infants with arthrogryposis multiplex congenita, a serious congenital syndrome characterised by multiple joint contractures and pulmonary hypoplasia. Although the aetiology of this syndrome is diverse, severely reduced movement *in utero* is thought to be the basic mechanism. Animal experiments have shown that sera from women with anticholinergic receptor antibodies can cause a similar range of anomalies *in vivo*.
- 2 Neonatal myasthenia gravis (NMG) is a more common manifestation of these antibodies, affecting 10–50 per cent of newborns delivered to women with MG. The onset is usually within 24 hours and most cases are mild, presenting with generalized hypotonia, poor sucking, difficulty in feeding and weak cry. Less commonly, ventilation is required, sometimes for a number of weeks. The newborn is usually treated with anticholinesterases but exchange transfusions, plasma exchange and intravenous immunoglobulins have been used in more resistant cases. The correlation between maternal disease severity, or antibody titres, and the incidence and severity of NMG is not a strong one. However, seronegative mothers may be less likely to have an affected baby, and affected babies themselves are usually seropositive.

Clearly, the pregnancy should be managed in conjunction with a neurologist. Anaesthetic and paediatric colleagues should be informed [E]. Regular fetal surveillance is warranted and polyhydramnios should be excluded. Preterm delivery is necessary only in severe crises and a vaginal delivery should be aimed for [E]. Problems may occur in second stage due to skeletal muscle fatigue and there should be a low threshold for instrumental delivery. Advice should be taken before any medications are prescribed, as various drugs may precipitate a myasthenic crisis. Magnesium interferes with neuromuscular transmission by inhibiting release of (ACh). Magnesium competitively blocks calcium entry at the motor nerve terminal. Therefore, magnesium sulphate for the treatment of hypertension or eclampsia should be used with extreme caution. The neonate should be carefully observed for signs of NMG and caution should be exercised with breastfeeding when high doses of anticholinesterases have been used. Drug doses may need to be reduced slowly to pre-pregnancy levels.

INTRACRANIAL VASCULAR EVENTS: 'STROKE'

'Stroke' is a generic term used to describe a cerebrovascular accident, the causes of which are many and varied. Assigning a diagnosis to 'stroke' is vital for appropriate treatment and prevention of further events.

Stroke can be further classified as shown in Table 17.5.

Across all age groups, hypertension, diabetes and cigarette smoking are the most common 'causes' of stroke, working through a common atherosclerotic pathway.

Retrospective studies [D] consistently show that the incidence of stroke is increased during pregnancy, and that this increase is mostly confined to the postpartum period. The aetiology of pregnancy-associated stroke is very different from that of stroke in general.

Various studies have estimated a stroke risk of between 5 and 10 per 100,000 deliveries, although a Canadian retrospective review gave a six-fold higher risk than this.¹⁴ Most do not find a significant increase in strokes antenatally compared with a female population of the same age distribution, but the increase in the postpartum period is striking. A US study published in 1996 found a relative risk for stroke in pregnancy of 2.4 overall (95 per cent CI 1.6–3.6); however, when subdivided into antepartum and postpartum periods, the relative risk in the first 6 weeks after delivery was found to be 9 for ischaemic stroke (infarcts) and 28 for haemorrhagic [D].¹⁵ Evidence from other studies supports these findings.

In women under 40 years of age, infarcts are more common than haemorrhagic strokes. However, this predominance of infarcts is less marked in the pregnancy-associated group.

Causes of pregnancy-associated strokes

Below are the causes of pregnancy-associated strokes found in two recent studies.^{14,15}

Infarcts

- Pre-eclampsia/eclampsia
- Primary CNS vasculopathy
- Carotid artery dissection
- Cardiac embolic events
- Coagulopathies (e.g. thrombophilias, APS)
- TTP
- Post-herpetic vasculitis.

Haemorrhagic

- Pre-eclampsia/eclampsia
- Disseminated intravascular coagulation

Table 17.5 Stroke classification

Ischaemic	Arterial
	Venous
Haemorrhagic	Subarachnoid
	Intracerebral

- Arteriovenous malformations
- Ruptured aneurysms
- Cocaine abuse
- Primary CNS vasculopathy
- Sarcoid vasculitis.

In a significant number of cases no underlying cause is found. The wide aetiology of stroke in pregnancy presents a diagnostic challenge. The subsequent treatment will depend very much on the diagnosis. Investigations undertaken to determine a cause may include:

- MRI/CT scanning
- cerebral angiography
- echocardiogram
- thrombophilia screen
- antiphospholipid testing.

Clearly, treatment and management of the pregnancy will depend on the diagnosis; anticoagulation, for example, may be necessary after a cerebral venous thrombosis. Haemorrhagic strokes caused by bleeding aneurysms or arteriovenous malformations (AVMs) carry a significant risk of re-bleeding if left untreated in pregnancy [D].¹⁶ Ideally, such abnormalities would be diagnosed and treated before conception, but some will present for the first time in pregnancy. AVMs, in particular, may enlarge as pregnancy progresses, perhaps in response to hormonal changes. Outside pregnancy they are a much less common cause of subarachnoid haemorrhage than aneurysms. In the two studies cited above, AVMs were found to be the cause of subarachnoid haemorrhage in more cases than a bleeding aneurysm (8 vs 3) [D]. A few will present with recurrent headaches and neurological deficit, but without haemorrhage. Treatment in these cases is the same as in the pre-pregnant state, with surgery (excision of AVM, clipping of aneurysm) or obliteration with neuroradiological techniques. However, some consideration must be given to fetal radiation exposure. Subarachnoid haemorrhage may present with headache, vomiting, reduced consciousness, neck stiffness and focal neurology. In view of the high risk of re-bleeding, most advocate early treatment rather than an initial delay. Nimodipine is used to reduce vasospasm, and hypertension must be controlled. Neurosurgery is normally tolerated well by the pregnancy, although decision-making can be complicated by reduced maternal conscious level. Vaginal delivery is encouraged if there is confidence that the source of the bleeding has been treated adequately, although this can be difficult sometimes with AVMs. A longer passive second stage is usually encouraged to reduce the need for the Valsalva manoeuvre, with early recourse to instrumental delivery [E]. If the aneurysm or AVM has not been treated, or this treatment has occurred recently, an elective caesarean section is advocated, as labour is considered by many to be a high-risk time for a first bleed or a re-bleed [E]. Of note, however, is that only one death has occurred from subarachnoid haemorrhage during labour in the last 6 years in the UK, leading some to believe that this risk has been previously overstated. Poor maternal clinical state (coma, brain-stem death) is of

course another indication for caesarean section. Epidurals can be used provided there is no evidence of raised intracranial pressure. Special anaesthetic techniques are used to limit the hypertensive responses found with intubation, which carry the risk of precipitating a re-bleed [E].

Investigation and treatment of the pregnant patient with stroke obviously require significant input from neurologists and neurosurgeons. However, all those in maternity care have an important part to play in stroke prevention. For example, women with APS and thrombophilias can be treated, once recognised, with prophylactic anticoagulation [D]. Optimal management of hypertension in pre-eclampsia and eclampsia will also help to reduce the associated stroke risk [D].

MIGRAINE AND HEADACHE

Tension headaches are more common in pregnancy, and migraines may present for the first time. Clinically they must be differentiated from much less common but far more serious causes of headache (see below). Making a diagnosis may involve special investigations and the help of a neurologist or radiologist. Treatment will depend on the cause.

A classic migraine attack in a woman with a history of migraines does not normally warrant review by a neurologist. Visual disturbance, aphasia and paraesthesia or numbness usually last no more than an hour or so, and are followed by a throbbing unilateral headache with associated nausea, vomiting and photophobia. However, as many as 1 in 10 women with migraine in pregnancy has no previous history [D]. In view of the considerable symptom overlap with other diagnoses, a specialised opinion may be warranted. This applies also to women with migraine who suffer a presumed attack with atypical or prolonged neurological deficits. Hemiplegic migraine, for example, may last for many hours and should raise the possibility of an alternative diagnosis.

Causes of headache in pregnancy

- Tension headache
- Migraine
- Pre-eclampsia
- Benign intracranial hypertension
- Cerebral vein thrombosis
- Meningitis
- Subarachnoid haemorrhage (see below)
- Intracranial mass
- Inadvertent dural puncture (spinal headache).

Between 60 and 70 per cent of women with migraine will improve, or be symptom free, during pregnancy [C]. Those women who have cycle-related migraines are most likely to note an improvement. No more than 10 per cent seem to deteriorate in pregnancy. Every effort should be made to avoid precipitating factors, such as chocolate and cheese. Non-drug therapies such as relaxation techniques, sleep, massage and ice packs can be tried. Acute attacks in pregnancy are normally

treated with paracetamol (rectal may be better than oral administration) and/or codeine-based drugs along with an antiemetic such as metoclopramide. Occasional use of NSAIDs is permitted, but should be avoided after 32–34 weeks [C]. Stronger opiates are sometimes needed. Ergotamine derivatives should be avoided, although studies have failed to show obvious harm. Sumatriptan, a serotonin antagonist, is in common use outside pregnancy. Data from the 16-Year Sumatriptan Pregnancy Registry of unintended pregnancy exposures have demonstrated no clear problems.¹⁷

Prophylaxis against migraine attacks in pregnancy is best provided by low-dose aspirin or amitriptyline (commencing with low doses such as 10 mg per day). Propranolol and atenolol have been used, with the awareness of the associated potential for intrauterine growth restriction. The safety of pizotifen and methysergide in pregnancy is still in question.

PARAPLEGIA

Pregnancy in a woman with a spinal cord injury (SCI) can present challenges to the patient and her obstetrician. Some problems that occur in able-bodied women are more likely to occur in women with SCI such as UTI, anaemia and venous thrombosis. Other problems are specific to women with SCI and include neurogenic bladder, spasticity, decubitus ulcers and autonomic hyperreflexia.

Antenatal management

- Antenatal management should take into account the level of SCI and the degree of paralysis. A formal assessment of renal, urological or pulmonary status may be appropriate.
- Women with spinal cord lesions at T6 or above are at risk of autonomic hyperreflexia and should be cared for in a setting where invasive monitoring and physicians experienced with autonomic hyperreflexia are available.
- Pre-eclampsia, intrauterine growth restriction and stillbirth are NOT more common in this population and antenatal testing for fetal wellbeing is not indicated in the absence of other obstetric indications.
- Preterm labour may be slightly more common in this population. In addition, although the majority of patients with SCI are able to perceive labour, the subjective experience may be different to that of able-bodied women and may delay presentation. However, serial cervical assessment (using ultrasound) and home uterine contraction monitoring have not proven useful in detecting women at increased risk of preterm labour in this population.

Intrapartum care

- Previous recommendations against performing inductions of labour have been made because of concern over autonomic hyperreflexia. Most studies available do not

provide enough detail to suggest that induced labour is more difficult to manage than spontaneous labour with regard to autonomic hyperreflexia and it is therefore reasonable to restrict inductions to obstetric indications.

- The mode of delivery in women with SCI is primarily determined by standard obstetric indications. However, spasticity and contractures can impair the ability to achieve a vaginal delivery. If the patient has limited abduction and rotation preventing use of the lithotomy position, she should be assessed for suitability of positioning on her side with flexion of the upper leg at the hip.
- A unique indication for caesarean section in women with SCI is intractable autonomic hyperreflexia unresponsive to pharmacological or anaesthetic manipulation. The surgery will continue to incite the process but can be life saving if the time to delivery seems remote.
- Attendant staff need to be aware of the risk of pressure ulcers and traumatic injuries in women with SCI; frequent changes in position are advised.
- Frequent bladder emptying or catheterisation will prevent overdistension in patients with a neurogenic bladder.
- The level and completeness of the spinal cord lesion determines the patient's perception of labour and the anaesthetic requirements:
 - Pain from the first stage of labour is transmitted by sympathetic fibres that enter the spinal cord at T10–12 and L1.
 - The second stage of labour involves pain from pressure and distension of perineal tissues. These signals travel along the pudendal nerve and enter the spinal cord at S2–4. Therefore patients with lesions above T10 may not perceive labour at all but those with lesions above T5–6 may benefit from anaesthesia to prevent autonomic hyperreflexia.
- SCI is not a contraindication to regional anaesthesia.

Postnatal care

- Once again, attendant staff need to be aware of the risk of pressure sores and traumatic injuries in the postnatal period.
- Care should be taken to avoid urinary retention, no matter what the mode of delivery, in order to prevent a deterioration in bladder function and to minimise the risk of urinary infection and autonomic hyperreflexia.
- Breastfeeding should be encouraged; no deficiency in the let-down reflex has been observed, even in patients with high cervical lesions.

PRENATAL DIAGNOSIS OF NEUROLOGICAL DISEASES

Although most severe neurological disorders limit life expectancy, many milder problems do not, and women suffering from these conditions may wish to become pregnant, or may present at the booking clinic. Alternatively, a healthy woman with a previously affected child may come under your care. Such individuals may or may not be interested in recurrence risks in their offspring. Good-quality information is needed so that an informed choice can be made. The first step is to seek out the true diagnosis. The term 'cerebral palsy', for example, does not give any indication of aetiology. Although cerebral palsy usually occurs as a result of various environmental factors, genetic factors are responsible for a few cases, raising the recurrence risk. 'Muscular dystrophy' is all too often assumed to be Duchenne's muscular dystrophy (an X-linked recessive condition); in fact, there are many different kinds of muscular dystrophy with different inheritance patterns. A careful family history is vital, but help is likely to be needed from neurologists, paediatricians and clinical geneticists.

Once the maternal diagnosis has been established, empirical recurrence risks can often be quoted. In a few cases genetic testing offers the possibility of more precise prenatal prediction. This entire process can take many weeks, and plans should be made before the woman actually becomes pregnant, if possible.

The *triplet repeat diseases* highlight best some of the complexities of prenatal testing. Huntington's disease, myotonic dystrophy, Friedreich's ataxia and fragile X all share a similar genetic abnormality. A three-basepair sequence (the 'triplet') which is repeated a variable number of times in the healthy gene becomes 'expanded', so that many more copies of the triplet are present and gene function becomes disrupted. To a degree, the disease severity may be related to the size of the expansion. Expanded sequences have a tendency to expand further, causing so-called 'anticipation', i.e. the condition becomes more severe in successive generations. Myotonic dystrophy provides the clearest example.

Myotonic dystrophy is the most common muscular dystrophy affecting pregnant women and occurs as a result of the disruption of a gene coding for a protein kinase on chromosome 19. The gene is disrupted by the expansion of a CTG triplet repeat; 5–35 CTG repeats is considered normal. More than 40 is abnormal, and mildly affected individuals will show a degree of expansion beyond this size. Severely affected individuals often have many thousands of repeats. Clinical features include muscle weakness, myotonia of hands and tongue, swallowing and speech disability, cataracts and

cardiac arrhythmias, testicular atrophy and peripheral insulin resistance. Learning disability occurs in those affected severely from a young age.

Myotonic dystrophy is an autosomal dominant condition, affected individuals having one normal and one abnormal allele. Their offspring have a 50 per cent risk of inheriting the mutated allele. Quite how severely affected the child will be is difficult to predict with any degree of accuracy. A woman with moderate-to-severe disease herself is likely to have a significantly expanded mutation already. If this is inherited by the fetus, further expansion is likely and the neonate will be born with severe congenital myotonic dystrophy. Such a pregnancy may be characterised by polyhydramnios and poor fetal movements. Preterm delivery is more common, and severe hypotonia and respiratory difficulties are evident at birth. Talipes and facial diplegia may be present and survival beyond the neonatal period is followed by significant developmental delay in most cases. A woman with minimal or absent disease (and therefore a shorter expansion) has a risk of approximately 1 in 10 that her child will be severely affected. However, if such a woman has delivered a severely affected newborn in a previous pregnancy, the risk of another badly affected child is higher (approximately 40–80 per cent). This reflects the greater likelihood that she has an inherently unstable mutation.

Inheritance and further expansion of the mutated allele can be detected by molecular testing carried out on placental biopsy material, although precise analysis of expansion size and prediction of outcome can still be difficult.

Chapter 18 Dermatological conditions

Louise Kenny

MRCOG

There are no recognised standards, but we would suggest the following.

Theoretical skills

- Be aware of the potential effects that pregnancy may have on skin disease and vice versa.
- Recognise that many skin problems carry a genetic, inheritable element.

Practical skills

- Be able to provide women with reassurance regarding the normal physiological cutaneous changes in pregnancy.
- Provide detailed information regarding the safety of various dermatological treatments in pregnancy.
- Recognise when to involve specialist help from a dermatologist.

PHYSIOLOGICAL SKIN CHANGES IN PREGNANCY

Physiological cutaneous skin changes during pregnancy are common and rarely cause major concern. Hyperpigmentation may occur of the nipples and areolae, axillae, linea alba (which becomes the linea nigra), face (melasma or cloasma), and pre-existing pigmented moles and freckles. Oestrogen is probably responsible for cutaneous vascular changes such as an increase in spider naevi, palmar erythema, and even the occurrence of head and neck haemangiomas. Oedema is almost universal, and venous varicosities of the legs, vulva and rectum often become more prominent or appear for the first time. Striae gravidarum are pinkish-purple linear markings on the lower abdomen and breast, which later fade to white and usually persist after pregnancy is over as depressed, irregular bands. Some women maintain that hair growth and condition improve in pregnancy. Postpartum alopecia, however, is a recognised phenomenon that is usually mild and transient.¹ Sebum secretion increases (see below), but apocrine activity may decline.

INTRODUCTION

Although this section of the book deals with pre-existing diseases and their interaction with pregnancy, the dermatological conditions of most interest to the obstetrician are the 'dermatoses of pregnancy', i.e. the skin conditions peculiar to pregnancy. These are thus discussed alongside pre-existing conditions.

The skin may be the sole organ affected by a particular condition or it may be just one of many involved in a multisystem disease. Skin disorders occurring as part of multisystem disease (connective tissue disease, infections and malignancies) are considered in the appropriate chapters. It is worth remembering, however, that the skin manifestation of these disorders may be the initial presentation of these conditions.

PRE-EXISTING CONDITIONS

Women with pre-existing skin problems are likely to present with a diagnosis already established. As with all pre-existing maternal conditions, one must consider the effect that both the disease and its therapies will have on the pregnancy, the labour, the fetus and the neonate. Conversely, the pregnancy may influence the course and nature of the condition itself.

The effect of pregnancy on atopic dermatitis (atopic eczema) and psoriasis is unpredictable.² The former often improves in pregnancy but may deteriorate postnatally, due to physical factors such as breastfeeding, environmental agents such as detergents or even immune factors. A generalised pustular psoriasis may occur in pregnancy (see below) and is more common in women with previous psoriasis. Sebum secretion increases in pregnancy and may be

responsible for the common deterioration of acne during pregnancy. Apocrine gland activity, on the other hand, declines in pregnancy, meaning that the rare conditions affecting these glands (hidradenitis suppurativa and Fox–Fordyce disease) are likely to improve. The pregnancy-associated suppression of cell-mediated immunity is thought to cause the often marked increase in human papillomavirus warty lesions (condylomata acuminata). In rare cases, these may obstruct the vagina. Only then are they an indication for caesarean section.

Impact of pre-existing skin diseases on the pregnancy itself is usually minimal in the absence of any multisystem involvement (clearly, connective tissue disorders and infections with skin involvement are quite different).

Conditions affecting the abdominal wall may interfere with abdominal delivery and delay wound healing. Vulval problems may similarly affect vaginal delivery and the healing of tears and episiotomies. A rare condition called X-linked ichthyosis is associated with steroid sulphatase deficiency, and this in turn is said to delay the onset of labour, increasing the need for induction for prolonged pregnancy.

Certain skin conditions have a genetic component and the offspring may be at risk of the condition themselves. A few examples are cited in Box 18.1.

One of the most important factors to consider is the potential impact that dermatological drugs and therapies may have on a pregnancy.³ A number of such treatments are confirmed teratogens and are absolutely contraindicated in pregnancy (Box 18.2). The retinoids are used to treat severe acne and psoriasis. Isotretinoin is especially harmful, causing CNS, craniofacial and cardiovascular abnormalities in as many as 50 per cent of exposed pregnancies.

Other drug treatments should be used only with careful consideration in pregnancy, including ciclosporin, hydroxyurea, penicillamine, psoralens and ultraviolet A (PUVA) and rifampicin.

A number of these medications may linger in body tissues for many months after treatment has ended. Great care must

Box 18.1 Examples of inheritable skin disorders

Autosomal dominant
 Ichthyosis hystrix and vulgaris
 Palmoplantar hyperkeratosis (tylosis)
 Epidermolysis bullosa simplex
 Ectodermal dysplasia (some forms)
 X-linked recessive
 X-linked ichthyosis
 Hypohidrotic ectodermal dysplasia
 Multifactorial
 Atopic eczema (the risk of some allergic problems may reach 50% in the offspring of a couple with one affected person; the risks are higher where both parents are eczema sufferers)
 Psoriasis (the children of two psoriatic parents have a risk of approximately 50% of being affected themselves)

Box 18.2 Dermatological treatments to be avoided during pregnancy

Acitretin and tazarotene (retinoids used in psoriasis)
 Isotretinoin (retinoid used to treat severe acne)
 Griseofulvin (antifungal treatment)
 Methotrexate (antimetabolite used to treat psoriasis)
 Podophyllin (used for genital warts)
 Tetracycline (used for skin infections/acne)
 Thalidomide (leprosy treatment)

be taken that women undergoing such therapies are made aware of the vital role of reliable contraception, which may need to be continued long after the treatment has stopped. The *British National Formulary* advises the following periods of time during which conception should be avoided after the drugs have been stopped [E]:

- acitretin – 2 years;
- methotrexate – 6 months;
- griseofulvin – 1 month.

It should be noted that these drugs may also carry potential harm through an effect on the male gametes. Men who have used griseofulvin, for example, are advised against fathering offspring within 6 months of treatment ending.

Emollients, dithranol, coal tar and topical corticosteroids are safe in pregnancy, as is chlorpheniramine.

DERMATOSES PRECIPITATED BY PREGNANCY

This section covers two groups of conditions:

- 1 skin conditions in which pregnancy is just one of a number of precipitating factors;
- 2 skin conditions unique to pregnancy.

Acne, erythema multiforme, erythema nodosum and generalised pustular psoriasis form the first group. Pre-existing **acne** may deteriorate during pregnancy, but may also present anew. **Erythema multiforme** and **erythema nodosum** are both caused by a multitude of other aetiological factors, which must be excluded before it is possible to attribute the onset to pregnancy alone. **Generalised pustular psoriasis** describes a superficial sterile eruption occurring on the background of widespread erythema, which is associated with fever, systemic upset and hypocalcaemia (with tetany) in the more severe cases. It carries significant perinatal mortality and is more common in those with a history of plaque psoriasis. A clinically identical condition called **impetigo herpeticiformis** was previously thought to be a pregnancy-specific dermatosis, but the two are now considered the same condition. Pregnancy appears to be one of a number of triggers for generalised pustular psoriasis.

Table 18.1 Pregnancy-specific dermatoses

Name	Incidence	Onset	Resolution	Clinical features	Histology	Immunofluorescence	Fetal effects	Recurrence	Management	Associated conditions
Polymorphic eruption of pregnancy (pruritic urticarial papules and plaques of pregnancy, toxæmic rash of pregnancy, toxic erythema of pregnancy)	1 in 250	27-40 weeks (usually late third trimester)	Usually within 2 weeks of delivery	Red urticarial papules and plaques. Rarely, vesicles and target lesions. Begins abnormally within striae Umbilical sparing May spread to thighs and occasionally limbs	Epidermal/dermal oedema Perivascular infiltration Patchy parakeratosis	Negative	None	Uncommon	Calamine lotion 1% hydrocortisone aqueous cream Antihistamines Systemic steroids	None
Pemphigoid gestationis (herpes gestationis)	1 in 3000-60,000	Second/third trimester (occasionally postpartum)	Few weeks postpartum to 1 year	Erythematous urticarial plaques. Vesicles and bullae form at the centre or periphery of plaques. Often begins periumbilically. Spreads to trunk and extremities	Perivascular inflammation Subepidermal blister	Positive	Possible increased risk of IUGR and preterm labour	Common	Moderate/strong topical steroids Systemic steroids Antihistamines	Graves' disease and other autoimmune conditions
Prurigo of pregnancy	1 in 300	25-30 weeks	Several months	No urticated lesions Multiple excoriated papules Abdomen and limbs	See polymorphic eruption of pregnancy	Negative	None	Recorded	Aqueous cream Topical steroids Antihistamines	Atopy
Pruritic folliculitis of pregnancy	Uncertain	Second/third trimester	Within 2 weeks of delivery	Masses of itchy red follicular papules	Non-specific folliculitis	Negative	None	Uncertain	Topical 10% benzoyl peroxide Mild topical steroids Antihistamines	None

This leaves four reasonably well-defined dermatoses found only in pregnancy (Table 18.1).

A diagnosis can usually be made on clinical grounds alone; however, pemphigoid gestationis can be confused with polymorphic eruption of pregnancy if there are no vesicles present. The two conditions are easily distinguished by immunofluorescence studies of skin biopsies. Pemphigoid gestationis is characterised by C3 deposition along the epidermal/dermal junction. IgG deposition is usually another feature, the target protein being a 180-kDa component of hemidesmosomes. Immunofluorescence studies are negative in polymorphic eruption of pregnancy. Clinical distinction is appropriate as pemphigoid gestationis has been linked to increased rates of stillbirth, IUGR and preterm labour [D].

Although this may represent biased reporting of poor outcomes, extra surveillance would seem warranted in these pregnancies [E].

Chapter 19 Drug and alcohol misuse

Louise Kenny

MRCOG

The RCOG has published statement No. 5, *Alcohol Consumption and the Outcomes of Pregnancy* (March 2006), and this is referred to where appropriate.

Relevant standards

To understand and demonstrate appropriate knowledge, skills and attitudes in relation to pregnant women who misuse alcohol and drugs.

Theoretical skills

Awareness of drug and alcohol misuse in pregnancy:

- Knowledge of the pharmacological actions of opioids, cocaine, marijuana, amphetamines, benzodiazepines and alcohol.
- Appreciate the acute and chronic maternal effects and associations of substance abuse to optimise recognition and management during pregnancy.
- Understand the fetal/neonatal effects of *in utero* exposure to these substances.
- Recognise the association between substance abuse and other health and social problems.

Practical skills

- Provide pre-conception counselling to a woman with a history of alcohol or drug misuse.
- Manage a pregnancy complicated by substance abuse.
- Liaise with social and specialist drug services to individualise care.

INTRODUCTION

The incidence of substance misuse in the UK varies widely by geographical location. Three per cent of under-35s in the UK are said to have a drug problem, although London, Glasgow, Liverpool and Manchester have traditionally been considered

the 'hotspots'. However, a recent cross-sectional audit of health records in a London specialist perinatal addictions outreach service reported that a total of 167 pregnant substance-using women were referred between 2002 and 2005. Compared with 1989–1991, there were significantly more pregnant women presenting at an older age, later gestation, with increased polysubstance use and a higher percentage of women from black or minority ethnic communities. Clearly the problem is increasing, and maternity services must have local guidelines and action plans in place to manage it. Alcohol is a particular concern. Recent data from a global cohort study of low-risk first-time mothers found that 34 per cent of women reported binge alcohol consumption in the 3 months before pregnancy, and 23 per cent of these participants reported binge alcohol consumption during the first 15 weeks of pregnancy.¹

There is a tendency to focus attention on the medical aspects of substance abuse in pregnancy. Although these drugs may involve actual harm to the pregnancy, the associated social and health problems are as important, if not more so. Throughout this chapter it will become clear that separating the two is very difficult, and the contributions made first by the drugs themselves and second by the socio-economic environment are almost impossible to disentangle. Separating the two is of greater theoretical than practical importance. Substance-exposed pregnancies are 'high risk', and tailored antenatal care must be provided that tackles all the problems, both social and medical.

Substances of abuse are rarely used in isolation. 'Polysubstance' misuse is the norm, and heavy alcohol consumption and tobacco smoking compound the harm done by classified drugs. The following discussion therefore does not tackle each drug independently, but aims to explore their individual contributions to each problem encountered in the pregnancy. Many studies demonstrating harmful effects of substance abuse in pregnancy are retrospective and little or no effort is made to control for confounding factors. Clearly, there are no randomised studies. Better study design is often associated with negative results or a diminution in the harm reported. There is little doubt, however, that drug use during pregnancy *is linked* to poorer outcomes.

PHARMACOLOGY

It is valuable to revise the basic pharmacological actions of abused substances, as these actions help to explain both the short-term and the long-term effects on the pregnancy outcome.

Cocaine

Cocaine is a CNS stimulant. It prevents the re-uptake of neurotransmitters (adrenaline, noradrenaline, dopamine) at nerve terminals, causing an exaggerated response to these chemical messengers. Increased motor activity, tremors, convulsions, tachycardia, generalised vasoconstriction, hypertension and hyperpyrexia may result. The sense of euphoria occurs as a result of dopamine accumulation within the mesolimbic system. Chronic cocaine use brings about dopamine depletion. Use of cocaine with alcohol results in a more powerful vasoconstrictor called cocaethylene.

Opiates

Opiates (heroin, methadone, morphine, buprenorphine) mimic the actions of the endogenous opioid peptides widely distributed throughout the CNS, which bind to mu, delta or kappa opioid receptors. These compounds have a wide diversity of physical functions but are intimately linked with pain perception and mood control. The 'reward circuitry' of the mesolimbic dopaminergic system is influenced by endogenous and exogenous opioids and is responsible for both the pleasurable effects and the psychological dependence found with opiate abuse.

Amphetamines

Amphetamines similarly enhance the dopaminergic neurotransmitter system. Ecstasy (3, 4-methylenedioxymethamphetamine – MDMA) is a derivative of metamphetamine. It causes accumulation of synaptic serotonin and dopamine, but direct axonal damage and serotonin depletion can occur with prolonged use.

Alcohol and marijuana

Alcohol and marijuana have fundamental non-specific actions on the neural membrane, in common with the sedative-hypnotic-anaesthetic group of drugs. They differ somewhat in their actions due to differing lipid solubilities, routes of intake, metabolic pathways and different ratios of stimulant and depressant effects. Marijuana, unlike alcohol, has hallucinogenic properties.

Benzodiazepines

The actions of benzodiazepines (diazepam, temazepam) are mediated through the neuroinhibitory gamma-aminobutyric acid type A (GABA-A) receptor. GABA and benzodiazepines have anxiolytic, sedative and hypnotic effects, and also affect cognition. They bring about muscle relaxation and act as anticonvulsants. GABA has trophic effects and this may be important in neurodevelopment. Excessive benzodiazepine use leads to receptor down-regulation and tolerance.

MATERNAL EFFECTS

The effects of substance abuse on the mother may be acute or chronic and may be specific to the drug used or part of a general pattern of illness found among substance abusers. It is vital for obstetricians to have an understanding of these problems, as they may present in the antenatal clinic or as emergencies on the labour suite. Furthermore, they may be confused with complications of pregnancy.

Acute maternal effects

Drug abuse is associated with a wide range of health problems, which may present acutely to various different health-care professionals.

Overdose

Excess alcohol intake causes ataxia, confusion, stupor and eventually coma.

Opiates in excess depress respiratory drive and may also cause coma.

Cocaine, amphetamines and ecstasy cause tachycardia, hypertension and hyperthermia, and predispose to cardiac arrhythmias, myocardial infarction, seizures and stroke. The potential for diagnostic confusion with fulminating pre-eclampsia and eclampsia is clear. Acute presentations also include aggression, paranoia and psychosis, particularly with the CNS stimulants such as amphetamines, ecstasy and cannabis.

Withdrawal

Withdrawal from the physically addictive substances may also present acutely. Alcohol withdrawal may result in blackouts, tremor, hallucinations, delirium and seizures. Opiate withdrawal is characterised by sweating, coryza and lacrimation. Pyrexia, nausea and vomiting, diarrhoea and abdominal pain, tachycardia and hypertension are also common.

Infections

Drug abuse is often associated with poor diet, poor hygiene and generalised immunosuppression. Pneumonia and TB may present acutely. Sexual disinhibition and prostitution increase the risk of sexually transmitted infections (STIs),

including HIV. Intravenous substance use predisposes to endocarditis, hepatitis and septicaemia (which may be fungal). Local infections such as cellulitis and osteomyelitis are not uncommon.

Other acute presentations

Hypoglycaemia, acute or chronic hepatic failure and Wernicke's encephalopathy may result from excessive alcohol consumption. Aspiration pneumonitis, subdural haematomas and rhabdomyolysis with acute renal failure are further examples of acute complications of substance abuse. All types of trauma, including road traffic accidents (RTAs) and grievous bodily harm, are more common among drug users.

Chronic maternal effects

The effects of HIV infection and chronic hepatitis (whether alcoholic or infectious) are well known. Nutritional deficiencies may cause peripheral neuropathy (vitamin B₁ and vitamin B₁₂), pellagra (niacin), cerebellar degeneration and Wernicke–Korsakoff syndrome (vitamin B₁). Poor venous access is common in IV substance users and this may cause difficulty during emergency situations (drug induced or pregnancy related). Femoral nerve neuropathy may result from frequent trauma during injection into the femoral vein. Obstructive and restrictive pulmonary lesions may occur, as can pulmonary hypertension.

OBSTETRIC PROBLEMS

Substance abuse has been associated with a number of obstetric complications, including:

- miscarriage
- preterm rupture of membranes
- preterm labour
- placenta praevia
- abruption
- pre-eclampsia
- breech presentation
- chorioamnionitis
- IUGR and IUD.

Although plausible biological explanations exist for why substances of abuse might cause these problems, the exact contribution from the drugs themselves is very difficult to isolate from the confounding factors such as smoking, poor nutrition and general health, lack of antenatal care and low socio-economic status.

Miscarriage

Studies examining rates of miscarriage in substance-exposed pregnancies are often retrospective and poorly controlled.

Confirmation by tissue diagnosis is often missing. Opiates, cocaine and CNS stimulants have all been implicated, but good-quality evidence is mostly lacking.

Most attention has been paid to the effect of alcohol on miscarriage rates, and large quantities have been shown to have abortive properties in animal experiments. There is general agreement that alcoholics have a higher rate of miscarriage, although it is almost impossible to separate the effect of the alcohol from the confounding effects of ill-health, poor nutrition and low socio-economic status. Alcohol consumption is closely related to smoking and caffeine use (coffee drinking), both of which have stronger causative relationships with miscarriage. North American studies have linked 'heavy drinking' (more than two drinks per day) with an increase in miscarriage rate, giving relative risk values of between 2 and 3. This association is not, on the whole, confirmed in European and Australian studies, where greater effort has been made to control for confounding factors.² Most agree, however, that more than six drinks a day for several days per week is associated with higher miscarriage risk [C].

There is no good evidence to suggest that the other substances discussed in this chapter cause miscarriage.

Teratogenicity

The only confirmed teratogen among this group of substances is alcohol. The **fetal alcohol syndrome** (FAS) describes a clearly defined group of problems caused by *in utero* alcohol exposure:

- prenatal or postnatal growth restriction/microcephaly;
- nervous system dysfunction (learning disability, intellectual impairment, ataxia, attention defects);
- characteristic facial appearance (mid-face hypoplasia, narrow palpebral fissures, underdeveloped philtrum, ptosis, rotated low-set ears).

Fetal alcohol spectrum is the term used to describe other alcohol-induced abnormalities that do not qualify for the 'full' diagnosis of FAS.

The relationship between alcohol consumption during early pregnancy and the incidence of FAS is not a simple one. Despite having the highest rates of worldwide alcohol consumption, France has a significantly lower rate of reported FAS than North America, where less alcohol is consumed. A number of reasons have been cited to explain this discrepancy, including a difference in drinking patterns between the two countries and a greater readiness to label newborns with the diagnosis of FAS in the USA. 'Heavy drinking' is defined as more than two drinks per day, or more than 45 per month. This group of women have an approximate incidence of FAS of 4 per cent. Alcoholics, or those drinking more than 18 units per day, carry a risk of one in three of their offspring having FAS. These figures are altered by socio-economic status, general health, smoking and possibly ethnicity, which all act as confounding factors. There is no clear threshold below which alcohol consumption is considered entirely safe; however, the

incidence of alcohol-related birth defects and FAS increases sharply after 3 units per day [C].³ 'Binge drinking' of more than 5 units in one session may be more harmful than taking the same quantity in 'divided doses', although there is no good evidence for this at present. Clearly this practice should be discouraged during pregnancy [E].

The relationship between benzodiazepine use in the first trimester and congenital anomalies, most notably cleft lip and palate, has been examined many times. A meta-analysis by Dolovich *et al.*⁴ included the 23 most technically robust studies. The cohort studies could not significantly link benzodiazepine use with any fetal abnormalities. The case-control studies, however, gave a three-fold increase in risk for all major anomalies and an odds ratio of 1.79 (1.13–2.82) for oral clefting. They suggest detailed scanning for those pregnancies exposed in the first trimester.

There are good scientific reasons why ecstasy and cocaine might act as teratogens, although the better-controlled studies and meta-analyses have not confirmed the effects found in laboratory animals exposed to high concentrations of these drugs *in utero*. Neurotransmitters can be found in the fetal brain from very early gestation, and it is likely that they are involved in neuronal migration and establishment of synaptic circuitry. It is simple to imagine how these processes could be disturbed by exposure to such drugs and bring about the microcephaly said to be characteristic of cocaine-exposed neonates.

After maturation of the muscularis layer of fetal cerebral vessels, acute vasoconstriction may lead to infarction followed by the subsequent development of cavitory lesions (e.g. porencephalic cysts). Vascular disruption secondary to cocaine use has also been postulated as a cause for the increase in gut, genitourinary and limb defects reported by some authors. Controlled studies have failed to support these findings.

A recent prospective follow-up study⁵ of 136 babies exposed to ecstasy *in utero* has reported a significant increase in the anomaly rate (15.4 per cent); however, almost half the women used other illegal substances or alcohol and most of the abnormalities were 'minor', raising the possibility of ascertainment bias. To reach statistical significance, the background congenital anomaly rate was quoted as 2–3 per cent; in fact, if minor abnormalities are included, it may be closer to 10 per cent.

Although congenital anomalies will undoubtedly complicate a proportion of pregnancies exposed to marijuana and opiates, no consistent pattern of abnormalities has been found. Most studies show no increase in anomaly risk or are uncontrolled and retrospective.

Preterm labour and abruption

The obstetric effects of cocaine have perhaps drawn the most attention. Its vasoconstrictive properties are thought to cause abnormal implantation, hypertensive episodes and abruption. Down-regulation of beta-adrenoreceptors in the myometrium may lead to increased uterine irritability and predispose

to preterm labour. Amphetamines and ecstasy may have similar effects, although there are far fewer data. Studies of cocaine use in pregnancy have confirmed the increased risk of preterm labour and abruption; however, these are often lost when confounders (alcohol use and smoking) have been accounted for.⁶

Opiate withdrawal is also thought to cause uterine excitability and result in preterm rupture of membranes and preterm labour [E]. However, smoking is more common amongst opiate abusers, and minimal antenatal care is the norm. Failure to consider the effect of these confounding factors means the effect of opiates itself is often overestimated.

The effect of prenatal alcohol exposure on the length of gestation remains unclear.

In utero growth and development

Intrauterine growth restriction and stillbirth more commonly occur in pregnancies exposed to high alcohol levels, opiates and cocaine. The vasoconstrictive properties of cocaine and ecstasy may cause placental insufficiency and predispose to abruption, uterine irritability and preterm labour. The high metabolic demands of a fetus alternately exposed to opiate 'highs' and withdrawals might also be responsible for IUGR and even stillbirth [E].

Fetal growth restriction is one of the three defining criteria for FAS. Although there are many reasons why growth might be restricted in pregnancies exposed to high levels of alcohol, it is generally held that alcohol itself has a growth-retarding action.

The OR of producing infants below the tenth centile of weight for gestational age compared with non-drinkers for women consuming less than 1 unit per day is 1.1 (95% CI 1.00–1.13), 1–2 units per day 1.62 (1.26–2.09) and 3–5 units per day 1.96 (1.16–3.31).⁷ Among women who continue to drink more than 2 units per day throughout the third trimester, 45% had an infant with a birthweight below the tenth centile for gestational age, whereas in those who successfully reduced or discontinued their alcohol consumption during the last 3 months of pregnancy there was no excess of low birthweight with only 8% falling below the tenth centile. Although low birthweight, is a consistent finding in opiate-exposed pregnancies, a *causative* link between opiate use and IUGR has been difficult to prove due to the action of the following confounding factors:

- 'polydrug' use;
- tobacco smoking and alcohol consumption;
- chaotic and reduced attendance for antenatal care;
- high rates of HIV and other STIs;
- low socio-economic status;
- poor nutrition.

Substituting methadone for heroin has a beneficial effect on prenatal growth, but this may have more to do with increased levels of antenatal care than the action of the heroin itself (see below).

The vasoconstrictive properties of cocaine suggest it should cause prenatal growth restriction. The Maternal Lifestyles Study (MLS)⁷ demonstrated a 450 g reduction in birthweight in cocaine-exposed pregnancies even after the effects of alcohol and tobacco were controlled for [C]. This growth limitation is thought to occur mostly in the third trimester.

NEONATAL EFFECTS

In the newborn period, substance-exposed infants are more likely to suffer low Apgar scores, infectious complications and CNS disturbance, and opiates may also cause neonatal respiratory depression. Prematurity, low birthweight and IUGR contribute as much to the neonatal problems as do the short-term actions of the drugs themselves.

Finnegan was the first to describe the **neonatal abstinence syndrome** (NAS). This results from the acute withdrawal of transplacental opioid which occurs at the delivery of a baby born to an opiate-abusing mother. The onset of the syndrome is normally within 24 hours of birth if the opiate used was short acting (e.g. heroin). It consists of:

- irritability, hypertonicity, tremor, exaggerated startle response and occasionally seizures;
- sweating and sneezing;
- abnormal sleep behaviour, high-pitched cry, poor feeding with weak suck and uncoordinated swallowing.

Methadone maintenance does not prevent NAS, but may delay its presentation until the second day of life due to its longer half-life.

Alcohol, cocaine and amphetamines have a less marked effect on neonatal behaviour, if any effect at all. Rare events such as neonatal hypertension, arrhythmias and necrotising enterocolitis are said to be more common in the offspring of cocaine users, although the confounding effects of prematurity are difficult to separate. Abnormal electroencephalogram (EEG) and brain-stem auditory-evoked responses have been demonstrated in these neonates, and the use of neonatal behavioural assessment scales has shown dampened arousal, poor orientation and reduced state control.

Amphetamine-exposed newborns occasionally demonstrate hyperactivity, poor feeding and disrupted sleep patterns. The neonatal effects of marijuana are debated. Greater irritability, tremors and startle responses have been reported, but a well-controlled Jamaican study⁹ has suggested that once again the postnatal environment is more important than drug exposure itself. In fact, neonatal scores were found to be higher in the offspring of heavy marijuana users. In rural Jamaican society, these women tend to be wealthier and more highly educated. Benzodiazepines may cause neonatal respiratory depression, reduced tone and poor feeding.

CHILD DEVELOPMENT

Tests of child development are complex and beyond the scope of this chapter. They examine many aspects of behaviour, including language and motor skills, attention and play, cognition and problem-solving, and arousal and affective expression. They themselves are open to interpretation and bias.

Mothers willing to participate in longitudinal studies may be more highly motivated, and superior parenting skills in cooperative families may make the effects of the substance abuse appear less significant. Children, as they grow up, may find that society's low expectations of their substance-abusing mothers are reflected on to themselves.

Alcohol

Impaired development of the CNS is a key criterion of FAS. Although children with FAS have an average IQ of less than 70, the consequences of alcohol consumption that does not result in the full syndrome are less clear. The literature is confusing and does not offer clear guidance, perhaps because of the aetiological difficulties discussed above.

Opiates

Opiate use in pregnancy is indeed associated with poor developmental outcomes for the offspring; however, it seems that confounding factors are most likely to be responsible, rather than the drug itself. Results of child development tests have been found to be lower at 1 and 2 years of age by some researchers. However, a clear harmful effect of opioids themselves on child development is not strongly suggested by the literature.

Cocaine

Head circumference is inversely related to cocaine exposure during pregnancy. Along with the reported association with serious fetal/neonatal intracranial pathology, it is unsurprising that cocaine itself is thought to be directly damaging to neurodevelopment, with or without confounding social factors. Indeed, neurophysiological testing of such children suggests reduced numbers of oligodendrocytes and impaired myelination.

Closer examination of the data on neurodevelopmental outcome has challenged this view, and the two sides of the debate are difficult to reconcile. The meta-analysis performed by Frank and colleagues¹⁰ selected 36 prospective and blinded studies in which polydrug use was uncommon. After controlling for confounding factors, there was no significant overall association between prenatal cocaine exposure and cognition, language and motor skills, behaviour, attention, affect or neurophysiology, up to 6 years of age [C].

This controversy is likely to continue. For practical purposes, cocaine use in pregnancy should be considered a

marker of 'high risk'. Independent of any direct actions of the drug, pregnancy and neurodevelopmental outcomes are nevertheless poor and will improve only with better access to healthcare and social support.

SCREENING FOR SUBSTANCE ABUSE IN PREGNANCY

Pregnant women who use drugs may avoid antenatal care for fear of inciting closer scrutiny of their lifestyles, which may often include other criminal activities. They may fear that their child, or children, will be removed from them. Because of this, they may present needing help only at the time of a social, domestic or medical crisis. All those caring for pregnant women should be vigilant for substance abuse and take the opportunity to institute specialised antenatal care whenever presentation occurs. Enquiry about illicit substance use should be routinely made of all pregnant women in a matter-of-fact way. Be prepared to ask more than once. Covert urine testing may confirm substance abuse, but be careful when disclosing this information source, as it may be seen as underhand and untrustworthy and may damage the fragile relationship between the woman and the healthcare services.

Screening for heavy alcohol consumption can be quickly carried out in all pregnant women using the TACE questionnaire. Only four questions are asked:

Tolerance: how many drinks does it take to make you feel high? More than two suggests a degree of tolerance and scores 2 points.

Annoyance: has anyone annoyed you by criticising your drinking? Answering 'yes' scores 1 point.

Cutting down: have you ever thought you needed to cut down your drinking? Answering 'yes' scores 1 point.

Eye opener: have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover? Answering yes scores 1 point.

A score of 2 or more points is considered a positive screen and carries a 70 per cent sensitivity for detection of heavy drinkers. Further questioning and assessment are needed of those who screen positive.

MANAGEMENT OF PREGNANCY COMPLICATED BY SUBSTANCE ABUSE

A multidisciplinary team approach is necessary to create a confidential, reassuring and non-judgemental environment in which the pregnancy outcome and childbirth experience can be optimised. This team will include social workers, specialist drug services, drug-liaison midwives, GPs, obstetricians and paediatricians.

'Harm minimisation' recognises the futility of simply telling users to stop using. It aims initially to promote a change in the nature of the drug taking, stabilise lifestyles and reduce criminal behaviour. Stopping drug abuse altogether is a much longer-term aim. Exchanging needles or moving to non-IV modes of delivery would be examples of harm reduction. Reducing alcohol and tobacco consumption and establishing methadone maintenance are particularly important aims in pregnancy.

Antenatal care

Significant improvements in pregnancy outcome are achieved by regular antenatal care, which should be tailored to the individual. Points to consider include:

- carefully targeted history taking;
- counselling about the possible effects of the drug abuse on the pregnancy;
- possible urine testing for illicit substances;
- discussion and delineation of achievable aims to reduce harm;
- ultrasound scanning to accurately date the pregnancy;
- screening for hepatitis B and C, HIV and possibly bacterial vaginosis;
- detailed anomaly scanning;
- serial growth scanning and fetal assessments as necessary;
- reflection on the need for a child protection case conference;
- communication with anaesthetic and paediatric services: cocaine and opiate abusers may pose particular problems for obstetric anaesthetists, and admission to a special care baby unit (SCBU) is very likely, even if only for observation.

Focused history taking from the pregnant drug abuser

- Type of drug(s) used, when, how often, how much and mode of administration.
- Does her partner use drugs?
- Has the woman particular fears or concerns of her own?
- Are there specific psychological or health problems leading to, or a consequence of, the drug abuse?
- What are the social/financial circumstances?
- Is she in any legal trouble?
- Does she drink alcohol or smoke tobacco?
- Does she practise safe sex?
- Does she share needles?

Women using street narcotics should be offered **methadone maintenance treatment** (MMT). Methadone has a longer half-life than heroin and blood levels remain more stable. Users are provided with a regular but limited supply, which offers the opportunity to remove themselves from the criminal high-risk behaviours often necessary to fund a street

habit and which carry such risk to the pregnancy. Having to attend regularly to obtain prescriptions allows close antenatal surveillance and healthcare. The fetus avoids opiate 'highs' and withdrawals and other possible harmful contaminants of street drugs. Compliance with these regimens can reduce neonatal mortality and increase birthweight, although the benefits are lost if MMT is supplemented with street 'top-ups', which many abusers need for the 'highs' not provided by methadone. Negotiating the dose with the user is a difficult task. Low doses (60 mg/day) are associated with higher rates of non-compliance. Twice-daily dosing regimens may minimise the trough levels and reduce relapses.

Women established on MMT may consider gradual withdrawal (e.g. a reduction in dose of 2–2.5 mg every 7–10 days). Anecdotal evidence recommends that this should occur in the second trimester, as leaving it until later risks preterm labour [E]. The greater risk of withdrawal during pregnancy is a subsequent relapse of illegal narcotic use. This is considered to carry the greatest risk of fetal harm, and withdrawal during pregnancy should be attempted only in highly motivated women with a stable, supportive and drug-free environment to which they can return.

Unfortunately, there is no such 'replacement' regimen for cocaine users. Harm reduction must involve a reduction in cocaine use. Without an incentive, it may be very difficult to gain the trust and cooperation of pregnant users who fear reprisals for their substance abuse.

Pregnancy is a relative indication for inpatient alcohol detoxification. Most programmes choose to treat the pregnant, alcohol-dependent woman with short-acting barbiturates or benzodiazepines. Chlordiazepoxide and other benzodiazepines, such as diazepam and barbiturates, are valuable for symptomatic treatment during medical withdrawal from alcohol. They are also potentially teratogenic. Some clinicians, therefore, recommend avoiding their use if at all possible. The risks versus the possible benefits of their use need to be assessed.

Disulfiram (Antabuse) is contraindicated during pregnancy. Its use has been associated with club foot, VACTERL association (the non-random co-occurrence of birth defects vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula and/or oesophageal atresia, renal and radial anomalies and limb defects) and phocomelia of the lower extremities. The woman who conceives while taking this drug should receive counselling before deciding to continue the pregnancy.

EBM

Using methadone during pregnancy (as opposed to no opiates at all) is associated with an approximate doubling of neonatal mortality. Use of both methadone and heroin carries a six-fold increase in neonatal mortality risk.

Intrapartum care

Labour may be the first time a pregnant substance abuser presents to medical services. It should be managed as normal, with a few additional points to bear in mind.

- Recommend continuous CTG monitoring in view of the increased risk of placental insufficiency and fetal compromise.
- Be aware that opiates may influence the CTG and interpretation may be more difficult.
- Avoid, as far as possible, fetal blood sampling, scalp electrodes and episiotomies to reduce the vertical transmission risk of hepatitis and HIV.
- Elective caesarean section before membrane rupture reduces HIV vertical transmission and possibly that of hepatitis C¹⁰ (although this needs confirmation).
- Give normal maintenance doses of methadone to prevent withdrawal. These will not provide analgesia, which should be offered in addition. Epidural analgesia may prove most effective if opioid receptors are already saturated by the illegal opiate.
- Those women who have undergone supervised withdrawal from opiates during the pregnancy should avoid systemic opiates in labour. Nitrous oxide and epidural analgesia are preferable.
- Naloxone should not be given to opiate-dependent mothers or their offspring – severe withdrawal effects may occur.
- In cocaine users, ephedrine may be less effective at reversing hypotension secondary to regional analgesia. Phenylephrine is a useful alternative.

Postnatal care

Above all, the new mother should be supported in her first few days, as any new parent should be. Indeed, she is likely to have minimal help when she leaves hospital. Ongoing assistance from the specialist midwife is vital.

- If the baby seems well it should be transferred to the postnatal ward with the mother. NAS usually presents in the first 2 days and the baby must be closely observed for signs of this. Methadone withdrawal may take a little longer, but will usually have begun by 4 days (the minimum time period that women are advised to stay in hospital). If the infant is demonstrating withdrawal symptoms, it will need special care facilities.
- Breastfeeding is encouraged in most women, even those on methadone. Infant weaning should occur gradually; fortunately the quantities of opiates reaching breast milk are small. HIV-positive women, those using large amounts of benzodiazepines and cocaine users are exceptions to this general rule. These women should be advised to bottlefeed. Hepatitis C is not a contraindication to breastfeeding.¹¹

- Babies born to hepatitis-B-positive mothers should be immunised.
- Drug misuse by a parent does not necessarily equate with child neglect or abuse, and automatic child abuse registration will only discourage women from seeking antenatal care. Social services should be informed of the delivery and decisions made about the levels of support needed to ensure child safety.
- Appropriate contraceptive advice must be provided before discharge.

KEY POINTS

- There is an increasing body of evidence suggesting harm to the fetus from heavy alcohol consumption in pregnancy.
- Binge drinking in early pregnancy may be particularly harmful.
- There is considerable doubt as to whether infrequent low-level alcohol consumption conveys any long-term harm.
- Alcohol is the only clear teratogen, although benzodiazepines may predispose to oral clefting.
- Moreover, the effects of alcohol and other drugs on short-term and long-term child development are still in question. Potent cellular actions and devastating complications such as intracerebral haemorrhage are well recognised, but have a less striking impact on the results of larger population studies.
- Regardless of the direct harm caused by drug or alcohol abuse during pregnancy, such behaviour is a powerful marker of poor obstetric outcome and should prompt close antenatal surveillance by specialised healthcare workers.
- The aim of antenatal care should be to minimise harm by setting realistic goals.
- All units should have a dedicated team with defined guidelines to optimise outcomes for mother and baby.

Chapter 20 Smoking

Andrew Shennan

MRCOG Standards

Theoretical knowledge

Describe and quantify the clinical effects of smoking in pregnancy.

Understand the concepts related to smoking prevention strategies in pregnancy.

Practical

Advise women regarding smoking in pregnancy.

INTRODUCTION

Smoking-related morbidity and mortality affect millions of individuals throughout the world. Each year, almost a quarter of all deaths in men can be attributed to a smoking-related cause and, although far fewer female deaths are related to smoking, the gap is rapidly closing. More women are becoming smokers in industrialised countries. The cause of this morbidity and mortality is largely related to the effects on cardiovascular disease although smoking is also a cause of cancer, particularly of the lung.

In the western world, almost a quarter of young women smoke and this affects their risks of developing gynaecological cancers such as cancer of the cervix. In recent years there is some evidence that this may be declining, particularly in countries where smoking has been banned in public places. Other risks, such as that of thromboembolic disease, are increased. Effects on the menopause and miscarriage, as well as low birthweight, have been reported. However, in spite of educational programmes to point out these obvious detrimental effects to fetal wellbeing, it has proved very difficult to introduce preventative strategies. Smoking remains a major preventable cause of low birthweight, preterm delivery and perinatal mortality; this section will review the relationship between smoking and pregnancy outcome, and management strategies to reduce adverse events.

INCIDENCE IN PREGNANCY

In the developed world approximately 20–30 per cent of pregnant women will report smoking; the figure of 27 per cent in the UK has been stable for some years although legislation banning smoking may now be influencing this and analysis of the impact is eagerly awaited. As with the non-pregnant population, there is a strong association with socio-economic background so that those from lower groups have considerably higher smoking rates. Generally actual smoking rates are about 3 per cent higher than reported rates, as evidenced by cotinine levels.¹

It has been reported that women who continue to smoke in spite of knowledge of the detrimental effects are more likely to have problems at work and, in general, are less well supported on a psychosocial basis. Women without partners, and who already have children, are less likely to stop.

AETIOLOGY AND CLINICAL EFFECTS

Prematurity

There is good epidemiological evidence that smoking is related to the risk of premature delivery, including early preterm birth. There is also an established relationship with perinatal death [C]. The association is strong and often dose related which, therefore, adds considerable evidence that the effect is causative and not related to other associated factors [C].

Women who smoke have approximately double the risk of premature delivery. This is principally due to spontaneous preterm delivery but it can also increase the risk of the need for iatrogenic delivery through association with placental abruption and placenta praevia [C]. Smoking is also a risk factor for preterm premature rupture of the fetal membranes.²

Lower mean birthweight has been associated with a high mean systolic blood pressure in later life in the children of mothers who smoke. Smoking may therefore be contributing

to the possible *in utero* programming effects with which reduce fetal growth potential is now thought to be associated.

Intrauterine growth restriction

It is established that low birthweight for gestation is more common in women who smoke.³ On average, babies will be approximately 200 g lighter as a result of smoking. There is a dose relationship to this effect and it is established that women who smoke more than ten a day will have lower birthweight than those who smoke less than this number, the effects being greater in male fetuses [C]. Even passive smoking can reduce birthweight.⁴

IQ

Cognitive performance is reduced in the children of mothers who smoke during pregnancy, even after adjustment for other confounding variables.⁵ Longer-term effects on the children may include influence on respiratory illness, over and above that which may be caused by the children living in a family where smoking continues [C].

Smoking and pre-eclampsia

There are many studies now that demonstrate an association between a reduced risk of pre-eclampsia and smoking [C].⁶ However, it is clear that any possible benefit in this reduction is completely superseded by the harmful effects of smoking [D]. Indeed, women who smoke and show the clinical signs of pre-eclampsia have much more severe disease. In these women there are increased rates of perinatal mortality, abruption and IUGR.

Infertility, ectopics and miscarriage

There is now evidence that both ovarian function and implantation may be affected by smoking, thus reducing the fertility of these women. There is also an increased incidence of ectopic pregnancy that is apparent from recent meta-analyses. The risk of miscarriage is also increased.

MANAGEMENT: SMOKING CESSATION IN PREGNANCY

A minority of women will stop smoking when they become pregnant. These individuals frequently smoke less and have better support from home, including a partner who gives up or is a non-smoker. Programmes that encourage smoking cessation have been associated with some improved outcome, in terms of less low birthweight and premature delivery [C]. However, these programmes are highly intensive before they are successful and standard advice from

midwives and other clinicians to stop smoking has had little impact on overall quitting rates during pregnancy [C]. Approximately 7 per cent of pregnant women who undergo focused counselling will give up smoking. However, a small number of individuals do stop on brief advice and, as this is inexpensive, it is worthwhile [E].

Specialist staff are known to be more effective than others, with more than a doubling of cessation rates [B].⁷ Unfortunately few women are willing to, or have the opportunity to, use these counselling services. Self-help material has some benefit in approximately 4 per cent of smokers. The effectiveness and safety of nicotine replacement have enabled improved cessation rates, and at 2 years there may be less unimpaired development of the baby.⁸

There is good evidence that stopping smoking will reduce the adverse effects of smoking in pregnancy, and result in an improvement in birthweight and early birth [B].⁹ In 72 trials, in spite of a modest reduction in the number of women who quit (6 per cent), there was a 10–15 per cent reduction in important obstetrics outcomes such as birthweight and preterm birth.¹⁰ Of note, those countries that have evaluated smoking bans following legislation have noted benefit in the post-ban period. For example, in Ireland there was a reduction in SGA.¹¹

KEY POINTS

- A quarter of pregnant women in the developed world smoke in pregnancy.
- Smoking in pregnancy is associated with prematurity, low birthweight and perinatal death, and is the single most preventable cause of these adverse events.
- In childhood, smoking in pregnancy is known to increase the risk of sudden infant death syndrome (SIDS).
- Most adverse events are dose related and reversed if pregnant women stop smoking.
- The children of mothers who smoke have lower IQs.

EBM

Specialist staff trained in counselling women about smoking are more likely to succeed in cessation programmes.

Chapter 21 Anaemia

Will Lester

MRCOG standards

Relevant standard

Candidates are expected to understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of anaemia.

In addition, we would suggest the following.

Theoretical skills

- Revise the physiological changes of the blood in pregnancy.

Practical skills

- Interpret laboratory test results to determine cause and management of different types of anaemia in pregnancy

- Serum iron and ferritin concentrations decrease secondary to increased utilisation and haemodilution
- Total iron-binding capacity increases.
- Iron requirements increase (due to expanding red cell mass and fetal requirements) from 2.5 mg/day in the first trimester to 6.6 mg/day in the third trimester (700–1400 mg total pregnancy).
- There is a moderate increase in iron absorption.
- Folate requirements increase in pregnancy (due to the fetus, placenta, uterus and expanded maternal red cell mass).
- There is no major effect on vitamin B₁₂ stores, although cobalamin levels decrease (hormonal effects and active transport to the fetus).

INTRODUCTION

Anaemia is the most common medical disorder of pregnancy.

Pre-existing bone marrow disorders and inherited haemoglobin (Hb) variants are discussed in Chapter 12. This chapter aims to revise the physiological changes in pregnancy, and discusses the maternal and fetal risks of anaemia, diagnosis and management.

PHYSIOLOGICAL CHANGES

- Plasma volume increases by 50 per cent.
- Red cell mass increases by up to 25 per cent.
- There is a consequent fall in Hb concentration, haematocrit and red cell count because of haemodilution.
- Mean cell volume (MCV) increases secondary to erythropoiesis.
- Mean cell Hb concentration (MCHC) remains stable.

DEFINITION

Anaemia is a pathological condition in which the oxygen-carrying capacity of red blood cells is insufficient to meet the body's needs.

Often the diagnosis is based on blood values, in particular Hb concentration. WHO recommends that the Hb concentration should not fall below 11 g/dL at any time during pregnancy,^{1,2} but many clinicians use the figure of 10.5 g/dL as a cut-off after the first trimester, as recommended by the Centers for Disease Control and Prevention of the USA.^{3,4} WHO defines postpartum anaemia as Hb <100 g/L.

INCIDENCE

Around 30–50 per cent of women become anaemic during pregnancy, with iron deficiency being responsible in more than 90 per cent of cases. The incidence of folate deficiency is around 5 per cent (though it is often underdiagnosed) and this is almost always the cause of megaloblastic anaemia in pregnancy, with vitamin B₁₂ deficiency being rare.

CLINICAL FEATURES

Anaemia is very often asymptomatic in pregnancy, with the diagnosis being made on routine screening. Clinical features include tiredness, dizziness, palpitation and lethargy. Pallor may be apparent.

SCREENING

Anaemia is routinely screened for in pregnancy by estimating the Hb concentration by means of an FBC at pregnancy booking and again later in pregnancy, usually at 28 weeks. This lacks specificity but has the advantage of being cheap and simple to perform. The presence of a low Hb does not reveal the cause of the anaemia and a normal Hb does not exclude iron depletion.

IRON DEFICIENCY ANAEMIA

Aetiology

Iron deficiency is the most common cause of anaemia in pregnancy. There are significant iron demands during pregnancy, secondary to expanding red cell mass and fetal requirements, which can be met by only a limited increase in iron absorption, and by utilisation of iron stores. If iron stores are already depleted because of menstruation, recurrent pregnancies and poor intake, anaemia will develop rapidly. During pregnancy, the total iron-binding capacity (TIBC) increases secondary to the increased plasma volume, and serum iron falls. As iron demands exceed supply during pregnancy, ferritin levels fall. Decreased Hb concentration is a late event in iron deficiency.

Consequences

The evidence regarding the consequences of iron deficiency anaemia in pregnancy is conflicting. From the maternal perspective, as well as the clinical features described above, it has been suggested that impaired function of iron-dependent enzymes causes alterations in muscle function, neurotransmitter activity and epithelial changes throughout the body.⁵ This has been used as the basis for the explanation for the apparent link between iron deficiency anaemia and preterm delivery, infection, medical intervention during labour and postpartum blood loss. It is clear that women with significant anaemia at the time of delivery will not tolerate blood loss as well, and are more likely to receive blood transfusion postnatally. From the fetal perspective, it is widely accepted that there is an increased risk of preterm delivery and IUGR; however, many of the studies have not controlled for other factors, such as smoking, that may be important.⁶ There is also conflicting evidence regarding the neonatal iron status and cognitive development and behaviour of babies born to iron-deficient mothers.⁷

Diagnosis

Iron deficiency can be present in the absence of anaemia, and other parameters of the FBC that usually give a clue to this (reduced MCV, MCH and MCHC) are not as accurate during pregnancy (Table 21.1). As the MCV increases in pregnancy, an MCV well into the 'normal' range does not exclude iron deficiency as an underlying cause; however, a significantly elevated MCV (>106) should also trigger consideration of folate or vitamin B₁₂ deficiency. It is also important that a microcytic anaemia is not automatically assumed to be caused by iron deficiency, as this may also be seen with beta-thalassaemia trait.

The diagnostic test for iron deficiency is a serum ferritin concentration. A concentration of <16 µg/L is highly sensitive for iron deficiency in terms of predicting absence of stainable iron in the bone marrow.⁸ Unselected screening of ferritin is expensive, however, and is not generally recommended.

Treatment

Efficacy of treatment

Although it is clear that iron supplementation improves the haematological indices, there is little robust evidence to prove, especially in cases of mild anaemia in pregnancy with no complications, that such therapy improves clinical outcomes for these mothers or their babies; however, it is standard practice to offer iron supplements unless there is a contraindication.

It is not essential to delay oral iron therapy for anaemic women pending a ferritin result (unless there is an alternative explanation, e.g. beta-thalassaemia trait) and one strategy is a trial of treatment as a first-line diagnostic test, whereby an Hb increment demonstrated at 2 weeks is a positive result.⁹

The standard first-line treatment for iron deficiency is oral iron replacement [B], which is usually effective if there is enough time (maximum increase in Hb is 0.8 g/dL per week). The recommended dose is 100–200 mg of elemental iron per day. Ferrous salts are absorbed better than ferric salts [B] and should be used in preference. There is little to choose between the different ferrous salts in terms of absorption and

Table 21.1 Haematological values¹

	Non-pregnant	Pregnant	Iron deficiency
Hb (g/dL)	12–15	11–15	<10.5
MCV (fL)	75–99	Increases	Decreases
TIBC (mmol/L)	45–72	Increases	Decreases by <15%
Serum iron (mmol/L)	13–27	Decreases	<12
Ferritin (mg/L)	15–300	Decreases	<12

- Hb, haemoglobin; MCV, mean cell volume; TIBC, total iron-binding capacity;

efficacy, and side effects are related to the amount of elemental iron contained. The choice of preparation should therefore be dictated by cost and patient tolerance, but it should be noted that a reduction in side effects is usually secondary to a reduction in the amount of elemental iron absorbed. Vitamin C taken simultaneously aids absorption [B], hence the common advice to take iron with fresh orange juice. There is, however, little to gain, other than increased cost, by using combination preparations with ascorbic acid included.

There is a 40 per cent risk of side effects with oral iron preparations, mainly gastrointestinal, and this can have a direct effect on tolerance and compliance. Slow-release preparations are often associated with a decrease in the incidence of side effects, but this is mainly secondary to decreased absorption of elemental iron, as most is not released from the preparation until it has passed through the first part of the duodenum, where iron absorption is optimal. For those with proven iron deficiency that cannot be managed with oral therapy because of lack of compliance, severe gastrointestinal side effects, continuing significant blood loss or malabsorption, parenteral preparations exist. It has been demonstrated that IV iron is most effective in improving the haematological indices, followed by intramuscular administration, with oral supplementation being least effective.¹⁰

However, this must be balanced against the invasiveness of administration and the possible adverse effects, which are mild with oral supplementation and most severe with the IV route, including anaphylaxis. It is important that a diagnosis of iron deficiency anaemia is confirmed prior to parenteral treatment.

Intramuscular iron

Some parenteral iron preparations can be administered by deep intramuscular injection. It can be associated with pain at the time of injection and staining of the skin. The dose is calculated depending on the degree of anaemia and patient weight, but requires repeated injections, usually over the course of several weeks.

Intravenous iron

There are various IV iron preparations that are now available with significantly fewer side effects compared with historical iron dextran solutions. Parenteral iron can reduce the need for blood transfusion when oral therapy has failed as long as there are no contraindications. Parenteral iron should be avoided in the first trimester of pregnancy. Some preparations allow administration of a total body dose in a single infusion.

Blood transfusion

Towards the end of pregnancy there may not be the time available to increase the Hb with iron therapy, and blood transfusion may be indicated as well as iron therapy.

It should be borne in mind that blood transfusion is not without risk,¹¹ and effective screening programmes should detect anaemia early enough to allow iron therapy to be utilised. However, transfusion is the most rapid way

to increase Hb concentration, but is a relatively slow way to increase iron stores.

Erythropoiesis stimulating agents

Recombinant human erythropoietin analogues are mainly used for the anaemia associated with erythropoietin deficiency in chronic renal failure, but can also be used to increase the autologous production of blood in normal individuals.

It has been used in cases of severe postpartum anaemia with success, and has been life saving in cases where blood transfusion is declined, for example Jehovah's witnesses. It has also been used during pregnancy in a small number of renal patients with no adverse maternal or perinatal complications.¹² Parenteral iron is usually given in addition to erythropoietin-stimulating agents to ensure effectiveness.

Prevention/prophylaxis

Prevention of iron deficiency is usually possible with a good balanced diet in the absence of ongoing blood loss. Identification and treatment of iron deficiency prior to pregnancy is optimal; however, many women enter pregnancy already iron deficient, or become so during pregnancy. Health education by the midwife regarding diet is therefore important.¹³

Guidelines produced by the British Committee for Standards in Haematology (BSCH)⁹ recommend that ferritin should be checked in pregnancy in non-anaemic women at increased risk of iron depletion (eg. previous anaemia, multiple pregnancy, consecutive pregnancies with less than a year's interval and vegetarians), and also pregnant teenagers, women at high risk of bleeding and Jehovah's witnesses. If the ferritin is <30 µg/L, a dose of at least 65 mg elemental iron can be offered and the FBC and ferritin checked 8 weeks later.

These guidelines also recommend that women with a known haemoglobinopathy (eg. beta-thalassaemia trait, HbSS) should have serum ferritin checked and offered therapeutic iron if the ferritin is <30 µg/L.

There has been much work carried out on the role of routine iron supplementation in pregnancy, and this has been the subject of a Cochrane Review.¹⁴ This meta-analysis of 40 trials including 12,706 women concluded that, although there is clear evidence of improvement in haematological indices in those women who receive iron supplements during pregnancy, there are not enough data to determine that routine supplementation with iron alone or in combination with folic acid has any substantial benefits or adverse effects on maternal

EBM

- Oral iron therapy with ferrous salts is the treatment of choice for iron deficiency anaemia in pregnancy [B].
- Vitamin C aids absorption but there is no evidence to support the use of combined preparations [B].
- There is insufficient evidence to recommend a policy of routine iron supplementation in pregnancy [A].

and fetal health and pregnancy outcomes (premature delivery and low birthweight) among populations in whom anaemia is common. The reviewers felt that there was not enough evidence to suggest a change in current recommended iron and folic acid doses with either modality of supplementation [A].

FOLATE DEFICIENCY

Aetiology

There is a significant increase in folate requirements during pregnancy because of the increased cell replication that takes place in the fetus, uterus and bone marrow (increase in red cell mass). Plasma folate concentrations decrease throughout pregnancy, reaching half the non-pregnant levels by term. The incidence of folate deficiency is higher in multiple pregnancies. Folate deficiency causes a megaloblastic anaemia, accounting for approximately 5 per cent of anaemia in pregnancy, although higher rates are found in other parts of the world and are thought to be secondary to poor diet. In the UK, many foods now have folate supplements added, making the recommended daily intake of 800 µg easier to achieve.

Consequences

There are clear links between periconceptual folate deficiency and neural tube defects,¹⁵ as well as a suggested association with other anomalies,¹⁶ hence the advice that all women planning a pregnancy should take 400 µg/day of folic acid and continue this for the first 12 weeks of pregnancy until the neural tube is closed [A]. From the maternal perspective, the consequences of folate deficiency are not just anaemia, but involvement of tissues with high rates of cell turnover, in particular mucous membranes; the effects of folate deficiency can thus be exacerbated by malabsorption if the gut mucosa is affected.

Diagnosis

During pregnancy a mild macrocytosis is often seen in the absence of folate or vitamin B₁₂ deficiency and, conversely, a macrocytosis may be masked by coexisting iron deficiency leading to a reduced MCV. Red cell indices are therefore not necessarily helpful for diagnosis, although a significant macrocytosis should raise suspicion of possible folate or vitamin B₁₂ deficiency. Examining the blood film may also be useful. Clinical suspicion is important and particular attention should be given to a dietary history which is typically low in fruit and vegetables.

Treatment

Severe folate deficiency is extremely rare, but, once megaloblastic haematopoiesis is established, treatment is impaired due to poor folate absorption from the affected gastrointestinal tract. In this situation, at least 5 mg oral folic acid daily is required.

Prevention/prophylaxis

The case for routine prophylaxis with 400 µg/day for the prevention of neural tube defects has already been discussed above. However, there are other situations in which folate prophylaxis is indicated. These include women taking anti-convulsant drugs [E] and those with haemolytic anaemias (see Chapter 27). In these situations, the recommended prophylactic dose is 5 mg/day throughout pregnancy.

VITAMIN B₁₂ DEFICIENCY

Vitamin B₁₂ deficiency is rare during the reproductive years, and can be associated with infertility; therefore, vitamin B₁₂ deficiency during pregnancy is uncommon. Absorption is unchanged by pregnancy, and vitamin B₁₂ is actively transported across the placenta to the fetus. Serum cobalamin levels drop significantly during pregnancy despite normal tissue levels and so a standard vitamin B₁₂ laboratory assay is of low diagnostic utility. The clinical history is therefore important (e.g. history of gastrectomy, Crohn's disease, vegan diet or a diet that suggests folate deficiency as the cause). There is some evidence that the holotranscobalamin assay is more specific in predicting genuine vitamin B₁₂ deficiency but this assay is not currently widely available and requires further studies to evaluate its clinical utility as part of routine laboratory testing.¹⁷

Management

In cases of known vitamin B₁₂ deficiency, treatment should be optimised prior to conception (and may be necessary to allow conception). Women on vitamin B₁₂ replacement therapy should continue this as normal. Virtually all diets that contain animal products will supply enough vitamin B₁₂ during pregnancy, although strict vegans may become deficient without supplements.

KEY POINTS

- Anaemia is the most common medical disorder of pregnancy, with iron deficiency being the most common underlying cause.
- Screening for anaemia in pregnancy is recommended in conjunction with dietary advice.
 - * Be aware of how pregnancy can affect normal laboratory parameters, e.g. increasing MCV and reduced vitamin B₁₂ levels.
- There is insufficient evidence to support routine iron prophylaxis in the absence of other risk factors.
- The role of periconceptual folate supplementation should be emphasised at pre-conceptual counselling.

Chapter 22 Abdominal pain

Clare L Tower

MRCOG standards

There is no specific established standard for this topic, but we would suggest the following points for guidance. Several of the many causes of abdominal pain can be found in core module 9, Maternal Medicine. A detailed discussion of every cause of abdominal pain in pregnancy is both impractical and cumbersome, and many of the disorders are discussed elsewhere in detail. Thus, this chapter aims to give an overview of the approach to abdominal pain in pregnancy, with a focus on differential diagnoses, and aspects of the approach that are specific to pregnant women.

INTRODUCTION

Abdominal pain is an extremely common complaint in pregnant women, with a majority of women experiencing it at some point during pregnancy. The vast majority is benign and self limiting. However, an approach to abdominal pain in pregnancy must enable identification of serious pathology to allow successful treatment to be implemented. There are many pitfalls in the assessment of pregnant women with abdominal pain and sadly several are found in the triennial maternal mortality report.¹ In particular, diagnosis of the 'acute abdomen', often defined as a collection of symptoms and signs of intraperitoneal disease best treated with surgery,² is notoriously difficult. The commonest surgical causes of the acute abdomen in pregnancy are appendicitis and cholecystitis.³

HISTORY AND EXAMINATION

In the same way as outside pregnancy, a systematic approach to the history and examination of the abdominal pain is required. A detailed outline of this can be found in many undergraduate textbooks. The gravid uterus and the physiological changes in pregnancy can mask some of the typical findings seen

outside pregnancy. For example, the location of the appendix becomes displaced upwards as gestation increases. Therefore, whereas the appendix may lie at McBurney's point in the first trimester, by the late third trimester it may become located in the right hypochondrium, or be located behind the pregnant uterus. The enlarging uterus also separates the intra-abdominal organs from the parietal peritoneum with increasing gestation. Therefore, signs of peritonism may be masked as the inflamed abdominal organ no longer irritates the parietal peritoneum. Furthermore, many associated symptoms and signs can also be those common in a normal pregnancy, for example nausea and vomiting. A thorough but focused history and examination will usually suggest a short list of likely differential diagnoses (Table 22.1), thus guiding further investigation. Causes can be considered as either obstetric or non-obstetric, then within a systems review, e.g. gastrointestinal, renal and other. Involvement of other specialists, such as gastroenterologists, urologists or surgeons, may be indicated.

INVESTIGATIONS AND IMAGING

The list of possible differential diagnoses will guide suitable and targeted investigations (Table 22.1). Knowledge of how biochemical and haematological markers differ from the non-pregnant state is imperative in order to understand the significance of the results. White cell counts are typically increased during pregnancy, as is alkaline phosphatase due to placental production. Biochemical markers such as urea and creatinine fall. A summary of the variations seen in the commoner investigations performed during pregnancy is given in Table 22.2.

There has been much debate about the suitability of varying imaging modalities during pregnancy, largely due to concerns about the effect on the fetus. Ultrasound is considered safe and widely used, and can be useful in the diagnosis of, for example, appendicitis and renal tract obstruction. It is widely available, cheap and does not require the use of contrast medium or ionising radiation. However, the accuracy can be operator dependent and it may produce inconclusive results. Diagnosis of renal tract obstruction is a common example of how pregnancy causes difficulties in interpretation of

Table 22.1 Differential diagnoses, key findings and investigations

Disorder	Key clinical features	Specific investigations	Management
Obstetric – early pregnancy			
Miscarriage	Pain and bleeding	USS, hCG and progesterone levels	Expectant, medical or surgical
Ectopic pregnancy	Pain followed by a small amount of bleeding, peritonism, shoulder tip and rectal pain; may present with diarrhoea	USS, hCG and progesterone levels	Expectant, medical or surgical
Ruptured corpus luteal cyst	Signs of peritonism	USS	Analgesia ± laparoscopy
Adnexal torsion	Twisting pain, peritonism Commoner in first trimester and postpartum	USS	Analgesia ± laparoscopy
Obstetric – late pregnancy			
Round ligament pain	Bilateral, stitch like	None	Analgesia and reassurance
Braxton Hicks	Painful/painless tightenings not causing cervical dilatation	Vaginal examination to exclude labour	Reassurance
Labour	Painful contractions	Vaginal examination, CTG, etc.	Consider tocolysis and steroids if preterm
Placental abruption	Constant pain, rigid uterus, sometimes frequent and short-lasting contractions ± bleeding	Fetal assessment, bloods	Resuscitation, delivery
Pre-eclampsia	Epigastric, right upper quadrant	All pre-eclampsia investigations	Treat blood pressure, consider delivery
Polyhydramnios	Tight, distended abdomen, difficult to feel fetal parts	USS, exclude diabetes, infection (TORCH)	Detailed fetal scan, consider amnio-drainage
Adnexal torsion	Twisting pain, peritonism	USS	Analgesia ± laparoscopy
Fibroid degeneration	Constant localised pain, over the fibroid	USS to confirm fibroids; degenerative cystic changes may be present	Analgesia
Uterine rupture	Sudden-onset constant pain, haemodynamic collapse, vaginal bleed, haematuria	All bloods, cross-match, CTG	Resuscitate and surgery
Acute fatty liver	Epigastric/right upper quadrant pain, often associated with malaise, nausea and vomiting; may be jaundiced and have ascites	All pre-eclampsia investigations – may have hyperuricaemia, hypoglycaemia, deranged LFTs. USS/CT or MRI of liver	Stabilise and deliver
Urinary retention (retroverted uterus)	Unable to pass urine, palpable and uncomfortable bladder	Catheter; USS will help exclude other causes	Conservative management; usually resolves after 12 weeks
Physiological obstruction of ureters	Renal angle tenderness	USS to assess renal pelviectasis (2 cm normal)	Usually conservative; if significant, may require nephrostomy
Chorioamnionitis	Tender uterus, offensive discharge, systemic signs of sepsis, usually preceded by ruptured membranes	Blood cultures, inflammatory markers, speculum, CTG	Intravenous antibiotics, resuscitate and deliver

(continued)

Table 22.1 Differential diagnoses, key findings and investigations (*continued*)

Disorder	Key clinical features	Specific investigations	Management
Symphysis pubis dysfunction	Suprapubic tenderness, over bone; worse on movement and standing on one leg	Full physiotherapy assessment	Physiotherapy, analgesia
Rectus abdominis rupture	Sudden-onset pain, usually precipitated by cough or vomit; rare and usually in multiparous women; may have associated haematoma	Exclude other causes of abdominal pain	Analgesia; expanding haematoma may require surgical exploration
Non-obstetric			
Renal tract causes Urinary tract infection	Dysuria, frequency of micturition	Urine dipstick, urine for culture	Increase oral intake of fluid, antibiotics
Pyelonephritis	Loin pain (renal angle tenderness), radiating round to abdomen and into groin, rigors	Blood cultures, urine dipstick and culture, renal USS	Antipyretics, IV antibiotics, IV fluids
Renal calculi	Loin pain (renal angle tenderness), radiating round to abdomen and into groin, often colicky in nature	Urine dipstick (microscopic haematuria), urine for culture, renal USS	Conservative management with fluids and analgesia; involve urologists
Gastrointestinal tract causes Constipation	Constant or colicky abdominal pain; infrequent, hard stools		Dietary advice, stool softeners
Gastritis/peptic ulcer disease	Epigastric pain, often constant or burning; duodenal ulcers relieved by food, gastric ulcers made worse by food; may be associated with nausea, vomiting, haematemesis	Gastroscopy if severe; involve gastroenterologists	Antacids and ulcer-healing drugs – H ₂ -receptor antagonists/proton-pump inhibitors
Appendicitis	Pain, not always localised to right iliac fossa, especially in third trimester; signs of peritonism; associated anorexia, nausea, vomiting and pyrexia	Inflammatory markers (white blood cell count, C-reactive protein); USS of abdomen; pyuria may be present	Involve general surgeons, surgical management
Bowel obstruction	Colicky abdominal pain, associated with vomiting and nil passed per rectum; high-pitched or absent bowel sounds; usually have risk factors; perforation will cause signs of peritonism	Abdominal X-ray; involve general surgeons; colonoscopy	Conservative management – IV fluids, nasogastric tube; may require surgery
Cholecystitis/ cholelithiasis	Epigastric or right upper quadrant pain (colicky or stabbing); may radiate through to back and be associated with nausea and vomiting; intolerance of fatty food; tenderness and guarding	USS of gallbladder/liver, LFTs	Conservative management – analgesia, fluids, antibiotics if infected; surgery may be indicated (see text)
Pancreatitis	Epigastric pain, radiates through to back; associated with nausea and vomiting	USS of upper abdomen, CT scan, LFTs, amylase and lipase three times normal, calcium low, high blood glucose	Involve surgeons, conservative management; use of prognostic scoring systems
Gastroenteritis	Generalised, usually crampy abdominal pains, associated with diarrhoea and vomiting	Stool sample	Fluids; manage at home if possible
Hepatitis	Right upper quadrant/epigastric pain; may be associated with jaundice	USS of liver, LFTs, hepatitis screen	Involve hepatologist, depends on underlying cause
Strangulated hernia	Peritonism, may be associated with bowel obstruction	Involve surgeons	Involve surgeons, treat bowel obstruction

(continued)

Table 22.1 Differential diagnoses, key findings and investigations (*continued*)

Disorder	Key clinical features	Specific investigations	Management
Inflammatory bowel disease	Generalised pain, associated diarrhoea, mucus and rectal bleeding, vomiting, weight loss	Inflammatory markers, sigmoidoscopy, colonoscopy	Involve gastroenterologists, steroids, mesalamine, other immune modulators such as azathioprine
Other Abdominal bleeding	Very rare; ruptured liver capsule, splenic artery aneurysms, aortic aneurysms, cause haemorrhagic shock and abdominal pain	FBC, cross-match, assess fetal wellbeing with CTG	Resuscitate, surgical management
Pelvic vein thrombosis	Often thrombosis of right/left iliac vein, causing groin tenderness, leg swelling, sometimes pyrexia	Doppler ultrasound, venogram, thrombophilia screen	Anticoagulation using LMWH, involve haematologists; may require filter in inferior vena cava
Systemic causes, e.g. DKA, increased calcium, sickle cell crisis	Generalised abdominal pain, associated with being systemically unwell	Urea, electrolytes, blood glucose, bone profile	Treatment dependent on cause; involve the general physicians
Trauma – remember domestic violence	Associated with bruising; domestic violence commonly results in abdominal trauma during pregnancy	Assessment of fetal wellbeing, Kleihauer's test, particularly if rhesus negative; check for other injuries	Ensure safety, specialist midwifery service, social input
Pneumonia	Right lower-lobe pneumonia may cause right upper quadrant pain; associated with respiratory symptoms	Chest X-ray, blood gases, inflammatory markers, sputum cultures	Antibiotics, may require oxygen and high-dependency support if severe

TORCH, toxoplasmosis, rubella, cytomegalovirus, herpes simplex and HIV; USS, ultrasound scan.

Table 22.2 Biochemical and haematological variations in pregnancy

Investigation	Non-pregnant	Pregnant	Notes
Haemoglobin (g/dL)	12–15	11–14	Haemoglobin falls, to lowest at around 32 weeks
White cell count ($\times 10^9/L$)	4–11	6–16	White cells increase; further increases in response to steroids when given for lung maturity, and in labour
Platelets ($\times 10^9/L$)	150–400	Can fall by around 10% in pregnancy	
C-reactive protein (g/L)	Does not vary in pregnancy		
Urea (mmol/L)	2.7–7.5	<4.5	Falls with increasing gestation
Creatinine ($\mu\text{mol/L}$)	65–100	<75	
Amylase	Generally unchanged in pregnancy		
Uric acid (urate) (mmol/L)	0.18–0.35	Generally considered as 0.1 x no. of weeks' gestation, e.g. 0.35 at 35 weeks	
AST/ALT (IU/L)	<40	Both usually lower in pregnancy, with 30 as upper limit of normal	
Alkaline phosphatase (IU/L)	30–130	Increases with gestation, up to around 400	

scan findings. Physiological dilatation of the renal collecting system occurs in pregnancy due to a combination of compression and smooth muscle relaxation secondary to progesterone. A physiological dilatation of up to 2 cm is considered 'acceptable', and is often greater on the right. In physiological dilatation, the ureter will taper to a normal calibre as it crosses the pelvic brim, but, in pathological dilatation, this is lost. Also, ureteric 'jets of urine' entering the bladder can be seen in physiological dilatation, a phenomenon that is also lost in pathological dilatation.⁴

If ultrasound produces inconclusive findings, further imaging may be needed. Investigations involving ionising radiation have often been avoided during pregnancy due to concerns about the radiation effect on the fetus in terms of teratogenesis, pregnancy loss and future malignancy. However, the overall risks are very small. Fetal risks, thought to be maximal with exposure between 8 and 15 weeks, are not increased by exposures <5 rad. Risks of subsequent carcinogenesis are also small. It is estimated that a 1 to 2-rad exposure may increase the risk of leukemia from 1:3000 to 1:2000.⁵ Table 22.3 gives

Table 22.3 Radiation doses⁵

Procedure	Fetal exposure mrad	Fetal exposure in dose equivalents
Chest X-ray (two views)	0.02–0.07 mrad	0.008 rem (0.08 mSv)
Abdominal X-ray	0.1 mrad	0.1 rem (1 mSv)
Intravenous urography	≥1 rad, depending on number of images	0.6 rem (6 mSv)
CT of the abdomen	3.5 rad	3 rem (30 mSv)

- Rad is the old non-SI unit of radiation; 1 rad = 0.01 gray in the SI system. As different types of radiation have a different impact on the human body, the dose equivalent is used in order to allow meaningful comparisons of damage. This incorporates a modifying factor (energy deposited per unit mass of tissue). The SI unit of this is the sievert (Sv), and the non-SI the rem.

approximate radiation doses of various types of investigation. For comparison, these are much lower than a long-haul intercontinental flight that provides a 15-mrem dose of radiation, and a short-haul flight that provides 6 mrem.⁶ Thus, fetal risks are minimal and should not prevent an important investigation in pregnancy. However, CT scanning is uncommonly used, with the main indications for its use being trauma and renal stone pathology in the second and third trimesters.⁷ There is growing interest and expertise in the use of MRI for the investigation of non-obstetric abdominal pain in pregnancy.⁸ This is considered safe although there remains debate about the use of the usual MRI contrast agent, gadolinium.⁹ This agent crosses the placenta and there are few data relating to safety in human pregnancy. Hence MRI in pregnancy should be without the use of intravenous contrast, although some authors consider oral use acceptable.⁸

DIFFERENTIAL DIAGNOSES

A list of specific differential diagnoses, investigations and management are given in Table 22.1. Several are discussed in other sections of the book. Hence, detailed descriptions are given only for significant conditions not discussed elsewhere.

Appendicitis

Appendicitis is the commonest cause of an acute surgical abdomen during pregnancy, with an incidence of 1 in 500–2000 pregnancies, and it accounts for 25 per cent of surgery conducted for non-obstetric indications. Diagnosis is often hampered due to the physiological effects of pregnancy. Ultrasound is useful, although less so during the third trimester, or if the appendix has perforated. As a result, approximately 5–50 per cent of pregnant patients who undergo appendectomy have a normal appendix.³ Similarly, perforation is more common in pregnancy, and is associated with significant fetal and maternal mortality. Fetal loss rates of up to 20–35 per cent have been reported in older studies with more recent studies suggesting loss rates up to 8 per cent,³ partly due to the high incidence of preterm labour secondary to peritonitis. Uncomplicated appendicitis without perforation has a low

fetal loss rate of around 2 per cent. Not surprisingly, maternal mortality increases in the third trimester.

Management of appendicitis is surgical, and involving general surgical colleagues early is recommended. Surgery can be open, using an incision over the point of maximal tenderness (may be right paramedian or midline in late pregnancy), or laparoscopic. Laparoscopic surgery is now considered acceptable during pregnancy, even during the third trimester.¹⁰ A 15-mmHg pneumoperitoneum is well tolerated by the fetus. Reports in the literature describe Veress needle insertion either in the mid-clavicular line or 2 cm below the inferior costal margin, or with the open Hasson technique. The open Hasson entry technique is recommended as it avoids insufflation of the uterus which would be catastrophic to the fetus. In cases in which there is diffuse peritonitis, intravenous antibiotics are recommended preoperatively. Caesarean section may also need to be considered if the mother is severely unwell, particularly as gestation approaches term.

Acute cholecystitis

Acute cholecystitis is the second commonest surgical cause of an acute abdomen in pregnancy, predominantly caused by gallstones or biliary sludge. Gallstone formation is more likely in pregnancy as progesterone predisposes to increased bile stasis and high levels of oestrogen increase the cholesterol secretion. Although gallstones have been reported in 1–3 per cent of pregnant women, they are commonly asymptomatic as cholecystitis affects only 0.1 per cent.³ This may increase as women continue to delay pregnancies until they are older. The signs and symptoms are largely the same as those found outside pregnancy and are summarised in Table 22.1. Serum levels of direct bilirubin and transaminases may be raised, and amylase may be raised. Alkaline phosphatase is of limited use due to placental production. Ultrasound will detect 95–98 per cent of gallstones, and, in acute cholecystitis, gallbladder thickening (>3 mm), pericholecystic fluid, sonographic Murphy's sign (focal tenderness under transducer when positioned over gallbladder), and dilatation of the intra- and extrahepatic ducts will be present.

Management can be medical or surgical. Until recently, medical management of hydration, analgesia and antibiotics was more common, with surgery being delayed until after

delivery of the baby. However, reports have shown that delaying surgery is associated with a high recurrence rate, longer hospital stay, increased risk of gallstone pancreatitis, spontaneous miscarriage and preterm labour. Therefore, surgical management using laparoscopic or open cholecystectomy during pregnancy is growing in popularity. Endoscopic retrograde cholangiopancreatography (ERCP) can also be used during pregnancy, using techniques to reduce the fetal radiation dose.

Bowel obstruction

The incidence of bowel obstruction in pregnancy is around 1:2500 and in 60–70 per cent is caused by adhesions.⁴ Volvulus occurs more commonly in pregnancy (25 per cent of bowel obstructions) and is believed to be due to the rapid change in size of the uterus having a physical influence on the surrounding mobile organs such as the caecum. Bowel obstruction has been associated with high maternal (6 per cent) and fetal (26 per cent) mortality rates, particularly in the third trimester, and the rates probably reflect delayed diagnosis.¹¹ Bowel surgeons should be involved in the management, and series have suggested that nearly a quarter of cases will require surgical resection.¹¹

Pancreatitis

Acute pancreatitis has an incidence of 1 in 3000–4000 pregnancies, and occurs most often in the third trimester.¹² As in the non-pregnant state, the two most frequent causes are gallstones and alcohol. Symptoms, signs and management are the same as in non-pregnancy. Pancreatitis can range from mild disease (80 per cent) through to a severe necrotising form. Historically, the maternal and fetal mortality rate has been high in severe disease (up to 37 per cent), but improvements in diagnosis, treatment and neonatal care have reduced this in recent years to a maternal mortality rate of <1 per cent, and a perinatal mortality rate of up to 18 per cent.¹² Serum amylase and lipase are key in the diagnosis and will typically be three times the upper limit of normal. Lipase is more sensitive, and therefore is currently the recommended test.¹³ Although these enzymes are useful for diagnosis, they do not aid in assessment of severity or prognosis. Prediction of which patients will progress to severe life-threatening disease is challenging. Therefore, there are several grading systems currently in use: Ranson's criteria, Glasgow score and the APACHE II (Acute Physiology and Chronic Health Evaluation II) assessment. Unfortunately, these systems are more complex to use in pregnancy as they do not account for the physiological effects of pregnancy on parameters such as white blood cell count. Therefore, management should involve surgical colleagues and is largely supportive with bowel rest, fluids, monitoring and analgesia. It has been suggested that pethidine and tramadol should be used as analgesia because they do not cause spasm of the sphincter of Oddi.² Women who are severely ill may require delivery of the baby.

Renal stones

Renal stones occur in approximately 1:200–1:2000 pregnancies, and may be associated with preterm labour.¹⁰ Management should involve the urologists, and between 64 and 84 per cent will resolve with conservative management of fluids and analgesia.¹⁴ Ultrasound is the initial investigation, but this may miss a partial blockage. Thus, an intravenous urogram (IVU) may be required. Outside pregnancy, unenhanced helical CT is the gold standard for diagnosis, and reports of use in pregnancy can be found in the literature. However, both these modalities involve a higher radiation dose. The presence of uncontrolled pain, sepsis, single kidney obstruction or preterm labour indicates that further interventions are required. Percutaneous nephrostomy, or a ureteric stent, can be used to temporarily relieve the obstruction. However, these may require replacing every 6–8 weeks. Ureteroscopy with a holmium laser is an option in pregnancy for stones smaller than 1 cm, and without sepsis.¹⁵

KEY POINTS

- Abdominal pain is very common in pregnancy.
- A systematic approach is required to identify serious from non-serious pathology.
- Differential diagnoses should be considered as pregnancy and non-pregnancy related.
- Diagnosis may be hampered by the physiological changes associated with pregnancy.
- Investigations should not be limited by pregnancy, particularly if the wellbeing of the mother may be adversely influenced.
- Appropriate involvement of other specialties is indicated.

Chapter 23 Malignancy

Louise Kenny

MRCOG

The RCOG have issued a consensus view arising from the 55th Study Group on Cancer and Reproductive Health:

<http://www.rcog.org.uk/files/rcog-corp/uploadedfiles/roupConsensuViewsCancerandReproductiveHealth.pdf> and a Green Top Guideline No.12 on Pregnancy and Breast Cancer: <http://www.rcog.org.uk/files/rcog-corp/GTG12PregBreastCancer.pdf>

Theoretical skills

- Recognise the influence that pregnancy has on the presentation and prognosis of malignant disease.
- Understand the need to balance benefit and harm to the fetus and the mother by delaying or proceeding with treatment.
- Know currently available evidence for guiding management and predicting outcomes for the more common cancers arising in pregnancy.

Practical skills

- Be able to manage a pregnancy with coexisting malignant disease.
- Be able to liaise with surgeons, oncologists, paediatricians and psychologists to create an individualised plan of care.
- Be able to manage a pregnancy complicated by an adnexal mass.
- Be able to manage a pregnancy with an abnormal cervical smear.

INTRODUCTION

Traditionally, the incidence of a new cancer diagnosis complicating pregnancy has been quoted as 1 in every 1000 pregnancies. However, there is evidence to suggest that

the incidence is increasing, perhaps in part driven by the trend towards delaying childbirth and consequently increasing maternal age. In general, the distribution of cancers occurring in pregnancy mostly mirrors the distribution of cancers in young women. A recent Australian population cohort study found that estimates for the most common types of cancer in pregnancy were higher than the published international estimates: melanoma of skin (45.7 versus 8.7 per 100,000), breast cancer (28.8 versus 19.3 per 100,000) and thyroid cancer (17.4 versus 14.4 per 100,000), and lower for cervical (8.4 versus 12.0 per 100,000) and ovarian cancers (3.6 versus 5.2 per 100,000).¹ The overall distribution in this cohort partly arises from the predominance of melanoma, for which Australia has the highest incidence in the world.

Pregnancy does not affect the course of the cancer itself. However, diagnosis is often delayed as the presenting symptoms of malignancy may be confused with the common symptoms of pregnancy. Both the investigation and treatment of a malignancy may carry risks for the fetus, and serious conflict may occur between the desire to treat the mother appropriately while limiting harm to the pregnancy.² Future prospects for child-bearing may be subsequently limited by surgery, radiotherapy and chemotherapy. Psychological adjustment to a diagnosis of cancer is likely to be more difficult while pregnant.³ Managing cancer during pregnancy therefore requires a multidisciplinary approach involving obstetricians, oncologists, paediatricians and counsellors. The role of an individual midwife or oncology nurse should not be underestimated [E].

EBM

Evidence to support management decisions in pregnancies complicated by cancer is derived mostly from retrospective uncontrolled studies [D]. Few case-control studies have been performed and the paucity of good-quality evidence must be made clear during patient counselling.

RADIOTHERAPY AND CHEMOTHERAPY DURING PREGNANCY

Fetal exposure to radiation and/or chemotherapeutic agents may potentially have a number of detrimental effects. These include:

- miscarriage and intrauterine fetal death;
- congenital anomalies;
- severe learning disability and microcephaly;
- prenatal and postnatal growth restriction;
- increase in the risk of childhood malignancy;
- infertility in the offspring;
- induction of germline genetic abnormalities.

Counselling couples about the fetal risks associated with cancer treatment is complicated by a lack of high-quality evidence. There have been no randomised trials, and publication and ascertainment bias skew the available data. Studies often involve small numbers, and are retrospective and unsystematic in their approach and follow-up. Chemotherapy and radiotherapy are often used in combination and the contributory effects of the illness itself on the pregnancy are impossible to isolate from other variables. Data are often out of date and irrelevant to newer management regimens. Experimental data from animal studies can be helpful, but there are marked interspecies differences and caution must be exercised in extrapolating directly to human pregnancies. Remember also that the background fetal anomaly rate is variably quoted as 3–6 per cent. All studies should be interpreted with this in mind.

Radiation exposure during pregnancy

Radiation dose is measured in grays and rads:

$$1 \text{ gray (1 Gy)} = 100 \text{ rad}$$

$$1 \text{ centi-gray (cGy)} = 1 \text{ rad.}$$

Calculating fetal exposure and radiation absorption during radiotherapy and radiological investigations is complicated and often imprecise. Although the primary radiation beam can be accurately directed and quantified, additional exposure occurs from leakage through the head of the linear accelerator, external scatter from beam modifiers and internal scatter within the patient. With appropriate shielding, fetal exposure can be reduced by as much as 50 per cent, although the effects of shielding can also be difficult to quantify. The gestation at which exposure occurs is also important for two reasons. Most importantly, fetal tissues show differential radiosensitivity throughout the course of the pregnancy (see below). Second, a larger fetus is more difficult to shield effectively and may lie closer to the irradiated field.

The effects of prenatal exposure to ionising radiation are described as either **deterministic** or **stochastic**. Deterministic effects are those where loss of function occurs due to cell destruction. The severity of the effect is dose related and a critical threshold exists below which the effect is not seen.

Miscarriage, intrauterine death, congenital anomalies and SMR are believed to follow this pattern. Stochastic effects are those where ionising radiation causes genetic cell modification and loss of cell-cycle control which, after a period of latency, leads to the development of cancer. Stochastic effects also demonstrate a dose–effect relationship, but without a threshold value.⁴

- Very early exposure to radiation during pregnancy (pre-implantation and early organogenesis; 0–2 weeks post-conception) will result in miscarriage or the pregnancy will continue unaffected.
- Mammalian animal experiments show that congenital abnormalities are more likely when exposure occurs during early organogenesis (3–7 weeks post-conception in a human pregnancy).
- Generalised growth and neurological development continue throughout normal pregnancy. Microcephaly, severe learning disability and permanent growth restriction remain potential risks for the fetus exposed during the remainder of the pregnancy. The 8- to 15-week period appears to be the time of highest risk and corresponds to a critical stage of cortical formation and organisation. There is minimal risk after 25 weeks, unless very high exposures occur.
- An increased predisposition to malignancy later in life appears to be a risk whatever the gestational age at which exposure occurs.

Evidence for the effects of radiation exposure during pregnancy is derived from three sources:

- 1 animal experiments;⁵
- 2 accidental human exposures;
- 3 the Japanese survivors of the atomic bomb.^{6,7}

The high rate of fetal loss occurring with exposure during pre-implantation (conception to day 10) has been confirmed by rodent experiments and epidemiological data from Nagasaki and Hiroshima. Miscarriage and intrauterine death occur with a threshold of 10 cGy in these first few weeks; however, this increases steadily towards term, at which time the lower threshold for causing intrauterine death is estimated as >1 Gy.⁴

Animal experiments, mostly involving rodents, have shown that exposure during organogenesis causes a variety of congenital anomalies, notably involving the skeleton, eye and urinary tract. The threshold, extrapolating to humans, is possibly as low as 5 cGy, with a marked dose–response effect. However, human studies have failed to find this effect, with the exception of microcephaly. Teratogenesis should nevertheless remain a concern. It may be that the critically sensitive time in the human fetus is shorter, or that pregnancies with major anomalies abort spontaneously or have gone unrecorded.

Destruction of neural cells or failure of their migration may lead to microcephaly and/or learning disability. Data from Japan⁷ has estimated a lower threshold for microcephaly of 10 rad (10 cGy), with the 8- to 15-week period being most crucial. The incidence of microcephaly was 40 per cent with exposures of 50 cGy or higher. Severe learning disability was

also found more commonly in the offspring exposed between 8 and 25 weeks, with lower thresholds for severe learning disability of 6 cGy (8–15 weeks) and 28 cGy (16–25 weeks). Studies of IQ reflect these observations.⁷

There are fewer data on the effect of radiation exposure on developing germ cells. Delayed menarche has been observed in Japanese girls exposed to radiation *in utero* with a threshold of 25 cGy. No increase in the rates of infertility has yet been demonstrated.

A safe exposure limit of 5 cGy during pregnancy has been suggested. However, this does not take account of possible stochastic effects that do not show a lower threshold. An increase in childhood malignancies has been reported in a famous Oxford study of pelvimetry during pregnancy in which exposures were typically 1 cGy (the Oxford Survey of Childhood Cancers).^{6,9} The background rate of childhood malignancy is 1 in 1300 before the age of 15. This study gave a relative risk of 1.4 for those offspring exposed *in utero* to pelvimetry. A pelvic CT scan typically exposes a fetus to approximately 2.5 cGy and this is thought to double the risk of a childhood malignancy. Clearly, setting a 5-cGy 'safe limit' may be considered simplistic, and the debate continues. Table 23.1 lists the mean fetal dose exposures predicted for various investigations. It is important to realise, however, that the actual dose is dependent on many factors and that the true value may be five-fold higher.

In practice, if cross-sectional imaging of the pelvis or abdomen is required during pregnancy, MRI is preferred over the use of CT scanning [E]. It is likely that single exposures carry greater fetal risk than divided doses, adding further to the difficulties in applying the available human data to real diagnostic and therapeutic scenarios [D].

Radiotherapy to the pelvis is contraindicated in pregnancy due to the effects on the fetus, which cannot be shielded. There are, however, situations in which radiotherapy remains a viable treatment modality in some cancers. Fortunately, shielding of the pelvis enables sufficient reduction in exposure to the fetus after the first trimester to allow the use of radiotherapy in the treatment of a number of cancers, e.g. breast cancer and lymphomas.

Table 23.1 Fetal radiation exposures during various radiological investigations³

Background radiation exposure	0.002 cGy/week
Chest/skull X-ray	<0.001 cGy
Mammogram	0.0004 cGy
Ventilation-perfusion scan with ^{99m} Tc	<0.2 cGy
Abdominal X-ray	0.26 cGy
IVU/lumbar spine	0.32 cGy
Bone imaging with ^{99m} Tc	<0.5 cGy
Abdominal CT	0.8 cGy
Barium enema	1.6 cGy
Pelvic CT	2.5 cGy

KEY POINTS

- The dose required to induce embryonal lethality increases sharply during the first trimester from 0.1 cGy at day 1 to >1 Gy after the first trimester. The fetal effects of radiation include intrauterine death, congenital malformations, developmental or growth retardation and late malignancy.
- Within the first 2 weeks post-implantation, exposure to radiation is thought to be an all-or-nothing effect (resulting in fetal death if affected). Conversely, anomalies result from exposure (to doses >0.1 Gy) in the later weeks of the first trimester.
- Radiotherapy to the pelvis is contraindicated in pregnancy due to the effects on the fetus, which cannot be shielded. There are, however, situations in which radiotherapy remains a viable treatment modality in some cancers.

Chemotherapy and pregnancy

Prior to implantation, the blastocyst is immune to the effects of chemotherapy. The period of organogenesis between 5 and 10 weeks is, however, a critically sensitive time. Exposure to chemotherapy during this period may be associated with malformations in 10–20 per cent of cases [D].¹⁰ After 12 weeks' gestation, malformations should be less common, although growth and neurological development remain potentially vulnerable throughout pregnancy.

A number of retrospective studies support these generalisations regarding the importance of the timing of chemotherapy during pregnancy. Congenital malformations seem no more likely if chemotherapy is given only during the second and third trimesters [D].¹¹ First-trimester exposure does indeed seem more hazardous, and this is somewhat dependent on the agents used [D].¹⁰

Antimetabolites carry the greatest risks to a first-trimester pregnancy. Although miscarriage is the most common outcome, aminopterin may cause neural tube, skeletal and clefting abnormalities. This anti-neoplastic agent has been replaced by methotrexate, which is structurally similar and has the same effects on the early fetus. Both should be avoided in the first trimester and later in the pregnancy where possible. A 14 per cent congenital anomaly risk has been quoted for **alkylating agents** (e.g. cyclophosphamide) if given in the first trimester. This risk falls to near background levels for administration in the second and third trimesters. The **antibiotics** such as doxorubicin and bleomycin do not have clear teratogenic effects, although they are still to be avoided in the first trimester where possible. **Vinca alkaloids**, such as vincristine and vinblastine, are harmful in animal pregnancies but this effect is not obvious in the few human pregnancies so far exposed in the first trimester [D]. Information is constantly updated with regard to the use of these drugs during pregnancy and it is wise to consult a drug information bureau before deciding management.

Other effects of fetal exposure to chemotherapy in the second and third trimesters are even less clear. Studies are conflicting with regard to prenatal and postnatal growth restriction, although one review concluded that intrauterine growth restriction occurred in 40 per cent of exposed pregnancies [D].¹⁰

The longer-term effects of fetal exposure to chemotherapy are also unclear. Survivors of cancer who received chemotherapy as children have been followed up closely with the assumption that late complications of treatment in this group might also be expected to occur in individuals exposed *in utero*. Investigators have looked for evidence of impaired intellect, reduced gonadal function (delayed puberty and reduced fertility), visceral damage and mutagenesis within germ cells. However, to directly apply these findings from individuals treated during childhood to those exposed to chemotherapy *in utero* makes the assumption that fetal cells behave in the same way as those of a child. This may not be the case, and fetal germ cells, for example, might be more susceptible to genetic damage than those of an older child.

However, there is currently no robust evidence to suggest that future fertility may be affected or to suggest any intellectual impairment or increase in the genetic problems in the next generation.

A more consistent effect of chemotherapy on the fetus is myelosuppression. A third of newborns delivered to women who received treatment for leukaemia during their pregnancy showed evidence of bone marrow suppression in one study [D].¹² Fortunately, this is rarely of clinical importance, and sepsis, serious anaemia and haemorrhage are uncommon in the neonate. However, it is good practice to avoid myelosuppressive agents in the 3 weeks prior to delivery, if possible [E].

Decisions regarding the timing of operative delivery should aim to avoid the increased susceptibility to maternal infection if performed within 2 weeks of a cycle of chemotherapy. Similarly, those prescribing chemotherapy need to be aware of the potentially dramatic dose changes required both during pregnancy and following delivery due to the attendant physiological changes.

Despite the lack of evidence for major harm from chemotherapy in the second and third trimesters, breastfeeding is usually discouraged if treatment continues into the puerperium [E]. This reflects unresolved uncertainties about the true safety of these agents and the knowledge that significant quantities do reach breast milk.

KEY POINTS

- Most cytotoxic chemotherapy molecules are small enough to cross the placenta and affect the fetus.
- The estimated risk of major teratogenicity in the first trimester is approximately 10–20 per cent. Use of combination agents increases the risk.

- Exposure during the second and third trimesters may give rise to growth restriction, prematurity and stillbirth, but are unlikely to be teratogenic.
- Delayed effects of exposure to chemotherapeutic agents appears to be rare. The currently available evidence suggests that there are no significant adverse effects on fertility or intellectual and neurological development in those exposed.
- Furthermore, no published data exists to suggest any increase in the rate of childhood malignancies in those subjected to chemotherapy *in utero*.
- Chemotherapy, where other treatment modalities are considered unsuitable, is therefore considered relatively safe in the second and third trimesters. Patients should be counselled regarding the increased risks of growth retardation (and consequent premature delivery) and stillbirth.
- There is no evidence to support using a reduced dose of chemotherapy in pregnancy [E].

SYMPTOM CONTROL IN THE PREGNANT PATIENT WITH CANCER

The symptoms of cancer and of normal pregnancy overlap and can easily be confused. Early satiety, nausea and vomiting, constipation, dyspnoea, fatigue and depression are all common during a normal pregnancy but can also be significant symptoms of malignancy. Every effort should be made to determine symptom aetiology when a known cancer coexists with pregnancy. Shortness of breath, for example, may simply be the effect of high progesterone levels and expanded tidal volume typical of the third trimester. However, in the cancer patient it may be a sign of pleural effusions, significant anaemia or lung metastases. Similarly, nausea and vomiting may have a more sinister cause, such as hypercalcaemia, electrolyte imbalance, uraemia and even intracranial metastases. Early advice from an oncologist should be sought when new symptoms arise.

Pain should be managed with paracetamol and opiates. NSAIDs are best avoided, especially in the third trimester. Tricyclic antidepressants can be safely used for neuropathic pain, but carbamazepine should not (see Chapter 27) [B].

Poor appetite may be secondary to depression, pain, and nausea and vomiting. Treatments for nausea include metoclopramide, prochlorperazine and cyclizine. Ondansetron and haloperidol can be used if necessary. Prednisone is effective for a number of symptoms, including nausea, anorexia and fatigue. Cannabis seems to be beneficial in a number of ways but is not advised during pregnancy [C]. Constipation is effectively treated with docusate, magnesium hydroxide and senna, all of which are safe in pregnancy.

The psychological adjustment to a diagnosis of cancer is always difficult, seldom more so than during pregnancy. Fears of limited life expectancy deprive couples of future hopes and plans for themselves and their family. Focusing on short-term

goals and enjoying the present are so much harder to do during pregnancy. More specifically, there may be anxieties regarding the effect of the disease or its treatment on the fetus. The question of termination of a wanted pregnancy will be extremely distressing. There may be conflict over what is best for the woman herself and what will do least harm to the pregnancy. Concern for other children and anxieties about future fertility add further to the crisis. There is remarkably little research or evidence to guide practice, but the involvement of a mental health team or counselling service should be offered at the very least.

SPECIFIC EXAMPLES

Breast cancer

Breast cancer occurs in approximately 1 in 3000 pregnancies and approximately 10 per cent of women with breast cancer who are younger than 40 years will be pregnant at diagnosis. There is evidence to suggest there may be a transient increase in breast cancer during the first 3–4 years following pregnancy. In a population-based prospective study of 802,457 Norwegian women aged 20–56 years, a short-term increase in breast cancer after full-term pregnancy was observed, with a peak 3–4 years after the delivery.¹³ Early menarche and late age at first pregnancy are also associated with an increased risk of breast cancer.

Pregnancy also increases the risk of breast cancer developing in carriers of *BRCA1* and *BRCA2* mutations. Carriers of these mutations who have children are significantly more likely to develop breast cancer by the age of 40 years than carriers who are nulliparous, with each pregnancy being associated with an increased risk of cancer. Having a baby at a young age does not appear to protect *BRCA1/BRCA2* carriers against subsequent development of breast cancer.

Stage for stage, the outcome is no different from that for breast cancers diagnosed outside pregnancy [B].¹⁴ Continuing the pregnancy certainly does not seem to have a deleterious effect on outcome, and termination of pregnancy is not indicated for this reason [D]. However, at diagnosis, pregnancy-associated breast cancer tends to be larger in size, more advanced and more likely to have metastasised to local lymph nodes. This, in part, may be due to the 6-month average delay in its diagnosis. This is thought to increase the risk of nodal metastases by at least 10 per cent.

Breast masses are common in pregnancy. Lactational adenomas, galactoceles, mastitis and infarction of hypertrophied breast tissue are all benign pregnancy-induced breast lumps that may masquerade as malignancy. Breast enlargement, greater vascularity and increased tissue density add to the diagnostic difficulty. Mammography is safe with appropriate shielding but has a lower sensitivity in pregnancy. Fine-needle aspiration or excisional biopsy should be performed if there is any suspicion of malignancy. Once carcinoma has been diagnosed, a chest

X-ray may be needed for staging, and once again this is safe with shielding [E]. CT scanning for metastases should be replaced by ultrasound and MRI. If necessary, technetium bone scans can be employed, exposing the pregnancy to 0.5 cGy.

A common surgical option for breast cancer is lumpectomy followed by postoperative chest-wall radiotherapy to reduce local recurrence risks. Radiotherapy for breast cancer might typically be 50 Gy. With appropriate shielding, fetal exposure may be as little as 4 cGy at very early gestations (5 weeks), rising to 14–18 cGy in the second trimester when the uterus is larger. This is above the ‘accepted’ threshold of safety, and a modified radical mastectomy, which does not necessitate postoperative radiotherapy, should normally be advised during pregnancy instead [E]. The surgery itself carries minimal risk, if any, to the fetus. Conservative breast surgery can sometimes be performed in the third trimester, with adjunctive radiotherapy delayed until the puerperium.

Chemotherapy for breast cancer in the second and third trimesters is not associated with obvious fetal harm.¹⁵ Where possible, the last dose should be given 3 weeks prior to delivery to limit the effects of fetal bone marrow suppression [E]. Tamoxifen use in pregnancy has previously been discouraged. Experiments in rodents have demonstrated anomalies similar to those found with *in utero* diethylstilbestrol (DES) exposure and an increased intrauterine fetal death rate. Although these effects appear to be species specific, there are only minimal human data testifying to the safety of tamoxifen in pregnancy and its use is not currently recommended. Trastuzumab, a monoclonal antibody targeted against the HER2/neu receptor, is contraindicated during pregnancy because of reported adverse fetal outcome. There are no data on other targeted therapies such as vascular endothelial growth factor antagonists, including bevacizumab.

Fetal surveillance by regular growth scanning is warranted, although a clear link with prenatal growth restriction has not been established. Placental metastases are found very rarely and there are no reports of breast cancer spreading to the fetus. Some authors suggest delivery at 34 weeks to limit the fetal exposure to chemotherapeutic agents. Others await spontaneous labour if fetal growth is normal. Neonatal blood sampling is necessary to exclude clinically relevant pancytopenia.

Pregnancy after breast cancer

With the high background incidence of breast cancer and progressive delay in child-bearing, it is not uncommon now to be asked for advice on this matter. Most studies have failed to show any effect on survival if pregnancy occurs after breast cancer [B].^{16–19} Although it can be argued that women with a more favourable prognosis are more likely to consider a pregnancy, the survival among node-positive patients was not affected by pregnancy either. It has been suggested that becoming pregnant soon after breast cancer may affect

long-term survival and that a delay should be advised. Studies that demonstrate a survival advantage with such a delay may simply be highlighting the improved prognosis for women who remain alive 2–5 years after the diagnosis. For younger women (who have a worse prognosis anyway), a delay of 2–5 years will have minimal impact on fertility. Allowing more time will help to give a more individualised prognosis. Such a delay may be more difficult to justify in women in their late 30s and 40s.

The use of tamoxifen during pregnancy is not recommended (see above). Breastfeeding is not contraindicated, but previous surgery and radiotherapy may impair subsequent lactation.

The following points are the recommendations given in the RCOG guideline:

- There is no indication that termination of pregnancy after diagnosis of breast cancer is necessary to improve the prognosis.
- Women planning pregnancy or who become pregnant after breast cancer should consult their clinical oncologist, surgeon and obstetrician.
- There is no evidence that the survival of women who have had breast cancer and subsequently become pregnant is compromised. However, an interval of at least 2 and preferably 3 years between treatment and conception is recommended.

Cervical cancer

The incidence of cervical disease in pregnancy is uncertain because reported series are retrospective. Some series include both pre-invasive and invasive lesions, whereas others include cases of cancer diagnosed during the pregnancy or during the postpartum period. The incidence of abnormal cervical cytological findings is estimated at 1–5 per cent of all pregnancies and the reported rate of cervical cancers ranges between 1 and 12 per 10,000 pregnancies. It commonly presents with vaginal bleeding but discharge and pain may also occur. A high proportion of cases are detected by cervical screening and are otherwise asymptomatic.

Cervical screening in pregnancy

False-positive cervical smears are more likely during pregnancy for a number of reasons:

- eversion of the squamocolumnar junction occurs as a consequence of high oestrogen levels and exposed columnar epithelium undergoes squamous metaplasia;
- cervical infiltration by leukocytes occurs in pregnancy;
- decidualisation of the cervix is a frequent finding;
- trophoblasts may be present in the cervical canal;
- relative immunosuppression may allow greater human papillomavirus (HPV) activity.

It is vital that the cytologist reading the smear is aware that it has been taken from a pregnant woman if false positives are to be kept to a minimum. In the UK it is not usual for routine

cervical screening to be carried out in pregnancy, and smears are normally deferred until the postnatal appointment. However, if there is clinical concern regarding the cervix, or if it seems unlikely that the individual will return after the pregnancy for a smear to be carried out, there should be no hesitation in performing it while the woman is pregnant.

Most studies show a high degree of concordance between cytology (smears) and colposcopy [B]²⁰ during pregnancy but the possibility of false-positive or false-negative results must always be considered.

Management of an abnormal smear in pregnancy

A reluctance to perform cervical smears during pregnancy may also arise from unfounded anxieties over the subsequent management of the abnormal smear. One study of colposcopy during pregnancy found concordance, overestimation and underestimation of the final diagnosis (based on cone histology) in 73 per cent, 17 per cent and 10 per cent, respectively, and this did not differ significantly from the non-pregnant control group.²¹ Indeed, unsatisfactory colposcopy is less common during pregnancy due to eversion of the squamocolumnar junction. Squamous metaplasia is more common and the cervix will usually look larger and have increased vascularity. Colposcopy during pregnancy therefore requires experience and careful judgement. Hacker and colleagues demonstrated a 99.5 per cent diagnostic accuracy for colposcopy, with only a 0.5 per cent false-negative rate (with no missed invasive lesions) among 1064 pregnant women.²²

If a smear taken in pregnancy has suggested low-grade cervical intraepithelial neoplasia (CIN) and the colposcopic impression agrees, these women can be managed by repeat colposcopy in each trimester, with a further evaluation in the postpartum period. There is no evidence that CIN progresses more rapidly in pregnancy, and indeed regression rates of 25–70 per cent have been documented for high-grade CIN first detected in pregnancy.²³

If the colposcopic impression is of a higher-grade lesion, it is vital that micro-invasive and invasive cancers are excluded. Older studies recorded an unacceptably high rate of complications with knife conisation during pregnancy, principally a >500 mL blood loss in 7–13 per cent of cases (mostly in the third trimester).²² Any causative association with miscarriage, preterm rupture of membranes, preterm delivery and chorioamnionitis remains uncertain, but concerns do exist. These concerns have seen a shift away from conisation in pregnancy towards the use of directed punch biopsies, which carry less morbidity. Concordance between directed biopsies and the final diagnosis is complete or within one degree of severity in over 95 per cent of cases [B].¹⁹ Missed invasive lesions are extremely uncommon. Treatment of CIN II and III should be delayed to the postpartum period, but colposcopy every 8 weeks antenatally is advised to monitor for progression of the lesion [E].

If micro-invasive or invasive disease is suspected, conisation or a large-loop excision procedure should be done early in

the pregnancy; the choice between these procedures depends on the size of the cervix, the clinical team's preference and the degree of suspicion.

Postpartum evaluation is extremely important for women who have antenatal colposcopy, even those who have undergone cone biopsy. Lesions may regress, persist or progress, and the diagnosis made during pregnancy may need to be upgraded. High rates of residual intraepithelial neoplasia and cytological abnormalities have been found following conisation, which should not necessarily be considered adequate treatment for CIN during pregnancy.²⁴

Management of cervical cancer in pregnancy

Cervical cancer is normally staged clinically by chest X-ray, cystoscopy, urogram and fluorine-18-labelled fluorodeoxyglucose (¹⁸FDG) CT scanning or MRI. Positron emission tomography (PET)-CT is not recommended in pregnancy because fetal absorption of the isotope exceeds recommendations. MRI is the investigation of choice for pelvic imaging during pregnancy.

Cervical cancer is usually treated surgically in its early stages. Chemoradiotherapy is reserved for more advanced disease due to the effects this treatment has on ovarian, bladder, bowel and sexual function. Knife conisation may be sufficient treatment for Ia1 (micro-invasive) cervical cancer outside pregnancy due to the low risk of recurrence or lymph node (LN) metastases. If this diagnosis is made during pregnancy and the cone biopsy margins are clear, the pregnancy should be allowed to continue, with vaginal delivery. However, the significant rate of positive margins and residual disease found with conisation in pregnancy makes further evaluation in the postpartum period imperative.²⁵ For women who have completed their families, a postpartum simple hysterectomy with ovarian conservation is recommended [E].

Higher-grade lesions (Ib1–IIa) are usually treated by simple or radical hysterectomy with LN sampling. Cancers presenting at less than 20 weeks' gestation have traditionally been treated immediately [E]. The hysterectomy can usually be performed with the fetus *in situ*; however, a hysterotomy, avoiding the lower part of the uterus, can be employed to remove the pregnancy and improve access if necessary. Delaying treatment until after delivery becomes an increasingly favourable option after 20 weeks' gestation for stage I cancers.²⁶ Nine studies involving 63 patients with stage I cervical cancer have examined the effect of a delay, varying between 1 and 32 weeks. Only one outcome was possibly affected by the delay. However, these studies are clearly non-randomised and the decision to delay should be made with oncologists and neonatologists after careful patient counselling. Steroids should be given to promote fetal lung maturation. Delivery at 32–34 weeks can now be justified with advances in the care of the preterm infant. Caesarean section is normally advised, due to theoretical concerns of haemorrhage from cervical lesions and increased malignant cell dissemination with vaginal delivery [E]. Local recurrence within episiotomy sites is well documented and is associated with a high mortality

rate. Radical hysterectomy at the time of caesarean section is associated with greater blood loss, but the rate of other complications is not increased [D].

Consideration should also be given to the use of neoadjuvant chemotherapy in the second and third trimesters. This may limit progression of disease and more confidently allow delay in surgical treatment, although its safety also remains in question.

Radiotherapy is employed with more advanced lesions (stage IIB and above) and usually takes the form of external beam *teletherapy* and intracavitary *brachytherapy*. The external beam alone employs 40–50 Gy. Most pregnancies will spontaneously abort after such high doses, usually within 5 weeks [D]. Occasionally, the fetus must be removed surgically. Preterm delivery of the fetus may be necessary at later gestations.

Where a lesion is very advanced, and the maternal prognosis poor, the woman may prefer to compromise her own treatment if this means limiting the risks to the fetus. Careful, sensitive counselling is clearly very important in this situation.

Ovarian cancer

The incidence of ovarian tumours in pregnancy is quoted as 1 in 1000 deliveries, although ovarian cancer is much less common (1 in 5000–18,000). Adnexal masses are found in approximately 1 in 100 pregnancies; 50 per cent measure <5 cm, 25 per cent are 5–10 cm and the remaining quarter are >10 cm in size. Box 23.1 lists various causes of adnexal mass found in pregnancy, in decreasing order of incidence.

There are various non-neoplastic ovarian lesions that are unique to pregnancy and that will resolve spontaneously after delivery. These include:

- luteoma of pregnancy;
- follicular cyst of pregnancy;
- hyperreactio luteinalis;
- granulosa cell proliferations;
- hilus cell hyperplasia;
- ectopia decidua.

With the extensive use of ultrasound for dating and assessing pregnancies, the recognition of adnexal masses in pregnancy has increased. Although most remain asymptomatic, 10–15 per cent will rupture, bleed or cause adnexal torsion [D], and

Box 23.1 The most common causes of adnexal mass in pregnancy

Functional cyst
Mature teratoma (dermoid)
Cystadenoma (serous and mucinous)
Para-ovarian cyst
Endometrioma
Leiomyoma
Malignancy (3–6 per cent of all cases)

these acute events are thought to increase the risk of miscarriage and preterm labour [D]. Occasionally, an ovarian mass may cause dystocia during labour or virilisation. As 1 in 20–50 ovarian lesions in pregnancy will be malignant²⁷ and as many as 1 in 6 may become symptomatic, a careful management decision has to be made when they are first recognised. Symptomatic adnexal lesions may need to be operated on immediately. Small (<6 cm) unilocular cysts are likely to resolve spontaneously before 16 weeks without causing harm and should be left alone [D].²⁸ A further ultrasound should be performed at 16 weeks' gestation. A persistent complex mass should prompt a laparotomy. Miscarriage is said to be less likely if intervention occurs at this point in the second trimester. Persistent simple cysts that are not associated with ascites and have no solid areas or thick septa within them can be treated conservatively. Dermoid cysts are often confidently diagnosed by ultrasound. These, too, can be left although the risk of a cyst accident must always be considered, as this may increase the risk of miscarriage. MRI may help with diagnosis in selected cases.

Tumour markers such as CA-125, AFP and hCG are helpful for diagnosis and treatment monitoring outside pregnancy. These substances may all be elevated during a normal pregnancy and do not usually feature in the diagnosis or management of the adnexal mass antenatally. Of note, however, an extremely high maternal serum AFP value, performed for fetal anomaly screening, has led to the diagnosis of endodermal sinus tumours on a number of occasions.

Surgery for an adnexal mass in pregnancy usually involves a lower midline incision, which allows adequate access with minimal uterine manipulation. Peritoneal washings should be taken and omental and peritoneal biopsies. Where appropriate, a simple cystectomy with ovarian conservation is attempted. Otherwise, a unilateral salpingo-oophorectomy should be performed. Frozen sections of the contralateral ovary can be taken to help intraoperative management, but bilateral oophorectomy should normally be avoided at the initial operation, as even malignant cases are usually early stage, chemosensitive or of low malignant potential. Para-aortic lymph node sampling and debulking should be considered in more complex cases, although it would be unusual for the uterus to need to be removed.

If an ovarian cyst is removed in the first trimester, it may have arisen from the corpus luteum and may have been providing hormonal support to the early pregnancy. It is accepted practice in this situation to provide progesterone supplementation until the second trimester is reached [D].

Management of ovarian cancer in pregnancy

The histopathological nature of ovarian cancer in pregnancy reflects the younger age of the affected population. Germ cell and epithelial cell cancers each account for 30–40 per cent of cases, but two-thirds of the epithelial group are of 'low malignant potential'. The remainder are mostly sex cord stromal tumours. Dysgerminomas are the most common malignant ovarian tumours found in pregnancy.

Stage I epithelial cancers, tumours of low malignant potential and stage Ia dysgerminomas do not require adjunctive treatment with chemotherapy. Other forms of germ cell tumour and more advanced epithelial cancers would normally be treated with chemotherapy postoperatively. Beyond the first trimester, the use of bleomycin, etoposide, cisplatin and vincristine/vinblastine has not been clearly linked with fetal harm, with a number of successful outcomes having been reported in the literature.²⁹ However, until more data have been collected, concerns will remain over the use of anti-neoplastic drugs during pregnancy, especially during the first trimester (see above).

Other malignancies

The principles of managing cancer in pregnancy can be illustrated by further examples:

- Older, uncontrolled studies suggested a poorer outcome stage for stage when melanoma presented during pregnancy. More recent, case-control studies show no difference in 3-year and 5-year survival rates [B].³⁰ Although melanoma is the malignancy most likely to metastasise to the placenta and fetus, this nevertheless rarely occurs. However, the placenta should be examined at delivery and sent for histopathology. The fetus will have metastases in 30 per cent of cases where placental involvement is found. Biopsy of the sentinel or draining node may be useful in predicting spread of malignant melanoma. A blue dye can be used to locate this lymph node, as an alternative to technetium-labelled sulphur colloid, avoiding fetal radiation exposure [D].
- Radiotherapy for head, neck and brain tumours usually carries a fetal dose exposure of <10 cGy due to the distance between the field and the uterus. Abdominal shielding can reduce this to <2 cGy.
- The treatment for Hodgkin's lymphoma and chronic myeloid leukaemia can often be delayed until after the pregnancy. Acute leukaemias and non-Hodgkin's lymphoma must be treated immediately, as the risks to the woman and her pregnancy from haemorrhage, anaemia and sepsis outweigh the possible fetal harm from chemotherapy, even in the first trimester [D].

KEY POINTS

- Pregnancy does not alter the course of cancer but may cause a delay in diagnosis.
- Sensitive methods of investigation can be safely employed during pregnancy.
- Safe treatments are available during pregnancy for dealing with all symptoms caused by cancer.
- Chemotherapy in the first trimester is associated with a significantly increased risk of fetal abnormalities. Treatment

during the second and third trimesters of pregnancy would seem to be safer, but the data are limited.

- Radiation exposure must be restricted to the very low levels found with investigative X-rays. Radiotherapy for pelvic, abdominal or chest malignancies usually carries excessive fetal risk, even with shielding.
- Management requires a multidisciplinary approach.

Chapter 24 Maternal infections in pregnancy

Tara Jayne Selman

MRCOG standards

- Conduct a booking visit including assessment of pre-existing infection and risk of infections.
- Formulate a management plan for treating and screening for infection.

Theoretical skills

- Have general knowledge of the immune system.
- Understand changes in the immune system and changes in pregnancy.
- Understand epidemiology, aetiology, signs/symptoms, investigation of infections in pregnancy.

Practical skills

- Recognise clinical presentation of the disease, performing necessary clinical investigations and treatment as part of a multidisciplinary team.
- Conduct pre-pregnancy counselling for women with pre-existing infection.

INTRODUCTION

The body has a natural resistance to infections with an ability to acquire resistance through natural exposure and vaccination. There are immune defences on the body's surface in the form of the epithelial skin barrier and IgA on mucosal membranes. The lymphatic system may trap organisms presenting them as targets for phagocytosis by macrophages. Those organisms that do enter the circulation can be destroyed by neutrophil or phagocytic cells. Acquired immune resistance is also present with the stimulation of antibody production (initially IgM) by plasma cells. Cell-mediated immunity also continues via the T lymphocytes. All of these systems remain in pregnancy; however, there are significant changes to tolerate the semi-allogenic fetus, resulting in a state of relative immunocompromise. These changes lead to an increase in the infectivity of certain infections such as cytomegalovirus (CMV) and herpes simplex virus (HSV). The changes in

maternal immune responses are also reflected by changes in autoimmune diseases: rheumatoid arthritis often ameliorates during pregnancy, although it can flare up.

This chapter covers infections that have significant impact on pregnant women's health or require significantly different treatment in pregnancy. Chapter 36 details those infections that have greater implications to the fetus.

VIRAL INFECTIONS

Rubella, parvovirus and CMV are all covered in Chapter 36, and the H1N1 virus in Chapter 65.

Herpes simplex virus

The virus is divided into two subgroups: type 1 associated with orofacial infections and encephalitis, and type 2 associated with genital infections, although there is a varying degree of overlap.¹

Epidemiology and aetiology

HSV is transmitted through close physical contact with mucosal surfaces or abraded skin and during sexual intercourse. HSV type 1 is commonly contracted in childhood, resulting in up to 90 per cent of the adult population having positive serology. HSV type 2 is generally contracted from adolescence with the onset of sexual activity.

HSV remains latent in sensory neurons; the trigeminal nerve in type 1 and the sacral ganglia in type 2. Reactivation then occurs as a result of triggers such as trauma, fever, stress, menstruation and ultraviolet light. The antibodies to the subtypes are thought to offer some cross-protection.

Presentation and diagnosis

Primary facial herpes is classically asymptomatic, but when appearing the lesions can be seen in the oral mucosa, lips and eyes. In contrast primary genital herpes is usually severe with lesions that start with erythema, progressing to vesicles and then ulcers and finishing with crusting involving the vulva and cervix, and lasting 2 weeks. The ulcerations can result in

associated lymphadenopathy, fever, malaise and retention of urine. Recurrent episodes tend to be less severe. Data from the USA suggests that 2 per cent of women acquire genital HSV in pregnancy, with the majority of cases being asymptomatic or not diagnosed correctly.²

Diagnosis is made initially by history and examination. In cases of suspected primary genital herpes a pregnant woman should be referred to a genitourinary physician for confirmation by viral polymerase chain reaction [C].³

Management

This chapter will concentrate on the management of genital herpes, which has major implications during pregnancy. Management is dependent both on gestation and on whether the episode is a primary or secondary occurrence.

All episodes of primary genital herpes should be managed jointly with genitourinary physicians. When primary genital herpes occurs in the first or second trimester management/treatment with aciclovir should commence without delay. This reduces the duration and severity of the symptoms and the duration of viral shedding. In the absence of disseminated disease oral treatment with 400 mg aciclovir three times a day for 5 days is appropriate. Women should be counselled that although not licensed in pregnancy aciclovir has been shown to be safe and well tolerated even when used in the first trimester.⁴ Symptomatic relief may also be achieved with paracetamol and topical lidocaine gel. Provided that the woman does not go on and deliver in the next 6 weeks, then vaginal delivery is advocated and the woman can be reassured that there is no association with congenital abnormalities.⁵ Evidence has shown that daily suppression with 400 mg aciclovir three times a day from 36 weeks should be recommended as it reduces the occurrences of HSV lesions and asymptomatic viral shedding [A].³

If primary genital herpes is suspected in the third trimester (from 28 weeks) then there are implications for mode of delivery. Elective caesarean section is recommended, especially if the lesions appear in the last 6 weeks of pregnancy, as the risk of neonatal transmission is then as high as 41 per cent [B].⁶ If a woman is 'labouring' and decides to continue for a normal vaginal delivery there may be some benefit in treating her with IV aciclovir and avoiding invasive procedures (e.g. fetal blood sampling). As literature reports that up to 15 per cent of cases will actually be recurrent episodes, when presenting at this gestation consideration should be given to type-specific HSV antibody testing [C]. The maternal management of an episode in the third trimester is the same as in early gestation, although aciclovir therapy will usually occur until delivery. Parents should be told that the data suggesting poor outcomes in such pregnancies are conflicting,⁸ with insufficient evidence to support the need for additional monitoring in pregnancy [B].

Women presenting at any stage of gestation with recurrent episodes are at low risk of neonatal infection. With lesions present at the time of delivery the risk of neonatal herpes is 0–3 per cent³ and hence it is reasonable to advocate normal vaginal delivery, even if the woman has active lesions at the time of delivery. Although invasive procedures may increase

the risk of neonatal transmission, as the background risk is low it is reasonable to perform these [C]. In those with recurrent episodes daily suppression with 400 mg aciclovir three times a day should be considered in the last 6 weeks of pregnancy [C].

In both primary and secondary outbreaks it is reasonable to expedite delivery when there are active lesions and pre-labour rupture of membranes at term. In primary herpes, when there is rupture of membranes in a preterm, pre-labour scenario, the decision for delivery or conservative management needs to be made by a multidisciplinary team. If a conservative approach is followed then the use of IV aciclovir should be considered. In the case of secondary herpes because the risk of transmission is low then the risks of prematurity prior to 34 weeks probably outweigh the advantages of delivery [C].

Those women with HIV co-infection should be treated in line with non-HIV-positive patients if the primary genital herpes occurs in the last trimester; however, there is some evidence to support a more aggressive approach for recurrent infection as there is evidence that the transmission risk to the neonate is higher. Therefore it is suggested that suppression therapy be commenced from 32 weeks. There is no evidence for the use of therapy in HSV-seropositive women without a history of genital herpes [C].⁹

KEY POINTS

- The management of women with genital herpes should be in conjunction with genitourinary medicine physicians.
- Aciclovir is considered safe to use in pregnancy, including the first trimester.
- If primary herpes occurs within 6 weeks of delivery elective caesarean section should be recommended.
- The risk of transmission of recurrent herpes to the neonate, even at term, is low and a normal vaginal delivery should be offered.
- Suppressive aciclovir should be considered in the last 6 weeks of pregnancy for those with a first- or second-trimester outbreak or recurrent episodes.

Varicella-zoster virus

The aetiology, presentation and diagnosis are covered in Chapter 36.

Prevention of chickenpox

Over 90 per cent of the antenatal population is seropositive for varicella-zoster virus (VZV) IgG antibody and hence primary infection in pregnancy is uncommon, occurring in approximately 3:1000 pregnancies. Prenatally vaccination of VZV IgG-seronegative women is possible and postpartum screening has been shown to be cost-effective; however, it is not currently routine practice.

At a booking visit if an antenatal woman gives no past history of chickenpox she should be advised to avoid close contact with people with chickenpox or exposed shingles.

The incubation period is 1–3 weeks and the disease is infectious for 48 hours prior to the appearance of the rash until the vesicles have crusted over (usually 5 days). If it is suspected that a significant contact has occurred then serology should be performed and if the woman is not immune to VZV, due to the potentially serious effects of the virus in adulthood and the relative immunocompromised state in pregnancy, it is recommended that varicella-zoster IgG (VZIG) be given. Administration is effective up to 10 days after contact as it has been shown to prevent or reduce the severity of the condition [C].⁹ Repeat dose of VZIG may be given if further exposure occurs 3 weeks or more after initial treatment. Women who have been treated with VZIG should be considered infectious for 8–28 days.

Treatment of chickenpox

Chickenpox in adulthood, although rare, can be associated with serious morbidity, with the development of pneumonia, hepatitis and encephalitis, and even mortality. These risks are increased in pregnancy with a five-times higher mortality rate of 3–24 per cent and with pneumonia occurring in 10 per cent of pregnant women with the disease. As a result of this it is recommended that a pregnant woman who presents with chickenpox within the first 24 hours of a rash should be treated with oral aciclovir [C].⁹

Hospital management with a multidisciplinary team approach is obviously needed in cases where a woman develops any signs or symptoms that may indicate a serious complication. It is also recommended that hospital referral should be made if there is a history of lung disease, smoking or corticosteroid use, or if the pregnancy is in the later half.

If the infection occurs at the time of delivery then, if possible, delivery should be delayed for 5–7 days to allow for antibody transfer from mother to fetus, as the risk of neonatal VZV is high and this is a condition associated with high morbidity and mortality. Treatment with aciclovir is also recommended [C]. No specific treatment is required if the woman develops shingles as the fetus/neonate will be protected by maternal antibodies.

KEY POINTS

- If a suspected non-immune pregnant woman comes in contact with chickenpox then maternal serology to confirm status is recommended.
- Non-immune women with contact should be given VZIG up to 10 days after exposure.
- Oral aciclovir should be administered within 24 hours of the rash developing.
- Intravenous aciclovir, with hospital admission, should be considered for women presenting at 36 weeks' gestation and beyond, and those with complications.
- Delivery should be delayed until at least 7 days after the onset of the illness.

Postnatally, if a woman develops chickenpox within 7 days of delivery then neonatal treatment with VZIG is recommended.

Human immunodeficiency virus

Epidemiology and aetiology

Infection with HIV occurs through sexual contact and contact with infected blood. The majority of HIV-positive women are from sub-Saharan Africa with a prevalence of 2–3 per cent; among UK-born women the prevalence, although increasing, is much lower at 0.3 per 1000.¹⁰ In pregnancy one of the major concerns, both for women with pre-existing infection and for those with new diagnosis, is the risk of mother-to-child transmission (MTCT). The majority of management in pregnancy and delivery revolves around interventions to maintain a low MTCT rate. Prior to such management in the UK transmission occurred in 25 per cent of cases; in comparison now, in diagnosed cases optimally managed, the risk is estimated at just 0.57 per cent,¹¹ with an overall rate of 2 per cent when considering all exposed infants, i.e. those who have been born to diagnosed and non-diagnosed women.¹²

Despite HIV screening being routinely offered to all pregnant women a small proportion of those who are HIV positive will be missed, either because they decline screening or because they seroconvert during pregnancy. The National Screening Committee (NSC) does not recommend routine re-screening at 28 weeks' gestation; however, those who refused screening at their booking visit should routinely be re-offered it at this stage of gestation.

Management of HIV in pregnancy

The management of both the newly diagnosed and those with pre-existing disease needs to be as part of a multidisciplinary team.

Those with a new diagnosis should be advised to have sexual-health screening [B]¹³ and it is suggested that those with pre-existing infection consider this in pregnancy as well [C]. All women should obviously be offered their routine antenatal screening, with the addition of screening for hepatitis C. This should include screening for trisomy 21, although women should be counselled as to the increased risk of a false-positive test as significantly increased levels of beta-hCG and low levels of AFP have been reported in HIV-positive patients.¹⁴ They also need to be counselled as to the risks of MTCT with chorionic villous sampling (CVS) and, to a lesser extent, amniocentesis. Any invasive prenatal testing should be delayed until the viral load is less than 50 HIV RNA copies/mL [C].

All pregnant women should be treated with combination antiretroviral therapy (cART) by week 24 of pregnancy [C]¹³ in order to limit MTCT, or prior to this if required for their own health. Those women who conceive on therapy should continue this. The type of therapy used and combinations should be guided by specialist physicians. There is increasing evidence that exposure to commonly used therapy, even

in the first trimester, does not increase the risk of congenital malformations. Viral load is then measured throughout pregnancy with frequency depending on initial load and the gestation at which cART is commenced.

Without other obstetric indications the mode of delivery for women taking cART should be determined at 36 weeks and be dependent on the viral load. For women on cART with a viral load less than 50 HIV RNA copies/mL, a plan for vaginal delivery should be made [C].¹³ When the viral load is 400 HIV RNA copies/mL or more at 36 weeks then delivery should be by planned caesarean section. For viral loads in between, the mode of delivery is unclear and should be guided by the actual viral load, the trend, additional obstetric factors and the views of the women [C]. A study of women delivered in the UK and Ireland with viral loads between 50 and 399 HIV RNA copies/mL showed an MTCT risk after caesarean section of 0.23 per cent compared with 1.06 per cent after planned vaginal delivery.¹¹

Guidelines have been reviewed and it is now recommended that for those women having a planned vaginal delivery (i.e. viral load less than 50 HIV RNA copies/mL), delivery should follow the same management as for a non-HIV-positive woman [C].¹³ Hence, as there is now thought to be little or no risk of MTCT, invasive procedures such as fetal blood sampling and the use of fetal scalp electrodes are no longer prohibited.

In women having planned elective caesarean section for a viral load >1000 HIV RNA copies/mL, treatment with IV zidovudine infusion should be commenced if they labour prior to section. This should also be used for those who present in labour with an unknown viral load.

In all cases of pre-labour spontaneous rupture of membranes after 34 weeks, delivery should be expedited [C].¹³ The recommendations for mode of delivery will depend on the viral load and use of cART. For those on therapy with a viral load of less than 50 HIV RNA copies/mL without other factors, induction of labour would be appropriate as it is no longer thought that a prolonged rupture of membranes beyond 4 hours incurs a significant risk of MTCT. For pre-labour rupture of membranes before 34 weeks the timing of delivery needs to be decided on a case-by-case basis, after the use of intramuscular steroids and optimisation of viral load, and should be decided after multidisciplinary discussion.

Postnatally the need to continue cART therapy should be determined by the HIV physicians in line with national guidelines for non-pregnant women. All women, independent of treatment and viral load, should be advised not to breastfeed [A]¹³ and offered lactation suppression therapy.

Hepatitis B virus

Epidemiology and aetiology

Hepatitis B virus (HBV) is an extremely infectious double-stranded DNA virus that has three major structural antigens: surface antigen (HBsAg), core antigen (HBcAg) and e antigen (HBeAg). This blood-borne virus is transmitted sexually, vertically or by blood contamination. Carriage among pregnant women in the UK is estimated at 0.5 per cent, rising to 1 per cent in inner cities.

Diagnosis and management

Acute infection is often asymptomatic or associated with non-specific signs such as nausea, fatigue and vomiting. In IV drug users 30 per cent will develop jaundice. Physical examination may reveal hepatomegaly, splenomegaly or lymphadenopathy in 5 per cent of cases. The virus can go on to cause acute and chronic hepatitis. The acute condition is usually self-limiting with only 1 per cent of cases developing fulminating hepatic failure.

The diagnosis of the condition is made by the detection of HBsAg. The detection of HBeAg indicates active disease and the disappearance of HBsAg and the appearance of surface antibodies indicate disease resolution and these antibodies will provide immunity. Resolution usually occurs within 3 months, although a small number of those infected will continue to have viral replication for much longer.

All pregnant women are routinely offered screening for HBV. Those women who present for the first time in pregnancy or who have active disease should be managed as part of a multidisciplinary team. It is essential to ensure partner screening and testing for other STIs.

The risk of vertical transmission depends on the antigen status of the women. There is a 95 per cent transmission rate in the presence of both HBsAg and HBeAg, compared with 2–15% when HBeAg negative. Ninety-five per cent of cases of transmission occur at the time of delivery.

KEY POINTS

- HIV screening should be offered to all pregnant women routinely in the first trimester.
- All HIV-positive women should be managed by a multidisciplinary team and have commenced cART at 24 weeks.
- Normal vaginal delivery can be recommended if the detectable viral load is less than 50 HIV RNA copies/ml and labour should be managed as per guidelines for low risk women.
- Advice should be given not to breastfeed.

KEY POINTS

- New presentations of HBV in pregnancy should be managed as part of a multidisciplinary team and women should be screened for other sexually transmitted infections.
- Infectious status should be ascertained and the neonate treated according to maternal antigen status.
- Management of labour should include avoidance of invasive monitoring and fetal blood sampling.

Prevention of HBV infections of the neonate is achieved by avoiding fetal invasive procedures during labour and the administration of passive immunoglobulin in the first 24 hours to neonates of highly infectious mothers. Hepatitis vaccination is given to those born of low-infectivity mothers.

When a baby has been immunised there is no contraindication to breastfeeding.

Hepatitis C virus

Epidemiology and aetiology

Similar to HBV, hepatitis C virus (HCV) is transmitted sexually and via contaminated blood. In the UK it is most commonly seen in IV drug users. There is an 80 per cent chance of an IV drug user becoming HCV positive in the first year of drug use.¹⁵ The overall adult prevalence of chronic HCV in western Europe is 0.5–2 per cent.

Diagnosis and management

HCV presents with non-specific symptoms associated with raised transaminase levels. Diagnosis should be made by identification of HCV RNA as antibodies are not detected until late in the disease. Early identification is essential as treatment with pegylated interferon and oral ribavirin can result in 50–80 per cent of those infected clearing the virus.¹⁶ Without treatment 80 per cent of those infected will go on to develop chronic infection.

Currently routine screening of all antenatal patients is not recommended; however, it should be considered for high-risk groups. Women with a new diagnosis should be managed in conjunction with a hepatologist. The overall risk of MTCT is 5 per cent.¹⁵ The likelihood of infection is linked to the presence of HCV RNA; with those pregnancies where the mother is HCV RNA negative, there is little or no chance of MTCT. Co-infection with HIV also increases the risk.

Currently intrapartum management should be the same as for HBV. There have been suggestions that elective caesarean section may prevent some MTCTs, however, the data are not conclusive and there are large studies that also refute this theory.

There is no evidence that avoiding breastfeeding reduces transmission. Currently there is no neonatal immunoprophylaxis available.

KEY POINTS

- Screening for HCV is recommend only for high-risk groups.
- MTCT is dependent on HCV RNA load.
- There is inconclusive evidence to support delivery by caesarean section.
- There is no contraindication to breastfeeding.

Hepatitis E and A viruses

Hepatitis E requires a special mention as pregnant women with acute infection have a risk of fulminant liver failure of 15 per cent, with a mortality rate of 5 per cent, which is above and beyond that seen outside pregnancy. The reason for this increased susceptibility is not clear. The virus is transmitted by the faecal–oral route and usually produces a self-limiting illness. The transmission route and self-limiting illness are similar to those seen in hepatitis A however, hepatitis A does not result in chronic illness or fulminant liver failure.

BACTERIAL INFECTIONS

Streptococcal A infection is covered in Chapter 65, UTIs in Chapter 13 and bacterial vaginosis and group B streptococci in Chapter 44.

Gonorrhoea

Epidemiology and aetiology

Gonorrhoea is caused by the Gram-negative intracellular diplococcus bacterium *Neisseria gonorrhoeae*. It is isolated from the epithelium of the genital tract, rectum, pharynx and eyes. Transmission is by direct inoculation of infected secretions from one mucous membrane to another. Ascending infection in women can result in uterine and tubal infection. It is most common among the younger age group (15–24 years) and is associated with multiple sexual partners, the presence of other STI and IV drug use.

Diagnosis and management

Between 30 per cent and 60 per cent of women will be asymptomatic. In those with symptoms the most common are increased or altered vaginal discharge (50 per cent of cases), lower abdominal pain (25 per cent of cases), bleeding during or after intercourse as a result of cervical infection, and dysuria. Rarely (less than 1 per cent of cases) disseminated infection resulting in fever, arthritis and skin disorders is seen, and these occur slightly more commonly in pregnancy.

Diagnosis can be made by several methods, none of which has 100 per cent sensitivity. Culture continues to offer a specific, sensitive and cheap diagnostic test at genital sites. It allows confirmatory identification and antimicrobial susceptibility testing, which is of increasing importance as antimicrobial resistance to *N. gonorrhoeae* continues to evolve. Selective culture media containing antimicrobials are recommended to reduce contamination [B]¹⁷

Acute gonorrhoea in pregnancy has been associated with miscarriage, preterm labour, pre-labour rupture of membranes and an SGA fetus. If an acute infection occurs at the time of delivery or in association with ruptured membranes there is a 30–50 per cent risk of neonatal transmission. Neonatal

infection presents in the first few days of life as bilateral purulent conjunctivitis. Prompt treatment with antibiotics is required to prevent blindness.

Pregnant women should be managed as per non-pregnant adult guidelines in conjunction with a genitourinary physician. Management includes screening for other STIs and advice on avoiding intercourse until the treatment has been completed and confirmed by repeat swabs. It is also important that the woman's partner has tested negative or been treated. Treatment is with 500 mg ceftriaxone intramuscularly as a single dose with 1 g azithromycin orally as a single dose [C].¹⁷

KEY POINTS

- Up to 60 per cent of infections will be asymptomatic.
- The most common symptoms are vaginal discharge or pelvic pain.
- Management should be as per non-pregnant adult guidelines in combination with a genitourinary physician.

Listeria monocytogenes

Epidemiology and aetiology

Up to 10 per cent of people carry *Listeria*, a Gram-positive bacterium, in their intestinal tract. The likelihood of infection depends on the strain of pathogen and the person's susceptibility. The majority of people will be unaware of the infection; however, pregnant women are among those vulnerable to the infection, hence the advice to avoid foods with an increased risk of contamination, such as raw meat, unpasteurised milk and raw unwashed vegetables.

Diagnosis and management

Listeria sp. can cause a range of non-specific symptoms including 'a flu-like illness' with fever, nausea and vomiting. In those that experience complications they can go on to develop septicæmia and meningo-encephalitis. It is also classically linked with the presence of meconium in very premature infants. The diagnosis is made by symptom-triggered culturing of the organisms from blood, stool sample or cerebrospinal fluid (CSF), or from serological testing.

KEY POINTS

- *Listeria monocytogenes* is found in up to 10 per cent of human intestinal tracts.
- Pregnancy increases a person's susceptibility to infection.
- Women should be advised to avoid foods that have an increased listeria contamination risk.

Treatment should be with penicillin as in the non-pregnant woman. *Listeria* infection has been linked to miscarriage, premature labour and stillbirth.

Chlamydia

Epidemiology and aetiology

Chlamydia trachomatis is the most common curable STI in Britain. Approximately 5–10 per cent of sexually active women under the age of 24 are infected with the serotypes D–K, responsible for 'occulogenital' transmitted strains of the disease. Risk factors for infection include age under 25 years, new sexual partner or more than one sexual partner in the past year (a new sexual partner being more important than the number of sexual partners), and lack of consistent use of condoms. *C. trachomatis* infection is frequently asymptomatic in both men and women, and ongoing transmission in the community is sustained by this unrecognised infection. In response to the evidence of high and increasing rates of infection, the Government has introduced a national chlamydia screening programme,^{18,19} with recommendations that screening be offered to all sexually active women below the age of 25 years, and those over 25 years who had a new sexual partner or two or more partners in the last year. Screening is performed on first-catch urine samples by ligase reaction test.

Diagnosis and management

Symptomatic women may present with an abnormal vaginal discharge, dyspareunia, abdominal pain or dysuria. Untreated, it can result in pelvic inflammatory disease and perihepatitis. In pregnancy, as well as these symptoms, there have also been links to premature labour, premature rupture of the membranes and low birthweight. When the infection occurs at the time of delivery transmission to the neonate is possible. In untreated mothers 35–50 per cent will develop conjunctivitis and 11–20 per cent pneumonia.

Treatment in pregnancy differs from the standard, as tetracyclines are contraindicated. Instead a 7-day course of erythromycin is recommended. If not tolerated then a Cochrane review shows amoxicillin to be a suitable alternative in pregnancy [A].²⁰ Management should be, as with gonorrhoea, in conjunction with genitourinary physicians.

PROTOZOA

Trichomonas

Epidemiology and aetiology

Trichomonas vaginalis is a vaginal infection most commonly seen with co-infection with other STIs, in smokers and in women with decreased education level and increased sexual partners.

Diagnosis and management

Women typically present with an offensive, frothy, copious yellow–green discharge. Other symptoms include dyspareunia and vulvovaginal soreness. In pregnancy vaginal bleeding may also be associated. The diagnosis can be made by saline wet preparation identifying motile flagellated trichomonads, culturing, immunofluorescence and enzyme immunoassay techniques.

Management should be as per the non-pregnant woman including referral to a genitourinary physician and the use of metronidazole. It is uncertain if treatment reduces the association with preterm birth.

Toxoplasmosis and syphilis

These infections are covered in Chapter 36.

Chapter 25 Gestational diabetes

Clare L Tower

MRCOG standard

Core curriculum, Module 8 (Antenatal Care) and Module 9 (Maternal Medicine)

Knowledge criteria

Understand the purposes and practices of antenatal care including screening for abnormality and arrangements and conduct of booking and follow-up visits.

Understand the epidemiology, aetiology, pathophysiology, clinical characteristics, prognostic features and management of gestational diabetes:

- Impaired glucose tolerance and type 1 diabetes;
- Maternal, fetal and neonatal hazards;
- Ketoacidosis;
- Drugs (insulins and hypoglycaemic agents).

Be able to describe the natural history of diseases and illnesses that run a chronic course.

Have knowledge of long-term management plans for chronic conditions.

Clinical competency

Conduct a booking visit and arrange appropriate investigations. Understand the positive and negative effects of screening on the individual.

Diagnose, investigate and manage, with direct supervision, type 1 diabetes and impaired glucose tolerance.

INTRODUCTION

Gestational diabetes mellitus (GDM) is defined as impaired carbohydrate tolerance resulting in hyperglycaemia, which first develops or becomes diagnosed during pregnancy. Some of these women have previously undiagnosed diabetes, usually type 2. It is clinically important for the management of the pregnancy, but also because it significantly increases an individual's long-term risk of developing type 2 diabetes. Women developing GDM face similar increased risks as diabetic women in terms of macrosomia and its associated complications, neonatal hypoglycaemia and late pregnancy

loss. Furthermore, their offspring are at increased risk of obesity and diabetes in the future.

PREVALENCE

The prevalence of GDM varies with the diagnostic criteria used (discussed below) and with ethnic group. The ethnic groups at particularly high risk are women from south Asia (India, Pakistan and Bangladesh) who have a relative risk 7.6- to 11-fold compared with white women and black Caribbean women (relative risk 3.1). Thus, the overall prevalence of GDM is between 1 and 5 per cent.¹

EPIDEMIOLOGY

Studies investigating risk factors for development of GDM vary with the definition of the disorder used, which in turn is dependent on the type of testing (see below). Systematic reviews have suggested that the risk factors (Box 25.1) are obesity, advanced maternal age, previous gestational diabetes, family history of diabetes, specific ethnic groups as above, high weight gain in early adulthood and current smoking [A].

There has been much debate regarding the use of screening strategies to detect GDM, and studies have investigated the use of risk factors to guide screening. An RCT comparing risk-factor-based screening from the United States found positive predictive values for a first-degree relative with type 1 diabetes (15%), a first-degree relative with type 2 diabetes (6.7%), a previous baby >4.5 kg (12.2%), glycosuria (50%), current

Box 25.1 Risk factors for gestational diabetes¹

- Body mass index >30 kg/m²

suspected macrosomia and polyhydramnios (both 40%).² Other traditionally quoted risk factors for which less robust evidence exists include twin pregnancy, polycystic ovarian disease, parity (related to maternal age), previous congenital abnormality and previous stillbirth.

The risks of developing GDM in subsequent pregnancies are high, with recurrence rates between 30 and 84 per cent.¹ A systematic review found that the risk was highest in the ethnic groups at particular risk of an initial presentation of GDM.¹ Furthermore, women who have required insulin treatment for GDM in a previous pregnancy have a recurrence risk of 75%.

CAUSES

Pregnancy is a state of increased insulin resistance, secondary to the secretion of placental hormones such as progesterone, cortisol, placental lactogen, growth hormone and prolactin. This insulin resistance, evident by the second trimester, persists throughout the pregnancy and resolves with delivery of the placenta. Normal pregnant women demonstrate an increased pancreatic β -cell response and hyperinsulinaemia. This facilitates the supply of glucose to the fetus by altering maternal energy metabolism from carbohydrate to lipids. Women with GDM have an exaggeration of this insulin resistance, possibly due to a limited ability of the pancreatic β cells to increase insulin secretion. This may represent an early marker of deterioration in β -cell function. A subset (1–38%) of women with GDM have islet cell auto-antibodies, including insulin antibodies and glutamic acid decarboxylase antibodies. These women may be more likely to be of normal weight and are at increased risk of subsequent type 1 diabetes. A minority of women (<5%) have specific glucokinase mutation resulting in β -cell dysfunction and inability to compensate for the insulin resistance. During the third trimester, this impaired ability to compensate for the insulin resistance results in an increase in blood glucose levels in response to a glucose load. Although this may not be sufficient to cause symptoms, the excessive glucose load is able to exert an adverse effect on the fetus, through fetal hyperglycaemia and hyperinsulinaemia.

SCREENING AND DIAGNOSIS

There is now good evidence that the treatment of GDM improves pregnancy outcome and these women are at risk of type 2 DM in later life. Screening in pregnancy offers an opportunity for targeted surveillance and early intervention. Women with any of the risk factors listed in box 25.1 should be offered screening for GDM using the oral glucose tolerance test (OGTT) at 24–28 weeks.¹ This involves a fasting venous plasma glucose then ingesting a 75g glucose load and testing the venous plasma blood glucose at 2 hours (Table 25.1). In addition, women with more than 2+ glycosuria on a single urine dipstick, or + on 2 or more occasions should also be

offered testing.¹ Fasting or random blood glucose, HbA1c or urinalysis should not be used for screening.

According to the NICE Diabetes in Pregnancy guidelines 2015, a diagnosis of GDM is made if the fasting plasma glucose is 5.6mmol/litre or more, or the two hour level is 7.8mmol/litre or more [A].¹ Women should be advised that a diagnosis of GDM will require increased monitoring and may lead to an increased risk of intervention during both pregnancy and labour prior to testing, to enable them to make an informed choice about screening. They should also be informed that whilst GDM can respond to diet and lifestyle changes some women need treatment with oral medications or insulin.

The optimal screening and diagnostic criteria for GDM have been hotly debated over the years. The NICE guideline 2015 changed the diagnostic criteria substantially from the previous 2008 guidelines which recommended the use of the WHO 1999 definitions.¹ Since that time, the evidence base has increased,³ in particular with the publication of the Hyperglycaemia and Adverse Pregnancy Outcomes (HAPO) study.⁴ This study conducted blind 2-hour 75 g OGTTs in over 23,000 non-diabetic women worldwide to examine the association between fasting, 1-hour and 2-hour plasma glucose levels and the primary outcomes of macrosomia (birthweight over the 90th centile), fetal hyperinsulinaemia and caesarean section rates. Plasma glucose levels were associated on a continuum with adverse outcomes and there was no threshold effect [B]. In 2010, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) published a consensus document in an attempt to achieve universal agreement on diagnostic criteria for GDM.⁵ Using the HAPO data, it developed a recommendation based on odds ratios of 1.75 for the risk of macrosomia, fetal hyperinsulinaemia and neonatal adiposity. It suggested universal screening of all pregnant women at 24–26 weeks, using a 2-hour OGTT, with a diagnosis of GDM if any glucose levels given in Table 25.1 are exceeded. If these criteria had been applied to the HAPO dataset, cumulatively 8.3 per cent of women would be diagnosed with GDM based on fasting levels, 14 per cent on 1-hour levels and 16 per cent on 2-hour levels. This has large implications for healthcare resources,⁶ as it represents a substantial increase over the current rates of around 3.5 per cent.³ These recommendations have been adopted by the American Diabetes Association but not the American College of Obstetricians and Gynecologists.

In addition to the HAPO data associating higher glucose with poor outcomes, there is now evidence that diet,

Table 25.1 Criteria for the 2-hour 75 g OGTT in the diagnosis of GDM at 24–28 weeks' gestation³

	IADPSG/SIGN	NICE ¹
	Venous plasma blood glucose (mmol/L)	Venous plasma blood glucose (mmol/L)
Fasting	≥5.1	≥5.6
1 hour	≥10	-
2 hours	≥8.5	≥7.8

lifestyle intervention and pharmacological therapies both lower maternal glucose and modify fetal growth in women with milder levels of hyperglycaemia (discussed below). The NICE guidelines 2015 acknowledge that the quality of evidence was low to moderate in terms of defining the diagnostic criteria, and a health economic analysis was also considered. Notably, the recommended diagnostic criteria differ from the WHO 2013 guidelines that adopted the IADPSG diagnostic thresholds. The guidelines therefore acknowledge that new evidence, including more robust health economic data will likely lead to a further review of these guidelines in the next 3–5 years.¹ The SIGN (2010) guidelines suggested a similar strategy to the IADPSG recommendations but based on risk factors (Table 25.2).⁷

Due to the high risk of recurrence, women who have had GDM in a previous pregnancy should be offered either early self monitoring of blood glucose or a 2 hour 75g OGTT as soon as possible after booking. If this test is normal, a repeat test at 24–28 weeks is recommended.¹

MANAGEMENT

Congenital malformations

As expected from the pathogenesis, there is no excess risk of major congenital malformations in women developing GDM, as blood glucose would be expected to be normal during organogenesis. The exception to this is those women who have pre-existing diabetes would thus have had hyperglycaemia during the first trimester. Some UK centres have described 12–20 per cent of women with GDM as having persistently impaired glucose tolerance on postnatal testing, and are thus likely to have type 2 diabetes.

Antenatal care

After diagnosis, women should be offered a review in a Joint diabetic antenatal clinic within one week.¹ This will enable early discussion of the implications of GDM, and also the recommended management, which will include a discussion of diet and exercise. In addition, women should be taught how to self-monitor blood glucose and all women should be referred to a dietician. Antenatal care should be focused on reducing the risks of GDM, namely fetal macrosomia and the possible increased risk of pre-eclampsia.⁶ Women benefit from a multidisciplinary management approach with access to obstetricians, diabetologists, dieticians, specialist nurses and midwives.

Glycaemic control

Several studies have now demonstrated the benefits of treating GDM. The Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) trial was published in 2005.⁸ This study randomised 1000 women with impaired glucose tolerance, to routine care or diabetic care (diet, monitoring and insulin as appropriate). There was a lower rate of serious perinatal complications (defined as death, shoulder dystocia, fractures and nerve injury) in the 490 women in the intervention arm (1%), compared with 4% in the 510 women in the routine care group. More women in the intervention group underwent induction of labour and more babies were admitted to special care, but there was no increase in caesarean section rate and significantly fewer babies had macrosomia. The number of women needing treatment to prevent one adverse outcome was 34. A study using a similar design but more stringent thresholds for GDM diagnosis, with a fasting blood sugar of <5.3 mmol/L, showed a small reduction in birthweight in the treatment arm, a halving of

Table 25.2 SIGN (2010) criteria for diagnosis of GDM

Gestation	Test	Fasting glucose (mmol/L)	1-hour glucose (mmol/L)	2-hour glucose (mmol/L)	HbA1c (mmol/mol)	Diagnosis and action
Booking	Fasting sugar or HbA1c to all women with risk factors as in Box 25.1	≥7.0	-	≥11.1	≥48	Manage as pre-existing diabetes mellitus
		5.1–6.9	-	8.6–11	42–46	Intermediate levels; assess need for immediate home glucose monitoring or reassess using OGTT at 24–28 weeks
24–28 weeks	Low-risk women fasting blood sugar	As below	-	-	-	As below
	OGTT for women with risk factors as in Box 25.1	≥5.1	≥10	≥8.5	-	Diagnose GDM

the percentage of large-for-gestational-age infants and those weighing more than 4 kg, a reduction in risk of shoulder dystocia from 4 per cent to 1.5 per cent, and a reduction in risk of hypertensive disorders.⁹ The primary goal of treatment is to achieve near-normal glycaemic control using blood glucose monitoring, diet and exercise, oral hypoglycaemic agents and insulin therapy, as studies have shown that women achieving lower glucose levels (fasting ≤ 4.9 mmol/L and 2-hour postprandial levels of 5.9–6.4 mmol/L) had the lowest complication rates.¹⁰ NICE 2015 recommends that strategies to control blood glucose should be tailored to the individual woman, and her preferences should be considered in addition to her blood glucose monitoring profile.¹

Diet and exercise

Lifestyle modifications, including dietary changes and exercise should be offered to all women diagnosed with GDM. Studies have shown that diets high in carbohydrates of low glycaemic index (GI) can improve overall glycaemic control and postprandial hyperglycaemia [A]. Several small observational studies have suggested that obese pregnant women with GDM may improve glycaemic control without any risks of ketonuria with a moderate (30%) reduction in calorie intake [C]. Increased exercise may also have beneficial effects, with several small studies showing improved glucose control and reduced need for insulin. Therefore, NICE guidelines suggest that women with GDM should choose diets containing low-GI carbohydrates and low-fat proteins. They should also be advised to undertake moderate exercise (30 minutes a day). Walking for 30 minutes after a meal may help improve blood glucose control.¹

Diagnosis and recommended management as outlined in NICE guidelines 2015 are summarised in table 25.2 As an initial treatment, women with a fasting plasma glucose at diagnosis of less than 7mmol/litre should be offered diet and exercise as a method of controlling blood sugar¹ as long as there are no other complications present such as polyhydramnios or macrosomia. They should be advised to test a fasting and a blood glucose one hour after a meal every day and that they should aim for the recommended target blood glucose levels stated in box 25.3.

Box 25.2 Targets for daily capillary plasma glucose¹

Fasting less than 5.3mmol/l and
1 hour after meals less than 7.8 mmol/l or 2 hours after meals
of less than 6.4mmol/l

If after 1–2 weeks of diet and exercise, blood glucose is not within these recommended levels, additional therapy should be offered.

Pharmacological treatments

Overall, 82–93 per cent of women with GDM will achieve glycaemic control with diet alone.¹ Poor control of blood glucose is associated with similar complications as for women with pre-existing DM (macrosomia, birth trauma, neonatal hypoglycaemia, perinatal death, induction of labour and caesarean section). Therefore, NICE guidance suggests that hypoglycaemic therapy should be considered if diet and exercise fail to achieve blood glucose targets over a period of 1–2 weeks.¹ Oral hypoglycaemic agents and insulin have been discussed in detail in Chapter 9. Options for treatment include oral hypoglycaemic agents (metformin or glibenclamide), regular insulin or insulin analogues. The choice is dependent on the particular patient and will depend on glucose control and acceptability. There are several studies demonstrating the clinical and cost-effectiveness of glibenclamide and metformin in GDM. A large Australian RCT comparing metformin with insulin in GDM randomised 363 women to receive metformin (46% required supplemental insulin) and 370 to receive insulin.¹¹ The primary outcome, a composite of neonatal outcomes including neonatal hypoglycaemia, respiratory complications, birth trauma, phototherapy, low Apgar scores and preterm birth, was the same (32%) in both groups. Interestingly, there was significantly less severe neonatal hypoglycaemia in the metformin group, but also a slightly higher rate of preterm birth less than 37 weeks. There was no difference in birthweight between the two groups, and women in the metformin group demonstrated lower weight gain (although the difference may not be clinically significant). Furthermore, metformin was more acceptable to patients.

Table 25.3 Recommended management of GDM at diagnosis (NICE 2015)

Fasting Plasma Glucose mmol/l at diagnosis	Complications	Management	Recommended pattern of blood glucose monitoring
<7	none	1–2 week trial diet and exercise	Fasting + 1 hour post meal daily
6.0–6.9	Polyhydramnios Macrosomia	Insulin \pm Metformin in addition to diet and exercise	Oral therapy or single dose intermediate or long acting insulin: fasting and 1 hour post meal daily
≥ 7	-	Insulin \pm Metformin in addition to diet and exercise	Multiple daily insulin doses: fasting, pre-meal, post-meal and bedtime daily

Therefore, it appears that metformin is a safe and acceptable treatment for women with GDM [B]. Therefore the current Scottish guidelines (SIGN 2010) recommend initial metformin or glibenclamide for women in whom lifestyle measures have two or more values above the following targets in a 2-week period.⁷

- ≥ 5.5 mmol/L pre-meal or ≥ 7.0 mmol/L 2 hours post-meal at ≤ 35 weeks
- ≥ 5.5 mmol/L pre-meal or ≥ 8.0 mmol/L 2 hours post-meal at > 35 weeks
- Any post-meal levels > 9.0 mmol/L.

NICE guidelines (2015) recommend metformin if blood glucose is not within the targets stated in box 25.2 within 1-2 weeks of diet and exercise intervention. In addition, women with polyhydramnios or macrosomia and a fasting plasma glucose of between 6-6.9mmol/l should be offered immediate treatment with insulin, with or without metformin. Similarly, if fasting blood glucose is 7.0mmol/l or more at diagnosis, insulin, with or without metformin should be offered as a treatment in addition to diet and exercise.¹ This, and the recommended daily monitoring regimen is summarized in table 25.2. If metformin is contraindicated or the woman finds the treatment unacceptable, then insulin therapy should be offered. Glibenclamide can be offered as an alternative to women who decline insulin, or in whom metformin cannot be tolerated.¹ HbA1c levels should not be used for monitoring blood glucose control routinely in the second or third trimesters of pregnancy in women with GDM.¹ However, it is recommended that HbA1c is tested at the time of diagnosis of GDM in order to exclude pre-existing type 2 diabetes.

Fetal monitoring

Women with GDM are at risk of developing fetal macrosomia. It has been suggested that this can be detected and predicted by the measurement of fetal abdominal circumference on ultrasound. A cohort study of 201 women with GDM reported the sensitivity of abdominal circumference at 30–33 weeks' gestation to predict macrosomia as 88 per cent, with a specificity of 83 per cent. The positive predictive value was 56 per cent and the negative predictive value 96 per cent.¹² One RCT of 141 women with GDM compared ultrasound at 28 and 32 weeks with 32 weeks alone.¹³ Insulin therapy was commenced if the abdominal circumference was greater than the 75th percentile. This study found that there were more macrosomic babies in the group scanned only at 32 weeks. Thus, although there is a lack of robust evidence, NICE suggests that insulin therapy should be considered if macrosomia is present [C].¹ There are no studies clearly demonstrating benefits of particular monitoring regimens in terms of frequency of ultrasound scans. However, fetal monitoring should be conducted as for women with pre-existing DM (see Chapter 9).

Timing and mode of delivery

The majority of studies investigating timing and mode of delivery include women with pre-existing and gestational diabetes. This is discussed in Chapter 9. The timing and mode of delivery should be discussed with women, especially during the third trimester.

NICE recommends that pregnant women with uncomplicated GDM be offered elective birth no later than 40+6 weeks' gestation.¹ This represents a change from previous guidelines and the current Scottish guidelines (SIGN 2010) that suggest delivery between 38 and 40 weeks if parameters are normal.⁷ Patient management should be individualised and timing and mode of delivery considered in the context of glycaemic control and fetal ultrasound findings. Women with complications should be electively delivered before this gestation but a woman with diet-controlled GDM, with good control and no evidence of macrosomia, does not need delivery before 40+6 weeks.¹

Intrapartum care

Intrapartum maternal hyperglycaemia poses the same risks to the fetus of neonatal hypoglycaemia in GDM as in type 1 and type 2 diabetes. This is discussed in Chapter 9. Thus, blood glucose should be tested every hour and maintained between 4 and 7 mmol/L.¹ A sliding scale of intravenous insulin and dextrose should be instituted if blood glucose falls outside this range. However, this recommendation is based on a single study of 85 women with GDM [C]. Women who have not required treatment with insulin in the antenatal period are less likely to require IV insulin and dextrose. Similarly, women undergoing elective caesarean section are unlikely to require intraoperative insulin and dextrose infusions if they have not required antenatal insulin treatment. Women who require steroid treatment for lung maturity should be treated in the same way as women with pre-existing diabetes (see Chapter 9). In all cases, care of women should be individualised, and a jointly agreed care plan involving the obstetrician and diabetic team should be agreed antenatally and documented in the notes.

Postnatal care

Women with true GDM are unlikely to require insulin following delivery, so women with GDM should stop all hypoglycaemic agents (oral or insulin) immediately after birth. In order to detect women with previously undiagnosed pre-existing diabetes, it is recommended that blood glucose monitoring be conducted in the early postnatal period.¹ NICE do not recommend a particular regimen for postnatal testing, but pre-meal and bedtime testing until blood glucose levels return to normal (4–6 mmol/L), then once daily while an inpatient, would be appropriate. Contraception should also be discussed prior to discharge. Women should be reminded of the symptoms of high blood glucose.

Future risks of developing DM

Women who have developed GDM are at increased risk of subsequent type 2 diabetes, with rates of progression within 5 years between 15 and 50 per cent [C].¹⁴ Women should be advised of the symptoms of hyperglycaemia and advised that lifestyle or pharmacological modifications may reduce the likelihood of developing type 2 diabetes.^{1,7} However, this advice is based on studies conducted on populations including older individuals and men. A systematic review and meta-analysis concluded that lifestyle interventions reduced the progression of impaired glucose tolerance to type 2 diabetes with a hazard ratio of 0.51 [A].¹⁵ NICE guidelines (2015) therefore recommend that women undergo testing for diabetes between 6 and 13 weeks after birth [A].¹

Prior to the 2008 NICE guidelines, the recommended test was the 75 g OGTT at 6 weeks postpartum and annually thereafter.¹⁶ Subsequently a study suggested that a postnatal fasting plasma glucose of 6.0 mmol/L or more could be used to select women who should undergo a full glucose tolerance test.¹⁷ In this study of 122 women tested 6 weeks postnatally, the fasting plasma glucose had a sensitivity of 100 per cent and a specificity of 94 per cent for identifying diabetes compared with a glucose tolerance test [D]. Thus, NICE suggested that changing from a glucose tolerance test to fasting plasma glucose could represent a cost saving to the NHS.¹ Current NICE guidelines recommend a fasting plasma glucose at 6–13 weeks, which may most conveniently be performed when the woman attends for her postnatal check.¹ If this is not possible or has not been performed, a fasting glucose or HbA1c should be offered after 13 weeks. The recommended actions based on this test is outlined in table 25.4. Ongoing management of women at moderate or high risk of developing type 2 DM is outlined in the NICE guideline on preventing type 2 DM.¹² The thresholds for defining moderate or high risk of type 2 DM differ in these guidelines compared to those used for women who have had GDM, in order to recognize population differences between studies. Women whose postnatal screening test is negative should be offered annual testing for diabetes. The 2010 SIGN guidelines recommend assessment at 6 weeks postnatally with a fasting blood glucose and then an OGTT if clinically indicated, followed by annual fasting blood glucose or HbA1c.⁷

KEY POINTS

- GDM is impaired carbohydrate tolerance that first develops during pregnancy.
- GDM is associated with increased risks of macrosomia and its associated complications, neonatal hypoglycaemia and late pregnancy loss.
- There are many well-defined risk factors, the main ones being ethnic origin, obesity and GDM in a previous pregnancy.
- There is current debate regarding screening and diagnostic testing for GDM. NICE guidelines recommend that women at risk should be tested using the 2-hour 75 g OGTT at 24–28 weeks' gestation.
- Women who have had GDM in a previous pregnancy should be offered early self-monitoring of blood glucose or an OGTT as soon as possible after booking and repeat at 24–28 weeks if normal.
- Diagnose GDM using a 75g 2 hour OGTT. Diagnosis should be made if the fasting plasma glucose is 5.6mmol/l or more, or the 2 hour level is 7.8mmol/l or more.
- Treating GDM reduces the incidence of complications.
- Diet and lifestyle modifications should be offered to all women. Additional treatment with oral hypoglycaemic agents and/or insulin may also be needed.
- Pregnant women with GDM should be managed in a joint obstetric/diabetic clinic involving the input of obstetricians, diabetologists, dieticians, specialist nurses and midwives. Review should be offered within 1 week of diagnosis.
- Women should be taught how to self monitor plasma glucose
- The target for fasting plasma glucose is less than 5.3mmol/l.
- Postprandial levels should be less than 7.8 mmol/L.
- Women on insulin or glibenclamide should be advised to maintain plasma glucose above 4mmol/l.
- Women with GDM should be offered monitoring of fetal growth and wellbeing.
- Women with uncomplicated GDM should be offered elective delivery by 40+6 weeks gestation.. Care should be individualised, and will depend on glycaemic control and development of macrosomia.
- Women with macrosomia should have the risks and benefits of different modes of delivery discussed with them.

Table 25.4 Recommended postnatal testing and actions in women with GDM (1)

Fasting plasma glucose result	HbA1C Result	Recommended action
Less than 6.0mmol/l	Less than 39mmol/mol (5.7%)	Advise that there is a low chance of diabetes at present Continue with lifestyle advice as they have a moderate risk of developing type 2 DM (NICE guidelines for the prevention of Type 2 DM) ¹² Recommend annual test for DM
Between 6–6.9mmol/l	Between 39 and 47mmol/mol (5.7–6.4%)	Advise that the woman is at high risk for developing type 2 DM. Offer advice and interventions in line with the (NICE guidelines for the prevention of Type 2 DM) ¹²
7.0mmol/l or more	48mmol/mol (6.5%) or more	Type 2 DM is likely, offer diagnostic test (1)

- Maternal blood glucose should be monitored hourly during labour and be kept between 4 and 7 mmol/L during labour and delivery. Women who are diet controlled are unlikely to need any specific treatment during labour.
- Women GDM are unlikely to require insulin postnatally so should stop all hypoglycaemic agents immediately after birth.
- Women should undergo early postnatal glucose monitoring to ensure that their blood glucose is in the normal range.
- Women who have had GDM are at high risk of developing type 2 diabetes in the future. This risk can probably be reduced by lifestyle modifications.
- Women should be screened for diabetes at the 6-week postnatal check with a fasting plasma glucose and annually thereafter.
- All women should receive postnatal advice regarding contraception and planning their next pregnancy.

CONCLUSIONS

GDM is a common condition that is increasing in frequency, particularly in association with increasing obesity. If poorly controlled, as with pre-existing DM it is associated with increased maternal and fetal risks. There has been considerable debate regarding the best screening and diagnostic strategies. Women with a diagnosis of GDM require multidisciplinary management. Although most can be managed using lifestyle intervention, a significant proportion will require pharmacological measures. Fetal monitoring and delivery is largely similar to women with pre-existing DM. Women who develop GDM are at significant risk of subsequent development of type 2 DM, offering an opportunity for prevention in the form of diet and exercise.

Chapter 26 Pre-eclampsia and non-proteinuric pregnancy-induced hypertension

Andrew Shennan

MRCOG standards

- Conduct pre-pregnancy counselling to a level expected in independent primary care.
- Manage severe pre-eclampsia/eclampsia.

In addition, we would suggest the following:

Theoretical skills

- Distinguish between the different causes of hypertension in pregnancy.
- Understand the principles underlying the pathophysiology of pre-eclampsia.
- Describe and quantify the risk factors for pre-eclampsia.
- Know the principles of management of the woman who presents with pre-eclampsia.
- Advise a woman with a previous history of pre-eclampsia.

Practical skills

- Know how to manage the woman with severe pre-eclampsia; this will involve detailed knowledge of fluid management, hypertension control, anticonvulsant prophylaxis and anaesthetic issues.
- Be able to treat eclampsia.

INTRODUCTION

Women who are hypertensive and pregnant must be subdivided into those with:

- chronic hypertension (see Chapter 8);
- pregnancy-induced or gestational hypertension (PIH).

Women with PIH are subdivided further: the majority have non-proteinuric PIH, a condition associated with less maternal

or perinatal mortality/morbidity, whereas a minority have the major pregnancy complication of pre-eclampsia.

It is imperative that every effort is made to accurately classify women with hypertension in pregnancy as having chronic hypertension, non-proteinuric PIH or pre-eclampsia. The aetiology and management of the three conditions are very disparate, as are implications for future pregnancies. The aetiology and management of chronic hypertension in pregnancy are discussed in Chapter 8. Women with non-proteinuric PIH need to be monitored to ensure that proteinuria does not develop and pre-eclampsia become apparent; non-proteinuric PIH is not an indication for admission unless there is severe hypertension, but induction of labour or antihypertensive treatment may be considered depending on gestation and blood pressure. This chapter focuses on pre-eclampsia.

Even in developed countries, women still die from pre-eclampsia and eclampsia, although most deaths are avoidable.¹ In the UK, fewer than ten women die each year. Eclampsia is now rarely associated with mortality, although severe hypertension and cerebral vascular accidents still occur.² Eclampsia has an estimated incidence in the UK of 26.8 cases per 100,000 maternities.² There were no maternal deaths in any eclamptic women, possibly attributed to the more judicious use of magnesium sulphate. Worldwide, however, maternal mortality from hypertensive disease accounts for approximately 60,000 deaths per year.

Because of concerns about the potential adverse effects of pre-eclampsia, many women who have a normal outcome require intensive surveillance; up to a quarter of antenatal admissions are as a direct result of monitoring and managing women with hypertension. Antenatal care is directed towards identifying women with hypertension and proteinuria. Day units reduce the need for inpatient management, but current methods for screening women at risk are poor and the onset and progression of the disease are unpredictable.

Perinatal mortality is also increased with pre-eclampsia. Pre-eclampsia is associated with IUGR, particularly when early in onset. Placental involvement also explains the association with placental abruptions. As delivery is the only cure,

the hypertensive diseases of pregnancy have become the most common cause of iatrogenic preterm birth. They account for 15 per cent of all preterm births, but up to a quarter of very-low-birthweight infants. There is strong evidence linking size at birth to health in adulthood, i.e. there are fetal origins of adult disease.³ Thus, the small babies resulting from pregnancies affected by pre-eclampsia have health implications in adult life, including an increased risk of hypertension, heart disease and diabetes when they become adults. Additional and significant longer-term health service resource implications result from subsequent learning disabilities and low IQ. Maternal disease severity and fetal involvement do not always correlate; for example, the babies of women who have eclampsia at term often have normal birthweight.²

CLASSIFICATION AND DEFINITION

The term 'pregnancy-induced hypertension' usually implies hypertension caused by, but unrelated to, other pathology associated with the pregnancy, a diagnosis that is difficult to make until after the pregnancy has ended.

Blood pressure and proteinuria define pre-eclampsia, but they are not fundamental to the aetiology and are more indicative of end-organ damage. In clinical practice, the threshold of abnormality is set low to identify at-risk cases, but this results in many women being identified with hypertension and/or proteinuria who are not at increased risk.

The International Society for the Study of Hypertension in Pregnancy (ISSHP), based on the recommendation of Davey and MacGillivray,⁴ uses the term 'gestational hypertension' to include all women with PIH whether proteinuric or not, as long as they had been previously normotensive and not proteinuric. Once proteinuria has developed, this is assumed to be pre-eclampsia (Box 26.1).

If any organ system known to have the potential to be affected by pre-eclampsia is involved, the possibility of the disease must be suspected; hypertension and proteinuria cannot be relied upon to define the disease. However, for pragmatic reasons, these signs must remain hallmarks for definition. Tests for liver, kidney, blood and placental involvement should always be sought if pre-eclampsia is suspected (see below).

INCIDENCE

The prevalence of pre-eclampsia varies with the definition used and the population studied; however, pre-eclampsia occurs in less than 5 per cent of an average antenatal population. In some recent prospective studies, the incidence has been as low as 2.2 per cent, even in a primigravid population, in which the condition is known to have the highest prevalence.⁵ The incidence of non-proteinuric PIH is approximately three times greater. Pre-eclampsia in women with a single risk factor is approximately 15 per cent.

Box 26.1 ISSHP classification (modified and abbreviated)

A. Gestational hypertension and/or proteinuria developing during pregnancy, labour or the puerperium in a previously normotensive non-proteinuric woman

1. Gestational hypertension (without proteinuria)
2. Gestational proteinuria (without hypertension)
3. Gestational proteinuric hypertension (pre-eclampsia)

B. Chronic hypertension (before week 20 of pregnancy) and chronic renal disease (proteinuria before week 20 of pregnancy)

1. Chronic hypertension (without proteinuria)
2. Chronic renal disease (proteinuria with or without hypertension)
3. Chronic hypertension with superimposed pre-eclampsia (new-onset proteinuria)

C. Unclassified hypertension and/or proteinuria

D. Eclampsia

Definitions

Hypertension in pregnancy:

- Diastolic BP >110 mmHg on any one occasion or
- Diastolic BP >90 mmHg on two or more consecutive occasions >4 hours apart

Proteinuria in pregnancy:

- One 24-hour collection with total protein excretion >300 mg/24 hours or
- Two 'clean-catch midstream' or catheter specimens of urine collected >4 hours apart with 2+ on reagent strip

AETIOLOGY

Although the primary events leading to pre-eclampsia are still unclear, it is now widely believed that a cascade of events leads to the clinical syndrome (summarised in Fig. 26.1). Although the inheritance of pre-eclampsia has yet to be characterised, there is a strong familial predisposition: a family history in either mother or sister increases the risk of pre-eclampsia four- to eight-fold. This genetic predisposition leads to a faulty interplay between the invading extravillous trophoblast cells (of fetal origin) and the maternal immunologically active decidual cells.

The faulty interplay results in a failure of trophoblast invasion into the myometrium and the maternal spiral arteries do not undergo their physiological vasodilatation.⁶ Only the most superficial decidual portion of the spiral artery is invaded by the trophoblast. This inadequate trophoblast invasion is also seen in pregnancies complicated by fetal growth restriction (without pre-eclampsia), demonstrating that the maternal syndrome of pre-eclampsia must be related to additional factors.

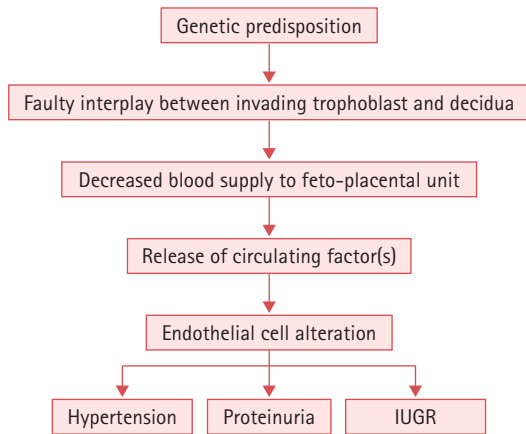

Fig. 26.1 Aetiology of pre-eclampsia. IUGR, intrauterine growth restriction

The diminished dilatation of the spiral arteries, associated increased resistance in the uteroplacental circulation and an impaired intervillous blood flow probably result in an inadequately perfused placenta. Ischaemia or ischaemia/reperfusion in the second half of gestation produces reactive oxygen species and oxidative stress in the placenta.

The placental hypoperfusion is also postulated to result in the secretion of a factor(s) into the maternal circulation that causes ‘activation’ of vascular endothelium.⁷

Endothelial cell activation explains the widespread manifestations of the disease, as the vascular endothelium trophoblasts regulate the remodelling of spiral arteries and enable normal vasculogenesis mediated through pro-angiogenic factors such as vascular endothelial growth factor (VEGF) and placental growth factor (PlGF). Soluble Fms-like tyrosine kinase 1 (sFLT-1) is a variant of the VEGF receptor, which is up-regulated in pregnancies with pre-eclampsia. It is known to antagonise VEGF and PlGF. Angiogenic factors are now increasingly used to predict⁸ and aid in management (see below).

Endoglin (sEng) is associated with pre-eclampsia as early as 15 weeks. PlGF increases from the first trimester but less so in those destined to develop pre-eclampsia, while sFLT-1 will increase.

Many markers of endothelial damage are raised. Pre-eclampsia is associated with lipid changes (there is a two-fold increase in triacylglycerols and free fatty acids), and an increase in lipid peroxidation, both in the placenta and systemically, suggests that oxidative stress (an imbalance between free radical synthesis and antioxidant defence) may be involved in the endothelial cell changes.

MANAGEMENT

Screening for pre-eclampsia

History

More than a third of pre-eclampsia cases occur in women with risk factors; a careful history will allow the clinician to assess risk.

A family history in a first-degree relative increases the risk of pre-eclampsia four- to eight-fold, illustrating the strong genetic influence [D]. A woman has double the risk of pre-eclampsia if pregnant by a partner who had previously fathered an affected pregnancy [D].

An immunological element to the disease process is evidenced by the effect of exposure to the paternal antigen, via either the fetus or the partner. Pre-eclampsia occurs more commonly in first pregnancies; miscarriages or terminations of pregnancy provide some reduction in risk in subsequent pregnancies [D]. However, in women with chronic hypertension, a prior miscarriage is a risk factor for progression to pre-eclampsia. A new partner increases risk, whereas non-barrier methods of contraception and increased duration of sexual cohabitation reduce risk [D].

Exposure to a partner’s ‘foreign’ antigens is common to these phenomena. Teenage mothers and pregnancies conceived by donor insemination have increased risk of pre-eclampsia, presumably due to the lack of exposure to such antigens [D].

Underlying medical disorders, particularly those involving vascular disease – such as chronic hypertension – increase the risk of pre-eclampsia (to over 20 per cent); this highlights the importance of the maternal susceptibility, as well as the placental aetiology in the disease process. All forms of glucose intolerance, including GDM, are associated with an increased risk [D]. This may be related to obesity, which is an independent risk factor.

Women with antiphospholipid syndrome and multiple pregnancies are at increased risk. Risk may be related to the size of the placenta; molar pregnancies have been associated with pre-eclampsia, as have pregnancies complicated by hydrops fetalis (mirror syndrome) or trisomy.

Women with a history of pre-eclampsia, particularly those requiring delivery before 37 weeks, all have about a 20 per cent chance of developing pre-eclampsia again [D].

Biophysical tests

The detection of raised blood pressure in early gestation is related to the subsequent risk of pre-eclampsia, even within the normal blood pressure range (i.e. the lower the blood pressure, the lower the risk). Automated blood pressure monitoring removes many of the errors of standard sphygmomanometry, but is only a weak indicator of risk, and these monitors may under-read in pre-eclampsia [D]. Two other biophysical tests have been investigated, but are not useful: isometric exercise testing and the roll-over test. Problems with reproducibility and poor predictor values mean that these have not been introduced into clinical practice. The angiotensin II sensitivity test, involving assessing the blood pressure response to infusion of the vasoconstrictor angiotensin II, has also shown poor predictor values in larger studies and is invasive, time-consuming and costly [B].

In contrast, Doppler analysis of the uterine artery waveform has reasonable sensitivity and specificity, and is relatively quick, non-invasive and relatively inexpensive if performed

at the same time as other ultrasound scans. Poor placental perfusion is a characteristic feature of pregnancies destined to develop pre-eclampsia, and therefore it would seem logical to identify those women who have increased resistance in this circulation. In pregnancies at increased risk of pre-eclampsia, there is persistence of a relatively high-resistance circulation with a notch. The later this test is performed, the better the predictive values [D]. At 20 weeks' gestation in a low-risk population, approximately one in five women will develop pre-eclampsia if she has an abnormal waveform; the prediction value is considerably greater at 24 weeks [D]. This screening test does allow women to be targeted for increased surveillance and possible prophylactic therapies. The importance of screening tests will escalate if an adequate treatment to prevent pre-eclampsia is established.

Biochemical tests

The simple measurements of plasma volume, haemoglobin concentration and haematocrit all have a weak association with the development of pre-eclampsia, but poor prediction values [D]. Uric acid and platelets are sometimes measured in women with chronic hypertension to predict superimposed pre-eclampsia, but are lacking in sensitivity and specificity. The measurement of second-trimester hCG and maternal serum AFP is associated with a two-fold increase in pre-eclampsia, and is likely to reflect the disease process that occurs at the uteroplacental interface [D]. This may also explain why low pregnancy-associated plasma protein (PAPP-A) is associated with higher risks in later pregnancy. These increases in risk are not sufficient to alter clinical practice significantly. Many markers of endothelial activation have been shown to be increased in pre-eclampsia. Some will rise before the clinical manifestations of the disease, but there is invariably overlap between the women who are subsequently normal and those who develop pre-eclampsia, again limiting clinical usefulness. Urinary excretion of calcium, microalbuminuria and prostacyclin metabolites have been investigated, as well as urinary kallikrein:creatinine ratios, and further work may eventually establish a combination of tests that could be clinically useful, perhaps by combining endothelial and placental markers of the disease. More recently, sFLT-1 and PlGFs have been used as a ratio to enhance prediction with better prediction than previous tests, but these have not been adopted into clinical practice.

The role of prophylaxis

Surveillance and timely delivery are the essence of current antenatal management in order to prevent the consequences of pre-eclampsia. Preventing the manifestation of the disease would be highly preferred. There are a number of potential therapies that have been investigated in an effort to prevent the occurrence of pre-eclampsia. Aspirin, calcium and fish oils have gained the most focus in this regard, although other substances, such as magnesium, zinc and even rhubarb, have been investigated. Aspirin, a cyclooxygenase enzyme inhibitor, reverses the imbalance between the vasoconstrictor

thromboxane A₂ and the vasodilator prostacyclin that is known to occur in pre-eclampsia. In a meta-analysis of individual patient data (31 randomised trials and 32,217 women), the use of anti-platelet agents (particularly low-dose aspirin) resulted in a significant 10 per cent reduction in the relative risk of both pre-eclampsia and serious adverse outcome.⁹ The number needed to treat in order to prevent pre-eclampsia was 114 and to prevent one serious adverse outcome was 51. Aspirin should be seriously considered in the management of very high-risk women and is likely to be safe. The dose, timing and the populations to be targeted are still being thoroughly investigated.

In a review of 12 RCTs in 15,206 women, calcium supplementation resulted in a significant reduction (52 per cent) in the relative risk of pre-eclampsia, with a higher effect in those at high risk (78 per cent) and with low calcium intake (64 per cent). Calcium supplementation may reduce parathyroid hormone release and intracellular calcium, leading to a reduction in smooth muscle contractility in women at risk of developing pre-eclampsia.¹⁰ Calcium supplementation warrants further research.

Fish oils containing *n*-3 fatty acids are thought to inhibit platelet thromboxane A₂. However, the four trials that have investigated their use have not shown any reduction in pre-eclampsia [A].

Improvements in prediction now allow increased surveillance and possible prophylactic therapies to be targeted. The importance of these tests will escalate if an adequate treatment to prevent pre-eclampsia is established. The promise of angiogenic markers combined with clinical risk factors now provides a realistic strategy to target therapies.⁸

The potential role of oxidative stress in the aetiology of the maternal syndrome of pre-eclampsia has resulted in a number of studies on the supplementation of antioxidant vitamins C and E. However, none of these has shown benefit.

Maternal and fetal assessment

Before any management decisions are made, the first task is to confirm the diagnosis of pre-eclampsia (see above under Screening for pre-eclampsia), in order to ensure that iatrogenic morbidity does not ensue [E].

When women present with hypertension, both the gestational age and the previous pregnancy history are important factors in establishing risk of progression to pre-eclampsia: late-onset hypertension after 37 weeks' gestation rarely results in serious morbidity to mother or baby [D], but prophylactic delivery may be justified as maturity is likely and induction of labour does not result in increased risk of caesarean section [A]. However, hypertension that presents early, particularly before 28 weeks, will result in pre-eclampsia developing in almost half of women.

Care in assessing blood pressure will prevent misdiagnosis; blood pressure measurement is poorly performed in clinical practice, for example digit preference (the practice of rounding the final digit of the blood pressure to 0) occurs in more than 80

per cent of antenatal measurements. The antenatal population within the UK has a significant proportion of obese women. The standard bladder used in sphygmomanometer cuffs (23 × 12 cm) undercuffs about a quarter of the antenatal population, resulting in the overdiagnosis of hypertension, usually by more than 10 mmHg. Overcuffing underestimates measurements, but usually by less than 5 mmHg, and is preferable in cases of doubt. Keeping the rate of deflation during measurement to 2–3 mm/s will prevent overdiagnosing diastolic hypertension. A similar effect is achieved by using Korotkoff 5; fewer women will be diagnosed as hypertensive than when Korotkoff 4 is used. Korotkoff 4 is also less reproducible [C], and RCTs have confirmed that all healthcare providers should be using Korotkoff 5 when measuring blood pressure in pregnancy [B]. Repeating the blood pressure, or obtaining a series of readings in the day unit, will limit the overdiagnosis of hypertension [E].

Errors in the interpretation of proteinuria are also common with dipstick urine analysis, and 24-hour collections of urine are necessary to confirm the diagnosis [E]. More than 300 mg in 24 hours is considered abnormal. Newer automated devices that can be used by the bedside relate the proteinuria to creatinine, and closely equate to 24-hour collections. The point-of-care test for albumin:creatinine ratio has an overall sensitivity of 97 per cent, a specificity of 98 per cent, a positive predictive value of 92 per cent and a negative predictive value of 99 per cent, which is equally effective regardless of the time of testing.

Every effort should be made to identify women at risk of life-threatening complications. Most women who present with eclampsia will not have had a recent blood pressure or urine analysis that was sufficiently abnormal to have identified them as at risk. Only just over half of women who presented with eclampsia had had prior hypertension and proteinuria diagnosed together. Blood pressure and proteinuria cannot be relied upon alone. The syndrome of pre-eclampsia is multisystemic and it is the ease of measurements of hypertension and proteinuria that has led to their adoption in the diagnosis of pre-eclampsia. Other organ involvement must be considered, such as fetal involvement, or other signs, such as epigastric tenderness. For pragmatic reasons, other signs have not been introduced to define the disease, but they are equally important.

Management remote from term

Early onset pre-eclampsia is frequently associated with placental insufficiency, which can result in IUGR, abruption of the placenta and fetal death [C]. Fetal wellbeing must be carefully considered in all cases. A symphyseal–fundal height should be carefully measured in all women who present with pre-eclampsia, in addition to an enquiry as to fetal movements [E]. At early gestations, or in pregnancies with suspected IUGR, it is usual to confirm fetal growth with ultrasound, and to assess the amniotic fluid volume and umbilical artery Doppler waveform [E]. Suspected fetal compromise is a frequent cause for delivery in pre-eclampsia.

Involvement of other organ systems in the affected women must be sought.

- Platelets are consumed due to the endothelial activation. A platelet count $>50 \times 10^9/L$ is likely to support normal haemostasis [E]; however, a falling platelet count, particularly to $<100 \times 10^9/L$, may indicate a need to consider delivery [E].
- Hypovolaemia results in an increased haematocrit and the haemoglobin may also be raised.
- If delivery or induction of labour is likely to be imminent, or if the platelet count is low, it is also sensible to screen for clotting abnormalities [E]. Pre-eclampsia can cause disseminated intravascular coagulation, and clotting must be adequate for regional anaesthesia.
- Uric acid, a measure of fine renal tubular function, is used to assess the disease severity, although severe disease can still occur with a normal uric acid level. Spuriously high levels of uric acid are associated with acute fatty liver of pregnancy.
- Raised urea and creatinine are associated with late renal involvement, but are not useful as an early indicator of disease severity (serial measurements may identify renal disease progression) [E].
- Pre-eclampsia can cause subcapsular haematoma, liver rupture and hepatic infarction, and liver transaminases should be measured. Aspartate transaminase (AST) and other transaminases indicate hepatocellular damage, and elevated levels may again indicate a need to consider delivery. It should be remembered that the normal range for transaminases is approximately 20 per cent lower than the non-pregnant range [C].

When liver involvement is associated with haemolysis and low platelets, this is known as HELLP (haemolysis, elevated liver enzymes and low platelet count) syndrome, which is a severe variant of pre-eclampsia. If proteinuria excretion is high (usually >3 g/24 hours), circulating albumin may fall, increasing the risk of pulmonary oedema. A raised AST can be associated with either haemolysis or liver involvement; lactate dehydrogenase levels are also elevated in the presence of haemolysis.

More recently it has been demonstrated that PlGF can be used in women with suspected disease to accurately determine who will require delivery in the short term (Chappell circulation).¹¹

Corticosteroids should be given to enhance fetal lung maturity and are safe in pre-eclampsia [D]. Steroid therapy may assist in the recovery from the HELLP syndrome and has been used in the postpartum period. It is not unusual to see a slight improvement in biochemical parameters in the ante-natal period associated with corticosteroid use [D].

The treatment of moderate hypertension may be detrimental to fetal growth [D].¹² However, severe hypertension should be avoided, and blood pressures $>150/110$ mmHg require urgent therapy (see below) [E].¹³

In women with an established diagnosis of pre-eclampsia, delivery should be considered once fetal lung maturity is likely (approximately 32 weeks' gestation), particularly if either maternal multi-organ involvement or fetal compromise

is apparent. However, women with pre-eclampsia presenting between 28 and 32 weeks can often be managed conservatively without substantial risk to the mother, as long as close inpatient supervision is maintained [E]. In such cases, conservative management reduces neonatal morbidity without significantly increasing maternal morbidity.

Maternal indications for delivery include an inability to control hypertension, deteriorating liver or renal function, a progressive fall in platelets or neurological complications. A non-reactive CTG with decelerations or a fetal condition that is clearly deteriorating often warrants delivery. It is now recognised that delivery at 37 weeks improves outcomes without detrimental effects on mode of delivery and the American College of Obstetricians and Gynaecologists recommends routine delivery even in women with hypertension without an established diagnosis of pre-eclampsia.¹⁴

Labour ward management of pre-eclampsia

A set protocol should be followed when a woman has severe pre-eclampsia [E].¹³ All staff working on the labour ward must be familiar with the protocol in use. Typical entry criteria for such a protocol would be:

- eclampsia, or
- severe hypertension (>160/110 mmHg) with + or >1 g/24 hours proteinuria, or
- hypertension (>140/90 mmHg) with ++ or >3 g/24 hours proteinuria with an additional complication such as headache, visual disturbance, epigastric pain, clonus (more than three beats) or a platelet count <100 × 10⁹/L or AST >50 IU/L.

The two main reasons why women die, as demonstrated by the Confidential Enquiry, are cerebral haemorrhage and adult or acute respiratory distress syndrome,¹ and the two most important aetiological factors for these are severe hypertension and excess fluid intake. Control of blood pressure and fluid balance is therefore crucial.

Intrapartum blood pressure control

Blood pressure should be measured frequently (every 15 minutes) [E]. To facilitate this, automated sphygmomanometers may be used, but these oscillometric devices under-read the blood pressure in pre-eclampsia. Large changes in blood pressure should therefore be confirmed with a mercury sphygmomanometer [E].

As intracerebral haemorrhage complicates a significant proportion of deaths, mean arterial pressures (MAPs) are used to guide management, and most protocols recommend the instigation of IV anti-hypertensive therapy at MAP >125 mmHg [E]. Labetalol is now recommended as first-line treatment [C]. Regimens vary but NICE guidelines now recommend a standard approach to hypertensive management (Viscintin) (Box 26.2).

Box 26.2 NICE hypertension guidelines

- Labetalol: IV bolus of 20 mg if the MAP remains >125 mmHg, followed at 10-minute intervals by 40-, 80-, 80-mg boluses, up to a cumulative dose of 220 mg. Once MAP is <125 mmHg, an infusion of 40 mg/h is commenced, doubling (if necessary) at 30-minute intervals, until a satisfactory response or a dose of 160 mg/h is attained.
- If labetalol is ineffective, hydralazine can be used. Third-line agents include sodium nitroprusside and nifedipine.

Hydralazine: IV bolus of 5 mg if MAP remains >125 mmHg, followed by further boluses of 5 mg up to a cumulative dose of 15 mg. Once the MAP is <125 mmHg, an infusion of 10 mg/h is commenced, doubling (if necessary) at 30-minute intervals, until a satisfactory response or a dose of 40 mg/h is attained.

Colloid should be infused prior to treatment if the baby is undelivered, to protect the uteroplacental circulation and prevent hypotension and fetal distress [E].

Fluid management

As women with pre-eclampsia can have a reduced intravascular volume, leaky capillary membranes and low albumin levels, they are prone to pulmonary oedema. Renal failure is a rare complication of pre-eclampsia that usually follows acute blood loss, when there has been inadequate transfusion, or as a result of profound hypotension. Oliguria without a rising serum urea or creatinine is a manifestation of severe pre-eclampsia and not of incipient renal failure.

Administration of intravenous fluid in response to oliguria must be performed with caution [E].

Most protocols limit fluid intake (in the form of IV crystalloid) to approximately 1 mL/kg per h [E]. A Foley catheter should be inserted and fluid balance recorded.

In a well-perfused women, oliguria (<400 mL/24 h) requires no treatment as such. A low threshold for CVP assessment is recommended; in the absence of invasive monitoring, repetitive fluid challenges are to be avoided. If the CVP is high (>8 mmHg) with persistent oliguria, a dopamine infusion can be considered (1 µg/kg per min) [E]. If the creatinine or potassium rises, haemodialysis or haemofiltration may be necessary, and the advice of a renal physician should be sought. The administration of diuretics temporarily improves urine output, but further decreases the circulating volume and exacerbates electrolyte disturbances; furosemide should be given only if there are signs of pulmonary oedema [E]. In particularly difficult cases, pulmonary artery catheterisation should be considered.

Anticonvulsant therapy

Magnesium sulphate (up to 8 g) can be used to control an eclamptic fit. Alternatively, diazepam (10 mg) can be used [E], although its depressive properties are longer lasting than the anticonvulsant properties. An eclamptic fit is usually

self-limiting, and prolonged fitting warrants a brain scan to rule out other pathology, such as an intracerebral bleed [E].

If an eclamptic fit occurs, magnesium sulphate is the prophylaxis of choice, as demonstrated by the Eclampsia Trial [B].¹⁵ In addition to reducing the incidence of further fits, the benefits of magnesium sulphate over both diazepam and phenytoin include a significantly lower need for maternal ventilation, less pneumonia and fewer intensive care admissions. Magnesium sulphate acts as a membrane stabiliser and vasodilator and reduces intracerebral ischaemia. It is usually given as a 2 g IV loading dose and a maintenance infusion at 1–2 g/h. In cases of oliguria, care must be taken, as magnesium sulphate is renally excreted. Toxicity is detected by the absence of patellar reflexes, but ultimately respiratory arrest and muscle paralysis or cardiac arrest will occur. The antidote is 10 mL of 10 per cent calcium gluconate.

Even with severe pre-eclampsia, eclamptic fits are rare (<1 per cent). However, the Magpie Trial evaluated magnesium sulphate versus placebo in women with pre-eclampsia and demonstrated a clear benefit of prophylactic therapy [A]. Magnesium sulphate halved the risk of eclampsia and probably reduced the risk of maternal death. There did not appear to be any substantive harmful short-term effects to either the mother or baby.^{15,16} Magnesium sulphate also reduces the risk of cerebral palsy in the fetus and is recommended for this reason alone in all premature deliveries prior to 32 weeks. The mother should receive the medication as per normal pre-eclamptic protocols.¹⁷

Anaesthesia

A general anaesthetic can be dangerous, as endotracheal intubation can cause severe hypertension. Regional blockade is the preferred method of analgesia for labour and of anaesthesia for operative deliveries [E], but a coagulopathy must be excluded. Platelet levels of $<80 \times 10^9/L$ should ensure haemostasis, and most obstetric anaesthetists will insert a regional block under these circumstances. Care must be taken to avoid arterial hypotension (particularly following postpartum haemorrhage) in view of the vasoconstriction and reduced intravascular volume. A low threshold for central invasive monitoring is necessary in women who require a caesarean section [E].

Postpartum care

As a third of eclamptic fits occur postpartum, intensive monitoring is required, usually for 48 hours after delivery. Although eclampsia has been reported beyond this time, it is unlikely to be associated with serious morbidity. Blood pressure is frequently at its highest 3–4 days after delivery. Antihypertensive therapy may therefore need to be continued after discharge home; in the absence of fetal considerations, the most effective therapy can be used – and drugs such as methyl-dopa discontinued.

All women who have suffered severe pre-eclampsia should be reviewed at a hospital postnatal clinic 6–12 weeks after delivery [E]. In addition to blood pressure and urine testing, tests of

renal and liver function should be instigated; residual disease may merit referral to a physician. Underlying predispositions to pre-eclampsia, such as an inherited thrombophilia or APS, should be excluded (multiparous women are more likely to have an underlying cause). The postnatal visit is also an excellent opportunity to discuss complications of the pregnancy and the planned management of any future pregnancy.

FUTURE CARDIOVASCULAR RISK

Women with pre-eclampsia have a four-fold increased risk of developing hypertension and nearly a two-fold increased risk of ischaemic heart disease, stroke and venous thromboembolism, even up to 14 years after the index pregnancy. Women who have early pre-eclampsia are at highest risk.¹⁵ This reflects a possible common aetiology or a long-term effect on disease development and highlights the possible need for earlier cardiovascular risk assessment and the commencement of preventive therapies at an earlier age. It is plausible that active assessment of cardiovascular risk up to 6 months postpartum may lead to earlier identification of cardiovascular risk and the potential for lifestyle modification.¹⁸

KEY POINTS

- Pre-eclampsia is a multisystem disorder involving the placenta, liver, kidneys, blood, and neurological and cardiovascular systems; hypertension and proteinuria are diagnostic signs.
- Both maternal and fetal morbidity and mortality are more likely to occur with early onset disease.
- Despite the many tests being investigated, pre-eclampsia cannot be accurately predicted. An abnormal uterine artery Doppler at 20 weeks will increase risk approximately six-fold in both high- and low-risk women.
- Cerebral haemorrhage and adult respiratory distress are common causes of death in pre-eclampsia; therefore acute management focuses on controlling blood pressure and restricting fluid intake.
- The use of anti hypertensive therapy in moderately hypertensive women demonstrates a significant reduction in severe hypertension only; there are no other proven additional benefits.
- Low-dose aspirin in pregnancy results in a small (10 per cent) but significant reduction in pre-eclampsia; there is an associated reduction in preterm delivery.
- Magnesium sulphate is the anticonvulsant of choice following an eclamptic fit, resulting in fewer fits and less maternal morbidity compared with diazepam and phenytoin. There is also a clear benefit to prophylactic magnesium sulphate therapy – the risk of eclampsia is halved, and the fetus may have a lower risk of cerebral palsy.

Chapter 27 Medication in pregnancy

Clare L Tower

MRCOG standards

There is no specific established standard for this topic, but we would suggest the following points for guidance. A good understanding of prescribing principles is necessary as this has relevance to the large majority of core modules.

INTRODUCTION

As around a third of pregnancies are unplanned, pregnant women conceive while taking a wide variety of both prescription and over-the-counter medications. It is reported that approximately 50 per cent of women will take medication during pregnancy.¹ Many pregnant women require medication for specific pregnancy- and non-pregnancy-related conditions. Therefore, a broad understanding of the impact of pregnancy on drug pharmacokinetics (drug handling) and pharmacodynamics (drug actions) is required. Furthermore, the large majority of drugs cross the placenta, and some drugs have significant fetal effects. For this reason, most drugs are not licensed for use in pregnancy, thus prescribing in pregnancy often lies outside licensed indications. A detailed discussion of all drugs is beyond the scope of this book. Therefore, this chapter will review the general principles and provide examples. A detailed discussion of prescribing for particular disorders during pregnancy can be found in the relevant sections of this book.

PRE-CONCEPTION COUNSELLING

Encountering women of reproductive age with significant medical problems, for which they are taking prescribed medications, is becoming increasingly common. It is beneficial for many of these women to be seen pre-conceptually for several reasons. First, it allows optimisation of therapy such that pregnancy can be commenced with the lowest achievable risks. Typical examples of this include optimisation of glycaemic control in diabetic women and the prescription of high-dose (5 mg) folic acid to women at particular risk, such as those with epilepsy. Second it allows drugs with potentially

teratogenic effects to be changed to a safer alternative. There is also the opportunity to discuss particular risks and concerns, of both the medical problem itself and the medications that will be prescribed during pregnancy. Pregnant women often worry about the effects of medications on an unborn baby, and it is usual for them to put the unborn baby's needs above their own. Thus, women may suddenly stop drugs in early pregnancy that may have a significant impact on their own health. Discussions in the pre-conception period will prevent such non-compliance in early pregnancy of important medications, such as antiepileptics or immunosuppressants.

EFFECTS OF PREGNANCY ON PHARMACOKINETICS AND PHARMACODYNAMICS

Absorption

Pregnancy is associated with a reduction in gastric motility and an increase in gastric pH, but studies have demonstrated that pregnancy has no measurable effect on drug bioavailability via these mechanisms.² Nausea and vomiting are probably of more importance in reducing drug absorption during pregnancy.³

Distribution

The volume of distribution is defined as the volume in which an amount of drug would need to be distributed to produce a particular blood concentration. Therefore, for drugs that are highly bound in the tissues, e.g. basic drugs such as amphetamines, the volume of distribution is large but the plasma concentration is low. For acidic drugs, such as warfarin, which are highly protein bound, the volume of distribution is relatively low, but the plasma concentration high. Therefore, volume of distribution is dependent upon plasma volume, tissue volume, and the amount of binding of a drug in the tissues and in plasma proteins. Pregnancy causes an increase in plasma volume that reaches a peak of 50 per cent at around 32 weeks' gestation. In addition, the concentrations of the two main drug-binding proteins, albumin and α_1 -acid glycoprotein, fall during pregnancy to around 70–80 per cent of

pre-pregnancy levels by term. Therefore, pregnancy results in an increase in volume of distribution (due to increased plasma volume) and an increase in the fraction of a drug that is unbound, or active, in the plasma (due to a fall in plasma proteins). Thus, measurements of total drug concentration, which are used for medications such as phenytoin and sodium valproate, underestimate the corresponding unbound or active concentrations. This may result in prescribing higher doses than necessary, which is particularly important as the teratogenicity of both these drugs is reported in registries to be dose dependent [D]. Thus, measurement of unbound concentrations should be used wherever possible. This is of particular relevance to drugs with a narrow therapeutic window.

Metabolism

Following oral ingestion, drugs are absorbed by the gut and undergo first-pass metabolism in the liver by numerous enzymes. Although the liver smooth endoplasmic reticulum is the main site of enzymatic metabolism, virtually all cells have the ability to metabolise drugs to some degree, with other main sites being the epithelial cells of the gut, kidney, lung and skin. There are many enzymes involved and their activity is modified by pregnancy. Furthermore, there may be an increase in hepatic blood flow in pregnancy.⁴

The cytochrome P450 (CYP) system is a major enzymatic system involved in drug metabolism, of which there are now 57 human genes and 59 pseudogenes described, divided into 18 classes. Not only does pregnancy alter the activity of these enzymes, but it also varies with gestation, drug interactions (e.g. enzyme inducers) and genotype. Different genotypes at CYP loci result in an individual being a poor metaboliser or an extensive metaboliser for a particular enzyme. The uridine 5'-diphosphate glucuronosyltransferase (UGT) is a further enzyme system demonstrating modification during pregnancy. Changes in drug metabolism can have a significant effect on active drug levels. Enzymes demonstrating increased activity will result in reduced plasma levels of a drug, requiring an increase in dose, and vice versa. Thus, variation of drug metabolism with pregnancy is complex and, although the

majority of enzymes increase in activity, some decrease. The overall effect is further compounded by genetic variation and the effect of plasma volume and plasma proteins described above. Table 27.1 illustrates this with examples of drugs in which variation in metabolism is observed. This should be considered when prescribing in pregnancy and, since there are so many unknown factors, clinicians must be guided by the overall clinical affect of a drug.

Renal clearance

Pregnancy causes an increase in renal blood flow and glomerular filtration rate of more than 50 per cent, which can have a significant effect on drugs that are predominantly excreted by the kidneys. Thus, the clearance of β -lactam antibiotics such as penicillins and cephalosporins is increased during pregnancy [C]. Although there may be lower plasma levels as a result, levels in urine may be higher, which may be a desired effect for treating UTIs. LMWHs, such as dalteparin and enoxaparin, also demonstrate increased renal clearance during pregnancy, which may require dose adjustments [C].⁵ Thus, a 20–65 per cent increase in dose for drugs that are renally excreted may be needed to maintain therapeutic levels [E].⁴

Drug transfer across the placenta

The majority of drugs are able to cross the placenta to the fetus to some degree, and there are very few that demonstrate no placental transfer. Transfer of drugs across the placenta can occur by passive transfer, active transport, facilitated diffusion, phagocytosis and pinocytosis.⁶ By far the commonest method is passive diffusion, or movement of a molecule down a concentration gradient, and this is determined by the lipid solubility, polarity and molecular mass of the drug. Therefore, small, unionised lipid-soluble drugs are able to cross at the fastest rate. This can be influenced by the degree of plasma protein binding, and by placental metabolism. Drugs with a molecular mass <500 daltons (DA), which is the large majority, are able to cross the placenta by passive diffusion. Heparin (both unfractionated and low molecular weight) is

Table 27.1. Examples of modification of enzyme activity with pregnancy⁴

Enzyme	Change	Drug	Effect
CYP1A2	↓	Caffeine, clozapine, olanzapine	Increased half-life, increased unbound and active drug
CYP2A6	↑	Nicotine	Lower levels
CYP2C9	↑	Phenytoin, losartan, NSAIDs	Reduced levels
CYP2C19	↓	Proguanil, PPIs	Higher plasma levels
CYP2D6	↑	>40 drugs, e.g. β blockers, SSRIs, anti-arrhythmics	Reduced levels
CYP3A4	Variable	>50% drugs, e.g. nifedipine	Variable effects
UGT	↑↑	Lamotrigine, zidovudine, morphine	Increased clearance, thus reduced levels

- PPIs, proton-pump inhibitors such as omeprazole; SSRIs, selective serotonin reuptake inhibitors such as fluoxetine.

the most well-known drug that is unable to cross the placenta due to its high molecular mass of between 3000 and 5000 Da, depending on the preparation.

Whilst it is generally considered that facilitated diffusion, phagocytosis and pinocytosis play little significant role in drug transfer, there is growing interest in placental active transport, utilising energy-requiring drug transporters. Energy is usually derived from adenosine triphosphate (ATP), or from electrochemical gradients. All these transporters work against a concentration gradient, and several have now been described within the placenta. These include: P-glycoprotein (multidrug-resistant gene *MDR-1* product) that is able to transport digoxin and dexamethasone; MDR proteins 1–3, able to transport methotrexate and ampicillin; and the monocarboxylate and sodium/multivitamin transporters, able to transport valproate and carbamazepine.⁷

Placental drug metabolism

There is growing evidence that the placenta expresses many of the enzymes able to metabolise drugs. These include many of the CYP enzymes, UGT, glutathione S-transferase and sulphotransferases. The study of the clinical effects of many of these enzymes is in its infancy. However, it is known that for some enzymes it varies with gestation, and the activity of many is altered by alcohol and cigarette smoking. Drugs that undergo metabolism in the placenta include steroids, such as dexamethasone, and alcohol.⁶

A better understanding of placental transfer and metabolism of individual drugs may help in the development of fetal therapy. For example, transplacental passage of anti-arrhythmic drugs has been used to treat fetal supraventricular tachycardias since the first report in 1980.⁸ The success rate of monotherapy is of the order of 50 per cent.⁹

Transfer of digoxin across the placenta is complex, involving both passive diffusion and active transport via P-glycoprotein. Co-administration of other antiarrhythmic drugs has been suggested to improve success by modifying P-glycoprotein transport of digoxin.⁶

Teratogenicity

A teratogen is an agent that is able to permanently alter the development, growth, structure or function of a developing embryo or fetus. The effect of drugs in the pre-implantation period (fertilisation to implantation) is often considered to be an 'all-or-nothing' phenomenon.¹⁰ In other words, a drug will result in injury to a large number of cells, causing complete loss, or only a few cells are affected and the remaining cells can compensate at this early stage, resulting in no malformation. The period of organogenesis (embryonic phase, weeks 2–8 post-conception) is the most critical. Within this period, each structure has a period of maximal vulnerability and, usually, the earlier the insult the more severe the resulting malformation. Some structures that have initially formed during embryogenesis are still vulnerable to effects in the fetal period of development (9 weeks to term). For example,

failure of neural tube closure arises during days 17–30 post-fertilisation to cause anencephaly and neural tube defects, but encephaloceles have also been described post-closure during the fetal period.¹⁰ Drugs that have an effect in this period are described as fetotoxic. Unfortunately, the teratogenicity of most drugs is established only after initial drug licensing, as pregnant women are excluded from human trials of new drugs. The classic and most famous example of this is thalidomide, which was introduced as an antiemetic in the 1950s and was subsequently withdrawn when it was found to cause phocomelia. Determining whether a particular drug is teratogenic is difficult, as there is a background population risk of major malformations of around 2 per cent, and data rely on retrospective reporting rather than robust RCTs.¹ This is particularly true for newer medications where data availability is limited.¹¹

Lactation

The principles of drug transfer from the maternal circulation into breast milk are the same as those across any membrane, and thus will depend on the lipophilic properties, degree of ionisation and plasma protein binding of the drug. The amount of drug that the infant is exposed to will be dependent upon volume of milk ingested, maternal plasma levels and infant excretion (which probably varies with age, and is less with increasing immaturity). Plasma protein binding has been shown to have a significant impact on levels in breast milk. Drugs that are highly protein bound result in less infant exposure via breast milk. Measurable infant levels were found only for drugs with less than 70 per cent plasma protein binding.⁴ Unfortunately, there are very few good data available on the drug exposure to infants via breast milk for the large majority of drugs, thus a risk–benefit analysis must be conducted on an individual basis. However, there are very few drugs for which breastfeeding is contraindicated.¹⁰ In general terms, the lowest effective dose should be used and, if there are concerns (or if there are no data about a drug), timing breastfeeds to avoid times of peak maternal plasma levels should be recommended [E].

Specific drug considerations in pregnancy

Prescribing during pregnancy requires careful consideration of the risks and benefits, in discussion with the woman herself. In general, use of the lowest number of drugs (monotherapy where possible) and the lowest effective dose are recommended, remembering the effects of pregnancy on plasma levels of a drug [E]. For some drugs, e.g. lithium and lamotrigine, therapeutic drug monitoring is recommended.³ Table 27.2 shows examples of the key considerations, applying the above principles, for particular drug classes during pregnancy and lactation. For obvious reasons, this is in no way exhaustive and more detailed discussions can be found in the literature referenced at the end of this chapter, or in the relevant sections of this book.

Table 27.2 Examples of drug-prescribing considerations during pregnancy

Drug	Pre-conception	Effects of pregnancy	Fetal considerations	Lactation
Cardiovascular system				
ACE inhibitors, ARBs	Should be changed to alternative if possible	Avoid – use only if no alternative with fetal monitoring of growth and liquor volume; stop if oligohydramnios [D, E]	Teratogenic in first trimester; renal and cardiac problems in late gestation [D, E]	Considered compatible
Antihypertensives	Optimise blood pressure control	Nifedipine may demonstrate increased clearance in third trimester [D, E]	Beta blockers associated with fetal growth restriction (less so with labetalol); IV doses should be given with fetal monitoring	Present in breast milk (except nifedipine, which is >90% protein bound); infants reported normotensive, so considered safe
Statins	-	-	Usually stop as may adversely affect placental development; studies ongoing	Considered compatible
Antibiotics				
Penicillins/cephalosporins	-	Increased renal excretion, lower plasma levels	Cross placenta, considered safe	Small amounts in breast milk; safe
Tetracyclines	-	-	Increased risk of NTD, cleft palate and cardiovascular effects (not doxycycline); tooth discoloration [D, E]	Found in breast milk; concerns about effects on teeth
Ciprofloxacin	-	-	Only small amounts cross placenta but has been associated with bone/cartilage problems; however, few data	Concentrated in breast milk; neonatal <i>Clostridium difficile</i> has been reported [D]
Analgesics				
Paracetamol	-	-	Safe	Safe
NSAIDs	-	-	Premature closure of ductus and kidney dysfunction >32 weeks [A]	Considered safe
Codeine	-	-	Has been inconsistently associated with respiratory tract malformations but considered safe for short-term use; may cause neonatal withdrawal	MHRA advise avoidance as may cause high levels of morphine in fast metabolisers, thus risk of cardiorespiratory depression in neonates [E]
Opiates	-	-	No major effects known, fetal dependence and withdrawal [D]	May improve fetal withdrawal symptoms; similar concerns regarding metabolism as for codeine but not subject to MHRA advice at time of writing [D]

(continued)

Table 27.2 Examples of drug-prescribing considerations during pregnancy (*continued*)

Drug	Pre-conception	Effects of pregnancy	Fetal considerations	Lactation
Gabapentin/ Pregabalin	-	-	UKTIS state no increased risk for gabapentin but limited data; pregabalin has shown teratogenicity and fetotoxicity at high doses in animals	Gabapentin present in breast milk, effects unknown; no data for Pregabalin so advise avoidance
Immunosuppressants				
Steroids	-	Usual maternal side effects; risk-benefit analysis to continuing treatment	Weak association with cleft lip; placenta metabolises 90% of prednisolone; association with reduced fetal weight [C]	Unknown levels in breast milk, but usually considered safe
Azathioprine	Counsel safe [D, E]	Considered safe [D, E]	Fetal liver lacks enzyme to convert to active metabolite (6-mercaptopurine)	Low concentrations of metabolites in breast milk; however, theoretically cause immunosuppression, thus usually not recommended for breastfeeding [E]
Cyclosporin	Counsel safe [D, E]	Counsel safe [D, E]	Increased risks of fetal growth restriction [D, E]	As above
Hydroxychloroquine	Counsel safe [D, E]	Counsel safe [D, E]	Counsel safe	Limited data but no reports of adverse effects; consider safe
Psychiatric drugs				
SSRIs	Consider changing to ones with lowest association with abnormalities (i.e. change from paroxetine); discuss risks and benefits	May require increased dose [D, E]	Paroxetine and sertraline associated with teratogenicity, such as cardiac defects, omphalocele (risk low approx. 2/1000); fluoxetine crosses placenta but not considered a teratogen [D, E]	Present in breast milk; avoid feeding at times of peak plasma levels; sertraline SSRI of choice ¹ [E]
Lithium	Risk-benefit analysis involving psychiatrist	Risk-benefit analysis involving psychiatrist; some suggest reducing/stopping just prior to delivery [D, E]	Cardiovascular malformations, floppy infant, neonatal arrhythmias, hypoglycaemia, thyroid dysfunction [D]	Found in breast milk; breastfeeding generally avoided as neonatal clearance slower than adult [E]
Tricyclic antidepressants	Consider safe	Risk-benefit analysis	May cause neonatal withdrawal, possible risk of miscarriage and growth restriction; not associated with malformations	Probably safe

Drug	Pre-conception	Effects of pregnancy	Fetal considerations	Lactation
Diazepam	Risk-benefit analysis involving psychiatrist; do not stop abruptly	Risk-benefit analysis involving psychiatrist; do not stop abruptly	Possible association with orofacial clefts and cardiovascular malformations; neonatal withdrawal, respiratory depression and 'floppy infant' syndrome [D]	Excreted in breast milk; causes sedation, lethargy; advise avoid [E]
Antiepileptics				
Sodium valproate	Optimise treatment on lowest dose; avoid if possible	Total concentrations fall, but more so than the unbound concentrations; as teratogenicity is dose dependent, need to measure unbound levels [D, E]	Teratogen that is rapidly transported to fetus; associated with 'valproate syndrome', developmental delay [D, E]	Enters breast milk; neonatal serum levels <10% of maternal levels [D, E]
Carbamazepine	Obtain control on lowest dose possible		Associated with facial dysmorphism, developmental delay, NTD, phalanx and nail hypoplasia [D, E]	Probably safe in breastfeeding [D, E]
Phenytoin	Obtain control on lowest dose possible	Total concentrations fall, but more so than the unbound concentrations; as teratogenicity is dose dependent, need to measure unbound levels [D, E]	Associated with congenital heart defects and cleft palate [D, E]	Low transfer in breast milk; considered safe [D, E]
Lamotrigine	Obtain control on lowest dose possible	Increased clearance due to increased UGT activity [D, E]	Crosses placenta, limited data as newer drug [D, E]	Low transfer in breast milk, therefore considered safe [D, E]
Anticoagulants				
Warfarin	Discuss risks, and make plan for pregnancy; depends on indication for anticoagulation	Depends on reason for use: in general, avoid use at period of greatest teratogenicity and after 36 weeks; may be safe to use heparin as alternative throughout pregnancy, but for women with metal valves this may not provide sufficient anticoagulation [E]	Teratogen; exposure between 6 and 10 weeks associated with embryopathy; higher dose (>5 mg/day) associated with higher fetal risk [D, E]	Does not enter breast milk as highly protein bound [D]
Heparin	Reassure safe in pregnancy	Safe in pregnancy; increased renal clearance, may require increased dose; monitoring of factor Xa levels if therapeutic (rather than prophylaxis is required) [D, E]	Does not cross placenta due to molecular size	Safe in breastfeeding

- ACE, angiotensin-converting enzyme; ARB, angiotensin type 1 receptor blocker; MHRA, Medicines and Healthcare products Regulatory Agency; NTD, neural tube defect; SSRIs, selective serotonin reuptake inhibitors; UKTIS, UK Teratology Information Service.

KEY POINTS

- Pre-conception counselling offers an opportunity to optimise drug therapy, change medications with teratogenic potential and discuss compliance of important medications.
- Absorption of drugs is not significantly altered by pregnancy.
- Pregnancy is associated with increased plasma volume and reduced levels of plasma-binding proteins, which results in an increased unbound, or active, drug concentration.
- Pregnancy alters the activity of many of the enzymes involved in drug metabolism. Effects vary with enzyme, gestation, genotype and other prescribed drugs, and thus are often difficult to predict.
- Renal clearance of drugs increases during pregnancy, resulting in lower plasma levels of drugs that are predominantly excreted via this route.
- Drugs cross the placenta predominantly by passive diffusion and there is growing interest in the active transporters. Thus, small, lipid-soluble, non-ionised drugs cross at the highest rate.
- The embryonic period of human gestation (weeks 2–8 post-fertilisation) is the period of greatest vulnerability to the teratogenic effect of drugs.
- Transfer of drugs into breast milk is determined by lipophilic properties of a drug, molecular size and polarity. Highly plasma-bound drugs (>70%) do not cross into breast milk.
- In general, drugs in pregnancy and breastfeeding should be used at the lowest effective dose, using the lowest number of drugs (monotherapy where possible).

Chapter 28 Maternal mortality

James Drife

MRCOG standards

Theoretical skills

- Candidates should be familiar with the most recent report of the Confidential Enquiry into Maternal Deaths (CEMD) in the UK.
- These reports, formerly published every 3 years, are now published annually. Candidates should be aware of previous findings but should not rely on out-of-date reports.
- Global efforts are now reducing maternal mortality in many countries. Candidates should be aware of the leading causes of maternal death worldwide and the strategies for tackling them.

Practical skills

Preventing maternal deaths requires a wide range of skills.

- Clinical skills are required to treat conditions such as postpartum haemorrhage and severe hypertension.
- Administrative skills are required to implement preventive measures such as routine thromboprophylaxis.
- Organisational skills on a wider scale may be needed to ensure that care is available to at-risk women.

INTRODUCTION

Maternal death is still common in many parts of the world but has become rare in developed countries. In the UK its infrequency means that when a maternal death does occur it can be a shattering experience for everyone involved. Lessons for prevention are best learned by aggregating cases nationally. The CEMD operated continuously in the UK for over 60 years and their methods have been emulated in many countries across the world. They are now being run by MBRRACE-UK (Mothers and Babies: Reducing Risk Through Audits and Confidential Enquiries –UK), which also undertakes surveillance of infant deaths and maternal and perinatal morbidities.

INCIDENCE

Worldwide

The WHO estimates that in 2010 there were 287,000 maternal deaths – a decline of 47 per cent from levels in 1990 – and that the global maternal mortality rate (MMR) is now 210/100,000 live births, down from 400/100,000.¹ Sub-Saharan Africa and southern Asia accounted for 85 per cent of the global burden in 2010, with one-third of the world's maternal deaths occurring in two countries, India and Nigeria. Of the 40 countries that still have an MMR of over 300/100,000, all but four are in sub-Saharan Africa, where 10 per cent of maternal deaths are due to HIV (Fig. 28.1). Elsewhere, MMRs over 300/100,000 are found in Laos, Afghanistan, Haiti and Timor-Trieste. When a high MMR is combined with a high fertility rate, the result is disastrous. In Chad, for example, a girl has a 1 in 15 chance of dying as a result of pregnancy or delivery, and in Afghanistan the chance is 1 in 30.

The UK

In the UK, maternal death occurs in around 1 in 10,000 pregnancies. The MMR rose from 9.9/100,000 pregnancies in 1985–7 to 13.9/100,000 in 2003–5, partly (but not entirely) due to more complete reporting of *indirect* deaths, which now outnumber *direct* deaths² (Table 28.1). In 2006–8, however, there was a statistically significant fall in the MMR to 11.39/100,000, and the downward trend included both black African and white ethnicities.

Incomplete reporting of maternal deaths occurs in all countries. Death certificate data are inadequate and if the UK relied only on these, the MMR would be 6.76/100,000 – around 60 per cent of the true rate. Instead, the UK makes strenuous efforts to ascertain as many of the deaths as possible. This has involved computer linkage of birth and death registration, and a long tradition of reporting maternal deaths to the national CEMD. The high ascertainment in the UK makes comparisons with other countries potentially misleading.

Confidential enquiries into maternal deaths

Since 1952, every maternal death in England and Wales has been the subject of a detailed enquiry, conducted by

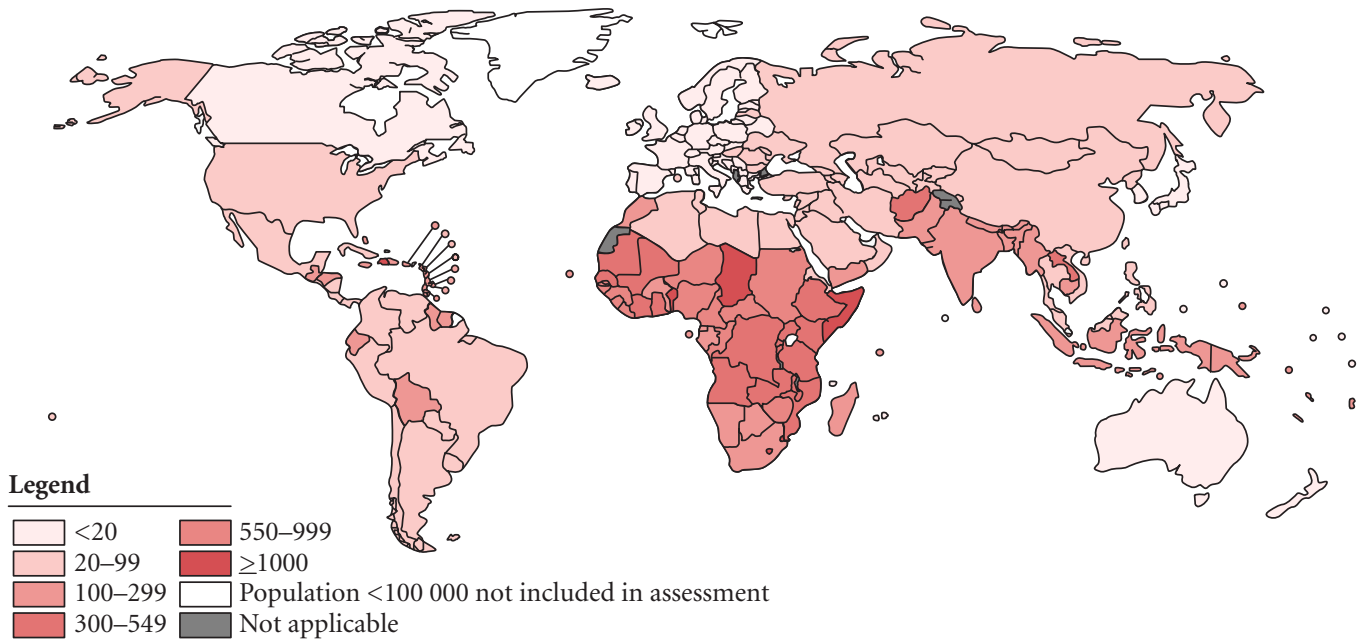

Fig. 28.1 World map of maternal mortality (From the WHO¹)

Table 28.1 Number of maternal deaths notified to the UK Confidential Enquiry

	1994–6	1997–9	2000–2	2003–5	2006–8
Direct	134	106	106	132	107
Indirect	134	136	155	163	154
Coincidental	36	29	36	55	50
Late direct	4	7	4	11	9
Late indirect	32	39	45	71*	24**
Total	340	317	346	432	344

*This increase in late indirect deaths was due to improved ascertainment.

**This reduction was due to a change in data collection: only deaths within 6 months of delivery were included.

clinicians –doctors and, nowadays, midwives. Any death during pregnancy or within a year after delivery is reported to the CEMD, which was initially run by the Ministry of Health and latterly by CMACE. In January 2013 the enquiry became part of MBRACE-UK (the acronym means ‘Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the UK’), which is part of the National Perinatal Epidemiology Unit, based in Oxford.³ The methodology is similar to that used by CMACE. Forms requesting all relevant details are sent to all clinicians involved in the case, and the completed forms are reviewed by national assessors in obstetrics, pathology, midwifery and, if appropriate, anaesthetics, general medicine, intensive care, and psychiatry (Fig. 28.2).

Cases are anonymised, so that those involved can comment frankly and make their own suggestions for improvements, and no blame is attached to individuals. MBRACE-UK covers England, Scotland and Wales, and a similar system

exists in Northern Ireland. Reports will be published annually. They are UK wide, making the identification of individual cases more difficult, and they make recommendations for improving practice.

DEFINITIONS

The definitions given here are those used by CEMD:

- *Maternal death*: death of a woman while pregnant or within 42 days of termination of pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes.
- *Direct death*: death resulting from obstetric complications of the pregnant state (pregnancy, labour and puerperium), from interventions, omissions, incorrect treatment or a chain of events resulting from any of the above.

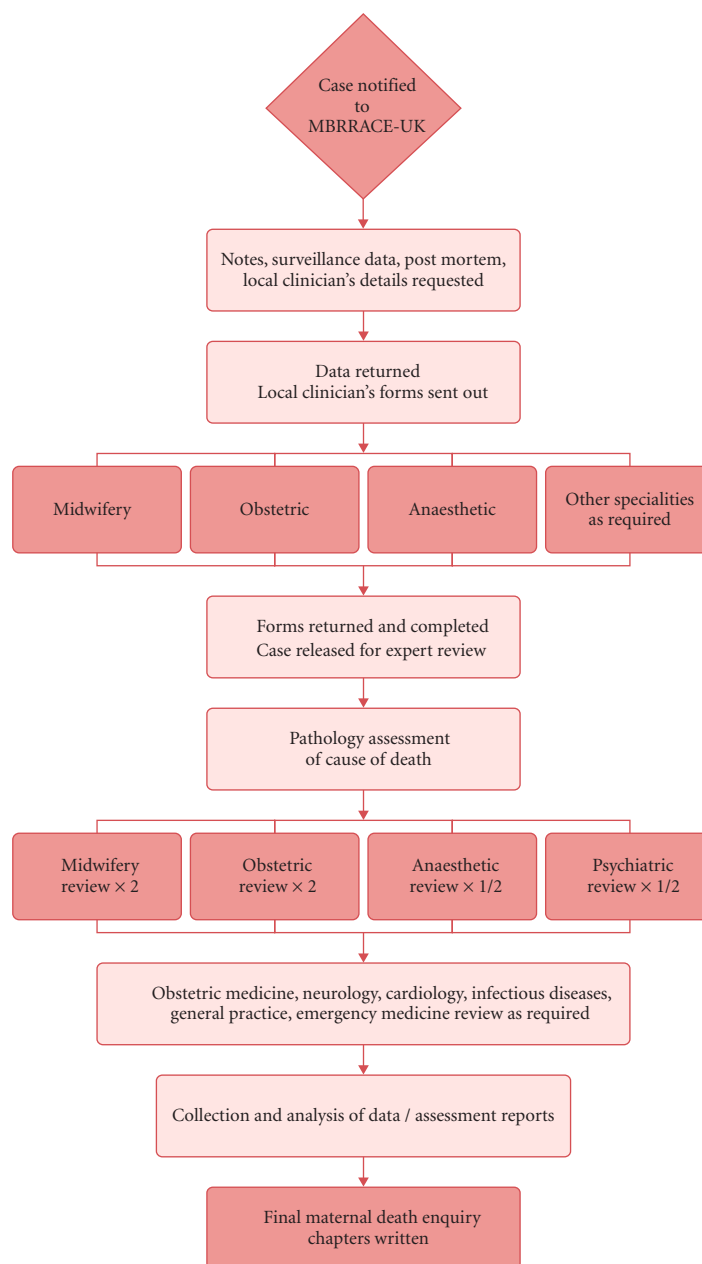

Fig. 28.2 MBRRACE-UK maternal death enquiry⁴

- *Indirect death*: death resulting from previous existing disease or disease that developed during pregnancy and was not due to direct obstetric causes, but was aggravated by the physiological effects of pregnancy.
- *Late death*: death occurring between 42 days and 1 year after abortion, miscarriage or delivery, due to 'direct' or 'indirect' maternal causes.
- *Coincidental death*: death from an unrelated cause which happens to occur in pregnancy or the puerperium.
- *Maternal mortality rate*: this is expressed in the UK as the number of deaths per 100,000 maternities. A 'maternity' is a clinical pregnancy ending in livebirth, stillbirth, miscarriage or abortion.
- The WHO, however, defines the maternal mortality *rate* as 'the number of maternal deaths per 100,000 women of reproductive age', and the maternal mortality *ratio* as 'the number of maternal deaths per 100,000 live births'. Close attention needs to be paid to definitions and denominators.

AETIOLOGY

The causes of maternal mortality are similar all over the world, although overall rates and the relative contribution of each cause vary from country to country.

Worldwide

The leading causes of direct death according to global estimates (Table 28.2) – haemorrhage, hypertensive disorders and sepsis – are largely treatable conditions.⁵ The underlying causes in many developing countries include lack of access to contraception, unsafe abortion, lack of primary care or transport facilities, and inadequate equipment and staffing in district hospitals. In 1990 only 55 per cent of deliveries in developing regions were attended by skilled health personnel, but in 2009 this proportion had risen to 65 per cent. There are wide disparities between regions: for example, in eastern Asia, which has experienced the greatest MMR decline, the contraceptive prevalence rate is now 84 per cent, compared with 22 per cent in sub-Saharan Africa, the region with one of the lowest MMR declines.¹

Education of women is important. In India, the states with high rates of female literacy also have high rates of contraceptive use and low MMRs. In all countries, safer care could be provided to illiterate women if there were the political will to do so.

Table 28.2 Global causes of maternal death⁵

Haemorrhage	22.9%
Hypertensive disorder	18.5%
Abortion	14.5%
Hepatitis	12.5%
Other infectious diseases	12.5%
Sepsis or infection	8.6%
Syphilis	6.2%
Obstructed labour	4.3%

• Figures are numbers of cases. (Figures in parentheses are cases with major substandard care.)

* Includes one case of choriocarcinoma that was classified as direct.

The UK

The specific causes of maternal death in the UK are shown in Table 28.3. The number of direct deaths has changed little in the last 12 years but the number of indirect deaths has steadily increased.

Direct deaths

THROMBOEMBOLISM

This was the leading direct cause of maternal death in the UK from 1985 to 2005, but the number fell dramatically to 18 in 2006–8, the first full triennium after the publication of a new RCOG guideline on thromboprophylaxis. This total was equally divided between antepartum and postpartum deaths. Three occurred before 12 weeks of pregnancy.

HYPERTENSIVE DISEASE

When the Enquiry began in 1952–4, there were 246 deaths from hypertensive disease in England and Wales. In 2006–8 in the UK, the total was 19. The condition is no less common, but care is now better. Of the 19 deaths in 2006–8, 9 were from intracranial haemorrhage.

HAEMORRHAGE

Haemorrhage is treated well in the UK. Out of over 2 million pregnancies in the triennium 2006–8, there were only 9 deaths from this cause. Two were from placenta praevia and two from abruption. Postpartum haemorrhage (PPH) caused five deaths. Two of the cases of PPH involved genital tract tears. Until 2000–2 a separate chapter was devoted to genital tract trauma but the reduction in deaths from this cause made this unnecessary.

AMNIOTIC FLUID EMBOLISM

Formerly, amniotic fluid embolism (AFE) was diagnosed only when the pathologist confirmed fetal squames in the lungs. From 1991 to 1993, clinically obvious cases have also been included, but only after assiduous assessment to rule out misclassification. There were 13 deaths from AFE in 2006–8 and the diagnosis was confirmed at autopsy in 11. The number of histologically confirmed cases has remained around 8–10 per triennium for over 20 years.

EARLY PREGNANCY DEATHS

This category covers deaths before 24 weeks' gestation (formerly the upper limit was 20 weeks). In 2006–8 six were from ectopic pregnancy (out of an estimated 32,000 cases), and five were from miscarriage. There were two deaths from sepsis after legal termination of pregnancy. Before the Abortion Act of 1967, there were around 30 deaths every year from criminal abortion, most of them being due to sepsis.

SEPSIS

Until 1935, streptococcal puerperal sepsis was the leading cause of maternal death in the UK, causing hundreds of deaths each year. Within 50 years this cause was eliminated and in the 1982–4 report a modest sentence – 'No deaths could be directly attributed to puerperal sepsis' – marked one of the great medical achievements of the twentieth century. Since 1985, however, there has been a small but steady rise in the number of deaths from sepsis to 18 in 2003–5 and then, worryingly, to 29 in 2006–8 (including 3 late deaths). Of the 29 deaths 13 were due to group A streptococcus, which is widely carried in the throat. All 13 women had, or worked with, small children. Nine of the women presented with septic shock after rapid progression of the illness.

ANAESTHESIA

Despite the rising caesarean section rate, the number of maternal deaths from anaesthesia fell steadily from 37 in 1970–2 to only one in 1994–6. Since then the number has risen to seven in 2006–8. This illustrates the need to maintain vigilance – then as now, the main lesson is that trainees must know the limits of their competence.

Indirect deaths

The 154 indirect deaths in 2006–8 were divided into 53 cardiac and 13 psychiatric cases, 3 cases of malignancy possibly affected by pregnancy and 85 'others'.

CARDIAC DISEASE

The total of 53 deaths made this the leading cause of maternal death in 2006–8. Formerly, the major cardiac problem was rheumatic heart disease, as it still is in many developing countries, but there were no deaths from this cause in 2006–8. The leading causes were cardiomyopathy and sudden adult death syndrome and the full list is shown in Table 28.4. The steady increase in deaths from heart disease is

linked with increasing obesity, increasing age at child-bearing and the continuing high rate of smoking among women in the UK.

PSYCHIATRIC

In 2006–8, four women committed suicide in pregnancy and nine within 6 weeks of delivery. Another 16 suicides were late indirect deaths, between 6 weeks and 6 months after delivery. Most of the methods were violent, such as hanging or jumping from a height. There were a further 38 cases in which psychiatric disorder caused or contributed to the death. In the past, not all psychiatric deaths were reported, but, after the enquiry highlighted the problem in the 1990s, case ascertainment improved and the extent of the problem of psychiatric disorders in pregnancy was at last recognised.

CANCER

In most countries, death from cancer during pregnancy is classed as 'coincidental' but, in the UK, deaths from cancer are classed as indirect if it appears that the pregnancy may have masked the disease or affected the diagnosis or outcome. CNS tumours in particular fall into this category.

OTHER INDIRECT DEATHS

There were 85 'other indirect' deaths in 2006–8. The main causes were diseases of the CNS (36 deaths), among which 14 deaths were due to epilepsy and 11 to subarachnoid or intracerebral haemorrhage. There were seven deaths from infectious diseases, two of which were due to HIV.

Coincidental deaths

The 50 coincidental deaths included 9 cases of neoplasia unaffected by the presence of pregnancy, 17 road traffic accidents and 11 cases of homicide – in seven cases by the woman's partner or close relative. Domestic violence, or intimate partner violence, is now a major concern to the maternity services and a chapter in the 2006–8 report is devoted to this problem. A further 34 women who died from other causes were known to be subject to domestic abuse.

Table 28.4 Deaths from cardiac disease in the UK, 2006–8²

Aortic dissection	7

Congenital heart disease	3
Total	53

PREVENTION

Worldwide

Almost 200 countries signed up to the eight Millennium Development Goals (MDGs) agreed at the UN Millennium Summit in 2000. MDG 5 is a 75 per cent reduction in the global MMR from its 1990 level by the year 2015. Various institutions including the WHO and the World Bank have supported work towards this target and substantial, but varied, progress has been made (Table 28.5).⁶ Several countries, such as South Africa and Malaysia, have set up confidential enquiries similar to the UK model. Enquiries can identify the major problems, but implementing their recommendations requires commitment from politicians, doctors, other healthcare workers and the population as a whole.

Postpartum haemorrhage can be reduced by routine oxytocics at delivery, and unsafe abortion by contraceptive

services and legal termination of pregnancy. Otherwise, the main need is less for prevention than for prompt treatment of pregnancy complications. This requires transport, trained healthcare workers, drugs and equipment. The importance of medical care in pregnancy and childbirth was underlined two decades ago by a comparative study in the USA, which showed that a religious group that had good general health but refused all modern medical care had a maternal mortality rate similar to those in developing countries.³

Past experience in the UK

Until 1935, the UK's MMR was around 400/100,000 (one death in 250 births), but it fell steadily between 1936 and 1985 (Fig. 28.2). Other indicators of public health, such as infant mortality, fell slowly and steadily during the twentieth century, but maternal mortality fell rapidly during and after the Second World War, when social conditions could hardly be

Table 28.5 Global changes in maternal mortality, 1980–2008

● From: Hogan *et al.*, *Lancet* 2010;375:1609–23.

said to be improving. This strongly suggests that the fall was due to specific factors, such as:

- antibiotics: sulfonamides were introduced in 1937 and penicillin in 1944; death rates from puerperal sepsis quickly fell;
- blood transfusion became safe during the 1940s;
- ergometrine, for the treatment and prevention of PPH, was introduced in the 1940s;
- better training of midwives and obstetricians: Midwives Acts were passed in 1902 and 1936, and the RCOG was founded in 1929;
- reduced parity: the average family size began to fall long before the pill was introduced in 1961;
- legalisation of abortion in 1967 was followed by elimination of criminal abortion as a cause of maternal death (Fig. 28.3).

The current picture in the UK

Preventing maternal deaths involves identifying the women most at risk and providing them with appropriate care. Using denominator data collected by the Office for National Statistics and, combining these with findings from the Confidential Enquiry, general risk factors can be identified.

General risk factors

- **Age.** The MMR begins to rise around the age of 35 and rises more sharply after 40. In 2006–8, the MMR was 8.2 in the 20–24 age group and 29.2 among women aged over 40. In the past the ‘grande multipara’ was recognised as a high-risk case, but age and parity go together and, as high parity became rare in the UK, the importance of maternal age became clearer.
- **Ethnicity.** A higher risk among black women compared with white women was documented in the UK for the first time in 1994–6 and has been found in many countries including the USA, France and the Netherlands. Although

in the UK the MMR in both black and white women has recently fallen, this disparity persists (Table 28.6). In 2006–8 black African and black Caribbean women were almost four times more likely to die than white women. Of the 28 black African women who died, only 9 were UK citizens, most of the others being recently arrived immigrants, refugees or asylum seekers. Black Caribbean women are much less likely to have language difficulties but are more likely than white women to be poor attenders for antenatal care. Social factors, such as communication problems, are important but a survey by UKOSS showed that severe maternal morbidity was 2.4 times higher in black African and black Caribbean women than in white women, and the increased risk persisted after adjustment for factors such as socio-economic status.

- **Social class.** The huge effect of social class was shockingly illustrated in the 1997–9 report, which showed that the MMR among the lowest social class in Britain was 135/100,000 –similar to that in a developing country – and that 97 of the 242 maternal deaths occurred in social class 9. This group includes itinerant people (‘travellers’), who tend to turn up at the wrong time or day at the antenatal clinic or fail to keep appointments. It is all too easy to overlook such people’s needs in a service that caters mainly to the wishes of more articulate and better organised women. Such detailed data are no longer available but the 2006–8 report shows that women whose husbands or partners were unemployed were nearly six times more likely to die than women with employed partners.
- **Obesity.** It is estimated that 25 per cent of women in the UK aged 16 or over are obese. In 2006–8, the BMI was available for 87 per cent of the women who died: almost 50 per cent were overweight or obese, with the figure rising to 78 per cent among deaths from thromboembolism and 61 per cent among deaths from cardiac disease. A UKOSS survey of morbid obesity (BMI 50 or over) showed increased risks of severe morbidity including a 4.5-fold increase in the risk of pre-eclampsia, and a 6-fold increase in the chance of requiring general anaesthesia.

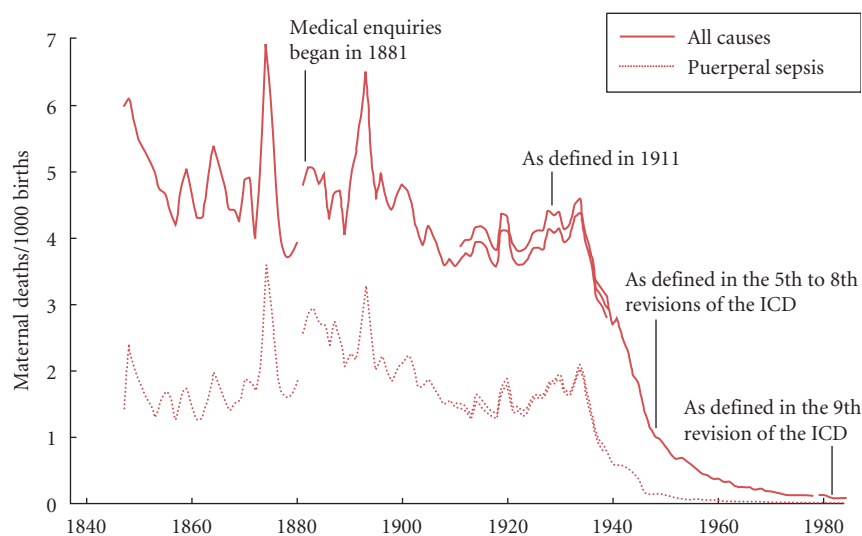

Fig. 28.3 MMR in England and Wales, 1847–1984 (reproduced from *Report on Confidential Enquiries into Maternal Deaths in England and Wales 1982–84*, published by HMSO, 1989)

- *Assisted conception.* Eight of the women who died in 2006–8 were known to have undergone assisted reproduction techniques (ARTs) including IVF. In the previous triennium, 2003–5, the total was nine, and four of those deaths were due to ovarian hyperstimulation syndrome. Multiple pregnancy is associated with a doubling of the risk of maternal death.

Substandard care

CEMD also identifies substandard care. Standards are rising all the time and the proportion of cases in which care falls below current standards has not changed over the years. Substandard care may involve only a minor aspect of the treatment and does not necessarily mean that the death could have been avoided. Nevertheless, in 2006–8 major substandard care was identified in 44 per cent of direct deaths and 31 per cent of indirect deaths. Examining these cases gives an insight into the challenges of real-life medical practice and helps to indicate how deaths may be avoided. Guidelines and protocols are everywhere but they can save lives only if they are understood and implemented. An example of their success is given in the next section, on thromboembolism.

Direct deaths

THROMBOEMBOLISM

In 2006–8 care was substandard in 10 of the 18 deaths from thromboembolism. Seven women received inadequate

thromboprophylaxis, and in six cases there was a failure to investigate chest symptoms in at-risk women, sometimes even after repeated presentation. Nevertheless, the main message in this triennium was the sharp fall in deaths from thromboembolism. This was due to better awareness of the condition, which meant few instances of unnecessary delay in treatment and few cases in which risks were ignored.

The reduction in deaths from thromboembolism since the 1990s occurred in two phases, each linked to an RCOG guideline. In 1995, the RCOG produced recommendations on thromboprophylaxis after caesarean section. Deaths after caesarean section fell dramatically in the next triennium (1997–9) whilst deaths after vaginal delivery did not change (Table 28.7). In 2004 the RCOG produced a guideline for thromboprophylaxis during pregnancy and after vaginal delivery,⁸ and a statistically significant fall in antepartum deaths and deaths after vaginal delivery followed in the next triennium (2006–8).

This is a good illustration of the close relationship between the Enquiry and a professional body whose guidelines are respected by clinicians. The thromboprophylaxis guideline was subsequently refined, with weight-specific dosage advice on LMWH, but the basic principles remain the same. Risk factors such as obesity and a personal or family history of thromboembolism should be identified as early as possible in pregnancy, and vigilance is needed for new risk factors during pregnancy, such as immobilisation or long-haul air travel. And, of course, symptoms must be promptly investigated.

Table 28.6 Ethnicity and maternal mortality in the UK, 2006–8²

HYPERTENSIVE DISEASE

A depressing feature of recent reports has been the unchanging number of deaths from hypertensive disease. In 2006–8 there were 19 deaths from pre-eclampsia/eclampsia, 9 of which were due to intracranial haemorrhage. An encouraging feature of recent reports, however, is the lack of deaths due to pulmonary oedema caused by fluid overload during treatment: in 1994–6 this was the cause of eight deaths but fluid balance protocols have improved greatly since then.

It is frustrating that intracranial haemorrhage due to inadequate antihypertensive therapy continues to be a leading cause of death. A decade ago it became clear that systolic blood pressure was often being ignored while attention was focused on the diastolic, and the reports have repeatedly recommended urgent treatment of severe hypertension. The 2006–8 report recommends: ‘Systolic blood pressures of 150 mmHg, or above, require effective antihypertensive treatment’ and ‘If systolic pressure is >180 mmHg, this is a medical emergency’. These simple recommendations are too often ignored, perhaps because they are not incorporated into local protocols.

HAEMORRHAGE

Major obstetric haemorrhage occurs in about 1 in 250 births, according to the Scottish Confidential Audit of Severe Maternal Morbidity. This means around 8000 cases of severe haemorrhage in the UK in 2006–8, and it is an indicator of the

quality of emergency care that there were only 9 deaths from this cause—a fall from 14 in the previous triennium. Five of the nine deaths were due to PPH.

Substandard care was noted in six cases, and a major failure in three of the cases of PPH was a lack of routine observation in the postpartum period, or a failure to appreciate that bleeding was occurring. The 2003–5 report recommended the use of colour-coded ‘MEOVS’ (Modified Early Obstetric Warning Sign) charts to help alert staff to warning signs such as an increasing pulse rate, and these have been widely adopted, but, as the 2006–8 report points out, ‘They are only useful if observations are made and abnormal readings acted upon’.

Two deaths were associated with placenta praevia accreta, which has become a concern because the rising caesarean section rate has led to more cases of placenta praevia implanted over a uterine scar. Key recommendations in previous reports have included the need to warn women about the future risks of caesarean section, and the need for placental localisation in women with a previous caesarean section. The reports have repeatedly stated that caesarean section for placenta praevia must be carried out by an experienced surgeon. Recent reports have stressed the importance of multidisciplinary planning when problems are anticipated and have recommended calling a second consultant when severe haemorrhage occurs. The fall in deaths suggests that these recommendations have been heeded.

Nevertheless, it is worth remembering that deaths from haemorrhage have fallen to single figures in the past, once in the 1980s and once in the 1990s. The cyclical rise and fall in deaths from this cause suggests that lessons are easily forgotten, and underlines the need for constant vigilance. The incidence of severe haemorrhage does not change.

AMNIOTIC FLUID EMBOLISM

Deaths from AFE have remained fairly constant in number, and in 2006–8 there were 13 deaths from this cause. In five of these cases there was no substandard care and, indeed, in two of these cases there was exemplary care, including prompt perimortem caesarean section. Substandard care in the remaining cases included poor organisation of transfer facilities, delay in contacting the consultant obstetrician and delay in communicating with relatives.

AFE used to be regarded as a condition with an almost 100 per cent mortality rate but important lessons have been learned from national surveillance conducted by UKOSS since 2005. A similar international registry has recently been established in the USA.⁹ UKOSS data showed a constant incidence of 2 per 100,000 pregnancies and an overall mortality rate of 16.5 per cent. It appears that high-quality supportive care can result in good outcomes for mother and baby, and the 2006–8 report concluded: 'Amniotic fluid embolism, particularly if the collapse occurs in a well-equipped unit, should now be considered a treatable and survivable event in the majority of cases.'

EARLY PREGNANCY DEATHS

Substandard care was present in the majority of deaths in early pregnancy in 2006–8. There were six deaths from ectopic pregnancy – the lowest number for 20 years – and substandard care included failure to consider the diagnosis in a woman who presented with diarrhoea, vomiting and abdominal pain, despite previous reports drawing attention to gastrointestinal symptoms as the sole presentation of ectopic pregnancy. A woman diagnosed with 'pregnancy of unknown location' in an early pregnancy assessment (EPA) unit received inadequate follow-up and died of an ectopic pregnancy. Five women died after spontaneous miscarriage – the highest number for 15 years. The introduction of EPA units has been associated with more conservative management of non-continuing pregnancies but their protocols must be meticulously followed and persistent bleeding needs to be recognised as an indication for prompt surgical intervention.

SEPSIS

Sepsis is now the leading cause of direct death in the UK. Death and serious illness from pregnancy-related sepsis are still very rare, however, which means that many healthcare workers will never have seen a case, making it difficult for them to recognise the earliest signs and symptoms. Streptococci can produce overwhelming sepsis in a frighteningly short time, but infection is often insidious in onset and may not reveal itself for several days postpartum, when the woman has gone home. The first presentation may be to a midwife, GP or junior doctor in the emergency department, and the main message of the 2006–8 report is 'Be aware of sepsis – beware sepsis'.

Among the 29 women who died in 2006–8, the fatal outcome was inevitable in many cases but might have been different in 12 if the infection had been diagnosed and treated more promptly. The first sign may be tachycardia. Tachypnoea is sepsis until proved otherwise. Immediate aggressive antibiotic treatment in the first 'golden hour' offers the best hope of recovery, and high-dose broad-spectrum IV antibiotic treatment must be started immediately without waiting for microbiology results.

Streptococci are transferred by droplet spread, and puerperal women should be advised to wash their hands before going to the toilet or changing sanitary towels. Women may make light of the initial symptoms and public awareness of the condition needs to be increased.

GENITAL TRACT TRAUMA

Death from genital tract trauma is now so rare that the 2006–8 report did not include a chapter on this cause, though genital tract tears were implicated in two deaths from PPH. Difficult forceps deliveries are rarely if ever attempted nowadays, though the resultant increase in the caesarean section rate has brought its own problems.

ANAESTHESIA

Of the seven deaths attributed to anaesthesia in 2006–8, three had major and three had minor substandard care. Two deaths were the result of failure to ventilate the lungs, one after induction of general anaesthesia and the other when a tracheostomy tube came out in a critical care ward. In 1967–9 there were 32 such deaths, and this was a major reason for the move to regional anaesthesia in obstetrics. Today general anaesthesia is infrequently used and the management of failed intubation needs to be rehearsed and assessed regularly. Anaesthetists have been assiduous in learning lessons from the successive reports of the CEMD.

Indirect deaths

Table 28.3 shows that although the proportion of cases with substandard care is lower among indirect deaths than among direct deaths, one-third of the indirect deaths were associated with major substandard care and, unlike direct deaths, the proportion did not fall in 2006–8.

CARDIAC DISEASE

There was major substandard care in 13 of the 53 deaths from cardiac disease in 2006–8, and there were lessons to be learned from another 14 cases. Failure to consider acute coronary syndrome was a repeated finding. ECGs can be normal between episodes of angina, and a single ECG does not exclude ischaemia. Failure to investigate chest pain was also a factor in four of the seven deaths from aortic dissection. It is gratifying that awareness of thromboembolism has increased but it is now necessary to remind clinicians that 'not all chest pain in pregnancy is the result of pulmonary emboli'. Aortic dissection is not confined only to women with Marfan's syndrome, and chest pain severe enough to require opiate analgesia needs full investigation. Cardiomyopathy may present up to 6 months after delivery, and women with known cardiomyopathy need referral to specialist units where obstetricians and cardiologists work together.

PSYCHIATRIC DISEASE

The 2006–8 report found that psychiatric care was less than optimal for 69 per cent of women known to be involved with psychiatric services in their current pregnancy. In most women the psychiatric team had not appreciated the severity of the woman's illness. Suicide risk must not be equated with social deprivation: over half of the maternal suicides were married, employed, living in comfortable circumstances and aged 30 or over.

Morbid fear of having their child removed was a feature in some cases. Referral to safeguarding teams should not be routine when mothers develop a mental illness but should take place as a result of risk assessment. When referral is necessary to safeguard the child, extra vigilance and care are required.

Most women who suffer maternal death from suicide have a past history of serious affective disorder. Women with a past history of severe mental illness complicating pregnancy have a 33–55 per cent chance of recurrence. All women should be routinely asked in early pregnancy about current and previous mental health problems. Questioning should be sensitive but explicit. Each unit should have a protocol for the management of women at high risk, and specialist perinatal psychiatric services, both inpatient and community, should be available.

In some deaths, physical symptoms and agitation were wrongly attributed to psychiatric disorder, leading to delay in diagnosis and treatment. This is particularly risky when a woman has no previous history of psychiatric disease or when she does not speak English or comes from an ethnic minority.

OTHER INDIRECT DEATHS

Of the 36 women who died from neurological conditions, 11 had major substandard care, and of the other 52 deaths from indirect causes 17 women had major substandard care. Only 6 of the 14 women with epilepsy had received pre-pregnancy counselling and in most of the cases of epilepsy the woman had not been referred for review by a neurologist despite her known history. This meant the opportunity was lost to consider adjusting the anticonvulsant dose or check drug levels if necessary. Women with epilepsy are still unaware of the rare but real risk of drowning while bathing unattended. A shower is preferable and the bathroom door should remain unlocked.

Five women died of asthma – a similar number to those in previous reports – and none had had specialist care in pregnancy, despite three having brittle asthma or multiple hospital admissions. Women often withhold or decrease their medication in pregnancy for fear of harming the fetus, and specialist referral can reassure them about this.

Coincidental deaths

ROAD TRAFFIC ACCIDENTS

Pregnancy is not a contraindication to the use of seat belts, and women should be advised that the belt is placed 'over and under the bump'.

DOMESTIC VIOLENCE

The 2006–8 report emphasises the importance of 'Asking the question' at some opportune point during the antenatal period. If abuse is disclosed on such routine questioning, this

must be recorded in a way that protects the woman from further violence and there must be local strategies for referral to a support network. If the woman chooses midwifery-led care, the midwife should receive support from an experienced colleague. Women who are known to suffer domestic abuse should not be regarded as 'low risk'.

Domestic violence may be the reason for late booking or poor attendance, or conversely for repeated attendance with minor injuries or non-existent complaints. Other warning signs include drug or alcohol abuse, or the constant presence of a partner at examinations. Every woman should be seen on her own at least once during the pregnancy. Staff must adopt a non-judgemental and supportive attitude¹⁰ and should remember that health professionals, too, may be victims of abuse.

THE FUTURE

Over the past 20 years, interest has been growing in 'near misses' – incidents that might have resulted in a maternal death but for prompt and effective treatment. These incidents occur more frequently than maternal deaths and in countries with a low MMR analysis of near misses should provide a more representative picture to allow policy guidance. One problem with this approach has been the wide variation in criteria for identifying cases,¹¹ but the WHO has developed a set of unified criteria along with a set of indicators for identifying quality of care.¹² Some of these criteria are laboratory based and questions have been raised about their practical value in low-resource settings, where the need is greatest.¹³

In the UK, a continuous audit of severe maternal morbidity in Scotland has been running since 2003, collecting data on consistently defined events in all consultant-led maternity units in Scotland.¹⁴ In 2006–8 1025 women experienced 1237 events, giving a rate of severe maternal morbidity of 5.88 per 1000 births. There were 13 direct and indirect maternal deaths in the same period, giving a mortality/morbidity ratio of 1 in 79. By far the commonest morbidity was major obstetric haemorrhage, defined as an estimated blood loss of 2.5 litres or more, which occurred in 4.5/1000 births. In 2011 the rate of morbidities except haemorrhage declined, but the rate of major obstetric haemorrhage increased, affecting 1 in 170 births. The rate is not affected by social class, except that the most affluent quintile were more likely to experience morbidity. There was a significantly higher rate of major obstetric haemorrhage in women with a BMI over 35.

Perhaps the most valuable lesson from audits of severe maternal morbidity is that even when the MMR is very low the risks of pregnancy have not gone away. The low rates of maternal mortality in developed countries are not due to improved health of the population but to effective intervention when problems occur. The rates of severe morbidity today, around 4/1000, are similar to the MMR in the UK before 1935 (Fig. 28.1), and to the MMRs in parts of Africa today.¹

Audits of morbidity and confidential enquiries into mortality are complementary. Aggregation of deaths classified

by cause teaches lessons that cannot be learned by looking at each of these rare events in isolation. In 2006–8 the reports of local investigations into individual deaths were available to the national assessors, who found that their quality was extremely variable. It is very difficult for a hospital to investigate such a rare and upsetting event without outside support, and a national perspective is essential.

SUMMARY

The worldwide total of maternal deaths has fallen to under 300,000 per year, but still represents a largely preventable tragedy. We know how to treat the conditions that cause these deaths. Ensuring that treatment reaches the women who need it is a matter of political will, and obstetricians have a duty to act as advocates for the women at risk.

In the UK, the maternity services have been successful in making pregnancy safe for most women but substandard care still occurs. Women from ethnic minorities are at increased risk, as are the most deprived sections of the community. The Confidential Enquiry led the way in revealing these disturbing facts, and others such as the risks associated with psychiatric disease, domestic violence and, today, obesity. The purpose of the enquiry is to save lives, and its recommendations are always firmly based on its findings. The importance of this process is increasingly recognised in the UK and worldwide.

One final point: although knowledge of the most recent report is essential, lessons of previous reports must also be remembered, and this may become even more important in the future when annual reports are published. To quote from the last of the triennial reports,² 'Experience has taught us that old messages need repeating, especially as new cadres of healthcare workers join the service, and there are always new and unexpected challenges'.

KEY POINTS

- Maternal death is the death of a woman while pregnant or within 42 days after the end of pregnancy. *Direct* deaths result from obstetric complications and *indirect* deaths from disease aggravated by, but not directly due to, pregnancy.
- Across the world the average MMR is now 210 per 100,000. Of the estimated global total of 287,000 maternal deaths every year, the vast majority are in developing regions.
- In developed countries the MMR is around 10 per 100,000 maternities. In Britain between 1936 and 1985 the MMR fell steadily due to antibiotics, blood transfusion, ergometrine, better training of midwives and obstetricians and the 1967 Abortion Act.
- Direct deaths in the UK fell in 2006–08, but it remains to be seen if that fall will be sustained. The leading cause of direct death is no longer thromboembolism, but sepsis.
- Indirect deaths in the UK outnumber direct deaths. The leading cause is cardiac disease.

- Risk factors for maternal death include age, obesity, low social class and black ethnicity.
- Most of the deaths worldwide, and many in the UK, are preventable

SECTION THREE

Fetal Conditions

This page intentionally left blank

Chapter 29 Biochemical screening

Michele P Mohajer

MRCOG standards

Theoretical skills

- Understand the biochemical components used in maternal serum screening and how they relate to specific malformations.
- Understand the limitations of maternal serum screening and the situations in which screening may be unreliable.

Practical skills

- Be able to counsel a woman about the screening tests available to her.
- Be able to explain about detection rates and limitations of screening.
- Be able to counsel parents who have had a screen-positive result.

INTRODUCTION

Over the last 50 years, many biochemical substances produced by the fetoplacental unit have been identified in maternal serum. A number of these have been found to be associated with certain fetal conditions and have been incorporated into national screening programmes. This section aims to describe those programmes, along with their advantages and disadvantages.

In 1956, the first biochemical marker identified in maternal serum was alpha-fetoprotein (AFP); the association between a raised serum AFP and open spina bifida was not demonstrated until 1974.¹

BIOCHEMICAL SCREENING FOR NEURAL TUBE DEFECTS

AFP is produced by the fetal liver. It crosses into the maternal serum from the amniotic fluid or via the placenta. Maternal serum AFP (MSAFP) rises throughout most of pregnancy (from 12 weeks to 32 weeks), hence accurate determination

of gestational age is mandatory. To allow for the increase in concentration in the second trimester, it is convenient to express all AFP values as a multiple of the normal median (MoM) at the relevant gestational age. The separation between the distribution of MSAFP levels in pregnancies with open fetal defects and that in normal pregnancies is greatest at 16–18 weeks' gestation, and therefore screening is optimum at this stage.

AFP screening was intended for the detection of open spina bifida, and not closed spina bifida. Using a cut-off level of 2.5 MoM, 79 per cent open spina bifida and 88 per cent anencephaly can be detected [C]. If all neural tube defects (NTDs) are considered, the detection rate is 72 per cent, with a false-positive rate of 0.001 per cent.²

Raised MSAFP is also associated with other fetal malformations or conditions, including:

- multiple pregnancy;
- abdominal wall defects (gastroschisis, exomphalos, bladder extrophy):
 - congenital nephrosis;
- spontaneous fetal loss.

There is also some degree of association between a raised MSAFP and the following conditions:

- pre-eclampsia;
- preterm delivery
 - low birthweight;
 - underestimated gestation;
 - low maternal weight;
 - African-Caribbean ethnic origin;
 - male fetus;
 - raised MSAFP in a previous pregnancy;
- smoking.

Levels of MSAFP may be lowered in association with other conditions, including:

- Down's syndrome (trisomy 21);
- Edward's syndrome (trisomy 18);
- type 1 diabetes;
- overestimated gestation;
- high maternal weight.

AFP screening now has a minor role in the detection of fetal defects due to the widespread use of sophisticated ultrasound

techniques. Using ultrasound to demonstrate the characteristic cranial signs of spina bifida (the 'lemon and banana' sign), the detection rate of all NTDs is 81 per cent [C], with a false-positive rate of 0.0003 per cent.³ This detection rate exceeds that of AFP screening programmes.

The role of amniocentesis in MSAFP screening

Prior to high-resolution ultrasound, amniocentesis was routinely performed to detect increased levels of AFP and acetylcholinesterase (AChE) in the amniotic fluid in an attempt to diagnose open fetal defects. The risk of fetal loss may be eight times higher when amniocentesis is performed in these circumstances [A], and it therefore should not be performed as an initial investigation.⁴

Many more biochemical substances have been identified that are produced during pregnancy. Many of these have been investigated for their usefulness in detecting pregnancy complications. Two notable hormones, human placental lactogen (hPL) and oestriol (E_3), were used widely to assess placental function. These have now been abandoned due to the development of better biophysical methods.

BIOCHEMICAL SCREENING FOR DOWN'S SYNDROME

The main area of development of other biochemical markers in pregnancy has been in screening for Down's syndrome (trisomy 21).

Down's syndrome is still the commonest cause of severe learning disability. The natural birth prevalence increases with maternal age, from 1 in 1500 under the age of 25, to 1 in 1000 at age 30, and to 1 in 100 at age 40. The overall incidence of the condition has increased due to women having their babies at an older age.

In the early 1980s, antenatal screening relied on identifying women above a specified age (e.g. 35 years) and offering them amniocentesis. In 1984, low MSAFP levels in the mid-trimester were found to be associated with Down's syndrome.⁵ Later, hCG was found to be raised in Down's syndrome, and unconjugated oestriol (uE_3) was found to be reduced. Division of hCG into its free subunits (alpha-hCG and beta-hCG) provided additional value in screening. More recently, a fourth biochemical marker, inhibin-A, has been found to be raised in Down's syndrome pregnancies.⁶

Subsequently, measurement of biochemical substances in the first trimester of pregnancy has also demonstrated an association with Down's syndrome. The two markers used are free beta-hCG and PAPP-A.

Accurate gestational age assessment is vital to the utility of these biochemical markers. Biochemical screening is applicable only to singleton pregnancies, so ultrasonic assessment is again mandatory. All markers vary with gestation, and so MoMs are used to determine abnormal values.

First-trimester screening

Two biochemical markers, namely free beta-hCG and PAPP-A, when measured between 8 and 14 weeks in combination with maternal age, can detect 62 per cent of Down's syndrome pregnancies, with a 5 per cent false-positive rate.⁸ These serum markers, when combined with maternal age and NT measurement, comprise a combined test, which has an estimated detection rate of 85 per cent for a 5 per cent false-positive rate.⁹ This test is usually performed in a single visit, which reduces the anxiety of waiting for a result.

First-trimester screening provides the opportunity to establish a diagnosis in early pregnancy (if CVS is utilised). This method of national screening requires substantial financial support for the training and education of health professionals, the provision of information and counselling services, and the expansion of expertise in diagnostic ultrasound and invasive tests such as CVS [C].

Second-trimester screening

Second-trimester screening is carried out between 15 and 20 weeks of pregnancy. Serum screening programmes incorporate:

- two components (MSAFP and total hCG or free beta-hCG): the double test;
- three components (MSAFP, hCG and uE_3): the triple test; or
- four components (MSAFP, hCG, uE_3 and inhibin): the quadruple test.

The screening performance of these markers improves with the addition of markers, such that, for a false-positive rate of 5 per cent, the detection rates for the double, triple and quadruple tests are 59 per cent, 69 per cent and 76 per cent, respectively.⁷ However, the extra cost of using additional serum markers must be considered.

Certain factors can influence serum markers:

- Type 1 diabetes and increased maternal weight lower all markers.
- Twin gestation produces approximately twice the level of all serum markers.
- Minor variations occur with ethnic differences and in smokers.
- Other conditions in which serum screening may be unreliable include maternal renal failure and severe dehydration (e.g. severe hyperemesis gravidarum).

The aim of screening is to maximise the detection rate with a low false-positive rate, in order that invasive testing is minimised.

Integrated/hybrid screening

Simultaneously using markers from both trimesters yields a better screening performance than using markers in either trimester alone. Thus, if the first-trimester triple test is combined with the second-trimester quadruple test, the detection

rate for Down's syndrome has been estimated at 94 per cent for a 5 per cent false-positive rate.¹⁰ If the false-positive rate is fixed at 1 per cent, the detection rate will be 85 per cent. This approach therefore yields a higher detection rate than any other screening test at a given false-positive rate. The SURUSS (serum, urine and ultrasound screening study) report showed that, if the risk cut-off level is fixed at 1:200, the detection rate is 89 per cent for a 2.4 per cent false-positive rate. The FASTER (First- and Second-Trimester Evaluation of Risk) trial showed comparable results.¹² However, the logistics of introducing such a screening system need to be considered. The result of the first-trimester screen would need to be concealed from the woman, and thus would negate the advantage of early prenatal diagnosis. If ultrasound facilities are not sufficiently developed to perform reliable NT measurement, the full, integrated test cannot be provided. In the absence of NT, the detection rate for the integrated test is 85 per cent for a 5.5 per cent false-positive rate.¹⁰ In addition, the infrastructure necessary for the organisation and counselling of integrated/hybrid screening far exceeds that required for the present screening programmes. Nevertheless, the enormous financial and emotional advantage of a test with a 1 per cent false-positive rate cannot be denied.

National recommendation for Down's syndrome screening

Current recommendations state that all pregnant women should be offered first-trimester screening (by 13 weeks and 6 days), but that provision should be made to allow for later screening (as late as 20 weeks 0 days).¹³ Ideally the combined test (NT +beta-hCG+PAPP-A) should be offered between 11 weeks and 13 weeks 6 days. For women who book later in pregnancy, the most clinically effective serum screening (triple or quadruple test) should be offered between 15 weeks 0 days and 20 weeks 0 days.

The NSC recommendations specified that, by 2008, all trusts should offer Down's syndrome screening to all pregnant women with the aim to improve detection to $\geq 90\%$ with a screen positive rate (SPR) $< 2\%$.

BIOCHEMICAL SCREENING FOR OTHER ABNORMALITIES

A number of other chromosomal abnormalities have been shown to be associated with biochemical markers:

- *Trisomy 18/trisomy 13*. These are the next most common aneuploidies surviving to birth. There is evidence to support serum screening for these, but it is not sufficiently robust to introduce into the NHS fetal anomaly screening programme at present. The mid-trimester anomaly scan is more sensitive and specific.¹⁴
- *Triploidy*. This chromosomal abnormality is inconsistent with survival. Affected pregnancies may be identified in

the mid-trimester, as there are very high or very low levels of AFP and hCG, and low levels of E_3 .

- *Turner's syndrome (45,X)*. In Turner's syndrome associated with hydrops, the serum markers show a pattern similar to that of Down's syndrome pregnancies. In those without hydrops, the hCG level is low.
- *Smith–Lemlie–Opitz syndrome*. This is an autosomal recessive condition associated with moderate-to-severe learning disability. In these pregnancies, uE_3 is very low or undetectable, and MSAFP and hCG tend to be low. The risk of a pregnancy affected with this condition can thus be calculated, and the diagnosis is confirmed by measuring 7-dehydrocholesterol (7-DHCO) in the amniotic fluid.

Adverse pregnancy outcome. Low markers in the first trimester (hCG and PAPP-A) and elevated mid-trimester MSAFP and inhibin are associated with preterm birth, fetal loss, growth restriction, placental abruption and pre-eclampsia.¹⁵

HEALTH ECONOMICS OF SCREENING

A major challenge in the delivery of Down's syndrome screening services is the need to set up an adequate organisational structure. This not only means dedicated laboratory facilities with computer-assisted test interpretation and expertise to provide invasive prenatal testing, but also a team of experienced coordinators to undertake the enormous workload of counselling. This counselling is essential, both prior to undertaking the test and in the event of a screen-positive result when invasive testing is contemplated. It is this last service provision that has poor structure in many screening programmes, and fiscal implications are generally underestimated. In the ideal structure, each unit should have a clear screening policy agreed centrally. A screening coordinator is responsible for reporting results to women and coordinating the local screening service. A local director of screening, of consultant status, guides and supports the service, and is attentive to advances in screening and their controlled introduction into practice.

EBM

- High-resolution ultrasound has a better detection rate for open fetal defects than a high MSAFP [C].
- With accurate ultrasound dating, second-trimester biochemical screening using four markers can detect 76 per cent of Down's syndrome pregnancies [B].
- First-trimester serum screening is as effective as mid-trimester serum screening [B].

KEY POINTS

- A raised MSAFP has good sensitivity but poor specificity for open fetal defects; mid-trimester ultrasound scan is considered superior with a greater sensitivity and specificity.
- Mid-trimester serum screening for Down's syndrome is widely available in the UK.
- Detection rates vary depending on the number of markers used.
- A dating scan must be performed prior to Down's syndrome screening.
- Combined (first-trimester) screening is the recommended method and should be offered to all pregnant women.
- Counselling before and after testing accounts for the bulk of the workload.

Chapter 30 Ultrasound Screening

Michele P Mohajer

MRCOG standards

Theoretical skills

- Understand which structural malformations can be identified by ultrasound screening.
- Know the expected detection rates of major fetal malformations.
- Understand the limitations of ultrasound examination.

Practical skills

- Be able to perform an ultrasound scan independently to identify features of the head, chest and abdomen.
 - Counsel regarding screening for fetal abnormalities.
- Be able to perform a third-trimester scan independently to assess viability, fetal presentation, placental localisation and liquor volume by deepest pool.

INTRODUCTION

The incidence of major structural abnormality is 2–3 per cent, and far exceeds all chromosomal abnormalities or single-gene defects. As a result of the technological development in high-resolution ultrasound equipment, the prenatal diagnosis of most major structural malformations is possible. As a consequence, there has been a significant fall in perinatal mortality rates due to the termination of affected fetuses. In addition to this role, ultrasound scanning is vital in determining gestation, viability and number of fetuses. The advent of such technological development has provided the foundation for the subspecialty of fetal medicine.

WHAT IS SCREENING?

The purpose of screening for fetal malformation is not simply to terminate the fetus prior to viability in order to reduce perinatal mortality rates. Although screening does reduce perinatal mortality rates, the identification of fetal malformation allows parents to make informed choices regarding their pregnancy. This facilitates physical and psychological preparation for the delivery of an infant with a birth defect, which may even take place in another centre. In addition, identification of certain abnormalities may allow parents to avail themselves of *in-utero* treatments that can improve the infant's condition prior to birth. Ultrasound screening can also be used to identify some fetuses with chromosomal disease, in which case invasive diagnostic procedures can be performed.

WHO SHOULD BE SCREENED?

Certain conditions increase a woman's chance of having a malformed fetus. So-called 'high-risk' groups can be identified, such as women with type 1 diabetes, maternal drug ingestion (e.g. anticonvulsants, warfarin) or a positive family history. However, 95 per cent of abnormalities occur in fetuses born to mothers who have no risk factors at all.¹ Therefore, routine ultrasound scanning of all pregnancies is the preferred method to identify structural malformations [A]. However, vast differences exist in detection rates, ranging from 16 per cent to 85 per cent.²⁻⁴

The reasons for these differences are unclear. The skill and training of the operator are important, but perhaps an important variable is the gestational age at which the scan is done. The optimum time for the identification of structural fetal anomalies is 18–21 weeks [B].^{5,6} Prior to performing the ultrasound scan, it is vital that the parents understand the objectives, the limitations and also the detection rates for the major malformations.⁶ This is ideally done by the provision of information leaflets [C].

TIMING OF SCREENING

The detailed fetal anomaly scan at 18–21 weeks

The scan initially checks viability and number of fetuses, as well as placental site and amniotic fluid volume. Standard views of the fetus are then taken.¹⁸ These are:

- 1 transverse section through the fetal head, assessing head shape and internal structures;
- 2 face: lips;
- 3 fetal spine: sagittal, coronal and transverse views;
- 4 fetal abdomen: longitudinal and transverse; identifying intra-abdominal organs: stomach, kidneys, bladder and ventral wall integrity and cord insertion;
- 5 transverse section through fetal thorax to examine four-chamber view of the heart and outflow tracts;
- 6 Limbs: identify three long bones in each limb, hands and feet.

Inability to obtain the standard images may occur due to fetal position or maternal size.

MAJOR STRUCTURAL MALFORMATIONS

CNS malformations

Many major structural defects of the CNS may be identified at the 20-week scan, and certain malformations can be identified at earlier gestations.

Neural tube defects

These malformations occur when there is a failure of dorsal fusion in early embryological life, such that neural tissue is exposed. NTDs (anencephaly, cephalocele and spina bifida) are the commonest CNS malformations in the UK, and much attention has been applied to the screening and prevention of these anomalies. Anencephaly is characterised by the absence of the cerebral hemispheres and cranial vault, and can be identified from as early as 11–12 weeks. The prognosis is uniformly fatal within the first hours or days of life. Cephalocele is a protrusion of the intracranial contents through a bony defect of the skull. These contents may include only meninges (cranial meningocele) or brain tissue (encephalocele). Ultrasound examination can identify a solid or cystic paracranial mass. The prognosis depends on the presence of brain tissue within the sac and other associated intracranial features. Spina bifida, in which the defect exists in the vertebral fusion, is the commonest CNS malformation. Demonstration of the lesion itself by ultrasound may be difficult. However, the intracranial signs associated with spina bifida, the Arnold–Chiari malformation (herniation of the cerebellum and brain stem through the foramen magnum), are more easily identifiable.⁷ This demonstration of the ‘lemon and banana’ sign has displaced MSAFP as the main screening test for spina bifida

in many units. The detection rate for open spina bifida on ultrasound screening is 81 per cent, with a false-positive rate of 0.0003 per cent.⁸

Hydrocephalus

This condition arises when there is an abnormal accumulation of CSF, resulting in enlargement of the ventricular system. It is commonly associated with other intracranial and extracranial abnormalities. Diagnosis on ultrasound examination is achieved by demonstration of enlarged lateral ventricles and anterior displacement of the choroid plexus. The three major forms are aqueduct stenosis, communicating hydrocephalus and the Dandy–Walker syndrome. This last syndrome is characterised by the addition of a cyst in the posterior fossa and defect in the cerebellar vermis, both of which are detectable on ultrasound. The prognosis is variable, again depending on the severity of the hydrocephalus and the presence of additional malformations.

Other less common CNS malformations may be identified on ultrasound. These include holoprosencephaly, iniencephaly, arachnoid cysts, porencephalic cysts, agenesis of the corpus callosum, hydrancephaly, microcephaly, intracranial tumours and aneurysm of the vein of Galen.

Cardiac malformations

Systematic examination of the fetal heart has enabled the prenatal diagnosis of many congenital heart defects. Since the fetal heart is almost horizontal, a transverse section through the fetal chest will demonstrate a four-chamber view. This standard view provides information about the position and size of the fetal heart, the cardiac chambers and the atrioventricular connections. Congenital heart abnormalities associated with an abnormal four-chamber view include:

- hypoplastic left heart;
- hypoplastic right heart;
- atrioventricular canal defect;
- large ventricular septal defect;
- large atrial septal defect;
- single ventricle;
- valve stenosis or atresia;
- Ebstein’s anomaly;
- cardiac tumour;
- cardiac situs abnormalities.

However, there is a wide variation in the ability of ultrasound screening for cardiac abnormalities, with detection rates varying from 6 per cent to 77 per cent.^{1,4} These differences may be related to the gestational age at which the scan is performed, the type of congenital heart abnormality and the experience of the operator. Several cardiac defects are associated with a normal standard four-chamber view. These include:

- tetralogy of Fallot;
- transposition of the great arteries;
- small atrial and ventricular septal defects;

- mild pulmonary or aortic valve stenosis;
- mild coarctation of the aorta.

With the improvements in paediatric cardiac surgery, prenatal diagnosis of cardiac conditions has become much more important. Parents can make informed choices, if given the realistic expectations of the problem.

Thoracic malformations

By obtaining transverse and longitudinal views of the fetal chest, space-occupying lesions, solid or cystic, may be diagnosed. The fetal lungs are uniformly echogenic. Fluid within the pleural cavity (pleural effusions) may be identified as a result of certain fetal conditions. Chylothorax, a relatively common cause of pleural effusion in neonatal life, is an accumulation of chyle in the pleural cavity. Bronchogenic cysts may appear as sonolucent areas within the fetal chest.

Congenital cystic adenomatous malformation of the lung (CCAML) is a condition whereby there is overgrowth of terminal bronchioles at the expense of saccular spaces. The ultrasound appearance varies according to the type: either macrocystic, with large cystic structures within the chest, or microcystic, where there is increased echogenicity of the lung tissue. Lung sequestrations may also appear as an echogenic mass. Cystic structures within the chest may also be demonstrated in the fetus with congenital diaphragmatic hernia. When there is a defect, the stomach or other abdominal contents may be demonstrated above the level of the diaphragm.

Gastrointestinal and abdominal wall malformations

Demonstration of the integrity of the abdominal wall is made on transverse and longitudinal views. Ventral wall defects, gastroschisis and exomphalos may be identified.

Gastroschisis is a para-umbilical defect, and can be diagnosed by the presence of herniated organs floating freely within the amniotic cavity. An exomphalos is a central defect surrounded by a membrane on which the umbilical cord is inserted. These defects may also be associated with an elevated MSAFP. In isolation, the prognosis for both of these malformations is good with surgical correction, but karyotyping should be considered in the case of exomphalos, as an association with aneuploidy exists. Rarer defects in the abdominal wall may be diagnosed, known as bladder and cloacal extrophy.

Intra-abdominal pathology may be diagnosed on ultrasound such as:

- fetal ascites;
- small and large bowel obstruction;
- meconium peritonitis;
- mesenteric, omental and retroperitoneal cysts.

Many of the obstructive malformations may be associated with polyhydramnios.

Urogenital malformations

The fetal kidneys and bladder are relatively easily identified structures in the mid-trimester. Many fetal renal problems are associated with a disturbance in amniotic fluid volume. By 16 weeks, the majority of the amniotic fluid is produced by the fetal kidneys. If oligohydramnios is diagnosed in the mid-trimester, in the absence of a history of ruptured membranes, fetal renal malformation must be suspected.

Renal agenesis may be bilateral or unilateral. If bilateral, there is associated anhydramnios, and the condition is fatal. Visualisation of the fetal kidneys in this situation is difficult due to loss of the acoustic window and may be facilitated by an amnio-infusion.

Infantile polycystic kidney disease is an autosomal recessive disease. Ultrasound diagnosis is made by the demonstration of bilateral, enlarged, hyperechogenic, fetal kidneys, absent fetal bladder and associated oligohydramnios. The prognosis is poor.

Obstructive uropathy may occur due to an obstruction at the urethra or ureter. Urethral obstruction, due either to urethral atresia or posterior urethral valves, may be demonstrated by the presence of a distended fetal bladder, hydronephrosis and hydronephrosis. Ureteric obstruction, which may be unilateral or bilateral, can be diagnosed by ultrasound by the demonstration of hydronephrosis.

In multicystic dysplastic kidney disease (MDKD), ultrasound examination of the fetal kidneys shows the presence of multiple cysts, and increased echogenicity of the surrounding parenchyma. The kidneys are enlarged and, where there is bilateral disease, the prognosis is fatal.

Tumours of the kidney and adrenal gland, if present in fetal life, can also be diagnosed on ultrasound scans.

Skeletal malformations

Diagnosis of skeletal abnormalities requires a full examination of the fetus, with a skeletal survey. This involves both morphological and biometric examination of the skull, vertebrae, ribs, long bones, and digits of the hands and feet. Measurement of the femur length at a dating scan may be the first clue to a skeletal problem.

Skeletal malformations may affect the whole skeleton and may be lethal, such as:

- achondrogenesis;
- thanatophoric dysplasia;
- short-rib polydactyly syndromes;
- fibrochondrogenesis;
- homozygous achondroplasia;
- osteogenesis imperfecta (perinatal type);
- hypophosphatasia (perinatal type).

Lethality is usually dependent on thoracic cage involvement and subsequent development of pulmonary hypoplasia.

Other skeletal problems, such as radial anomalies, talipes equinovarus, femoral hypoplasia, facial clefts and digital

anomalies, may be identified and may form part of another syndrome, including chromosome anomalies.

The prognosis depends on the involvement of other, non-skeletal, malformations.

The overall detection rate of skeletal problems is 90 per cent.⁹

Hydrops fetalis and cystic hygroma

This is a condition in which fluid accumulates within the body cavities and soft tissues of the fetus. The aetiologies of this condition are numerous (see Chapter 40).¹⁰ Visualisation of fluid within the fetus is relatively easy, and the commonest area of fluid accumulation is at the fetal neck, the cystic hygroma. This is usually due to lymphatic obstruction, and is recognised as a cystic structure adjacent to the fetal neck. Cystic hygromas are frequently associated with chromosomal abnormalities. Smaller degrees of fluid in this area are referred to as nuchal oedema or nuchal translucency. As detailed below, it is this latter anomaly that has been identified at earlier gestations (11–14 weeks), and has now been incorporated into screening programmes for aneuploidy.

SCREENING FOR CHROMOSOMAL DISEASE

Many structural malformations identified on scan may be associated with chromosomal disease, such as:

- cystic hygroma;
- cardiac defects;
- exomphalos;
- holoprosencephaly;
- microcephaly;
- diaphragmatic hernia;
- oesophageal/duodenal atresia;
- renal anomalies;
- radial aplasia;
- micrognathia;
- clinodactyly of the fifth finger;
- polydactyly;
- talipes;
- facial clefts.

At the time of the 20-week scan, minor ultrasound abnormalities may be seen that may also be associated with aneuploidy. These are known as ‘soft markers’. They may not constitute a structural defect, but, when seen along with another risk factor for chromosomal disease, karyotyping may be considered. Soft markers include:

- nuchal oedema;
- mild renal pyelectasis;
- hyperechogenic bowel;
- echogenic intracardiac foci;
- strawberry-shaped skull;

- mild ventriculomegaly;
- shortened long bones;
- choroid plexus cysts;
- clenched fists;
- rocker-bottom feet;
- sandal gap;
- single umbilical artery.

These soft markers have been included in some screening programmes for Down’s syndrome. However, apart from nuchal oedema, there is no strong evidence at present that the other soft markers are helpful in identifying Down’s syndrome [A].¹¹

A recent NHS fetal anomaly screening programme has refined recommendations such that only the following markers should be referred for further management:

- Nuchal oedema (>6 mm);
- Ventriculomegaly (atrium 10 mm or greater);
- Echogenic bowel;
- Renal pelvic dilatation (>7 mm AP);
- Small measurements compared with the dating scan (<3rd centile);
- Facial clefting.

Choroid plexus cysts, head shape, cisterna magna (in the absence of brain abnormality), echogenic foci and two-vessel cord should not be recorded or referred, and should be considered as ‘normal variants’.¹²

FIRST-TRIMESTER SCREENING

Ultrasound scanning in the first trimester was primarily introduced for viability and accurate dating. With improved resolution, a number of fetal defects may also be seen, such as:

- anencephaly;
- holoprosencephaly;
- encephalocele;
- Dandy–Walker syndrome;
- cardiac anomalies;
- gastroschisis;
- exomphalos;
- megacystis;
- diaphragmatic hernia;
- multidysplastic kidney;
- some skeletal dysplasias.

Using a combination of transabdominal and transvaginal ultrasound, up to 59 per cent of major structural defects may be diagnosed at the 11- to 14-week scan.^{12,13}

An important component of the first-trimester scan is the NT measurement, which is the maximum thickness of the subcutaneous translucency between the skin and the soft tissue overlying the cervical spine. It has not only been shown to be an effective screening test for aneuploidy, but also may identify a fetus at risk of cardiac defects, skeletal dysplasias and genetic syndromes.¹⁴ There are sufficient data to show that NT

screening for Down's syndrome at 10–14 weeks is superior to serum screening with multiple markers at 15–20 weeks' gestation [A]. Assessment of the fetal nasal bone during the first trimester may improve the detection of Down's syndrome. However, studies of general population screening have not been able to support this.¹⁴

First-trimester combined screening (nuchal translucency + hCG + PAPP-A) is now the recommended screening test for Down's syndrome (see Chapter 29). The counselling, expertise and training required to successfully implement such a national screening test have been challenging.

HAZARDS OF THE ULTRASOUND SCAN

Many epidemiological and laboratory studies have been performed to search for evidence of the possible biological effects of diagnostic ultrasound. Childhood cancer, dyslexia, non-right-handedness, delayed speech development and reduced birthweight have all been implicated, but as yet there is no good evidence to establish a firm link between ultrasound and these end-points.¹

Although a sophisticated investigation, there are limitations to ultrasound. Adequate visualisation of the fetal anatomy may not be possible due to the fetal position or maternal habitude. In situations of gross maternal obesity, confirmation of fetal viability may be extremely difficult.

Visual confirmation of fetal normality appears to promote a positive attitude towards the pregnancy, with improved compliance on healthcare issues such as smoking and alcohol.¹⁵ However, the detection of fetal defects and, in particular, soft ultrasound markers may generate immense anxiety and rejection, even if the subsequent invasive testing proves that the fetus is healthy. Hence, for the successful maintenance of ultrasound screening programmes, a framework of skilled midwives, sonographers and counsellors is necessary. This is not only to deal with parents in whom a fetal abnormality has been diagnosed, but also to ensure that, prior to the ultrasound scan, women have a clear idea about what the test is likely to achieve and its reliability in doing so.

Perhaps the greatest hazard of ultrasound is misdiagnosis.

EBM

- Screening the whole population rather than selective scanning is the most reliable way to identify a fetal abnormality [A].
- A scan undertaken between 18 and 21 weeks is the most effective method to identify a wide range of fetal abnormalities [B].
- Screening for fetal abnormality reduces the perinatal mortality rates through identification and termination of affected pregnancies [A].

KEY POINTS

- Detailed ultrasound at 18–21 weeks is an important screening examination in which most life-threatening malformations can be diagnosed.
- Pregnant women should receive clear information regarding the objectives of the ultrasound examination and the likelihood of finding an abnormality.
- The success of the ultrasound examination depends on the operator, the ultrasound equipment, the fetal position and the maternal habitude.
- When an abnormality is detected on ultrasound, the parents should have ready access to skilled counsellors who are able to provide them with full information, options and support in order to allow them to make an informed choice.

Chapter 31 Invasive and non-invasive prenatal diagnosis

Michele P Mohajer

MRCOG standards

Theoretical skills

- Understand the indications for an invasive test.
- Know the advantages and disadvantages of each test.

Practical skills

- Be able to counsel a woman about the procedure and its risks.
- Have observed other procedures such as chorionic villous sampling, placental biopsy, cordocentesis, intrauterine transfusion.

INTRODUCTION

High-resolution ultrasound has enabled direct access to the different constituents of the gestational sac from the middle of the first trimester of pregnancy. An ever-increasing range of invasive techniques is being developed to facilitate the diagnosis of chromosomal and single-gene defects, metabolic disorders, intrauterine infection, fetal anaemia, thrombocytopenia and some structural problems.

All invasive procedures carry a small risk of fetal loss. Early prenatal testing provides the opportunity for surgical termination of the pregnancy if required, but the earlier invasive testing tends to increase the fetal loss rate. Non-invasive techniques for identifying fetal cells in maternal blood and cervical mucus have been the focus of much research.¹ This technique of non-invasive prenatal diagnosis (NIPT) using free fetal DNA (cfDNA) with detection rates of >99 per cent has now become incorporated into clinical use¹⁵ but is not currently available within the health service in the UK. Developments in techniques employing multiplex PCR have enabled reliable prenatal diagnosis of fetal blood groups² and fetal aneuploidy.³

The routinely used invasive procedures are amniocentesis, CVS and fetal blood sampling (FBS).

AMNIOCENTESIS

Amniocentesis involves the aspiration of amniotic fluid from the amniotic sac via a needle inserted through the maternal abdomen. It is the commonest prenatal diagnostic procedure in the UK. It was first introduced in 1966 for the diagnosis of genetic disease.⁴ It was subsequently used to confirm open NTDs by measurement of liquor alpha foeto protein in the presence of a raised MSAFP (see Chapter 29).⁵ It is usually performed between 15 and 16 weeks' gestation.

Method

Using an aseptic technique, a 22-gauge needle is inserted through the maternal abdomen under direct real-time ultrasound control with continuous needle-tip visualisation. This method is more successful than blind techniques [B]. Fluid (15–20 mL) containing fetal cells is aspirated into a syringe and sent to the genetics laboratory for testing.

Indications for amniocentesis

The main indication for amniocentesis is for fetal karyotyping. In view of the risk of miscarriage, the procedure is offered when there is an increased risk of aneuploidy, such as for:

- women with positive screening for Down's syndrome;
- women of advanced maternal age (traditionally 35 years);
- ultrasound detection of an abnormality or soft markers;
- parental balanced translocation;
- a previous history of chromosomal abnormality.

One of the major disadvantages for the woman has been the long wait for the result, which may take from 2 weeks to 4 weeks. Molecular genetics has developed two techniques, which have permitted the rapid diagnosis of the many major chromosomal abnormalities. These two tests, fluorescence *in-situ* hybridization (FISH) and quantitative fluorescence polymerase chain reaction (QF-PCR), can provide results in 24–48 hours.⁶ FISH relies on the unique ability of a portion of single-stranded DNA (known as a probe) to hybridise

with its complementary target DNA sequence. By attaching a fluorescent label to the appropriate probe, diagnosis of autosomal trisomies for chromosomes 13, 18 and 21, and X and Y chromosomes can be made in 6–8 hours by direct fluorescent microscopy. QF-PCR uses highly polymorphic small tandem repeat markers, which allow distinction between normal and trisomic DNA samples. Diagnosis of the major chromosomal abnormalities (trisomies 13, 18, 21 and sex chromosome copy number abnormalities) can be performed in 24–48 hours. Both techniques share the same diagnostic dilemma in that conventional chromosomal analysis is required to detect other chromosomal disorders. However, as a result of its reliability, rapidity and relatively low cost, QF-PCR has been introduced in most laboratories as an adjunct to long-term culture.⁷ Where the indication for amniocentesis is a screen-positive result, QF-PCR may be the only technique offered.

Amniocentesis is also used for the diagnosis of single-gene disorders. However, culture of the cells and extraction of the DNA often means a significant delay in receiving the result.

Using PCR techniques, amniocentesis can also be used to facilitate the diagnosis of certain congenital infections (see Chapter 36), such as cytomegalovirus and toxoplasmosis.

Amniocentesis no longer has a role to play in isoimmunised pregnancies. The absorbance difference at the wavelength 450 nm provided an indirect measurement of the bilirubin in amniotic fluid. However, in view of the increased likelihood of further sensitisation, other non-invasive methods for estimating the degree of fetal anaemia are now in routine use (fetal, middle cerebral artery, Doppler peak systolic velocity).⁸

Amniocentesis is also no longer used to estimate the AFP and AChE for the diagnosis of NTDs. Amniocentesis performed in the presence of raised MSAFP is associated with a significant increase in fetal loss [A].

Complications

The fetal loss rate from the procedure varies, but the only RCT of low-risk women reports a rate of 1 per cent [A].⁹ Many units report their own miscarriage rate based on their own individual audit data. Operator experience has been shown to be important [B]. Adequate levels of training (30 procedures per year) are necessary to maintain success and reduce complications, although postgraduate training is moving towards a competency-based rather than a numerical goal. Cell culture may fail in 0.5 per cent of amniocenteses, necessitating a further invasive test.

Early amniocentesis

Owing to the relative ease of the procedure, amniocentesis at earlier gestations was performed in order to provide women with the advantages of early prenatal diagnosis. Early amniocentesis can be performed from 10 weeks' gestation. However, the technique is considered unsafe prior to 14 weeks as it carries a higher fetal loss rate (7.6 per cent), increased fetal talipes

and respiratory morbidity, and reduced amniocyte culture rate compared with other procedures [A].¹⁰

CVS AND PLACENTAL BIOPSY

These procedures refer to the sampling of placental tissue. Placental biopsy is the term used when the procedure is performed after the first trimester. Placental tissue can be obtained by catheter, needle aspiration or biopsy forceps. Transabdominal and transcervical methods are both used. The procedure can be performed from 10 weeks' gestation. Early diagnosis allows the woman the option of termination before 13 weeks' gestation.

Transabdominal CVS

Using aseptic techniques, an 18- to 20-gauge needle is inserted through the maternal abdomen to the placental site under direct ultrasound guidance. Placental tissue is aspirated into a syringe attached to the needle. Similarly, a fine biopsy forceps can be used through an outer guide needle. If the placenta is completely posterior and low lying, access via the transabdominal route may not be possible.

Transcervical CVS

This method is ideal for the posterior low-lying placenta. The cervix and vagina are visualised through a speculum and cleaned with sterile solution. Transabdominal ultrasound is performed to visualise the cervical canal. The needle, catheter or biopsy forceps is then introduced through the cervix towards the placenta under ultrasound guidance, and a sample is taken.

The choice of a transabdominal or a transcervical approach should be dependent on operator experience, the placental site and the axis of the uterus. Transcervical CVS is associated with less discomfort than the transabdominal approach, but there may be concern regarding the potential risk of infection with the transcervical route. However, several randomised trials show almost identical miscarriage rates with the two routes [A].¹⁶

Indications for CVS

CVS has the advantage of yielding a large amount of tissue and is therefore the method of choice when large amounts of DNA are required in the diagnosis of monogenic disorders. With the increasing use of early screening tests for Down's syndrome, and with high-resolution ultrasound detecting abnormalities in the first trimester, CVS is more frequently requested.

Although direct chromosome preparations and other rapid cell culture techniques have allowed rapid karyotyping, QF-PCR is now widely used for rapid test reporting.⁷ This is advantageous to parents who do not wish to wait for results

and who wish to avail themselves of early termination if an affected fetus is found.

Complications

The fetal loss rate has always been considered to be higher with CVS than with amniocentesis. Second-trimester amniocentesis is safer than early amniocentesis or transcervical CVS, and is the procedure of choice in the second trimester [A]. CVS should be regarded as the procedure of choice when testing is required before 15 weeks' gestation. The procedure-related loss above the individual background risk is considered to be 1 per cent.¹¹

Placental mosaicisms can occur in about 2 per cent of cases. This presents counselling difficulties and necessitates further invasive testing to obtain fetal cells.

There has been concern regarding the association of CVS and limb defects. This complication appears to be related to the procedure being performed at earlier gestations. Subsequent studies have shown no association when the procedure is performed after 10 weeks.¹²

FETAL BLOOD SAMPLING

Sampling of blood from the fetal circulation has now been used for a variety of diagnostic purposes. It requires expertise, and should be performed by clinicians with extensive experience in all other ultrasound-guided procedures.

Method

The procedure can be performed from 16 to 18 weeks' gestation onwards. However, before 20 weeks it carries increased risk of cord accidents. A 20-gauge needle is introduced through the maternal abdomen under direct ultrasound control. Fetal blood can be aspirated from either the placental insertion or the fetal insertion of the umbilical cord. Cardiac puncture or intrahepatic vessels may also be sampled.

Indications for FBS

Rapid high-quality karyotyping can be obtained with this method within 48–72 hours. This is particularly useful when an abnormality is detected late in the pregnancy.

FBS is also vital in the diagnosis of fetal haematological problems such as anaemia and thrombocytopenia. It has also been used to assess the acid–base status of the fetus in growth restriction, but non-invasive biophysical methods and Doppler studies are more routinely used.

Complications

Bleeding at the site of the needle and fetal bradycardia may occur as a result of the procedure, especially in association with the umbilical artery site. The overall procedure-related fetal loss is 1–2 per cent. Introduction of infection may occur

and, more importantly, if the mother is carrying HIV or other viruses, transmission to the fetus may occur.¹³

FETOSCOPY

With improvement in fiberoptic technology, direct *in-utero* visualisation of the fetus can now be achieved. This may be useful for identifying small structural abnormalities and facilitating direct organ biopsy, such as skin and muscle biopsy. Organ biopsy can also be performed under ultrasound control. This is used only in specialist centres and >80% of indications is for the treatment of severe twin-to-twin transfusion syndrome.

COUNSELLING

The decision as to which invasive test is required must be tailored to the individual mother. It is imperative that she is given full details of the range of tests available, the procedures, advantages and disadvantages, and risk of fetal loss or damage. This information should be given well before the procedure is attempted, allowing her to make her decision, and should be non-directive. The discussion should be followed up with written information.¹⁴

CONCLUSIONS

These invasive procedures allow the diagnosis and assessment of a large number of abnormalities, so that parents can make choices about the continuation or otherwise of their pregnancies. Early diagnostic procedures provide the advantage of early termination, if sought, but must be balanced against the increased fetal loss, or the possibility of terminating a fetus that may have miscarried spontaneously. Rapid molecular tests have improved the waiting time for results but have limitations. Further developments in the identification of fetal cells in maternal tissues will inevitably reduce the necessity of invasive diagnostic tests.

EBM

- The rate of miscarriage following amniocentesis is approximately 1 per cent [A].
- Early amniocentesis has a higher complication rate than CVS and mid-trimester amniocentesis [A].
- Amniocentesis performed under direct ultrasound visualisation is associated with higher rates of success [B].

KEY POINTS

- Amniocentesis is the most commonly performed prenatal diagnostic procedure.
- CVS should not be performed at less than 10 weeks' gestation because of the association of limb defects.
- Most invasive tests other than amniocentesis are generally performed in a tertiary referral centre.
- The specific invasive test should be tailored to the individual woman's circumstances and wishes.
- A team of specialist counsellors should be available for the parents both before and after invasive techniques are performed.

Chapter 32 Understanding genetics and genetic tests

Fiona Mackie and Denise Williams

MRCOG standards

Theoretical skills

Genetic modes of inheritance, common genetic conditions, the importance of screening and the diagnosis thereof.

- Modes of inheritance (Mendelian, multifactorial)
- Cytogenetics
- Phenotypes of common aneuploidies (Down's syndrome, Edward's syndrome, Patau's syndrome, Turner's syndrome, Klinefelter's syndrome, triple X, multiple Y)
- Translocation
- Molecular genetics (DNA transcription, DNA translation, DNA blotting techniques, gene amplification techniques, principles of gene tracking)

Pre-conception care

- Principles of inheritance of disease

Practical skills

- Counsel about genetic disease
- History taking and pedigree analysis
- Demonstrate an ability to explain correctly and place in context for the women: genetic disorders and their inheritance with examples such as Tay-Sachs disease, cystic fibrosis and thalassaemia

INTRODUCTION

Genetic factors are known to contribute to the majority of human diseases, so information about an individual's genetic make-up may be important to their clinical care and that of their family. In this chapter we describe the basic genetic mechanisms and provide relevant information to help identify patients with, or at risk of, a genetic condition, so that they can be counselled appropriately. This will include information

about genetic testing, recognising its uses and limitations, and understanding which patients should be referred to specialist clinical genetics services.

Our understanding of genetics is growing rapidly and exciting developments both in laboratory techniques and computer science mean that an increasing number of genetic diagnoses are now possible. However, the disadvantages of this expanding field include the creation of ethical dilemmas and detection of conditions for which there is no cure.

CLASSIFICATION OF GENETIC DISORDERS

Genetic disorders are classified into:

- multifactorial
- chromosomal
- single gene
- mitochondrial
- somatic mutations.

Most conditions seen by healthcare professionals are multifactorial. In multifactorial inheritance, a condition occurs as the result of a combination of environmental factors such as obesity or smoking, and numerous genetic factors. More rarely a condition occurs because of an alteration to the number or structure of a chromosome, or a mutation in an individual gene. It is important that these 'chromosomal' and 'single-gene' disorders are recognised as they may have significant implications to the wider family. Mitochondrial disorders always show maternal inheritance and, as they are rare, will not be discussed further. Disorders due to somatic mutations are unlikely to be encountered in obstetric practice, but are extremely common and play an important role in the development of many cancers. A few conditions may be the result of environmental factors alone, e.g. fetal anticonvulsant syndrome. These environmental conditions are also not discussed here.

CHROMOSOMAL DISORDERS

Chromosomal disorders are very common and are estimated to affect at least 7.5 per cent of all conceptions. However, they usually result in a non-viable pregnancy, so the liveborn frequency is 0.6 per cent. About 60 per cent of early spontaneous miscarriages have a chromosomal abnormality, 5 per cent of late spontaneous miscarriages and 4–5 per cent of stillbirths. The clinical features that suggest a chromosomal disorder in a child are:

- multiple congenital anomalies;
- short stature including IUGR;
- learning difficulties;
- microcephaly;
- dysmorphism.

There are two main types of chromosome abnormality: numerical and structural. These are associated with an error during meiosis.

Numerical abnormalities: aneuploidy describes a chromosome problem that is caused by an extra or missing chromosome. The most common examples of aneuploidy are Down's syndrome, which is caused by an extra copy of chromosome 21 (trisomy 21) and Turner's syndrome

(monosomy X, X0) (Table 32.1). The exact mechanisms causing aneuploidy are not known, but generally they are more likely to happen at an advanced maternal age. If a couple has a baby with a numerical chromosome abnormality, they are at higher risk of having another baby with aneuploidy compared with the general population, irrespective of maternal age (with some exceptions).

Structural abnormalities: these result from chromosome breakage, followed by abnormal repair. The most common structural abnormalities are translocations, inversions, deletions and duplications. A detailed knowledge about chromosome structure, meiosis and mitosis is required to understand the aetiology of these abnormalities, and referral to a clinical geneticist is recommended.

Translocations occur when there is breakage of two different (i.e. non-homologous) chromosomes which then exchange fragments. This can either be balanced or unbalanced:

- A translocation is balanced if there is an even swap of genetic material between the two chromosomes – no net loss or gain of any chromosome material; there is the correct amount of material present, but in a different order. The individual is clinically normal, but is said to be a 'carrier' of the balanced translocation. A balanced

Table 32.1 Common aneuploidy (numerical) chromosome conditions

Condition	Genetic error	Features
Down's syndrome	Trisomy 21 (95%) Robertsonian translocation of Ch 14:21 (3%) Mosaicism (1%)	<ul style="list-style-type: none"> • Learning disabilities • Hypotonia • Cardiac abnormalities: ASDs, VSDs, AVSDs most common • Gastrointestinal abnormalities: Hirschsprung's disease, duodenal atresia, imperforate anus • Dysmorphic features: upslanting palpebral fissures, speckling of the iris (Brushfield's spots), flat facial profile, brachycephaly • Single palmar crease • Subfertility • Increased risk of: acute myeloid/lymphoblastic leukaemia, Alzheimer's disease, hypothyroidism
Edward's syndrome	Trisomy 18	<ul style="list-style-type: none"> • Low birthweight • Cardiac abnormalities: ASDs, valvular abnormalities • Abdominal abnormalities: exomphalos, inguinal/diaphragmatic hernia, renal malformations • Facial clefts • Spina bifida • Severe-to-profound developmental delay • Microcephaly • Dysmorphic features: prominent occiput, simple ears, over-riding fingers, rocker-bottom feet • 90–95% die <1 year old

Condition	Genetic error	Features
Patau's syndrome	Trisomy 13	<ul style="list-style-type: none"> ● Low birthweight ● Holoprosencephaly ● Cardiac abnormalities: VSDs, ASDs ● Abdominal abnormalities: omphalocele, renal malformations ● Microphthalmia/anophthalmia ● Cleft lip +/- palate ● Post-axial polydactyly ● Dysmorphic features: hypotelorism, scalp defects ● Microcephaly ● Severe to profound developmental delay ● 90–95% die <1 month old
Turner's syndrome	Monosomy X (X0)	<ul style="list-style-type: none"> ● Proportionate short stature ● Lymphoedema ● Congenital heart disease; coarctation of the aorta, ASDs ● Horseshoe kidney ● Gonadal dysfunction; 'streak ovaries' ● Webbed neck (redundant neck skin due to resolving cystic hygroma) ● Cubitus valgus ● Intelligence normal ● >99% of affected pregnancies will spontaneously miscarry.
Klinefelter's syndrome	XXY	<ul style="list-style-type: none"> ● Tall stature ● Male karyotype ● Infertility ● Hypogonadotrophic hypogonadism ● Small testes, poorly developed secondary sexual characteristics, gynaecomastia
Triple X syndrome	XXX	<ul style="list-style-type: none"> ● Normally clinically normal, so often not diagnosed ● Tall stature ● Mild learning disabilities in 15–25%
Multiple Y syndrome	XXY	<ul style="list-style-type: none"> ● Normal phenotype, often not diagnosed ● Tall stature

ASD, atrial septal defect; AVSD, atrioventricular septal defect; VSD, ventricular septal defect.

translocation is important because of the risk of producing chromosomally 'unbalanced' products. This may cause a chromosomally abnormal baby presenting with multiple congenital anomalies including learning difficulties, still-birth, miscarriage or subfertility.

- A translocation is unbalanced if there is an uneven swap of genetic material between the non-homologous chromosomes. This results in both extra and missing chromosome material, which is nearly always clinically significant. The unbalanced translocation may arise for the first time in an individual, or may have been inherited from a parent with the 'balanced' form of the translocation. Two main types of translocation exist: reciprocal

and Robertsonian translocations. Reciprocal translocations may involve any of the chromosomes, including the sex chromosomes, whereas Robertsonian translocations involve only chromosomes 13–15, 21 and 22. A relatively frequent translocation is the Robertsonian 14;21 translocation which predisposes to Down's syndrome (Fig. 32.1). It is important to note that the other possible outcomes demonstrated in Fig. 32.1 (monosomy 14, monosomy 21, and translocation trisomy 14) are not viable, and will miscarry.

Inversions occur when a single chromosome breaks in two places, then the segment of genetic material between the

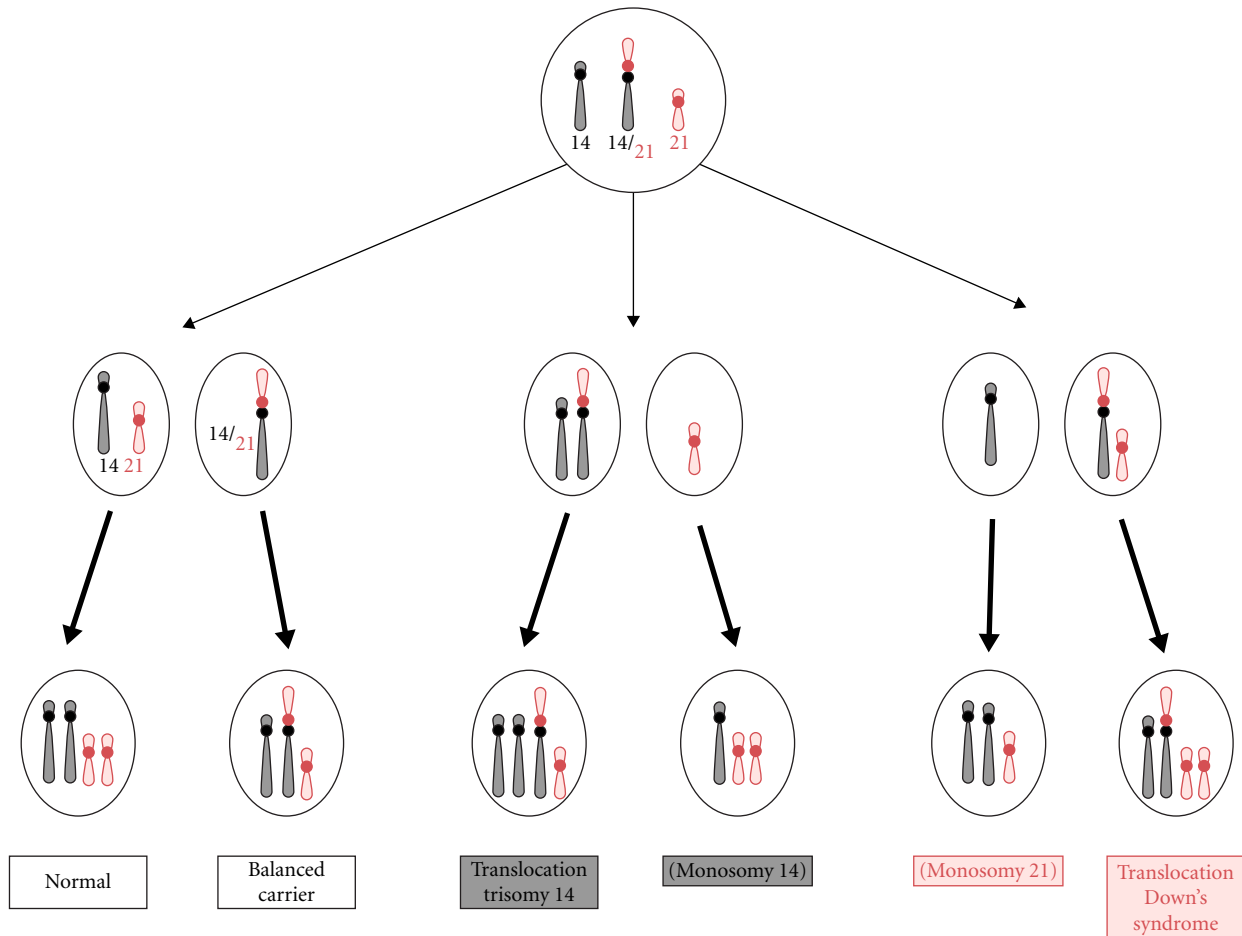

Fig. 32.1 Robertsonian translocation

breaks turns through 180° and rejoins. As with translocations an inversion may be balanced or unbalanced. A carrier of a balanced inversion will be healthy; the medical significance is the increased risk of producing unbalanced gametes. Unbalanced inversions present in the same way as unbalanced translocations. There are two types of inversion: paracentric (excluding the centromere) and pericentric (including the centromere). With few exceptions the unbalanced products of a paracentric inversion are not compatible with viability.

Deletions occur when there is loss of any part of a chromosome. If a large amount of genetic material is lost this will usually produce a non-viable pregnancy. If only a small amount of genetic material is lost, the pregnancy may be viable, but result in physical abnormalities and learning difficulties in the child. Two common examples are DiGeorge's syndrome (22q11.2 gene deletion), and cri-du-chat syndrome (deletion of the short arm of chromosome 5) (Table 32.2).

Duplications occur when there are two copies of a segment of a chromosome, thus resulting in extra genetic material. Duplications are more common than deletions and are normally less harmful. A duplication of the long arm of chromosome 15 is relatively frequent, though the phenotypic effect can be difficult to interpret, particularly when the diagnosis is made antenatally.

Chromosomal mosaicism

Another occurrence to be familiar with is that of chromosomal mosaicism. Chromosomal mosaicism refers to the presence of two or more cell lines in an individual, which differ from each other in chromosome number or structure. Although the individual has developed from a single fertilised egg, the two cell lines means that they have two different genotypes. Mosaicism commonly results from errors in cell division during mitosis, but other explanations exist. Mosaicism in chromosomal disorders is well known. For example, about 1 per cent of patients with trisomy 21 mosaic for cell lines with two copies of chromosome 21 and cell lines with three copies of chromosome 21 (Fig. 32.2).

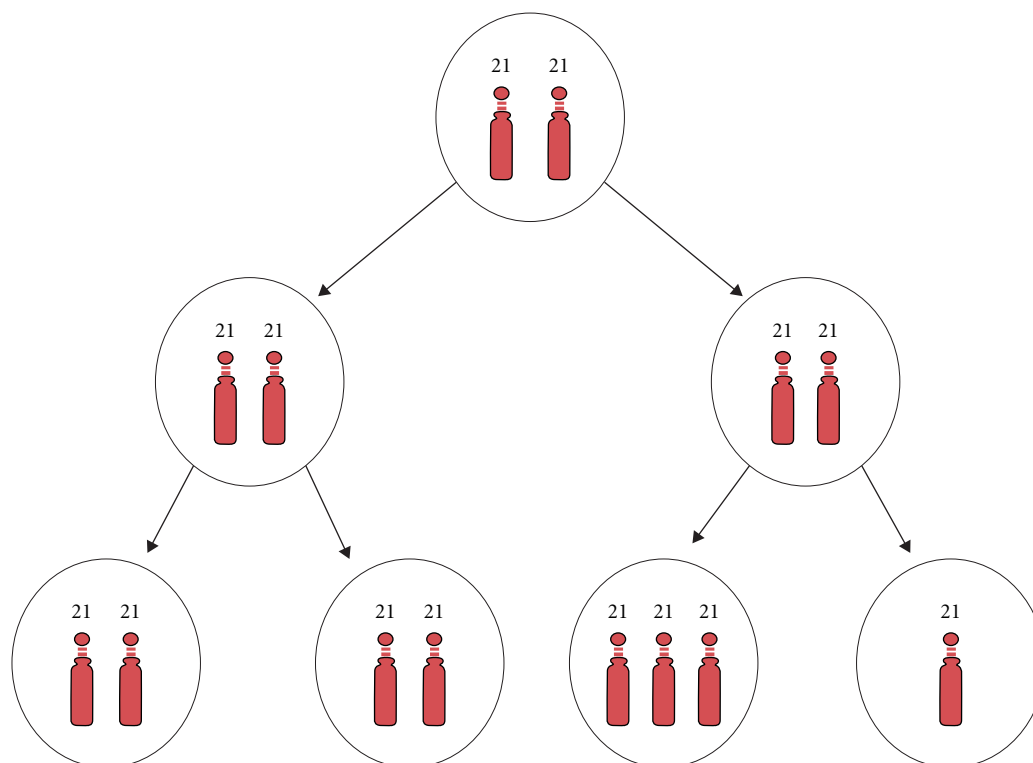

The presence of a normal cell line in mosaicism tends to improve the clinical outcome for some patients. In conditions where a chromosomal abnormality is known to result in miscarriage, mosaicism for the same abnormality can be seen in children.

A well-known mosaic condition is the Pallister–Killian syndrome which is caused by the presence of an abnormal extra chromosome called an isochromosome 12p in a proportion of body cells.

Table 32.2 Deletion syndromes

Condition	Genetic error	Features
DiGeorge's syndrome	22q11.2 deletion New (90–95%) Familial (5–10%)	<ul style="list-style-type: none"> • Congenital heart disease, especially tetralogy of Fallot • Cleft lip +/- palate • Hypocalcaemia/hypoparathyroidism • Hypoplastic thalamus, thus prone to infections • Learning disabilities in some
Cri-du-chat syndrome	Deletion of short arm of chromosome 5 New (85–90%) Unbalanced product of familial translocation (10–15%)	<ul style="list-style-type: none"> • Characteristic cry like a meowing kitten • Feeding problems • Hypotonia • Cardiac abnormalities: ASDs, VSDs, PDAs, tetralogy of Fallot most common • Dysmorphic features: down-slanting palpebral fissures, strabismus, flat nasal bridge, micrognathia • Single palmar crease • Microcephaly • Severe cognitive, speech and motor delay • Behavioural problems

PDA, patent ductus arteriosus.

**Fig. 32.2** Chromosomal mosaicism

Placental mosaicism

The finding of a mosaic karyotype following CVS or amniocentesis is extremely difficult and needs to be interpreted in the context of the pregnancy as a whole. Referral to the clinical genetics service is essential, but it may still be difficult to provide a clear prognosis. Mosaicism can also be restricted to the placenta so-called confined placental mosaicism (CPM). When mosaicism is detected following CVS, an amniocentesis or FBS is usually recommended so that further chromosome analysis can be performed. Most pregnancies that are diagnosed with CPM continue to term with no complications and the children develop normally. However, some pregnancies with CPM are complicated by IUGR and the pregnancy loss rate is higher than among pregnancies without CPM. This means that once CPM is diagnosed a pregnancy needs to be monitored closely.

SINGLE-GENE DISORDERS

Single-gene (or Mendelian) disorders (Table 32.3) are caused by mutations in a single gene. They are described as autosomal (the mutation is in a gene on the non-sex chromosomes, 1–22) or X-linked (the mutation occurs in a gene on the X-chromosome). Three main types of single gene disorders exist:

- autosomal dominant;
- autosomal recessive;
- X-linked recessive.

Although the individual disorders are rare, there are over 6500 disorders listed as single-gene disorders, so collectively these types of condition are relatively common.⁵ The family tree can provide useful information about how a condition runs in the family (see Fig. 32.3a for an example).

Mosaicism may also occur with single-gene disorders and there are many examples of this in clinical practice. A parent who appears to have a mild condition may in fact be mosaic. Their children will be more severely affected if they receive a germ cell with the mutant allele, as this will then be present in every cell in their body.

Some autosomal dominant and X-linked recessive disorders can occur anew. This means that the mutation has arisen for the first time in that individual, i.e. it has not been inherited and the parents are unaffected. Recurrence risks are small, but increased above the general population risk due to the possibility of mosaicism in the germ cells (so-called germline mosaicism).

Autosomal dominant conditions

An individual is affected by an autosomal dominant condition if that condition manifests in heterozygotes, i.e. an individual with one normal and one mutant copy of the relevant gene (Fig. 32.3b).

The main points about autosomal dominant conditions are:

- Each child of an affected parent has a 50 per cent chance of inheriting the condition.
- Males and females are equally affected.
- Males and females can both transmit the disorder.
- There may be variable expression – the severity of the disorder in the offspring may be similar/more severe/less severe than in the parent.
- There may be clinical variability of a condition due to reduced or incomplete penetrance. Penetrance refers to the proportion of individuals with a particular genetic mutation who are affected. If some people with a mutation do not develop the condition during their lifetime,

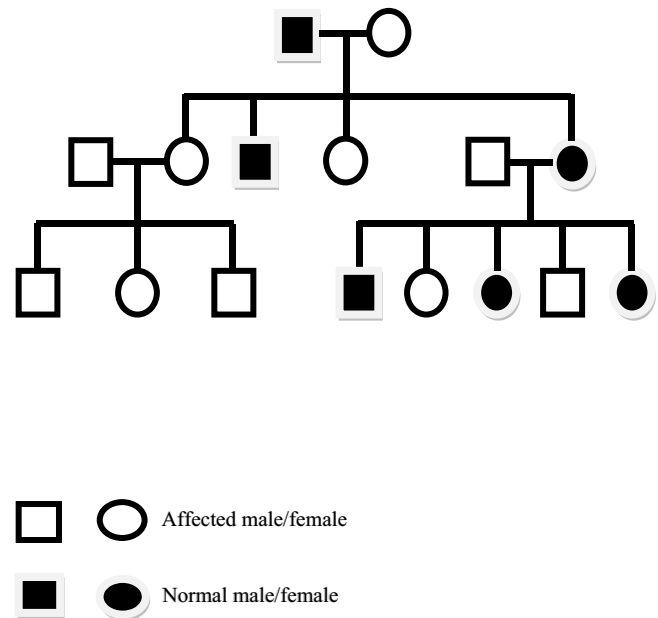

Fig. 32.3a Example of family tree, specifically for a autosomal dominant disorder

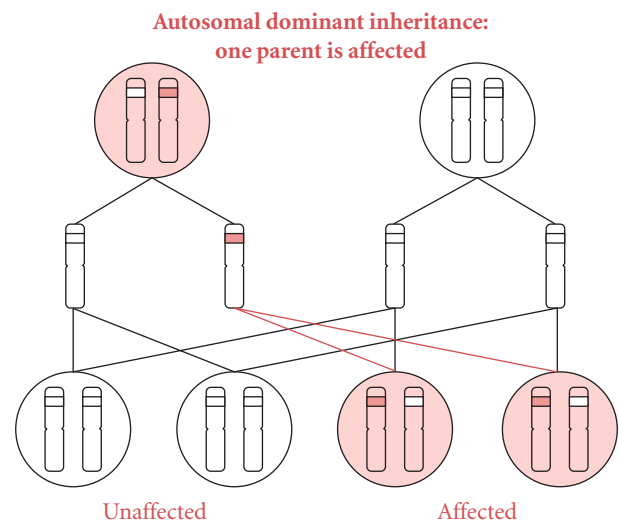

Fig. 32.3b Example of autosomal dominance inheritance

the condition shows reduced or incomplete inheritance. Inherited breast and ovarian cancer due to *BRCA1* and *BRCA2* mutations shows incomplete penetrance, as not everyone with the mutation will develop cancer.

Autosomal recessive conditions

An individual is affected by an autosomal recessive condition if that condition only manifests in homozygotes or compound heterozygotes i.e. an individual in which there is a mutation in both copies of the relevant gene (Figs 32.4a and 32.4b).

Fig. 32.4a Example of a family tree, specifically for an autosomal recessive disorder

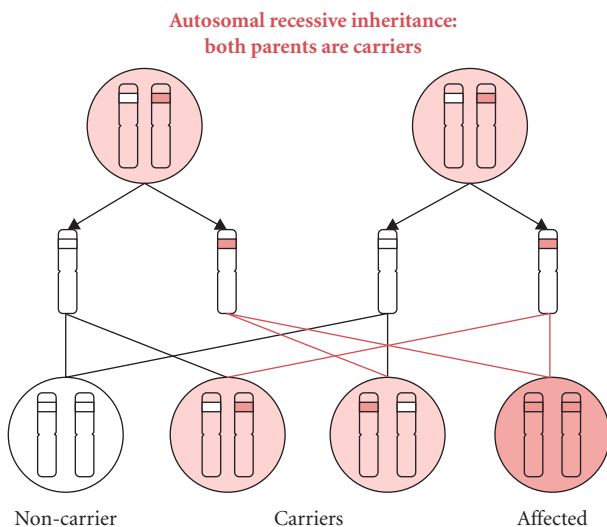

Fig. 32.4b Example of autosomal recessive inheritance

The main points about autosomal recessive conditions are:

- The risk that carrier parents will have an affected child is 25 per cent (1 in 4).
- Males and females are equally affected.
- Healthy siblings of an affected individual have a two-thirds risk of being a carrier.
- All children of an affected individual whose partner is not a carrier will be obligate carriers.
- Consanguinity increases the risk of serious congenital and genetic disorders, most commonly autosomal recessive conditions. The birth prevalence is approximately double that for children of unrelated parents.

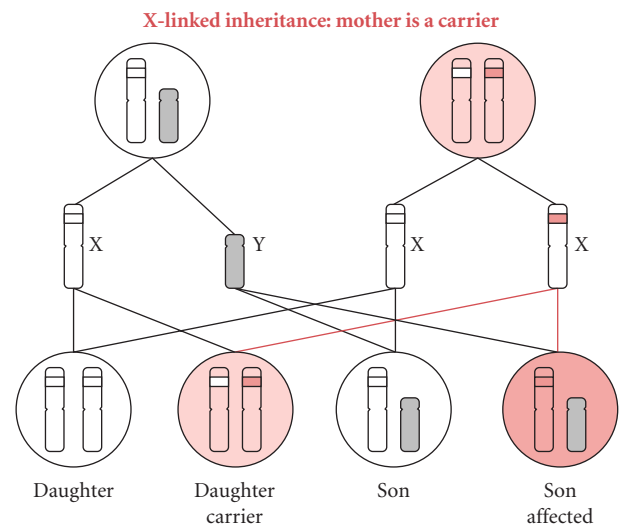

Fig. 32.5a Example of X-linked recessive inheritance where mother is a carrier

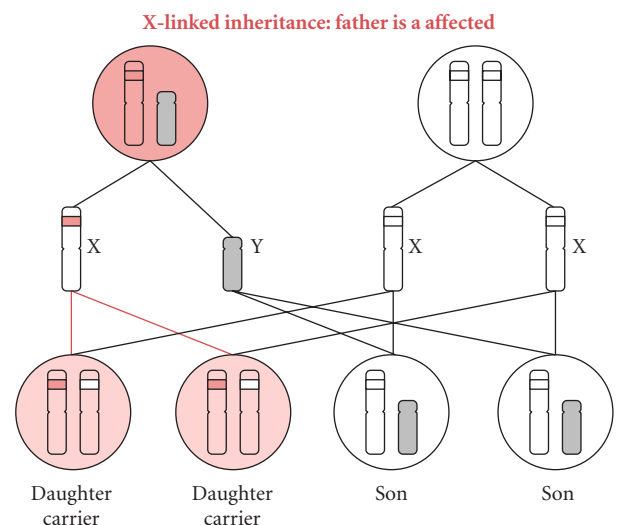

Fig. 32.5b Example of X-linked recessive inheritance where father is affected

Table 32.3 Common single-gene conditions

Condition	Genetic error	Features
Achondroplasia	Autosomal dominant <i>FGFR3</i> gene; chromosome 4 99% of affected individuals have one of two mutations	<ul style="list-style-type: none"> • Most common cause of disproportionate short stature • Normal life expectancy in the majority; a minority have hydrocephalus, obstructive sleep apnoea or middle-ear dysfunction • 75% due to new mutation, with parents of normal stature • Antenatal diagnosis may detect short limbs, but often not until third trimester • Gene testing routinely available
Huntington's disease	Autosomal dominant Huntington gene; chromosome 4 Caused by expansion in 'CAG' triplet repeat	<ul style="list-style-type: none"> • Peak age of onset 40–45 years • Chorea • Neuropsychiatric disturbance • Dementia • Age-dependent penetrance
Inherited breast (and ovarian) cancer	Autosomal dominant Two major genes: <i>BRCA1</i> : chromosome 17 and <i>BRCA2</i> : chromosome 13 Numerous mutations	<ul style="list-style-type: none"> • <5% of breast cancer in UK population is due to an inherited predisposition • The family tree suggests familial breast cancer when several women have had breast cancer on one side of the family, the diagnosis is made at a young age, an individual has had breast cancer more than once or has had early onset breast and ovarian cancer, a male with breast cancer in the family, along with other affected females • Women with mutations in <i>BRCA1</i> and <i>BRCA2</i> have a significantly increased lifetime risk of developing breast and ovarian cancer and should be offered additional screening
Sickle cell anaemia	Autosomal recessive Beta-globin gene; chromosome 11 One mutation	<ul style="list-style-type: none"> • Causes episodes of pain, chronic haemolytic anaemia and severe infections, usually from early childhood • Target cells and Howell-Jolly bodies seen on blood film • Sickle-shaped red blood cells, often precipitated by infection, can lead to vaso-occlusive/splenic sequestration/aplastic/haemolytic crises • Heterozygotes have partial protection against malaria • Included in NHS newborn blood spot screening programme
β -Thalassaemia	Autosomal recessive Beta-globin gene; chromosome 11 More than 200 different mutations identified Heterozygotes may have a mild anaemia and are said to have thalassaemia trait or thalassaemia minor	<ul style="list-style-type: none"> • Group of inherited conditions; beta-thalassaemia major is the most common • There is a reduced rate of synthesis of the beta-haemoglobin chain • Skeletal deformities if diagnosis made late • Haemochromatosis • Healthy at birth • Severe hypochromic, microcytic anaemia between 3 months and 1 year. Blood film shows target cells and fragmented RBCs • For children born in UK, near normal life expectancy
Cystic fibrosis	Autosomal recessive <i>CFTR</i> gene; chromosome 7 Δ -F508 (c.1521_1523delCTT) most common mutation, but >1000 different mutations identified. Mutations differ in different ethnic groups	<ul style="list-style-type: none"> • There is viscous mucus production due to problem with a chloride ion protein involved in anion transport • Recurrent chest infections • Pancreatitis • Malabsorption • Subfertility • Meconium ileus • Can present antenatally with hyperechogenic bowel • Included in NHS newborn blood spot screening programme

Condition	Genetic error	Features
Infantile Tay-Sachs disease (hexosaminidase A deficiency)	Autosomal recessive <i>HEXA</i> gene; chromosome 15	<ul style="list-style-type: none"> Progressive neurodegeneration, seizures, blindness and deafness from 3–6 months of age Most die <4 years old Common in Jews of Ashkenazi ancestry
Duchenne muscular dystrophy	X-linked recessive Dystrophin gene familial (66%) new (33%)	<ul style="list-style-type: none"> Delayed motor and speech milestones Progressive proximal muscle weakness, initially lower limbs, then ascending upwards and resulting in muscle wasting and fibrosis Cardiomyopathy Specialist care from a multidisciplinary team dramatically improves quality of life Average life expectancy: 25 years

X-linked recessive conditions

X-linked recessive conditions are seen in males when a mutation is present in the relevant gene on their only copy of the X-chromosome. Females have two X-chromosomes and are said to be carriers if they have one normal copy and one ‘mutant’ copy of the relevant gene. Female carriers of X-linked recessive conditions rarely show any features of the condition (Figs 32.5a and 32.5b).

The main points about X-linked recessive conditions are:

- The mutant genes are on the X-chromosome.
- All males who inherit the mutation are affected.
- Carrier females are unaffected.
- When a carrier female has a pregnancy there are four possible outcomes, all equally likely: affected son, unaffected son, carrier (unaffected) daughter, non-carrier daughter. Put another way, sons of carrier females have a 50 per cent chance of being affected, and daughters of carrier females have a 50 per cent chance of being unaffected carriers.
- When an affected man has children, all of his daughters will be carriers; none of his sons will be affected. This means that the family tree will not show male-to-male transmission. However, many X-linked conditions are so severe that affected males do not reproduce.

MULTIFACTORIAL CONDITIONS

Most conditions seen by healthcare professionals are multifactorial. In multifactorial inheritance, a condition occurs when ‘environmental’ influences, such as diet, act on a genetic predisposition to develop a condition. Examples of such adult-onset conditions include type 1 diabetes and asthma. Common birth defects, such as cleft lip +/- palate and NTDs are also inherited in this way.

Knowledge about the environmental factors predisposing to the condition can help reduce the risk of developing these conditions. For congenital malformations, the best example of this is the use of periconceptual folic acid to prevent NTDs.

GENETIC TESTING

Genetic tests may be used to detect, confirm or rule out a genetic condition. During pregnancy these tests provide parents with information so that they may avoid the birth of a baby with a serious genetic condition, or it may start discussions about coping with a child with that condition. A directory of genetic tests available in NHS laboratories is available on the UK Genetic Testing Network (UKGTN) website.¹⁰ The UK National Screening Committee provides recommendations to Public Health England for the Fetal Anomaly Screening Programme (FASP) in the UK.¹¹ The most common laboratory techniques for investigating an individual for a possible chromosomal or single-gene disorder are shown in Table 32.4.

New methods of genetic testing

More powerful methods of genetic testing are now possible, but are not yet routinely available in NHS laboratories, though they are being used in many research projects, including in prenatal settings. These are known as exome and genome sequencing.⁷ Both techniques are an extension of next generation sequencing and enable the entire genetic make-up of an individual to be analysed. Their potential is enormous, allowing genetic diagnoses to be made when this was not possible previously.² However, for each patient a large amount of data is generated and interpretation of results can be extremely challenging. Such techniques are not undertaken without full understanding and consent from the patient.

Table 32.4 Common laboratory testing techniques for various genetic disorders

Technique	Application	Reporting time from sample receipt in laboratory
Karyotyping; routine chromosome testing	Counts the number of chromosomes and looks for structural changes in the chromosomes. Most commonly performed on blood (WBC), amniotic fluid cells, placenta, skin and bone marrow, but almost any tissue can be used. Unlike other methods of genetic testing, karyotyping will detect balanced chromosomal rearrangements and is the preferred method for investigating couples who have experienced recurrent miscarriages	14-21 calendar days
PCR	A laboratory technique used to increase the amount of DNA in a sample by several orders of magnitude	3 working days
QF-PCR	A method combining PCR and the labelling of chromosomes 13, 18, 21 and each sex chromosome with 'fluorescent' markers which allows the number of copies of each chromosome to be assessed. Used mainly as a rapid prenatal test for these common trisomies	3 working days
Multiplex ligation-dependent probe amplification (MLPA)	Detects deletions or duplications of part of a gene or whole chromosome. Used in many clinical settings; e.g. in prenatal diagnosis for the detection of common aneuploidies; in oncology clinics for the detection of deletions of the <i>BRCA1</i> and <i>BRCA2</i> genes	3 working days
FISH	Detects the presence or absence of a specific DNA sequence on the chromosomes. FISH uses a fluorescent probe which attaches itself to the exact part of the DNA that a scientist wishes to visualise. Most commonly used to detect deletions such as 22q11.2 deletion. increasingly replaced by microarrays	Antenatal results reported simultaneously with routine chromosome testing
Microarray-based comparative genomic hybridisation (array CGH); 'microarrays'	Relatively new method of looking for subtle chromosome imbalances. The technique compares a sample of patient DNA with a control sample which has no known genetic alterations, so allowing the detection of loss or gain of genetic material. The deletions and duplications (copy number variants [CNVs]) detected by this method are much smaller than those possible by routine karyotyping and are often referred to as microdeletions and microduplications. Array CGH may benefit families as it may provide a diagnosis, when this was not possible previously. However, some chromosome and DNA alterations have not previously been reported and their significance is not known. This can make results difficult to interpret	14-21 calendar days
DNA (Sanger) sequencing	Checking for alterations in the order of bases in the genetic code. The method used to determine the exact order of the bases (C, G, A and T) in a particular gene. Interpreting the results requires expert knowledge as a variation in the 'sequence' will be significant and cause genetic disease only if the function of the protein it produces is affected. Results of uncertain significance may be found. Only possible antenatally if mutation in family is known.	10 working days
Next generation sequencing (NGS)	There are several different NGS methods which allow large-scale DNA sequencing in a single test. Often used to sequence a subset of genes that predispose to a group of conditions, e.g. inherited cancer syndromes. Generates an enormous amount of data requiring expert interpretation	No time frame, not yet used in clinical practice

Another exciting prospect is the recent development of non-invasive prenatal diagnosis for aneuploidy using cell-free fetal DNA (cffDNA),¹³ which is known to be present in small quantities in maternal plasma, thus allowing the diagnosis of fetal genetic disorders from peripheral maternal blood samples and avoiding the risks associated with CVS and amniocentesis. Testing for aneuploidy by cffDNA is in the initial stages of being introduced into UK clinical practice,^{1,14} and is already in use in the USA. Non-invasive prenatal diagnosis

for other genetic disorders is much more difficult technically, but it is these families who will benefit most as they have the greatest risk of recurrence. Testing for one or two conditions, most notably achondroplasia and thanatophoric dysplasia, already exists. A number of research projects in this area are ongoing and hope to develop reliable techniques which can be translated into clinical practice. This is an area of rapid development and advice from the local clinical genetics service is recommended.

COUNSELLING ABOUT GENETIC DISEASE

Genetic counselling advises patients at risk of a potentially hereditary disorder about the consequences of the disorder, the probability of developing or transmitting it and the ways in which this may be prevented, avoided or ameliorated. Ideally couples should receive counselling prior to conception, but this is possible only if factors known to increase the risk of genetic disorder have been identified before pregnancy. Such factors include a previous child with, or a family history of, a single-gene disorder, a parent having a chromosome anomaly, advanced maternal age, parental consanguinity, ethnic origin and population carrier screening. For many families a genetic condition becomes apparent during pregnancy only after an abnormal ultrasound scan or after biochemical screening test results. This is extremely stressful. Further prenatal genetic testing may be helpful in providing additional information about the aetiology of the problems, which can help couples make more informed choices. This is most likely to be by an invasive diagnostic test such as CVS or amniocentesis. These tests do carry a small risk of miscarriage (1–2 per cent) but often provide useful information, particularly about the fetal karyotype. Couples should be given the opportunity to understand the nature of the problems seen and the different options available to them, before making a decision about the management of the pregnancy. This may include referral to other specialists including neonatologists, paediatric cardiologists, neurologists or surgeons. Decisions people make are very personal; some couples accept the risk and have no further testing, others choose to refine the risk with further tests, whilst some may choose to terminate the pregnancy. Many factors are considered before making a decision including the prognosis for the child, the impact of the disorder on the family, financial considerations and religious beliefs. Patient support groups such as Antenatal Results and Choices (ARC)³ and Unique¹⁵ can provide valuable support to families at this difficult time. It is important that we give couples as much information as possible in order to facilitate the tough decisions surrounding further management of their pregnancy.

Ongoing follow-up and support are essential and needs to include information about the likelihood of the same problem occurring again and risks to other family members. Couples who have a high chance of having a further affected pregnancy should have the opportunity to discuss the different options available to them. This may include undertaking a further pregnancy (accept risk, prenatal diagnosis or preimplantation genetic diagnosis if available, donor egg or sperm), postpone pregnancy hoping that prenatal testing will become available in the future, adoption or choose to have no further children.

KEY POINTS

- Taking a detailed family history can help identify patients with, or at risk of, a genetic condition.
- The majority of conditions are inherited. The most common modes of inheritance are chromosomal, single gene and multifactorial. Single-gene disorders show autosomal dominant, autosomal recessive and X-linked recessive inheritance.
- It is essential to have a definitive diagnosis in order to give precise information about the condition including accurate recurrence risks. If a diagnosis has been made by another healthcare professional, seek confirmation of that diagnosis whenever possible. Genetic testing can provide useful information that may contribute to the clinical care for some patients and families. Genetic tests are permanent (unlike a patient's Hb result). It is therefore important to recognise its uses and limitations.
- Genetic diseases are rare, but collectively common (around one person in every 17). They are most appropriately managed by a team of specialists and referring patients to local genetics services can facilitate this.
- It is important to be aware of the ethical dilemmas surrounding genetic testing in families.

Published Guidelines

There are no NICE or RCOG Greentop Guidelines on prenatal genetic testing, although ACOG has published a variety of committee opinions on genetic testing and the RCOG has published a Scientific Impact Paper on non-invasive prenatal testing.

Chapter 33 Management of fetal anomalies

Michele P Mohajer

MRCOG standards

Theoretical skills

- Familiarise yourself with the more common diagnosable conditions and their prognoses.
- Understand the advantages and disadvantages of surgical and medical termination of pregnancy.
- Understand the abortion certificates HSA 1 and HSA 4.1.
- Understand the pattern of inheritance of the commoner genetic disorders.

Practical skills

- Be able to perform a first-trimester termination of pregnancy under indirect supervision.
- Be able to manage early and late (medical) termination of pregnancy.
- Have taken part in or observed bereavement counselling with parents who have suffered fetal loss.

INTRODUCTION

The management of the pregnancy in which an abnormal fetus is identified involves a whole multidisciplinary team of specialists. This team comprises the sonographer, fetal medicine specialist, geneticist, neonatologist and paediatric surgeon, along with the nurse specialists within each team. When the diagnosis is made, clear information should be made available to the parents regarding the condition, prognosis and level of disability, should the baby be born alive. This may be very difficult to achieve. Many conditions have such a wide variation in outcome (e.g. Down's syndrome and spina bifida) that accurate prediction may not be possible. When given an adverse prenatal diagnosis, parents are deeply shocked and experience acute grief. They may not be able to take in the information given to them. Written information, contact numbers and support groups are important, but parents may

have great difficulty reaching a decision, especially one that results in the termination of the pregnancy. Therefore, management includes not only the practical aspect of the specific disorder, but also the psychological support for the parents and family involved in the pregnancy.

PRACTICAL MANAGEMENT

Termination of pregnancy

When parents are told of a fetal abnormality, they must make decisions, the most important being whether to continue or terminate the pregnancy. The response to diagnosis will be tempered by the options available to the parents, including *in-utero* treatment, postnatal treatment or termination. If the condition is lethal, the decision to terminate may be easier, but, more often than not, the condition carries a risk of physical or mental impairment, which is difficult to quantify. Once a serious abnormality has been diagnosed, evidence shows that the parents will terminate the pregnancy in 80–90 per cent of cases.¹

Conditions that are considered lethal include:

- anencephaly;
- bilateral renal agenesis;
- lethal skeletal dysplasias;
- some severe complex cardiac defects;
- triploidy;
- trisomies 18, 13 and 15.

Other conditions are not lethal, but are well documented as being associated with long-term handicap, and include:

- spina bifida;
- trisomy 21 and other chromosomal abnormalities;
- cardiovascular abnormalities;
- muscular dystrophies;
- phocomelia.

If the decision to terminate is reached, the methods available and associated risks must be discussed with the parents.

METHODS OF TERMINATION

Surgical termination

Surgical termination may be performed by vacuum aspiration or dilatation and evacuation. Vacuum aspiration or suction curettage is the method used until the end of the first trimester. Dilatation of the cervix prior to surgery is achieved by passing graduated metal dilators or inserting vaginal prostaglandin preparations. Abortion is then performed by the use of a Perspex suction tube connected to vacuum apparatus. The inherent risk associated with abortion relates to the use of general anaesthesia and the invasive nature of the procedure – with complications of haemorrhage, uterine perforation and infection. The incidence of haemorrhage is 1.5/1000, uterine perforation 1–4/1000 and of cervical trauma 1 per cent. Post-abortion infection occurs in up to 10 per cent of cases and is significantly reduced if prophylactic antibiotics are given [B]. Suction curettage has been shown to produce lower risks of these complications than sharp curettage.² Complications are lessened the earlier the gestation.¹¹ Couples should also be informed of the risk of failed abortion, which occurs in 2.3/1000 surgical terminations.

Dilatation and evacuation is performed in some areas up until 20 weeks' gestation. Mechanical dilatation of the cervix to 14 mm is performed, and fetal parts are extracted with the use of appropriate instruments. This may be done under ultrasound control. Cervical dilatation may be complicated by cervical tears, uterine perforation and the creation of false passages. The use of cervical priming agents such as mifepristone, misoprostol and gemeprost has improved the safety of the procedure [B].³ It is a very distressing procedure, but safe and effective when undertaken by specialist practitioners with a sufficiently large caseload [A]. However, it is not widely available. It also prevents a full postmortem examination of the fetus being carried out in order to confirm any ultrasound diagnosis.

Medical termination

Medical termination of pregnancy has been revolutionised by the introduction of prostaglandins and the antiprogestone mifepristone.

Gestations of 9 weeks (63 days) or less can be successfully terminated with mifepristone 600 mg, followed 48 hours later by a prostaglandin (gemeprost or misoprostol). Less than 0.5 per cent will fail to respond to this regimen,⁴ which should be the method of choice at these gestations [A]. However, the diagnosis of fetal abnormality is extremely rare by 9 weeks' gestation and so medical termination is usually performed in the second trimester. Medical termination has the additional advantage of allowing the opportunity for a postmortem examination. Pre-treatment with mifepristone (200 mg) sensitises the myometrium to prostaglandin agents and so reduces the induction–abortion interval [B]. Misoprostol is the prostaglandin of choice as it requires specific conditions

for storage and transfer. The risk of failure to terminate the pregnancy is 6/1000.

The standard regimen is: mifepristone 200 mg orally, followed 36–48 hours later by misoprostol 800 mg vaginally, then misoprostol 400 mg orally to a maximum of four oral doses.

Third-trimester termination and intrauterine fetocide

Since 1990, termination of pregnancy after 24 weeks has become legal if there is a lethal abnormality or sufficient evidence that the infant will be born with serious mental or physical disability.⁵ This is an extremely distressing situation to all involved, including the parents, obstetricians and midwives. The safety of medical termination has made late termination much safer, but the law states that the fetus must not be born alive. This requires intrauterine fetocide – which is achieved by fetal intracardiac injection of potassium chloride (KCl) via a 20-gauge transabdominal needle under ultrasound control. This procedure should be performed by an operator experienced in invasive fetal procedures. Fetal sedation may be necessary prior to the fetocide. This is achieved by the administration of diazepam or pethidine into the fetal circulation. An ultrasound should be performed 1 hour after the injection of KCl to ensure cessation of fetal heart pulsation.

When the abnormality is incompatible with survival, fetocide is not mandatory, but the delivery management should be carefully discussed with the parents and health professionals involved and a care plan agreed. If the condition is not lethal, fetocide should be offered after 21⁺⁶. Failure to do so contradicts the intention of the abortion.¹⁰

The assessment of the level of disability is an extremely difficult area. Although the outcome of some abnormalities is well documented, an accurate prognosis of many prenatally detected anomalies is not possible. Advice from genetic specialists, counsellors and support groups may be sought, but ultimately the decision to terminate the pregnancy will rest with the parents. Consideration should be given to karyotyping the fetus by sending a fetal blood sample (and banking DNA) for cytogenetic analysis (with informed consent).

The postmortem examination

Parents may find the prospect of a postmortem examination of their baby very distressing, but it is a vital part of the management. Although high-quality ultrasound provides an accurate diagnosis of major fetal pathology, postmortem examination provides more detail, identifies abnormalities that permit a more specific diagnosis and modifies genetic counselling. Important diagnostic refinements are identified in up to 40 per cent of cases.⁶

The issue of postmortem examination has become further complicated by the legal requirement of consent. Consent is now required for the postmortem examination of fetuses at all gestations and, additionally, if tissues or organs are retained for later study or research. If parents do not consent

to a postmortem examination, it is important to request photographs, X-rays and a sample of tissue (skin or placenta) for cytogenetic studies, which may provide additional information.

THE CONTINUING PREGNANCY

The pregnancy may continue for many reasons. For example, the condition may be amenable to postnatal treatment. This particularly applies to structural malformations that can be surgically corrected, such as:

- gastroschisis;
- exomphalos;
- diaphragmatic hernia;
- duodenal atresia;
- some cardiac defects (Fallot's tetralogy, ASDs, VSDs, transposition of the great vessels);
- posterior urethral valves;
- cleft lip.

It is important that parents receive full information regarding the treatment and long-term outcome of the condition; this is preferably provided by the surgeon performing the procedure. Certain conditions such as gastroschisis will require continued fetal surveillance throughout pregnancy, as there may be growth problems or loops of bowel may become obstructed. Most pregnancies will also require continued surveillance for psychological support. Even though parents have been given optimistic expectations of the outcome, they will be anxious throughout, and need constant reassurance from all members of the team. If paediatric surgical teams are not within the hospital, parents may have to travel to a main centre to receive both prenatal counselling and delivery if their neonatal unit is unable to cope with their situation.

Certain fetal conditions are amenable to intrauterine therapy.

Hydrops fetalis is discussed in Chapter 40. Cases secondary to fetal anaemia may respond to intrauterine fetal blood transfusion. Fetal tachydysrhythmias may also result in fetal hydrops. Maternal administration of antiarrhythmic drugs (digoxin, flecainide, amiodarone) is effective in converting the fetal rate to sinus rhythm and also reversing the hydrops.⁷

If fluid is in a particular cavity, for example a pleural effusion, its presence may compromise normal lung development. Pleural drainage may be performed, as both a diagnostic and a therapeutic procedure. If the fluid accumulates, a pleuro-amniotic shunt can be inserted. This shunt procedure can be applied to other conditions. In the case of posterior urethral valves, outflow obstruction can be so severe as to cause bilateral hydronephrosis and irreversible renal damage. A vesico-amniotic shunt can be inserted into the fetal bladder and so bypass the urethral obstruction.

Sophisticated techniques to perform intrauterine surgery have been developed. If a diaphragmatic hernia is present early in pregnancy, the presence of a mass in the fetal chest compromises fetal lung development such that the infants often die of pulmonary hypoplasia. *In-utero* endoscopic placement of a balloon in the fetal trachea may improve outcome.⁸

Parents may elect to proceed with the pregnancy because there is not enough certainty or evidence that the malformation will result in a significant degree of mental or physical disability. This decision will vary among individuals and depend on their own particular circumstances, for example an infertile couple with a long-awaited pregnancy may accept the risk of potential handicap more than a multigravid mother for whom the risk of a handicapped child may compromise the wellbeing of her existing family.

Examples of such abnormalities include:

- Dandy–Walker malformation;
- agenesis of the corpus callosum;
- distal limb abnormalities;
- some cardiac defects.

Finally, parents may not want termination, even if the condition has a 100 per cent mortality rate, because of religious or moral beliefs. These wishes must be respected.

The management of these continuing pregnancies requires skilled, personalised care. There are few published data that consider the psychological impact of continuing the pregnancy with a prenatally diagnosed abnormality. There are reasons to hypothesise that women who elect to continue a pregnancy may experience a better psychological outcome than women who terminate: such women are thought to be spared the guilt associated with decision-making. However, some reports suggest that these women would seek early prenatal diagnosis in a subsequent pregnancy. Management of continuing pregnancies includes communication between hospital and community health workers, continuity of care with the same personnel, adequate time and repeated counselling (outside routine clinic hours), written information and contacts with support groups.⁹ Serial ultrasound scans may be requested to provide reassurance that the baby is still alive and growing.

The management of the pregnancy with a malformation requires additional considerations as well as emotional support. Parents need to be prepared for:

- how, where and when their baby will be delivered;
- what their baby will look like;
- what will happen to their baby after delivery.

There may also be practical difficulties if delivery is to take place in a tertiary centre. The costs of transport, childcare and subsistence must be considered.

Discussion needs to occur with other healthcare professionals as to the timing and appropriate place of delivery of the fetus.

PLANNING FOR THE FUTURE

Once the pregnancy is over, carefully planned follow-up is an essential part of the management. In the case of termination or death of the infant, time for grieving must be allowed. Grief reactions will vary among individuals depending on different circumstances. Some couples want intensive counselling and contact with the medical team, whereas others want time away from what has become an emotionally painful environment. Postmortem results may provide additional information as to the precise diagnosis. This could influence the management of a subsequent pregnancy and the choice of a prenatal test.

Referral to a genetic specialist may be required in order to assess the risk of recurrence and possibly to investigate other family members. Follow-up with the paediatric or neonatal team involved is an important part of the bereavement counselling.

Parents will require information on the availability of early, reliable prenatal diagnosis if another pregnancy is contemplated.

Couples may require more than one bereavement counselling session, either because the results are incomplete or because they wish it. Sensitivity to the individual's needs is essential in this situation.

Finally, a letter summarising the discussion should be sent to the parents. This provides documentation and also allows the information to be assimilated at a later date, away from the hospital environment.

EBM

- Termination of pregnancy is more likely if the diagnosis is made earlier in gestation [C].
- The risks of termination of pregnancy are reduced if abortion is performed at earlier gestations [B].
- Psychological stress is high after termination, with 40 per cent of women showing symptoms of psychiatric morbidity [B].

KEY POINTS

- Parents must have as much access to information as possible before making a choice.
- Referral to a tertiary centre may be necessary for further investigation or treatment.
- Psychological morbidity is high following termination for fetal abnormality using either surgical or medical methods.
- Whether or not they continue the pregnancy, the parents will need long-term support from both hospital specialists and the community.

Chapter 34 Previous history of fetal loss

Abi Merriel and Arri Coomarasamy

MRCOG standards

Theoretical skills

- Understand the epidemiology, aetiology and pathogenesis of fetal loss.
- Understand the indications and limitations of investigations (endocrine, anatomical, immunological, genetic, radiological and bacteriological).

Practical skills

- Be able to manage subsequent pregnancies in women with a history of late fetal loss/stillbirth.

INTRODUCTION

An estimated 2.64 million stillbirths occurred in 2009.¹ Approximately 98 per cent of this burden lies in low- and middle-income countries.² The global stillbirth rate is approximately 18.9 per 1000 total births, whereas in high-income settings, the rate is 3.1 per 1000 total births.¹ In the UK, 1 in 200 babies is born dead, with 3558 stillbirths (4.9/1000 total births) occurring in 2012.³ Each family that experiences a stillbirth encounters their own personal response to their loss and healthcare staff may be among a small group of people with whom they can talk openly.⁴ Many parents will have questions about their possible future pregnancies in terms of timing, risks, care during pregnancy and chances of having a healthy baby.⁴ Given their past loss, for many couples another pregnancy may be an 'emotional rollercoaster'.⁴ Many women with a history of pregnancy loss have increased risks for future pregnancy loss and other obstetric complications.⁵ Therefore, expert support is often required and this should be provided by staff who have the right attitude, training, knowledge and skills.⁴

DEFINITIONS

In the UK, a fetal loss up to 24 completed weeks of gestation is defined as a miscarriage. A *late* fetal loss is defined as *in-utero* death delivering between 22⁺⁰ and 23⁺⁶. A stillbirth is defined

as a baby delivering with no signs of life after 24 completed weeks of pregnancy. These definitions are not universal. According to the International Classification of Diseases, a stillbirth is defined as a baby born at 22 completed weeks of pregnancy or weighing at least 500 g. However, in order to allow international comparisons, the WHO recommends reporting babies born dead from 28 completed weeks gestation or 1000 g or more as a stillbirth.⁶ For the purposes of this chapter, we have grouped late fetal losses and stillbirths and will refer to them as intrauterine fetal deaths (IUFDs).

CAUSES OF IUFD

Placental pathology contributes to over half of IUFDs.⁷ Placental abruption accounts for a population-attributable risk for stillbirth of 15 per cent.⁵ In addition, placental insufficiency contributes to fetal growth restriction, which is identified in 40–60 per cent of stillbirths.⁷ One large cohort study showed that there were 12 times higher odds of a growth-restricted fetus being stillborn compared with a normally grown baby.⁸

Infection contributes to approximately 12 per cent of IUFDs. Its burden seems to be more in IUFDs of earlier gestations (less than 28 weeks) in the context of chorioamnionitis and preterm pre-labour rupture of membranes.⁷ Infective agents contributing to IUFDs include parvovirus, cytomegalovirus, toxoplasmosis and *listeria*.⁸ Chronic infections should also be excluded, e.g. syphilis.⁹

Umbilical cord accidents or abnormalities such as true cord knots may contribute to (8 per cent) or cause (9 per cent) IUFDs.⁷

Medical and pregnancy disorders contribute to nearly 25 per cent of cases, and are causal in 7 per cent of cases. Diabetes and hypertensive disorders are the most important conditions leading to this burden.⁷ Other diseases can also have a significant effect on a pregnancy, for example Antiphospholipid Syndrome (APLS) (especially with renal involvement) and thrombophilias.⁸ Although most high-income settings have rhesus disease prophylaxis, the contribution of red cell antibodies to fetal demise continues to exist.⁸

Intrapartum deaths contribute to approximately 14 per cent of third-trimester IUFDs in high-income settings; however, in

parts of sub-Saharan Africa and Asia over 50 per cent of these deaths are intrapartum.⁶ In high-income settings, one series has suggested that, whilst 9 per cent of stillbirths were intrapartum, only 3 per cent of these were attributable to intrapartum events.⁷

Congenital abnormalities are associated with 6–12 per cent of stillbirths.

Unexplained causes are assigned to up to 60 per cent of IUFDs.⁸ However, much of the published literature suggests that, when IUFDs are fully investigated, only one in four IUFDs still remains unexplained.¹⁰ Fig. 34.1 illustrates the causes of stillbirth in the UK in 2009.

RISK FACTORS FOR IUFDS AND STILLBIRTH

Several important and potentially modifiable risk factors have been identified across numerous studies and have been summarised in a meta-analysis: maternal weight, maternal smoking, maternal age, parity, SGA, placental abruption, and pre-existing maternal diabetes or hypertension.⁵ These risk factors may exist alone or may combine, for example, in women delaying child-bearing in high-income settings. The most important of these modifiable risk factors is maternal weight.

The IUFD rate among multiple gestations is four times higher than for singletons. This is particularly important to consider in the context of the use of assisted reproductive technologies.¹¹ Alcohol and illicit drug use may serve to increase the risk of an IUFD.¹¹

Other well documented risk factors for IUFDs include lack of access to antenatal care,⁵ educational attainment of the mother,⁵ ethnic origin¹¹ and socio-economic status.^{5,11}

INVESTIGATION AND RISK ASSESSMENT

Some of the factors involved in fetal loss have a clear causal link, such as an abruption or a cord event, whilst others may have a contributory role, e.g. obesity. Some losses may be associated with multiple aetiologies, e.g. a fetal loss could be directly linked to an abruption, but the woman may have risk factors such as APLS and pre-eclampsia. In order to provide the parents with as much information as possible they should be offered investigations to determine the reason for the death of their baby. This will aid accurate risk prediction and allow planning of risk modification.¹² If writing to another hospital, it is prudent to request copies of the original investigation reports. The RCOG recommends that the investigations in

Primary cause of Stillbirth using the CMACE maternal and Fetal Classification

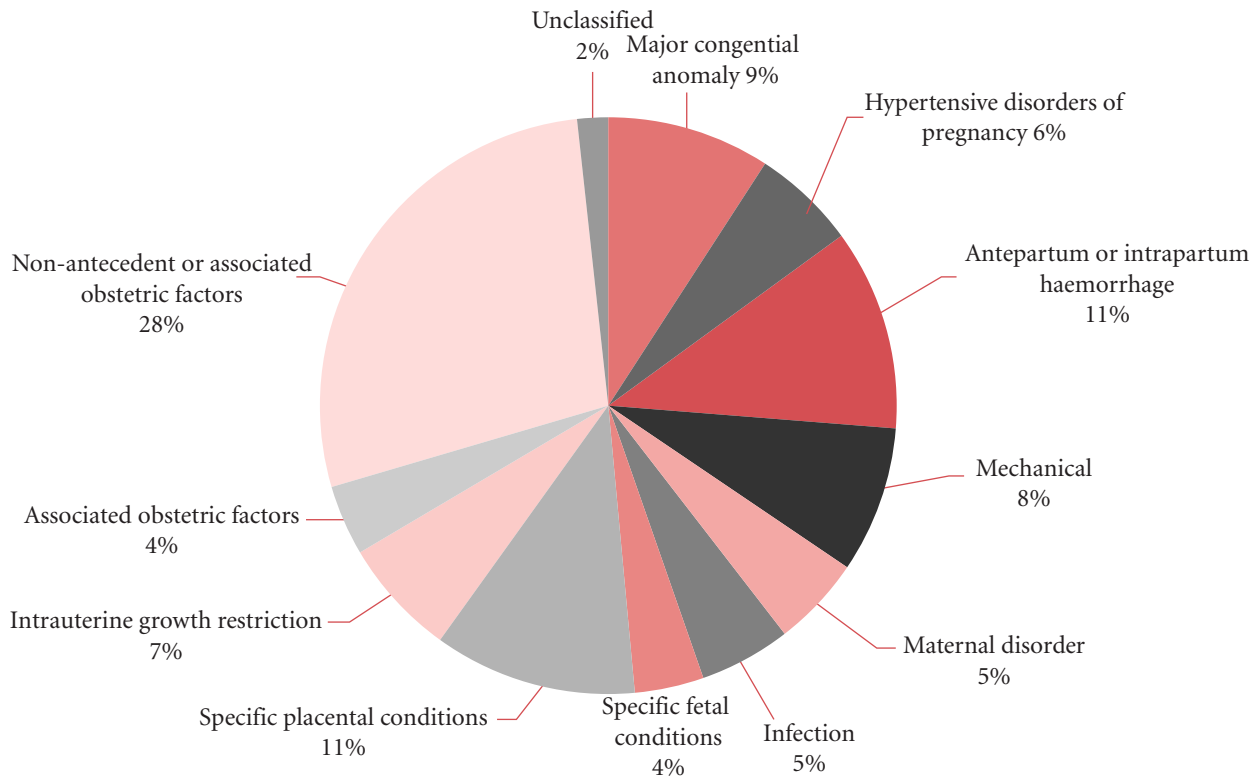

Fig. 34.1 Causes of stillbirths in the UK in 2009¹⁴

Table 34.1 Adapted from RCOG Guideline on Late IUFD and Stillbirth¹²

Test to be considered	Reasons for test
Maternal standard haematological tests including CRP and bile salt	Pre-eclampsia and its complications
	Multi-organ failure in sepsis or haemorrhage
	Obstetric cholestasis
Maternal coagulation times and plasma fibrinogen	DIC
Kleihauer Disseminated intravascular coagulation	Lethal fetomaternal haemorrhage
	To decide level of requirement for anti-RhD gamma-globulin
Maternal, fetal and placental bacteriology (blood cultures (maternal and fetal), midstream urine, vaginal and cervical, fetal and placental swabs)	Suspected maternal bacterial infection
Maternal serology (viral screen, syphilis, tropical infections)	Occult maternal-fetal infection
Maternal random blood glucose and HbA1c	Occult maternal DM or GDM
Maternal thyroid function	Occult maternal thyroid disease
Maternal thrombophilia screen	Maternal thrombophilia
Anti-red cell antibody serology	Immune haemolytic disease
Maternal anti-Ro and anti-La antibodies	Occult maternal autoimmune disease
Maternal alloimmune antiplatelet antibodies	Alloimmune thrombocytopenia
Parental bloods and fetal and placental tissues for karyotyping	Parental balanced translocation/mosaicism
	Aneuploidy, single-gene disorders
Maternal urine for cocaine metabolites	Occult drug use
Postmortem examination may be full or limited at the request of the parents (external, autopsy, microscopy, X-ray, placenta and cord) by a specialised perinatal pathologist	To attempt to explain the cause of the fetal death

Table 34.1 are considered in the event of a late pregnancy loss.¹²

Once a cause and/or associated risk factors have been established, an attempt should be made to estimate the risk of adverse obstetric outcomes, particularly IUFDs, for the specific woman.

For many couples with a previous pregnancy loss, risk identification, future risk estimation and future pregnancy management plans may have been discussed in the follow-up consultation(s) after their previous loss. Generally, such plans should be adhered to, unless there are clear reasons to deviate. If changes are necessary, it is important to explain to the couple the need for the changes.

CLASSIFICATION OF IUFDs AND STILLBIRTH

The previous successes in improving outcomes in IUFDs have largely been due to the specific targeting of appropriate interventions, e.g. rhesus immune prophylaxis resulted in a

95 per cent reduction in stillbirths from Rh isoimmunisation.⁸ In order to develop targeted interventions it is vital that the causes of IUFDs are appropriately identified. One of the biggest challenges with this is the number of different classification systems (over 35) and the fact that they are not all applicable across different healthcare settings.⁶ Some of the contemporary internationally accepted systems include: Amended Aberdeen, Extended Wigglesworth, PSANZ-PDC, ReCoDe, Tulip and CODAC.¹³ In January 2008, a new Perinatal Death Notification (PND) form, including a new classification of cause of death, was introduced by CEMACH. This tool has enabled a reduction in the number of unexplained IUFDs from approximately 50 per cent to 28 per cent in the report published in 2011.¹⁴

CONSIDERING A SUBSEQUENT PREGNANCY

For couples planning another pregnancy following an IUFD, the timing of the pregnancy and the likelihood of recurrence of pregnancy loss are important concerns. SANDS

Guidelines for Professionals⁴ suggest the following approach in helping couples planning to have a baby after a previous pregnancy loss:

- 1 Offer parents time to discuss their ideas, concerns, expectations and feelings, together as a couple and individually, to help reach a decision about timing of pregnancy.
- 2 Offer parents the opportunity to discuss the specific individualised risks for the mother and baby in a future pregnancy.
- 3 Reassure parents that there is no specific right time for them to try for a baby.
- 4 Encourage the parents to look after and look out for each other physically and emotionally, particularly focusing on ways of reducing their anxiety (e.g. with the use of relaxation techniques).
- 5 Offer pre-conception advice to reduce or manage risks, e.g. cessation of smoking and weight reduction.
- 6 Offer and organise referral to other specialists as appropriate, e.g. geneticists and, if the parents wish, a counsellor.
- 7 Acknowledge that a future pregnancy is likely to be stressful, but emphasise that there will be support to ensure the couple's and baby's health.

IUFD recurrence

Several cohort studies have been undertaken to investigate the likelihood of recurrence of IUFDs. Each of these studies has its limitations; one of the more recent ones based on a Scottish database suggested an increased risk of IUFDs in a subsequent pregnancy with an adjusted OR of 1.96 (99% CI 1.60, 2.41). However, this study was unable to adjust for cause of first stillbirth.¹⁵ In an earlier Australian study, limited to unexplained IUFDs, there was no statistically significant increase in IUFDs in a subsequent pregnancy (OR 1.62; 95% CI 0.63, 4.20).¹⁶ What the various studies agree on is that the increased risk of a subsequent IUFD for a woman where no cause has been determined is small. However, there does tend to be increased obstetric intervention leading to prematurity, emergency caesarean section and PPH.⁹

Pre-pregnancy management strategies

If a woman is diagnosed with a treatable condition that may have contributed to her previous IUFD, e.g. diabetes, thyroid disease or chronic renal disease, this disorder must first be optimised. Most infections are acute, but it is still important to exclude and treat chronic infections, e.g. syphilis, prior to embarking on another pregnancy.² Periodontal disease should also be identified and treated as chronic disease has been linked to worsened perinatal outcomes.⁹

It is important, as with any pregnancy, to optimise the woman's health prior to a pregnancy. This can be targeted around addressing the key modifiable risk factors: obesity and

smoking.⁵ In addition to this, ensuring that women are taking the appropriate supplements of folic acid and vitamin D is prudent.

Couples may have questions about the optimum interval between their IUFD and becoming pregnant again. This may be particularly important considering the psychological implications of an IUFD. Mothers may experience more anxiety with a short inter-pregnancy interval, whereas partners may suffer more with a delay in conception.¹² Short inter-pregnancy intervals of less than 6 months are associated with increased risk of adverse perinatal outcomes;¹⁷ however, this risk remains low.¹²

Antenatal care

The antenatal period may be a time of significant stress for a woman with a previous IUFD. Women often request increased surveillance and testing in a subsequent pregnancy.¹⁸

Initially, accurate dating and availability of combined screening will provide the opportunity to offer testing for aneuploidies, as trisomies 21, 18 and 13 are the commonest conditions associated with fetal death.

Consultant-led care should be recommended to women who have had a previous IUFD.¹² This approach will offer the opportunity to arrange regular antenatal visits, which can provide reassurance to the woman. In addition serial assessment of fetal growth, plotted on customised charts, can be initiated where appropriate.^{9,12}

All women with an unexplained IUFD should be offered screening for GDM.¹² One intervention of proven benefit is to offer women heparin when medically indicated (e.g. APLS, inherited thrombophilias, cardiac disease requiring anticoagulation).²

For patients who travel to or live in malaria-endemic areas the use of insecticide-treated nets during pregnancy is essential.²

Delivery planning

Women with previous IUFDs who are at high risk due to contributing factors or who have had an unexplained stillbirth should be advised to deliver at an obstetric unit.¹² Many couples are extremely anxious and may request to be delivered early.¹⁸ No studies have adequately investigated the effects of scheduled induction of labour on the fetus; however, what is known is that the higher rates of induction of women with previous IUFDs is coupled with an increase in instrumental deliveries and caesarean sections.¹² Many clinicians consider delivery by 39 weeks to be an important intervention for women with previous unexplained IUFDs.⁹ The psychological benefits of elective induction should be weighed against the risk of respiratory distress syndrome (albeit small) and risks of induction (e.g. abnormal CTG, uterine hyperstimulation and instrumental deliveries).

KEY POINTS

- The stillbirth rate in the UK is 4.9/1000.
- Of all stillbirths, 98 per cent occur in the developing world.
- Several different classification systems exist for identifying causes of IUFDs; a new perinatal death reporting system in the UK has resulted in fewer unexplained IUFDs – approximately one in four is unexplained.
- Risk factors for stillbirths include: maternal weight, smoking and age, parity, SGA, placental abruption, pre-existing maternal diabetes mellitus and hypertension.
- Risk evaluation should include a careful review of past history, notes and investigation results, and assessment for current risk factors (e.g. smoking and BMI).
- Timing of pregnancy and likelihood of another pregnancy loss are major issues to couples with previous fetal loss; SANDS provides guidelines to counsel such couples.
- Recurrence of IUFDs following unexplained IUFDs may be slightly increased, but is still very small.
- In future pregnancies, fetal growth evaluation, ideally using a customised growth chart reference, is important, especially in a previous IUD with a normally formed SGA baby.
- Induction of labour by 39 weeks is preferred by many couples with a past history of stillbirth, and endorsed by most obstetricians.

Postnatal care

A previous IUDF makes a woman vulnerable to depression, especially if the inter-pregnancy interval is short.¹⁹ Vigilance and appropriate management are necessary.

Chapter 35 Multiple pregnancy

Bill Martin

MRCOG standards

Theoretical skills

- Understand the different forms of twins and their risks.
- Understand the potential problems of multiple pregnancies and the general principles of management.

Practical skills

- Be able to discuss with a patient the differences between monochorionic and dichorionic placentation.
- Be able to discuss the general complications of multiple pregnancies.
- Be able to discuss the increased perinatal risk of multiple pregnancies.

INTRODUCTION

Dizygous pregnancy rates vary with maternal age, race, nutrition and geography. The highest rates are reported in sub-Saharan Africa (Nigeria – 40/1000 births) and the lowest in the Far East (Japan – 6.7/1000 births)¹. Monozygous twinning rates are, however, fairly constant, at 3–5/1000 births, although there is some anecdotal evidence that the incidence is also increasing. Multiple pregnancies have increased in the UK from 11.1/1000 maternities in 1988 to 15.9/1000 maternities in 2012.² On average, 1 in 5 IVF pregnancies results in multiple births compared with 1 in 80 for women who conceive naturally. With approximately 13,000 IVF babies being born each year this contributes significantly to the multiple birth rate.³ Though predominantly dizygotic, pregnancies that result from assisted conception techniques are at greater risk of monozygotic division than those spontaneously conceived. In 2009, the Human Fertilisation and Embryology Authority (HFEA) launched the elective single embryo transfer (eSET) policy, which allowed centres to develop their own

eSET strategy, with the aim of reducing the UK IVF multiple pregnancy rate to 10 per cent over a period of years.³

MATERNAL RISKS

The mother is at increased risk for several pregnancy complications, including miscarriage, hyperemesis gravidarum, premature labour and delivery, anaemia, pre-eclampsia, antepartum and postpartum haemorrhage, polyhydramnios, operative delivery and increased stay in hospital. Women who have twins are also at increased risk of having problems with breastfeeding and developing postnatal depression.

FETAL RISKS

Multiple pregnancies are associated with an increase in fetal and neonatal mortality compared with singleton pregnancies. The perinatal morbidity and mortality increase with increasing order of multiple pregnancy. The majority of perinatal deaths are associated with preterm birth and IUGR⁴ (discussed further below). The stillbirth rate for twin births is 2.5 times that for singleton births, and the stillbirth rate for triplet and higher-order births is 3.1 times that for singleton births. The neonatal death rate for twin births is 6.7 times that for singleton births with the neonatal death rate for triplet and higher-order births being 14.8 times higher.⁴ Monochorionic (MC) twins have an increased loss rate (14.2 per cent) compared with dichorionic (DC) twins (2.6 per cent), mainly due to losses before 24 weeks. The differential loss rate is mainly the result of twin–twin transfusion syndrome (TTTS) which accounts for 20 per cent of stillbirths in multiple pregnancies.⁵

Preterm labour

Twins are five times more likely to be born preterm compared with singletons,⁶ and delivery before 32 weeks is approximately twice as common in MC compared with DC twins.⁶ Nearly 27 per cent of triplets deliver prior to 32 weeks.

IUGR

Growth restriction of one or more of the fetuses in a multiple pregnancy is very common. The aetiology is not well understood, but (in the absence of TTTS) occurs in one twin in 10 per cent of MC and DC twins.⁵ Twin birthweight discordance has been demonstrated to be a risk factor for preterm birth and adverse perinatal outcome. The NICE guideline recommends using a 25 per cent discordancy to identify a clinically important indicator of IUGR that merits referral for a tertiary fetal medicine opinion.⁴ The presence of discordant growth in twins presents difficulties in management, more so in MC compared with DC due to the presence of vascular anastomoses in the former.

Single fetal death

This may occur either early in gestation or later as the pregnancy progresses. Fetal death after 24 weeks' gestation is relatively uncommon, occurring in 1.1 per cent and 3.6 per cent of dichorionic diamniotic (DC/DA) and monochorionic diamniotic (MC/DA) twin pregnancies, respectively.⁷ Morbidity to the surviving fetus depends on the chorionicity of the pregnancy. When one MC twin dies *in utero*, there is a 12 per cent risk of death and an 18 per cent risk of neurological damage. The same figures for DC twins are 4 per cent and 1 per cent.⁵ These complications are usually as a consequence of severe hypotension occurring during the death of the other twin.

The risk of cerebral palsy is increased in the surviving twin after a co-twin death, and same-sex twins are at greater risk than unlike-sex twins. The likely cause, in addition to the consequences of prematurity, is twin–twin transfusion problems associated with monochorionicity.

TTTS

TTTS is a condition that complicates up to 15 per cent of MC twin pregnancies.⁵ It is characterised by haemodynamic imbalances caused by unidirectional deep arterio-venous anastomotic vessels (AVA) and a relative lack of superficial vascular anastomoses (arterio-arterial [AAA] and veno-venous [VVA] anastomoses) which have bidirectional potential and can, if present, protect against those imbalances. TTTS can occur in MC/MA twins but is rarer, possibly because of the presence of protective AAAs.⁵ In 5 per cent of cases TTTS can reverse with the donor becoming the recipient and vice versa (twin anaemia polycythaemia sequence or TAPS). This can occur after treatment with amnioreduction or laser.

The diagnosis requires the ultrasound demonstration of polyhydramnios around one twin (the recipient) and oligohydramnios around the other twin (the donor), with the separating membrane completely covering this fetus (stuck twin). The recipient twin is usually appropriately grown for gestational age, has a large distended bladder and may, if severely compromised, be hydropic. Recipient fetuses may also develop cardiac dysfunction and neonatal hypertension.

The donor twin, on the other hand, is frequently severely growth restricted, with abnormal umbilical artery Doppler waveforms. If untreated, the perinatal mortality rate of TTTS is extremely high (>90 per cent). Although twin–twin transfusion is usually a gradual process, it can happen suddenly with the death of one twin, usually the recipient.

Twin reversed arterial perfusion (TRAP) sequence

This complication occurs in approximately 1 per cent of MC pregnancies. It is characterised by an acardiac twin, which receives its blood supply via a large AAA from a normal co-twin (known as the 'pump' twin). This results in absent or rudimentary development of the upper body structures as the acardiac twin is supplied with deoxygenated blood. The perinatal mortality of the pump twin is considerable, with death usually occurring through complications of high-output cardiac failure leading to hydrops fetalis or polyhydramnios-induced preterm delivery.

Congenital anomalies

There is an excess of malformations in twins compared with singleton pregnancies.⁴ These include malformations arising from the process of development and are often midline structural anomalies (e.g. NTDs, cardiac and cleft lip anomalies). An extreme example is the development of conjoined twins. Other malformations occur through disruption in a previously normally formed fetus. Disruptions are more common in MC pregnancies and consist of predominantly vascular-type lesions (e.g. hydrancephaly, porencephaly, small bowel atresia). A further mechanism leading to maldevelopment is the constraint of sharing the uterine cavity (e.g. talipes, congenital dislocation of the hip).

Other fetal risks

There are complications that usually arise in the third trimester and in particular in the intrapartum period. These include: intrapartum hypoxaemia through entanglement (interlocking twins); umbilical cord accidents such as cord prolapse which are more likely in multiple pregnancy due to an increased frequency of malposition; and cord entanglement in monoamniotic (MA) twins.⁵

KEY POINTS

- Preterm labour and delivery are the biggest cause of adverse perinatal outcome in multiple pregnancy [B].
- Maternal risks relate mainly to increased uterine distension and the development of pre-eclampsia [B].
- An excess of congenital malformations means that examination of multiple pregnancies by detailed ultrasound scanning is mandatory [B].

MANAGEMENT

Diagnosis and determination of chorionicity

Dizygous twins are always DC/DA. The chorionicity of monozygotic twins depends on the timing of embryo splitting after fertilisation. They may be:

- DC/DA, if <3 days;
- MC/DA, 4–7 days;
- MC/MA, 8+ days.

The early establishment of chorionicity is crucial to management of twins.⁵ Complications are greater in MC compared with DC twins. Twenty per cent of twins are MC but such pregnancies are associated with an almost 26 per cent risk of perinatal mortality.

In the first trimester, chorionicity may be determined with nearly 100 per cent accuracy. In contrast, mid-trimester assessment is only 80–90 per cent accurate. If two placentae are visualised or if the fetuses are discordant for gender, the pregnancy must be DC. Visualisation of the *twin-peak* or *lambda* sign is also useful in the diagnosis of dichorionicity; however, the absence of this sign is not as reliable in the confirmation of monochorionicity. Membrane thickness has also been used to assign chorionicity. In difficult cases, zygosity studies may need to be performed, but there is no evidence that this approach improves overall outcome in MC twins.

Screening for aneuploidy and prenatal diagnosis

Serum screening in multiple pregnancies is not as reliable as in singletons. Therefore the screening method of choice is combined screening employing NT scanning plus biochemical tests – PAPP-A and β -hCG. This allows screening in the first trimester with calculation of a risk for each fetus.⁸ Before any invasive procedure is undertaken for karyotyping, careful ultrasound mapping of the different placentae and gestational sacs is important to assist in subsequent management when the karyotype results are available. The pregnancy loss rates for genetic amniocentesis in twins are considered similar to those seen in singletons. No data exist on loss rates with amniocentesis for higher-order multiples. CVS is also possible in multiple pregnancies. Although CVS carries a higher loss rate, it has the advantage of being performed earlier, but may be less reliable than amniocentesis as up to 4 per cent of CVS samples show evidence of co-twin contamination.

Monitoring of fetal growth

Serial growth scans should be performed to evaluate fetal growth velocity and to detect any abnormalities in umbilical/fetal artery Doppler waveform analysis and amniotic fluid volume. In DC twins, 4-weekly scans from 24 weeks should

be employed to try to identify growth restriction, with more frequent scans if growth appears suboptimal. MC pregnancies should be monitored fortnightly from 16 weeks.^{4,5}

The management of growth restriction in twin pregnancies needs to consider the risks to both the fetuses. Severe growth restriction in one fetus in a DC pregnancy might warrant a conservative approach (even allowing the growth-restricted fetus to succumb *in utero*), thus sparing the healthy fetus the risks of iatrogenic prematurity. This situation is more complicated in MC pregnancy due to the presence of vascular anastomoses which could lead to damage/demise of the co-twin under these circumstances (see below).

Multifetal pregnancy reduction (MFPR)

In higher multiple pregnancy, with expectant management (i.e. non-reduction), 17 per cent and 28 per cent deliver at less than 29 weeks with triplets and quadruplets, respectively. In addition triplets and quadruplets have higher rates of other adverse outcomes including increased perinatal death, major anomalies, need for neonatal intensive care, respiratory distress syndrome, intrauterine growth restriction and serious neurological morbidity. Due to these issues and the additional increased maternal risk (e.g. pre-eclampsia), there is a consensus that multifetal pregnancy reduction at approximately 12 weeks should be offered to women with triplets (and higher multiples) to lower the incumbent risks.

With increasing experience, post-procedure miscarriage rates are now <10 per cent, such that reductions from triplets to twins and from quadruplets to twins carry outcomes as good as those of unreduced twin gestations, and the chance of taking home a live baby increases from 80 per cent to 90 per cent.

Preterm labour

Prediction of preterm labour in twin pregnancies is as difficult as in singleton pregnancies. Cervical assessment has been suggested as one method to evaluate the risk of preterm labour. However, the frequency of monitoring/assessment of the cervix is unclear. In singleton pregnancy a cervical length of 15 mm is predictive of preterm labour. In twin pregnancies, the mean cervical length is similar to that of singletons (38 mm), but a cervical length of 25 mm at 23 weeks' gestation predicts about 80 per cent of women who deliver spontaneously at <30 weeks, with a false-positive rate of approximately 11 per cent.⁹

Home uterine monitoring, fetal fibronectin estimation, prophylactic cervical cerclage, progesterone supplementation and tocolysis have not been shown to reduce the incidence of preterm labour in twin pregnancies⁴ and have largely been abandoned.

There is currently not enough evidence to support a policy of routine hospitalisation for bed rest in multiple pregnancies. No reduction in the risk of preterm birth or perinatal death is evident, although there is a suggestion that fetal growth is improved. Indeed, in uncomplicated twin pregnancies, there

is a suggestion that bed rest may be harmful in that the risk of very preterm birth is increased.

Antenatal steroids

The 2011 NICE guidelines⁴ recommend the use of corticosteroids in a targeted way, i.e. where preterm delivery is considered likely. Untargeted (prophylactic) steroids are not recommended. Steroids should be offered in MC twin pregnancies as part of a planned delivery after 36 weeks, and similarly in triplet pregnancy as part of planned delivery after 35 weeks (see below).

Treatment of TTTS and TRAP

Treatment options for pregnancies affected by TTTS and TRAP have included serial amnioreduction, septostomy, selective feticide and laser ablation of the communicating anastomoses. A recent Cochrane Review (2014)¹⁰ concluded that although, compared with amnioreduction, laser does not appear to improve survival significantly, it remains the treatment of choice due to the significant reduction in long-term neurological morbidity. Amnioreduction continues to have a place where laser therapy is not available or where TTTS occurs late in pregnancy (>26 weeks' gestation). The RCOG Guideline⁵ concludes that TTTS before 26 weeks should be treated at regional fetal medicine centres by laser ablation. In advanced TTTS where one of the twin pair is *in extremis*, selective feticide is an option, allowing the survival of one twin with an 85 per cent success rate. Current management of TTTS therefore favours amnioreduction or expectant management for stage 1, laser ablation for stages 2–4, and selective reduction if imminent fetal demise of one twin threatens the co-twin.

A rare complication of MC twin pregnancy, with or without TTTS and which may occur following seemingly successful laser therapy, is TAPS. There may be no discordance in liquor volume but there is a large difference in Hb level. Severe sequelae may result including hydrops fetalis and fetal death. Optimal treatment is unclear but these cases require tertiary-level management.

In cases of TRAP, disruption of the acardiac twin's cord or intrafetal vessel ablation with laser, diathermy or the more recently available radiofrequency interstitial thermal ablation (RITA) are the available treatments with survival reported in >70 per cent of pump twins.

Treatment of co-twin death

In DC pregnancies, expectant management is indicated. Regular assessment of the pregnant woman's coagulation status is necessary in order to detect changes in the coagulation system that may occur. In both MC and DC pregnancies, if one twin dies there is risk of death or neurological damage in the surviving twin (see above).⁵ Management depends upon the

gestation and on the elapsed time since the fetal death. When death has occurred within 24–36 hours at an early gestation, fetal blood sampling with rescue transfusion may be considered if the surviving fetus is anaemic as indicated by middle cerebral artery Doppler (TAPS). At later gestations, delivery may be more appropriate if there are significant concerns regarding the wellbeing of the survivor. But caution must be exercised as any damage is likely to have occurred and delivery may only add risks of prematurity and not improve outcome.

If a co-twin death has occurred some time previously, consideration should be given to appropriate imaging of the surviving fetus's brain with either ultrasound or MRI to detect cystic changes. If these changes are apparent, offering termination of the pregnancy is an option.

Labour and delivery

The NICE guidance⁴ suggests the following approach.

Women with uncomplicated MC twin pregnancies should be informed that elective birth from 36 weeks 0 days does not appear to be associated with an increased risk of serious adverse outcomes. For women with uncomplicated DC twin pregnancies the equivalent gestation is 37⁺⁰ weeks.

Both MC and DC twins should be informed that continuing uncomplicated twin pregnancies beyond 38 weeks 0 days increases the risk of fetal death.

Women with triplet pregnancies should be informed that continuing uncomplicated triplet pregnancies beyond 36 weeks 0 days increases the risk of fetal death.

Thus women with uncomplicated MC twin pregnancies should be offered elective birth from 36 weeks 0 days (after antenatal corticosteroids). DC twin pregnancies should be offered elective birth from 37 weeks 0 days and triplet pregnancies should be offered elective birth from 35 weeks 0 days, after a course of antenatal corticosteroids has been offered.

If elective birth is declined, appointments with a specialist obstetrician should be made with weekly ultrasound assessment of wellbeing and fortnightly fetal growth scans.

If there is evidence of TTTS or other complications, timing of delivery must be individualised.

The mode of delivery is decided based on the presentation of the first twin. Vaginal delivery is preferred in vertex–vertex presentations. The optimal mode of birth for the second twin presenting as non-vertex is unknown, with retrospective reviews in the literature providing support for both caesarean birth and vaginal birth for the second non-vertex twin.

For the very-low-birthweight infant (1500 g), opinion is divided as to the optimal mode of delivery. Whereas some advocate caesarean delivery in all cases, there is little evidence that caesarean section improves perinatal outcome.

For MC/MA twins delivery should be around 32 weeks and be by caesarean section [C].⁴ Although some authors suggest that triplets and higher-order multiples may be safely delivered vaginally despite the obvious difficulties in monitoring, caesarean section is the more usual mode of delivery.

KEY POINTS

- Determination of chorionicity is important to allocate pregnancy risk [B].
- Combined screening is the method of choice for aneuploidy screening [B].
- Prenatal diagnosis using amniocentesis or CVS is suitable in multiple pregnancy [B].
- Ultrasound assessment should be carried out every 4 weeks from 20 weeks in DC twins and every 2 weeks from 16 weeks in MC twins (good practice point) (RCOG).⁵
- The management of TTTS and TRAP necessitates referral to an appropriate fetal medicine unit [B,D]. Such conditions carry high perinatal mortality, even with treatment.
- Optimal treatment of TTTS is laser ablation [A].
- Cervical length measurement may be useful in predicting preterm birth in multiple pregnancy [B].
- Uncomplicated MC twins aim to deliver vaginally by 36–37 weeks (good practice point) (RCOG).⁵
- Uncomplicated DC twins aim to deliver vaginally by 37–38 weeks (good practice point) (RCOG).⁵

CONCLUSIONS

The management of a multiple pregnancy is a major challenge for obstetricians. These pregnancies are at increased risk of maternal and fetal complications that require specialised management. There is an increasing vogue to manage these patients in specialised multiple pregnancy clinics, with access to a fetal medicine specialist with a special interest in multiple pregnancy.

Chapter 36 Fetal infections

Tara Jayne Selman

MRCOG standards

Theoretical skills

- Knowledge of the most common maternal infections that can result in fetal morbidity and mortality.
- Understand the maternal and fetal tests that can determine *in-utero* infection.
- Appreciate the long-term implication of fetal infection.
- Understand the treatment and preventive measures.

Practical skills

- Be able to counsel pregnant women with regard to the risk of fetal infection, diagnostic methods, treatments and pregnancy options, and refer appropriately those at risk of fetal infection to a fetal medicine unit.

BACKGROUND

The majority of common maternal infections acquired during pregnancy are of little or no consequence to the fetus; however, there are some important infections that have significant sequelae for the fetus and may result in anything from fetal demise through to structural difference and neuro-development delay. The effect on the fetus is dependent on not only the type of infection but also the gestation acquired. Prenatal diagnosis is usually initiated as a result of routine screening at booking, a history of exposure of the mother to infectious contacts or differences seen on ultrasound scan. Independent of the infection type, management always requires a multidisciplinary team approach including microbiologists, obstetricians, fetal medicine experts and paediatricians. This team is responsible for confirming maternal infection and determining, with potential confirmation

of, the risk of fetal infection. For those with an infected fetus careful and empathetic counselling is then necessary covering any intrauterine treatment, fetal surveillance and in some situations the possibility of termination of pregnancy.

This chapter will concentrate on the prenatal diagnosis and management of some of the more common or serious fetal infections.

RUBELLA

Introduction

The rubella virus (formerly known as German measles as it was described first by two German physicians) is found only in humans and is transmitted by aerosol via the respiratory tract, with close contact usually required for transmission.

The national immunisation programmes in many countries have made this disease increasingly rare as a result of herd immunity; however, one should have a high index when seeing immigrants to the UK. Studies in the UK from antenatal screening results have shown that 4–8 per cent of immigrant women, but less than 2 per cent of UK-born women, are susceptible to rubella infection.¹

Rubella is normally a mild disease, especially in children, although it can cause more severe symptoms in adults. There is an incubation period on average of 14 days (12–23 days) prior to the development of the classic non-confluent maculopapular rash seen first on the face then spreading to the trunk. There is often a lymphadenopathy, most commonly suboccipital, post-auricular and cervical, prior to and lasting after the disappearance of the rash. These signs are often accompanied by a prodromal phase with malaise and low-grade fever and also headache, sore throat and cough. In 20–50 per cent of cases the entire infection may be subclinical. In adults the most common complications are arthralgia and arthritis; rarely post-infection encephalopathy (1:6000) and thrombocytopenia (1:3000) are seen. The viraemia occurs for 7 days prior to the rash developing and for 7–12 days after the onset of the rash, hence a person is infectious for over 2 weeks.²

Maternal diagnosis

Laboratory confirmation of rubella infection is required as the condition frequently is subclinical or has associated signs and symptoms that are indistinguishable from other infections such as parvovirus B19 and group A streptococcus.³ An acute infection may be diagnosed by isolation of the virus from throat swabs, but it is more common for an acute rubella-specific immunoglobulin (IgM) response to be isolated [C] using fluorescent immunoassay techniques. The presence of rubella-specific IgG indicates previous infection or immunisation and immunity is normally lifelong.

Fetal infection

There are few prospective studies using sensitive laboratory techniques to accurately determine the rate of fetal infection. The most vulnerable gestation for transplacental infection is in the first trimester, occurring in approximately 80 per cent of cases. Of these, congenital defects occur in about 85 per cent, with multiple defects common if the infection was in the first 8 weeks of gestation, and in 20 per cent of cases in this gestation range the infection results in miscarriage.^{4,5} After 12 weeks the risk to the fetus declines rapidly to somewhere in the region of 25 per cent in the early second trimester.

Fetal rubella infection can result in a number of abnormalities referred to collectively as congenital rubella syndrome. These classic abnormalities are heart defects (patent ductus arteriosus, pulmonary stenosis, pulmonary arterial hypoplasia), eye defects (cataracts, microphthalmos, retinopathy), CNS problems (mental and psychomotor delay, speech and language delay), microcephaly and sensorineural deafness.⁵ Fetal infections later in the pregnancy may result in isolated deafness. There is emerging evidence to suggest that *in-utero* exposure to rubella may have long-term mental health sequelae with individuals being at higher risk of schizophrenia in adulthood. The virus is thought to prevent maturation of critical brain structural and functional components implicated in the aetiology of the disorder.⁶

The exact pathogenesis of congenital rubella infection is not fully understood. One hypothesis is that the virus crosses the fetus via the chorion in the first trimester and virus-infected desquamated epithelial cells are transported to the fetal circulation and fetal organs. In early pregnancy the fetal immune response has not developed and fetal damage may be by viral retardation of division, induced apoptosis of essential cells, or interference with the cell cycle and tissue necrosis.^{7,8}

Diagnosis in the fetus and management

When primary infection has occurred in the first 12 weeks of pregnancy a woman should be counselled that the risk of congenital defects is very high and some women may wish to terminate the pregnancy.

The rate of infection declines rapidly between 12 and 18 weeks and is almost zero after 20 weeks,² hence counselling

at this gestation is inevitably more focused on prenatal diagnosis. Fetal blood sampling to measure levels of rubella-specific IgM can be performed and rubella-specific RNA identified using reverse-transcriptase polymerase chain reaction (RT-PCR) [C,D].⁹ The risk of false-negative results and the uncertainty over the effects on the fetus of infection should be discussed with the woman prior to testing.

Treatment and prevention

In the absence of an antiviral drug to treat rubella or prevent transmission, the cornerstone of prevention is childhood vaccination. Primary rubella vaccination failure is rare, with many studies showing a 100 per cent seroconversion rate. Vaccination programmes have been shown to be cost-effective in both developing and developed countries if coverage rates of more than 80 per cent are achieved. Pre-pregnancy counselling should include evidence of immunity, with vaccination offered to susceptible women [C]. There is insufficient evidence to support rescreening of previously seropositive women and no data to support or refute the principle of offering rubella vaccination to women who have low titres. In the UK the vaccine, which contains attenuated rubella virus, is usually given in combination with measles and mumps vaccines as the MMR. The vaccine is contraindicated in pregnancy and pregnancy should be avoided for 1 month afterwards.

KEY POINTS

- Maternal infection in the first trimester results in an extremely high rate of fetal transmission and subsequent congenital rubella syndrome [C].
- Termination of pregnancy should be discussed as part of counselling when the infection has occurred in the first trimester due to the high risk of congenital malformations [C].
- Prenatal diagnosis should be considered when maternal infection has occurred in the second trimester as the risk to the fetus declines rapidly between 12 and 18 weeks' gestation.

CYTOMEGALOVIRUS

Introduction

Cytomegalovirus (CMV) is a ubiquitous double-stranded DNA virus that belongs to the herpes virus family. It is one of the most common congenital infections, with the prevalence of congenital CMV at birth in the region of 1 per cent. The reported incidence of primary maternal infection in pregnancy is 0.7–4.1 per cent, with transmission to the fetus occurring in approximately one-third of cases.¹⁰ Approximately 50–70 per cent of pregnant women show serological evidence of previous infection. Although recurrent infection can

lead to fetal infection the risk of transmission is much lower (1–3 per cent), as is the severity of fetal infection.

Almost all CMV infections in non-immunosuppressed pregnant women are asymptomatic with only a small proportion (up to 5 per cent) displaying a mononucleosis-like syndrome.¹¹ Transmission of the virus requires close contact between individuals though contaminated urine, saliva, semen, cervical secretions and breast milk.

Maternal diagnosis

Due to the asymptomatic nature of the condition laboratory testing is relied upon for maternal diagnosis. CVM IgG has a high sensitivity and specificity as a sign of a past or recent infection. Seroconversion from two samples will provide the most accurate and reliable diagnosis of a primary infection. Although CMV IgM is suggestive of a recent or ongoing infection with a high sensitivity, its specificity is low. If a sample has both CMV IgM and IgG, comparison with a sample early in pregnancy can aid in diagnosis. Alternatively CMV IgG avidity testing can be performed. This test will examine the binding capacity of CMV IgG antibodies which is low early after infection.¹²

Fetal infection

Eighty to ninety per cent of neonates with congenital CMV infection are asymptomatic in the neonatal period. On ultrasound the fetus may exhibit IUGR, microcephaly, cerebral atrophy, ventriculomegaly, intracranial calcification and/or fetal hydrops. The presence of fetal abnormalities on ultrasound worsens the prognosis. The likelihood of CMV having an effect on the fetus is not gestation dependent, but the sequelae differ. In early infection fetal brain anomalies are more frequently seen and the neonate is more likely to be symptomatic in comparison to later infection where hepatitis and thrombocytopenia are more common. Congenital CMV infection is the most common cause of deafness and learning disabilities in the UK, as rubella, measles and mumps have become much rarer due to vaccination. The outcome for the 10 per cent of neonates who are clinically affected at birth is poor. There is an associated mortality rate of 30 per cent and 90 per cent will have severe neurological sequelae. Of those asymptomatic at birth 10–15 per cent will develop long-term sequelae.

Diagnosis in the fetus and management

The diagnosis of fetal infection may be suggested by maternal serology and ultrasound findings. Women with CMV infection in pregnancy should be offered fetal diagnosis which is usually by quantitative PCR on the amniotic fluid, although it is possible from CVS and fetal blood [C].¹³ The diagnostic sensitivity is high if the sample is taken after week 21 of pregnancy (once fetal diuresis is established) and 6 weeks after maternal serum is positive [B]. A negative result still has to be treated with caution as it can be falsely negative due to CMV levels

being too low to detect. As the fetus may still be affected in the absence of ultrasound findings, termination of pregnancy should be discussed alongside serial ultrasound surveillance.

Treatment and prevention

There is no vaccination for CMV, although research has shown CMV glycoprotein B vaccine may potentially reduce the incidence of maternal and congenital CMV infection, with a suggested 50 per cent vaccination efficacy rate; phase 3 trials are awaited.¹⁴ There is also no effective fetal therapy. Ganciclovir can transiently reduce viral shedding and may reduce the audiological consequences of CMV in some infected infants [C,D].

KEY POINTS

- Pre-pregnancy immunity to CMV is in the range of 55–85 per cent.
- Primary infection rate in pregnancy is 1–4 per cent with an approximate 40 per cent fetal transmission rate [C].
- Congenital CMV incidence is between 0.3 and 3 per cent [C].
- Ten per cent of neonates with congenital CMV will be symptomatic at birth. There is a poor prognosis in this group with a 30 per cent mortality rate, and in survivors up to 90 per cent have neurodevelopmental delay and 60 per cent hearing loss.

TOXOPLASMOSIS

Introduction

Toxoplasmosis is a unicellular protozoan that is found worldwide, although it is more common in tropical areas. Seroprevalence in Europe is high: up to 54 per cent in southern European countries, decreasing with increasing latitude to 5–10 per cent in northern Sweden and Norway. The cat is the definitive host and produces oocysts and sporozoites. Ingestion leads to the formation of tachyzoites; these cause parasitaemia and further dissemination in subsequent bradyzoites which lead to latent infection with the formation of tissue cysts in the skeletal muscle, heart muscle and CNS tissue. Toxoplasmosis can be transmitted to pregnant women through ingestion of tissue cysts in raw or inadequately cooked meat, or in uncooked foods that have been in contact with contaminated meat. It can also be transmitted through inadvertent ingestion of oocysts and sporozoites in cat faeces and contaminated surface water.¹⁵ It is not possible to confirm the source of infection; however, there is a wide consensus among experts that acquiring toxoplasmosis is often associated with unsafe eating habits. In adults the infection is usually asymptomatic, although they may develop a mild malaise, lethargy and lymphadenopathy.

Maternal diagnosis

As with rubella and CMV the diagnosis of maternal infection is usually a serological one. When IgM and IgG are identified conversion from a seronegative sample taken at booking is helpful in accurately confirming the diagnosis. Without such a sample interpretation is more difficult as low levels of CMV IgM can be found for up to several years after an acute infection.¹⁶ Presumed positive testing can be confirmed in laboratories using specific and sensitive ELISA testing [C].

Fetal infection

Congenital toxoplasmosis has a classic triad of chorioretinitis, intracranial calcifications and hydrocephalus. The likelihood of fetal infection and the severity are gestation dependent. In the first trimester fetal infection will often result in miscarriage; if miscarriage does not occur maternal infection is less likely to result in congenital infection; however, if it does occur the differences are usually more severe. As pregnancy progresses the likelihood of transplacental passage increases but fetal injury is less likely.¹⁷

Diagnosis in the fetus and management

Fetal infection can be identified by PCR of amniotic fluid [C].¹⁸ When counselling a woman the gestation that the infection is likely to have occurred (if known) should be taken in to account as well as the parasitic load of the amniotic fluid, with infections acquired before 20 weeks' gestation and a parasite load of 1100 parasites/mL amniotic fluid, and women with fetal anomalies shown on ultrasound, having a poor prognosis. In such pregnancies termination should be discussed with the parents.

Treatment and prevention

On confirmation of maternal infection recommendations are still that spiramycin should be commenced to reduce the likelihood of fetal transmission [C];¹⁸ however, a Cochrane review of treatment of toxoplasmosis infection in pregnancy failed to identify studies to support this.¹⁹ It is thought that, for an effect to be seen on clinical outcome (reduction in neurological symptoms rather than in chorioretinitis), treatment needs to be commenced within 4 weeks of infection [C]. Hence spiramycin should be commenced before PCR results from amniocentesis and continued even if this is negative, due to the theoretical risk of later infection from the placenta infected earlier in pregnancy. Some recommend that, with a positive PCR from amniotic fluid from 18 weeks, combination therapy of pyrimethamine (avoided in the first trimester due to potential teratogenicity risk) and sulfadiazine be used.

Due to the potential ineffectiveness and risks of treatment, prevention is of primary importance. This requires prenatal education on the importance in pregnancy of handling and cooking meat correctly, wearing gloves to handle

cat litter and avoiding contact with objects that are potentially contaminated with cat faeces.

KEY POINTS

- In the UK it is felt that the risk of congenital toxoplasmosis is low and routine screening of pregnant women would not be cost-effective [C].
- Public education is needed to prevent infection during pregnancy.
- It is possible that early maternal treatment may reduce transmission or at least reduce neurological sequelae.
- Fetal risk is gestation dependent. Severe congenital disease occurs in up to 25 per cent of fetuses infected in the first and second trimesters.

PARVOVIRUS B19

Introduction

Parvovirus B19, also commonly referred to as fifth disease or erythema infectiosum, is a small single-stranded DNA virus that at least 50 per cent of pregnant women are seropositive for and hence immune to. The virus is often asymptomatic in adults, although they may initially present with symptoms similar to a common cold followed by the classic slapped-cheek rash. Adults who are symptomatic will often experience a polyarthropathy syndrome. The virus is spread via aerosol route and those infected are contagious for 5–10 days prior to the rash developing. Significant contact is required to contract the virus. This is defined as being in the same room as the infected person for over 15 minutes, or face-to-face contact. The infection is usually seen in epidemics.

Maternal diagnosis

The diagnosis is again a serological one which is triggered by a history of significant contact with an infected party (usually a child) or due to fetal finding. A positive serological diagnosis is made in the presence of parvo-specific IgM antibodies. These usually appear 2–3 days after an acute infection and may persist up to 6 months. The presence of specific IgG is seen a few days after the development of IgM and usually remains lifelong, and hence is evidence of previous infection and confers lifelong immunity. If viral exposure was recent then it is possible that it is still within the incubation period and it is suggested that if a woman is seronegative she be retested 2–4 weeks later.²⁰

Fetal infection

The virus itself is not thought to be teratogenic [D]; however, the effects of transmission to the fetus can be serious and fatal. The risk of transplacental infection increases with gestation,

from 15 per cent until 15 weeks to 25 per cent thereafter and up to 70 per cent towards term. In early pregnancy (first and early second trimester) there is a 9 per cent fetal loss rate. After this gestation the risk to the fetus is of developing hydrops secondary to fetal anaemia or cardiac dysfunction from acute myocarditis [C,D]. The virus has a predilection for erythropoietic cells which leads to a transient but severe pancytopenia.²¹ There is in the region of a 3–10 per cent risk of developing hydrops following infection and once present a 50 per cent risk of fetal demise.

Diagnosis and management

Diagnosis is made either as a result of isolation of the virus from PCR at amniocentesis or from fetal blood sample performed as part of the investigation of fetal hydrops [C]. Fetal hydrops usually occurs 2–4 weeks after the acute fetal infection. A fetus potentially identified as being at risk due to maternal serology, but not showing signs of infection, should be monitored by ultrasound weekly for up to 8 weeks after maternal exposure for signs of fetal hydrops, and with middle cerebral artery, peak systolic velocity measurements to predict fetal anaemia. A fetus with either hydrops or anaemia requires management at a tertiary fetal medicine centre. The management is controversial as 30 per cent of cases of hydrops will resolve spontaneously due to the self-limiting nature of the virus, however there are no robust methods to determine in which fetus this will occur and hence active management of all cases usually occurs. A fetal blood sample (via cordocentesis or intrahepatic umbilical vein) is taken to confirm the underlying diagnosis of fetal anaemia and its cause, and intrauterine transfusion is given [C].²²

KEY POINTS

- There is a 1:5 risk of transplacental infection of the fetus in non-immune pregnant women [C].
- The risk of fetal infection is gestation dependent.
- The time interval between maternal infection and fetal consequence is 4–5 weeks.
- Fetal consequences of infection can be self-limiting and treatable. Management should be in a tertiary referral fetal medicine centre capable of performing intrauterine transfusion [C,E].

SYPHILIS

Introduction

Syphilis is caused by the spirochaete *Treponema pallidum*. Often women infected with syphilis are not aware of their condition, with the primary painless genital sores going unnoticed. Secondary syphilis presents several weeks or months later with cutaneous, mucosal and sometimes systemic symptoms. It is

at this stage that syphilis is most contagious and it can last up to a year. Finally the infection enters a latent stage which may have an absence of clinical manifestations, but can still result in transplacental fetal infection.²³ Worldwide this is a common cause of both fetal growth restriction and fetal hydrops.

Maternal diagnosis

Screening of antenatal patients for syphilis is part of the national screening programme. Unlike most common bacterial infections *T. pallidum* cannot be cultured rapidly or cheaply. There are several serological tests that are used such as VDRL (Venereal Disease Reference Library), RPR, FTA-abs (fluorescent treponemal antibody absorption test), MHA-TP (Microhemagglutination assay) or TPI assay (Triose Phosphate isomerase assay).

Fetal infection

Spirochaetes can cross the placenta from 14 weeks' gestation, with the risk of fetal infection increasing with gestational age.²⁴ During the first 4 years of acquiring syphilis an untreated pregnant woman will have a 70 per cent chance of transmitting the infection to the fetus. The results for an infected fetus are profound and range from spontaneous miscarriage and stillbirth through to non-immune hydrops, growth restriction and preterm delivery. About two-thirds of liveborn infants with congenital syphilis are asymptomatic at birth and later are affected with deafness, neurological impairment and bone deformities.

Diagnosis and management

Fetal infection can be diagnosed by serology from fetal blood sample, detecting syphilis-specific IgM antibodies (maternal IgM does not cross the placenta), or alternatively *T. pallidum* DNA can also be detected using PCR techniques with amniotic fluid [C].²⁵ Ultrasound features which are suggestive of infection may also be seen e.g. fetal hydrops, hepatomegaly, placentomegaly and small bowel dilation. Hepatomegaly appears to be the most sensitive ultrasound marker [D].

There is no treatment for an infected fetus and as with all serious fetal infections discussion around termination of pregnancy is appropriate.

Treatment and prevention

The use of penicillin has formed the long-stay treatment for syphilis and remains so, as unlike other sexually transmitted infections (STIs) it has not yet developed a resistance to this. When syphilis is diagnosed in pregnancy a penicillin regimen appropriate for the stage of disease should be used [C], with monthly serology titres allowing evaluation of the adequacy of treatment. In theory penicillin treatment will prevent the transplacental passage of the pathogen; however, as many as

KEY POINTS

- Worldwide congenital syphilis is still a major cause of perinatal morbidity and mortality.
- The risk of transplacental transmission is greatest within the first year of untreated maternal syphilis.
- If untreated, of those pregnancies infected 30 per cent of fetuses will die *in utero* and 30 per cent in the early neonatal period, with the others developing late congenital symptoms.

14 per cent of women, despite the recommended treatment, will have a fetal death or deliver a neonate with congenital syphilis [C].^{26,27}

VARICELLA

Introduction

Varicella-zoster virus (VZV) is a highly contagious DNA virus of the herpes family. It is transmitted by respiratory droplets and by direct personal contact with vesicle fluid. The primary infection is characterised by fever, malaise and a pruritic rash. During pregnancy the illness tends to be more severe than in childhood and it can result in maternal pneumonia, encephalitis or myocarditis. The incubation period is 7–21 days and a person is infectious 48 hours before the rash appears and continues to be infectious until the vesicles crust over, typically 5 days. Over 90 per cent of the antenatal population in the UK are seropositive for VZV-specific IgG antibody, so infection is uncommon, affecting 1 in 1000 pregnancies. Following primary infection the virus remains dormant in sensory nerve root ganglia and can become reactivated to give a vesicular erythematous skin rash in a dermatome distribution, i.e. shingles. It is possible to acquire the infection from exposed sites.²⁸

Maternal diagnosis

For a woman with no previous history of chickenpox and a significant history of exposure the risk to the woman can be determined by looking for serological evidence of VZV IgG. The diagnosis itself is made from examination of the classic rash. Although treating seronegative women with significant contact with varicella-zoster immunoglobulin, and those with active disease with aciclovir, is important for maternal health, there is no evidence to prove that it reduces the risk of transmission of VZV to the fetus.²⁸

Fetal infection

The effect of VZV on the fetus is gestation dependent. In the first trimester fetal infection may lead to spontaneous miscarriage. From as early as 3 weeks until 28 weeks' gestation it is possible for the fetus to develop fetal varicella syndrome (FVS), although the risk overall is small: 1–2 per cent until

20 weeks, with most cases occurring after the first trimester²⁹ and rapidly declining towards 28 weeks with no cases reported after 28 weeks.³⁰ Fetal varicella syndrome consists of limb deformity, microcephaly, hydrocephaly, soft tissue calcification and IUGR.

Diagnosis and management

Diagnosis of fetal infection can be made by ultrasound findings. There is usually a time lag of at least 5 weeks after the primary infection before fetal differences are seen.²⁸ Amniocentesis may be performed to confirm the diagnosis with PCR identification of VZV DNA. In the absence of ultrasound scanning finding a positive amniocentesis has a high sensitivity but low specificity for the development of VZV. If the PCR is positive but the ultrasound normal at 17–21 weeks the risk of FVS (fetal varicella syndrome) is low; if repeat ultrasound scanning at 24 weeks is also normal then the risk of FVS is almost zero. The risk, conversely, is very high if there are ultrasound features and positive PCR [D].

Treatment and prevention

There is no intrauterine treatment currently available. For women known to be seronegative varicella vaccine can be administered. This is a live attenuated vaccine and hence pregnancy should be avoided for 1–3 months after administration.

Chapter 37 Tests of fetal wellbeing

Alexander Heazell

MRCOG standards

Knowledge criteria

- Management of pregnancy complications including: fetal growth restriction, pregnancy-induced hypertension, prolonged pregnancy and reduced fetal movements.

Clinical competency

- Manage women with fetal growth restriction or reduced fetal movements.
- Assess fetal wellbeing by maternal history, cardiotocography and ultrasound scan.

Relevant guidance from the RCOG

- Green Top Guideline 10A – Severe pre-eclampsia/eclampsia.
- Green Top Guideline 31 – Investigation and management of the SGA fetus.
- Green Top Guidelines 57 – Management of reduced fetal movements.

INTRODUCTION

Tests of fetal wellbeing in the antenatal period aim to reduce perinatal morbidity and mortality and infant morbidity by correctly identifying fetal compromise *in utero* so that appropriate intervention (usually delivery) can be instigated. To achieve the desired clinical impact a test must have sufficient sensitivity and specificity and be coupled to an effective intervention. For example, a perfectly predictive test with sensitivity and specificity of 100 per cent will have no clinical value if there is no intervention to prevent the outcome. In practical terms no such perfect test exists; tests must be sufficiently sensitive to predict or identify a compromised fetus but must also be specific to prevent unwarranted intervention and parental anxiety.

Development of tests that can achieve the required sensitivity and specificity is challenging as the poor outcomes they aim to detect and prevent are comparatively rare, increasing the likelihood of a false-positive result. The comparative rarity of stillbirth or severe neonatal morbidity means that studies to test these interventions need to be very large and are thus expensive and difficult to undertake. Therefore, current practice is often based on a lower quality of evidence than one would hope for.

FETAL COMPROMISE

Fetal compromise has no widely accepted definition. However, in practice fetal compromise usually describes a series of events culminating in fetal hypoxia which in turn leads to acidaemia. If the cause persists then the fetus is at risk of severe morbidity (e.g. cerebral palsy) or will ultimately die. Potential causes of fetal compromise may be acute or chronic and include: impaired maternal nutrient or oxygen supply, uteroplacental dysfunction, impaired blood supply to the fetus (e.g. cord accident) and fetal anaemia (e.g. fetomaternal haemorrhage). Of these, placental dysfunction is the most frequent cause of antepartum fetal compromise. It is important to note that placental dysfunction can occur as the end-point of various pathological processes (e.g. abnormal development, infarction, inflammation, infection), the discussion of which is beyond the scope of this chapter.

In the presence of nutrient and oxygen deprivation secondary to placental dysfunction, the fetus initially responds by reducing its growth rate (Fig. 37.1).¹ Persistent nutrient and oxygen deprivation may lead to further adaptations, including reduction in fetal movements and redistribution of fetal blood flow. Changes to fetal and placental blood flow may occur which can be detected using Doppler ultrasound of the umbilical artery, middle cerebral artery and ductus venosus. Changes to the fetal heart rate trace are a late sign of fetal compromise and are regarded as a pre-terminal event. Therefore, signs of fetal compromise and tests to detect it may detect problems at different stages of its development. Consequently, each strategy to evaluate fetal wellbeing has the potential for false-positive and false-negative results depending on the timing of that investigation and the cause of fetal compromise.

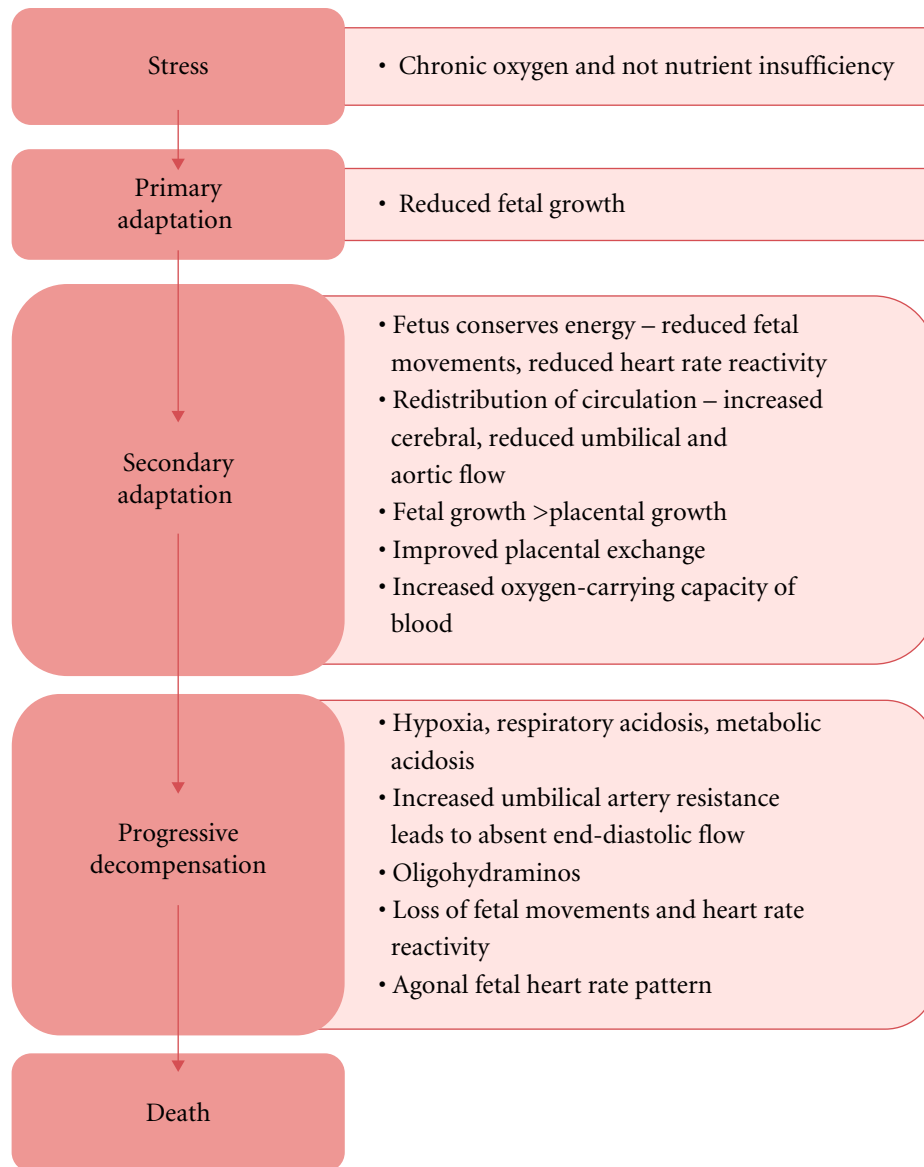

Fig. 37.1 The proposed fetal response to stress that results in adaptations to fetal growth, altered fetal movements, altered fetal blood flow and ultimately changes to the fetal heart rate. (Reproduced with permission from Warrander *et al. Medical Hypotheses* 2011;76(1):17-20)

TESTS OF FETAL WELLBEING

Tests of fetal wellbeing can be grouped by method into biochemical tests of placental function, evaluation of fetal activity/fetal movements, ultrasound-based techniques including Doppler ultrasound and evaluation of fetal heart rate traces.

Biochemical tests of placental function

Since fetal wellbeing is to a large extent dependent on placental function, one way of evaluating fetal wellbeing is to assess placental function. Prior to the advent of ultrasound in obstetrics various biochemical tests were employed to assess placental and fetal wellbeing including measurement

of E_3 , hPL and hCG in maternal plasma, serum and urine.² The utility of these markers was not robustly assessed prior to a switch to ultrasound evaluation of fetal wellbeing from the mid-1970s onwards. A systematic review found only one study of 622 women with high-risk pregnancies comparing women who had E_3 measured with those who did not [A].³ This showed no difference in perinatal mortality or rates of planned delivery between the groups. Recently, interest in biochemical markers of placental function has increased again. One small study found that in pregnancies before 35 weeks' gestation measurement of PIGF was able to differentiate placental fetal growth restriction from constitutionally small fetuses with 86 per cent specificity and 100 per cent sensitivity [C].⁴ Another report of 625 women with suspected pre-eclampsia found that a measurement of

PIGF <5th centile is more accurate than currently used tests to diagnose pre-eclampsia with a sensitivity of 98 per cent [B].⁵

Fetal movement counting

Maternal perception of fetal movement (FM) is defined as a swish, roll or kick and is usually perceived after 20 weeks' gestation, increasing to a maximum around 32 weeks which plateaus until term.^{6,7} There should be no reduction in FM until the onset of labour. There have been several attempts to numerically define normal FM and reduced FM (RFM) but few studies have been devised and validated in women with low-risk pregnancies.⁸ No numerical definition (e.g. <10 movements in 12 hours) has been shown to be superior to maternal perception of RFM.⁸ Thus, the current definition is based on the subjective maternal perception of RFM. Presentation with RFM is common (approximately 5 per cent of pregnancies) and RFM occurs before stillbirth in 55% of cases.⁹ Importantly, women who present with RFM and who have a live baby at presentation are at a 2 to 3-fold increased risk of stillbirth.¹⁰ RFM is associated with altered placental structure and function which adds biological plausibility to the link between RFM and stillbirth [C].¹¹

Structured fetal movement counting (FMC), when mothers are asked to count baby's movements, does not reduce perinatal mortality [A],¹² although this may reflect an incorrect alarm limit (e.g. 10 movements in 12 hours) or a lack of intervention. This meta-analysis was dominated by one large RCT of 68,000 women which showed no reduction in perinatal mortality in women assigned to count fetal movements.¹³ Importantly, the perinatal mortality rate in all women in this study was very low, suggesting that awareness of FM and the need to present with RFM may be more important. A large case-control study in Norway found a significant reduction in perinatal mortality following the introduction of information to increase maternal awareness of FM and RFM, combined with standardised management including an ultrasound scan to detect SGA fetuses [B].¹⁴ This approach is currently being tested in a stepped-wedge cluster trial in the UK (AFFIRM study; NCT01777022).

A systematic review found no trials specifically addressing the management of RFM.¹⁵ Current management of women presenting with RFM after 28 weeks' gestation is to perform a CTG to exclude fetal compromise and consider performing an ultrasound scan for fetal biometry, liquor volume and umbilical artery Doppler if risk factors for fetal growth restriction are present. Current guidance recommends that these tests be performed in all women who present with RFM on two or more occasions as they have an increased risk of fetal growth restriction and stillbirth [B].¹⁶ If these investigations are abnormal then appropriate intervention should be initiated. If the investigations are normal then women should be reassured but encouraged to present if they have further concerns regarding RFM.¹⁶

Ultrasound assessment of fetal biometry and Doppler ultrasound

This is covered in more depth in the chapter on fetal growth restriction (Chapter 38). For the purposes of this chapter the role of these techniques in identifying fetal compromise will be considered. Ultrasound scanning has been used to measure fetal size for many years. In late pregnancy this usually involves measuring the biparietal diameter (BPD), head circumference (HC), abdominal circumference (AC) and femur length (FL) using a standardised approach. The AC or a combination of these measurements can be used to give an estimated fetal weight (EFW) using a variety of formulae.¹⁷ The individual parameters or combined EFW can be plotted against normal ranges; ideally these should be customised for maternal physical characteristics (height, weight, ethnicity, parity).¹⁸ A systematic review and meta-analysis of 8 trials involving 27,024 participants found that routinely performing ultrasound fetal biometry in the third trimester does not reduce perinatal mortality [A].¹⁹ However, the studies included in the review were largely completed before 2000, and did not all combine intervention following the ultrasound scan and are also underpowered to show a difference in perinatal mortality in a low-risk population.

Blood flow through various fetal and maternal vessels can be evaluated by application of Doppler ultrasound. Doppler assessment of blood flow through the umbilical cord is thought to reflect downstream placental resistance to flow. The clinical utility of umbilical artery Doppler depends on the population to which it is applied; in high-risk pregnancies measurement of umbilical artery Doppler is associated with a significant reduction in perinatal mortality [A].²⁰ In contrast, its measurement in low-risk pregnancies has no beneficial effect on outcome [A].²¹ Measurement of flow in other vessels such as the middle cerebral artery and ductus venosus has been assessed in smaller trials. The results of the TRUFFLE study, which compared standard monitoring based on umbilical artery Doppler alone, computerised CTG and ductus venosus Doppler, are awaited.²²

Ultrasound biophysical profile

The ultrasound biophysical profile (BPP) describes an ultrasound-based assessment of fetal wellbeing over a 30-minute period which involves observation of fetal breathing movements, limb/body movements, fetal tone and posture, estimation of amniotic fluid volume and fetal heart reactivity determined by CTG (Table 37.1) [C].²³ Each component is scored as normal (2) or abnormal (0) with scores under 8 regarded as abnormal. A retrospective analysis of 86,955 BPP recordings demonstrated a very high negative predictive value of 99.9 per cent, but a lower positive predictive value of 35 per cent [C]. Systematic review and meta-analysis of 5 trials including 2,974 participants showed no significant reduction in perinatal mortality following the use

of BPP in women with high-risk pregnancies comparing BPP vs conventional monitoring [A].²⁴

Ultrasound grading of placenta

Grannum *et al.* described a subjective assessment of placental echo-texture in an attempt to sonographically identify placental dysfunction.²⁵ Due to its subjective nature this approach is complicated by high intra- and inter-observer variability and a lack of understanding about what placental echogenicity actually measures [C].^{26,27} Nevertheless, one clinical trial of 2,000 women showed a reduction in perinatal mortality [B].²⁸ More recent studies have reported that a 'jelly-like' placenta and focal echogenic cystic lesions (ECLs) are related to intervillous thrombosis and fibrin deposition [C].^{29,30} Although the presence of ECLs is associated with a poor prognosis in fetuses with severe growth restriction, there have been no studies to determine whether this approach reduces perinatal mortality or morbidity.³¹

CTG and computerised CTG

CTG is used to assess the fetal heart rate (FHR) before and during labour. Before labour this is sometimes referred to as a non-stress test (NST) in contrast to a stress test when Syntocinon or nipple stimulation is used to induce contractions and their effect on the FHR is observed. The NST-CTG pattern can be analysed manually or automatically by a computer algorithm. Manual assessment involves assessment of the baseline rate, variability, accelerations and decelerations to form an overall impression (Fig. 37.2A). The baseline describes the average FHR and baseline variability describes the fluctuations in baseline FHR or the 'bandwidth' of the trace. The baseline variability reflects the balance between the sympathetic and parasympathetic nervous systems and is reduced in fetal compromise. Accelerations are transient increases of FHR >15 beats/min for >15 seconds and are thought to

be associated with fetal activity and indicate fetal wellbeing. Whilst the absence of accelerations in labour is of uncertain significance, absence of accelerations for a period >40 minutes would be abnormal. Decelerations describe a decrease of the FHR of >15 beats/min from the baseline FHR for >15 seconds. The presence of decelerations in an antepartum CTG is abnormal. An example of a normal and abnormal antepartum NST-CTG is shown in Figs 37.2B and 37.2C. Despite a relationship between the features of an NST-CTG and fetal compromise the efficiency of NST to predict perinatal morbidity and mortality is <40 per cent.³² Therefore, it is unsurprising that a systematic review and meta-analysis of 6 studies of 2,105 women showed no reduction in perinatal mortality. There was no increase in obstetric intervention [A].³³

It is well recognised that there is a large intra- and inter-observer variation in manual interpretation of NST-CTG. Computerised algorithms have been developed to increase the objective nature of NST-CTG assessment and detect subtle changes missed by clinicians. The most widely accepted are the Dawes Redman criteria developed in Oxford, UK (Box 37.1).³⁴ This approach emphasises the importance of variability, particularly short-term variability (STV) of 3.75-second epochs. The STV is a better predictor of fetal compromise than accelerations or decelerations [C].³⁵ A systematic review and meta-analysis of two studies of 469 women demonstrated that computerised assessment vs traditional assessment of NST-CTG found a significant reduction in perinatal mortality to 0.9 per cent compared with 4.2 per cent, although this was not statistically significant for preventable deaths [A].³³

The NST-CTG may be augmented by vibro-acoustic stimulation (VAS), when a probe is held over the maternal abdomen and a sound is transmitted to the fetus via the maternal abdomen. This is thought to be safe for the baby but may precipitate increased fetal movements. Systematic review and meta-analysis of 12 trials including 6,822 women showed that VAS reduced the incidence of non-reactive antenatal CTG tests by 38 per cent compared with no stimulation [A]. In addition, VAS increased fetal movements.³⁶

Table 37.1 Individual components of the biophysical profile score²³

Component	Definition of normal (score 2)
Fetal breathing movements	More than one episode of >30 seconds duration within a 30-minute time frame
Limb/body movements	Four or more discrete body movements (including fine motor movements)
Fetal tone and posture	Active extension and return to flexion, opening and closing of mouth and hands
Amniotic fluid volume estimation	Maximum pool depth >3 cm
FHR reactivity	Normal NST-CTG over 20 minutes

A

	Reassuring	Non-reassuring	Abnormal
Baseline	110–160	100–109 161–180	<100 >180 Sinusoidal pattern >10 min
Variability	≥5 beats/min	<5 for 40–90 min	<5 for 90+ min
Accelerations	Present	The absence of accelerations in an antenatal CTG is non-reassuring	
Decelerations	None	Typical variable decelerations Single prolonged deceleration for up to 3 min	Atypical variable decelerations of late decelerations for 30+min Single prolonged deceleration for >3 min

B

C

Fig. 37.2 (A) Protocol for assessing antepartum non-stress test cardiotocograph (NST-CTG). (B) Normal antenatal NST-CTG showing a normal baseline, variability and presence of two accelerations during the duration of the recording. (C) Abnormal antepartum NST-CTG showing reduced variability and no accelerations; this infant was born by emergency caesarean section with evidence of severe acidosis.

Box 37.1 Dawes Redman criteria for a normal computerised CTG recording³⁴

Baseline heart rate between 116–160 beats/min. Slightly lower or higher may be acceptable after 30 minutes if all other parameters are normal.

No evidence of sinusoidal fetal heart rhythm.

Long-term variation (mean range of variation around baseline for 1 minute >1st centile for gestation).

Short-term variation should be ≥ 3 ms.

More than one FM or three accelerations.

No large decelerations ≥ 20 beats.

No errors or decelerations at the end of the recording.

SUMMARY

Evidence regarding the tests to confirm fetal wellbeing or suspect fetal compromise is of variable quality. There is reliable evidence for the use of umbilical artery Doppler in high-risk pregnancies and computerised NST-CTG. Likewise, evidence suggests that routine measurement of fetal size by ultrasound scan and umbilical artery Doppler in low-risk pregnancies is not associated with a reduction in perinatal mortality, although there are issues with underpowered analyses. The value of other methods to assess fetal wellbeing has not been assessed by rigorous trials.

KEY POINTS

- Manual interpretation of NST-CTG does not improve pregnancy outcome.
- Computerised CTG assessment is more effective than conventional NST-CTG interpretation.
- Biochemical assessment of placental function does not improve pregnancy outcome.
- Maternal awareness of FM is associated with fetal wellbeing.
- After maternal perception of RFM, fetal wellbeing should be assessed by NST-CTG and consideration given to ultrasound assessment of fetal growth.
- Current evidence does not support the routine use of ultrasound measurement of fetal growth after 24 weeks' gestation.
- Umbilical artery Doppler reduces perinatal mortality in high-risk pregnancies but not in low-risk populations.
- Ultrasound BPP does not improve pregnancy outcome compared with NST-CTG and may increase obstetric intervention.
- Placental echogenicity assessed by ultrasound is complicated by wide variation in measurements, but one trial found a reduction in perinatal mortality.

Chapter 38 Small for gestational age and intrauterine growth restriction

Jennifer A Tamblyn and R Katie Morris

RCOG curriculum

- To understand and demonstrate appropriate knowledge regarding fetal growth restriction epidemiology, aetiology and pathogenesis, diagnosis, prevention, monitoring, management, delivery and complications.
- To be clinically competent in the antenatal management of fetal growth restriction.

INTRODUCTION

Intrauterine growth restriction (IUGR) is a major cause of perinatal mortality and morbidity¹ [B]. Antenatal awareness that the fetus is not growing well is an essential quality indicator of maternity care.

The definition of small for gestational age (SGA) for a fetus *in utero* is an estimated fetal weight (EFW) that measures <10th percentile on ultrasound (US). This diagnosis does not necessarily imply pathological growth abnormalities, and may simply describe a fetus at the lower end of the normal range. Fetal AC or EFW <10th centile can be used to diagnose an SGA fetus, and severe SGA is classified as an EFW or AC <3rd centile.

IUGR is not synonymous with SGA. It denotes a pathological process in which a fetus does not attain its biologically determined growth potential. It is necessary to differentiate growth restriction from SGA, since this modified intrauterine growth pattern can cause significant fetal compromise in addition to the complications associated with SGA. Serial US growth measurements identify IUGR, which is defined by a reduction in AC and/or EFW growth velocity when measured at least 3 weeks apart.² Since an objective definition of reduced growth velocity remains undefined at present, visual assessment of AC and EFW growth trajectory remains standard clinical practice. As outlined below, abnormal placental artery Doppler studies also reflect the presence of placental vascular pathological mechanisms, and importantly identify

those pregnancies at increased risk of perinatal mortality. Identification of SGA remains important since the likelihood of IUGR is significantly higher in severe cases.

PHYSIOLOGY OF FETAL GROWTH

The regulation of fetal growth is complex and is based upon maternal, placental and fetal interactions. The primary determinants are nutrient and oxygen placental transfer, which are dependent upon the interaction of genetic determinants, endocrine signalling and substrate supply. Approximately 40 per cent of fetal growth is determined by genetic factors that influence production of growth factors, e.g. insulin growth factor 1 (IGF-1) and IGF-2, transplacental substrate transport and the rate of tissue formation.³ The remaining 60 per cent is determined by the fetal *in-utero* environment, which in turn primarily reflects maternal physiology and placental function.

In normal fetal development, exponential growth reaches maximum velocity during the third trimester. At this time there is a significant increase in total fetal body fat mass.⁴ To facilitate increased nutrient transport and fetal growth, functional maturation of the placenta progressively occurs across gestation.⁴

Placental nutrient transport is reliant upon placental surface area, protein transporter concentration and transporter binding affinity for essential nutrients such as glucose, amino acids and fatty acids.⁵ Placental oxygen diffusion is determined by fetal–placental surface area, and placental fetomaternal blood flow. Maternal cardiac output, which increases by 30–40 per cent during normal pregnancy, increases uterine perfusion from 50 ml/min in week 10 to 1300 ml/min at term. This large increase in uterine perfusion exceeds the minimal requirements for fetal oxygenation, and serves to protect against acute variations in perfusion.⁵

Regarding the fetal circulation, one-third of total cardiac output is directed to the placenta during mid-gestation and one-fifth at term.⁶ Towards the end of pregnancy there is also an increase in recirculation of umbilical blood in the fetal body. Fetal circulatory adaptations exist to ensure preferential distribution of blood flow, first to the liver (70–80 per cent),

followed by the heart where there is streaming of nutrient-rich blood within the right atrium to supply the myocardium and brain. Finally, the ductus venosus (DV) shunts oxygenated umbilical blood directly to the heart, bypassing the liver, to maintain adequate blood flow to the cerebral, cardiovascular and adrenal systems for fetal growth and function.⁵

A major, final, non-genetic factor determining fetal size in all pregnancies is 'maternal constraint'. This refers to a set of poorly defined physiological processes by which maternal and uteroplacental factors act to limit the growth of the fetus and influence its predetermined growth trajectory.³

Clearly the regulation of fetal growth is complex and as outlined is dependent upon maternal, placental and fetal interactions. Abnormalities may involve any of these compartments, resulting in a complex multisystem disorder as outlined below.

AETIOLOGY OF SGA

The aetiologies of IUGR are diverse, involving multiple complex mechanisms. Approximately one third is determined by genetic factors, while two thirds are environmental.

The most common cause of IUGR (80–90 per cent) is placental insufficiency. Abnormal invasion of fetal trophoblast cells for implantation and vascular remodelling is hypothesised causative and is associated with smaller placentae and reduced nutrient exchange.⁴ There is also abnormal uterine and umbilical artery (UA) perfusion on both sides of the placenta, and disproportional or reduced placental perfusion subsequently results in both inefficient oxygen and nutrient maternofetal exchange. Unlike acute hypoxia, in chronic deficiency the FHR is maintained until late fetal decompensation ensues. This reflects preferential redistribution of blood flow to the cerebral, cardiovascular and adrenal systems which serves to preserve fetal growth and function within the adverse setting.⁶

In general, most placental causes of IUGR involve maternal vascular compromise resulting in placental ischaemia, such as pre-eclampsia.⁷ Growth restriction is normally asymmetrical in this setting, characterised at birth by reduced AC, length and weight, with preserved fetal HC.⁸ A prior history of placenta-mediated disease is also a risk factor for a subsequent SGA neonate. This includes pre-eclampsia and prior stillbirth;⁷ in particular those with a history of previous, preterm, unexplained stillbirth, due to its association with SGA.⁹ Regardless of cause, women who have previously had an SGA neonate have a 3.9 (2.14–7.12)-fold increased risk of a subsequent SGA (birthweight [BW] <10th centile).⁷ This risk is increased further following two SGA births, or if another risk factor for SGA, such as maternal hypertension, coexists.¹⁰ Placental abruption and unexplained antepartum haemorrhage are also risk factors for restricted fetal growth.^{11,12}

There are numerous underlying aetiologies of IUGR which are not caused primarily by placental insufficiency, but indirectly lead to it. This includes other maternal medical

conditions that lead to reduced uteroplacental blood flow, reduced maternal blood volume and/or oxygen-carrying capacity, or decreased nutrition to the fetus; namely diabetes with vascular disease,¹³ renal disease¹⁴ and APLS.¹⁵ SLE¹⁶ and certain cardiac conditions, in particular cyanotic congenital heart disease,¹⁷ present an increased risk.

There are certain non-modifiable maternal factors associated with IUGR which are not disease related. These include ethnicity (Indian/Asian),¹⁸ nulliparity,¹⁹ maternal SGA²⁰ and maternal age ≥ 35 years (higher for women ≥ 40 years),²¹ a low maternal pre-pregnancy weight,²² and a short (<6 months) or long (>60 months) inter-pregnancy interval,²³ and are thus also implicated in IUGR.

Considering other non-placental causes of IUGR, restriction is often symmetrical at birth and is frequently caused by an early fetal insult. Several maternal exposures have a seemingly causative relationship with an SGA infant, including moderate alcohol intake,²⁴ drug abuse (cocaine, a potent vasoconstrictor, being the most significant),²⁵ cigarette smoking²⁶ and caffeine consumption ≥ 300 mg/day in the third trimester.²⁷

Genetic diseases of the fetus constitute 5–20 per cent of causes of IUGR,²⁸ with a higher incidence in more severe cases. The commonest chromosomal defects are triploidy (total 69 chromosomes) and trisomy 18, both of which are often severe and present as early as the first trimester. Trisomies 13 and 21 are also causative and are similarly associated with early onset growth restriction. Trisomy 16, which is usually lethal in the non-mosaic state, can cause growth restriction when occurring as confined placental mosaicism. Up to 16 per cent of cases of IUGR have been associated with confined placental mosaicism. Partial deletions of chromosomes such as 4q (Wolf–Hirschhorn syndrome), and 5q (cri-du-chat syndrome), as well as complete deletion of a sex chromosome in Turner's syndrome (45X), have been linked. Finally, a number of single gene disorders and uniparental disomy chromosomal aberrations are also associated with IUGR.²⁸

In the absence of identifiable congenital defects, inborn errors of metabolism and structural malformations, in particular congenital heart disease, diaphragmatic hernia, abdominal wall defects, and anencephaly have also been identified as associated with IUGR.²⁸

Fetal infections implicated in SGA include rubella, CMV, HIV, toxoplasmosis, malaria and VZV.²⁸ The most common pathogens reported are CMV and toxoplasmosis, which should be tested for most frequently. Rubella is less of a threat due to vaccination. Syphilis is still encountered in pregnancy both in developed and developing countries, and testing should be offered in those considered at risk.²⁹ Malaria is the predominant infectious cause in endemic regions such as Africa and south-east Asia. Women considered at risk should again be advised to have testing.²⁸

In multiple pregnancies IUGR is also more common, in particular MC gestations. Twin gestations physiologically decrease their growth rate after about 28 weeks of gestation. Discordant growth of multiples is usually defined as a

20 per cent reduction in EFW of the smaller compared with the larger fetus.²⁸ If less than 30 weeks, this may represent TTTS; it may also be a marker of structural or genetic anomalies, infection or placental insufficiency as for singleton births. Importantly, the risk of mortality or neonatal morbidity is higher among neonates in SGA-discordant twins than in appropriate-for-gestational-age (AGA)-discordant twins (20 per cent versus 6 per cent).³⁰

At present there is insufficient evidence to determine how these risk factors relate to each other, and consequently how they should be managed. The most recent RCOG guidance does aid clinicians by stratifying each risk factor for SGA into 'minor' and 'major' categories based upon the most current evidence.² As discussed below, the investigation and management of SGA and IUGR are also guided by this classification.

DIAGNOSIS OF SGA

SGA is diagnosed ultrasonographically and is defined as a fetal AC or EFW <10th centile. Severe SGA is classified as an EFW or AC <3rd centile. Antenatal detection of SGA is important since there is an increased risk of perinatal mortality and morbidity. However, US assessment of growth velocity is superior to single estimates of final AC or EFW in the prediction of suboptimal perinatal outcomes.³¹ It is therefore important to differentiate SGA from IUGR, given the higher prevalence of adverse outcomes. To accurately assess a change in fetal size (AC or EFW), two measurements of AC or EFW at least 3 weeks apart are required.³² In current clinical practice this is subjectively assessed by visual interpretation of the customised growth chart. Whether a more objective, standardised measure of FGR should be used is contentious. More frequent measurements of fetal size are appropriate only where BW prediction is relevant outside the context of diagnosing SGA/IUGR.

A major challenge in obstetrics is the accurate and timely detection of SGA. Despite increased awareness, a significant proportion of cases are still undetected antenatally. The reported accuracy of the symphysio-fundal height (SFH) measurement alone to detect SGA is highly variable (average sensitivity 65 per cent, 50 per cent false-positive rate)[B].³³ Furthermore, in a low-risk population, the sensitivity for SGA has been found to be as low as 21 per cent [C].³⁴

Effective screening for IUGR is therefore essential and begins by accurate pregnancy dating. In all cases of suspected SGA the mother's menstrual history, relevant assisted reproductive technology information, and either a first-trimester or an early second-trimester dating US should be reviewed carefully. Crown-rump length (CRL) may be used to date a pregnancy up to 13 weeks. CRL should not be used later than this due to increased fetal flexion. As an alternative, biparietal diameter and/or HC is used; some units include femur length measurement.³⁵ Recalculating dates in a first-trimester small baby should not be routinely performed,

as this may represent early onset growth restriction. Smith *et al.*, who investigated the association between low BW and fetal size in the first trimester (4229 pregnancies), found that when the CRL was 2–6 days smaller than expected there was a significantly increased risk (compared with normal or larger expected CRL) of BW <2500 g at term (RR 2.3; 95% CI 1.4–3.8), and BW <5th centile for gestational age (GA) (RR 3.0; 95% CI 2.0–4.4). The data suggest that suboptimal first-trimester growth may be associated with SGA.³⁶ In cases for which the last menstrual period is unknown and there are no US data prior to 13 weeks, US may calculate GA to within 7–10 days up until 20 weeks. However a high index of suspicion for SGA should be maintained, and beyond this limit US should not be used to adjust the estimated due date.

At each antenatal visit, women receive an SFH measurement. This should ideally be plotted on a customised centile chart since this improves accurate SGA detection.^{37,38} Taking account of maternal characteristics (height, weight, parity and ethnic group), as well as GA at delivery and infant sex, improves identification of neonatal SGA babies at high risk of morbidity and mortality compared with the prior population centiles.³⁷ Pathological factors such as smoking and hypertension are excluded to predict the optimum weight a baby can achieve at term.³⁸ The use of customised growth charts also improves the predictive accuracy of adverse prenatal outcome in the setting of SGA: specifically threatened preterm labour, antepartum haemorrhage, PIH, pre-eclampsia, stillbirth and early neonatal death [C].²² Importantly, individual growth velocities of low-risk fetuses with a normal outcome are less likely to cross beneath the 10th centile when using customised reference standards (reduced false-positive rate).³⁹

A single SFH that plots below the 10th centile or serial measurements that demonstrate slow or static growth (i.e. they cross centiles in a downward direction) should prompt immediate referral for sonographic assessment. For low-risk pregnancies in the UK, SFH currently represents the primary mode of surveillance, even though it is not highly predictive of SGA: sensitivity 27 per cent and specificity 88 per cent.⁴⁰ Since the standard measurement of fetal AC or EFW in the third trimester of low-risk pregnancies is not found to significantly reduce the incidence of neonatal SGA, or improve perinatal outcome, routine fetal biometry is not currently justified.⁴¹ Only in women for whom SFH measurement is likely to be inherently inaccurate (BMI >35, large fibroids, polyhydramnios, multiple pregnancy) is serial biometry routinely performed.³³

In view of the above, a comprehensive antenatal booking assessment to identify women at risk of developing SGA is vital to ensure identification of those women requiring sonographic surveillance. All women with one major risk factor for SGA (Table 38.1) are advised to receive serial US assessment of fetal size at 26–28 weeks.² They should also receive an assessment of wellbeing with UA Doppler from this point since in high-risk populations this is found to reduce overall perinatal morbidity and mortality[A].^{42,43} An abnormal result reflects the presence of placental vascular pathological

Table 38.1 Summary of risk factors for an SGA neonate

A. Available From History at Booking		
Risk Category	Risk	Minor or Moderate
<i>Maternal risk factors</i>		
<i>Age</i>	Maternal age ≥ 35 years	Minor
	Maternal age >40 years	Moderate
<i>Parity</i>	Nulliparity	Minor
<i>BMI</i>	BMI <20	Minor
	BMI 25-29.9	Minor
	BMI ≥ 30	Minor
<i>Maternal substance exposure</i>	Smoker	Minor
	Smoker 1-10 cigarettes per day	Minor
	Smoker ≥ 11 cigarettes per day	Moderate
	Cocaine	Moderate
<i>IVF</i>	IVF singleton pregnancy	Minor
<i>Exercise</i>	Daily vigorous exercise	Moderate
<i>Diet</i>	Low fruit intake pre-pregnancy	Minor
<i>Previous pregnancy history</i>		
<i>Previous SGA</i>	Previous SGA baby	Moderate
<i>Previous Stillbirth</i>	Previous stillbirth	Moderate
<i>Previous pre-eclampsia</i>	Pre-eclampsia	Minor
<i>Pregnancy Interval</i>	Pregnancy interval <6 months	Minor
	Pregnancy interval ≥ 60 months	Minor
<i>Maternal medical history</i>		
<i>SGA</i>	Maternal SGA	Moderate
<i>Hypertension</i>	Chronic hypertension	Moderate
<i>Diabetes</i>	Diabetes and vascular disease	Moderate
<i>Renal disease</i>	Renal impairment ¹⁵	Moderate
<i>APLS</i>	Antiphospholipid syndrome	Moderate
<i>Paternal medical history</i>		
<i>SGA</i>	Paternal SGA	Moderate
B. Current Pregnancy Complications		
<i>Threatened miscarriage</i>	Heavy bleeding similar to menses	Moderate
<i>Fetal anomaly</i>	Echogenic bowel	Moderate
<i>Pre-eclampsia</i>	Pre-eclampsia	Moderate
<i>Pregnancy induced hypertension</i>	Mild	Minor
	Severe	Moderate
<i>Placental abruption</i>	Placental abruption	Minor
<i>Unexplained APH</i>	Unexplained APH	Moderate
<i>Weight gain</i>	Low maternal weight gain	Moderate
<i>Exposure</i>	Caffeine ≥ 300 mg/dy in third trimester ⁴⁰	Moderate
<i>Down's syndrome marker</i>	PAPP-A <0.4 MoM	Moderate
BMI body mass index; IVF in-vitro fertilisation; SGA small for gestational age; APLS antiphospholipid APH ante-partum haemorrhage; PAPP-A pregnancy associated plasma protein A		

mechanisms and identifies pregnancies at increased risk for perinatal mortality, without increasing the rate of inappropriate obstetric intervention. Again reviews of the clinical utility of UA Doppler strongly suggest that this should not be used as a routine screening modality for women at 'low risk' of SGA.⁴⁴

Women who have multiple minor risk factors for SGA are currently referred for a UA Doppler assessment at 20–24 weeks of gestation.² If abnormal (mean pulsatility index [PI] >95th centile [bilaterally] and/or 'notching'), serial US measurements and UA Doppler from 26–28 weeks of pregnancy are advised since persistence after 24 weeks has a moderate predictive value for a severely SGA neonate [A].⁴⁵ In the third trimester, UA Doppler has limited predictive accuracy for adverse outcomes in SGA and is therefore not routinely used. It is also not performed in women with a major risk factor for SGA since the negative likelihood ratio (predictive strength of a normal result) is not sufficient to negate the risk of SGA [A].⁴²

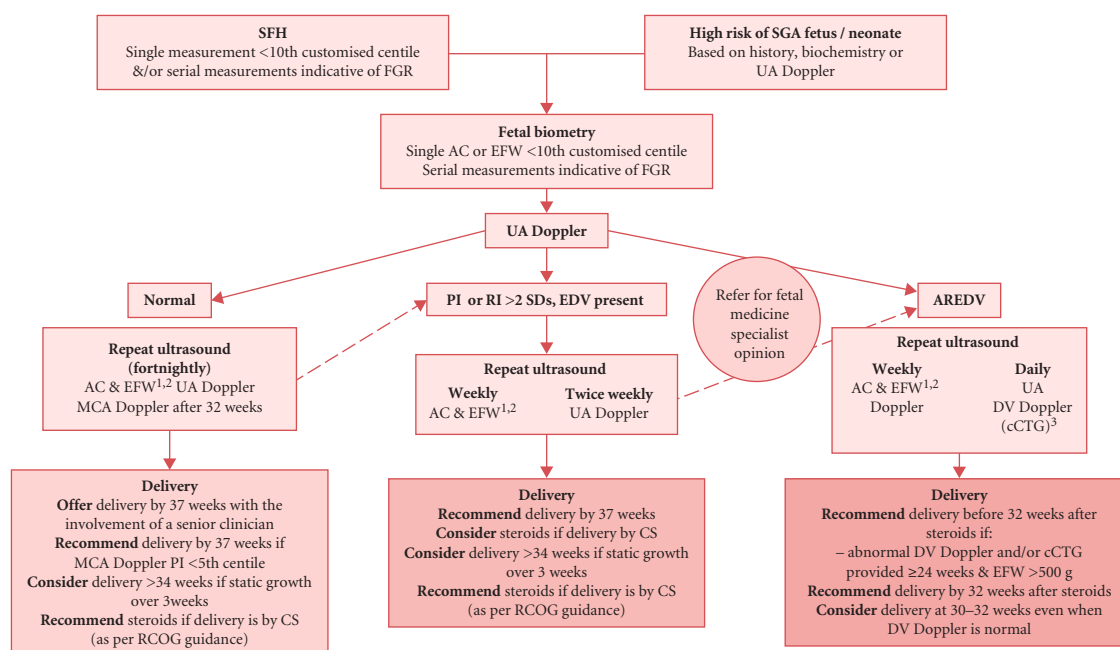

Serial US measurement of fetal size and assessment of well-being with UA Doppler is also routinely advised following detection of an echogenic fetal bowel or when first-trimester levels of PAPP-A are low (<0.415 MoM). The reasons for this are beyond the scope of this chapter; however, both are independently associated with neonatal SGA and fetal mortality [C].^{46,47}

In the first-trimester UA Doppler studies are not currently recommended since low end-diastolic velocities and an early

diastolic notch are considered normal.² However, recent evidence from a large systematic review (55,974 women) suggests that there may be value clinically in the setting of IUGR. The sensitivity and specificity of abnormal flow velocity waveforms (resistance index [RI] or PI ≥90th centile and 'notching') for early-onset fetal growth restriction were 39.2 per cent (95% CI 26.3–53.8) and 93.1 per cent (95% CI 90.6–95.0) respectively. These findings suggest that, in high-risk women, UA Doppler studies performed at initial dating may aid detection of early onset IUGR [A].⁴⁸

INVESTIGATION AND SURVEILLANCE OF THE SGA FETUS

Following antenatal diagnosis of SGA, investigations are required to identify a potential underlying cause. Comprehensive reassessment for any potential SGA risk factors (Table 38.1) that may have been overlooked at booking, and/or developed during the antenatal period, is particularly important following detection. Any changes in personal or socio-economic circumstances may be contributory and should also be explored. Comprehensive re-evaluation of fetal anatomy and uterine/UA Doppler studies is essential for identifying a potential underlying cause and for the assessment of fetal wellbeing. Determining whether SGA is symmetrical or asymmetrical is of less importance clinically

¹ Weekly measurement of fetal size is valuable in predicting birthweight and determining size for gestational age

² If two AC/EFW measurements are used to estimate growth, they should be at least 3 weeks apart

³ Use cCTG when DV Doppler is unavailable or results are inconsistent – recommend delivery if STV <3 ms.

AREDV, absent/reversed end-diastolic velocity; cCTG, computerised cardiotography; EDV, end-diastolic velocity; FGR, fetal growth restriction; MCA, middle cerebral artery; STV, short-term variation; SFH, symphysis-fundal height.

Fig. 38.1 The management of the SGA fetus. (Reproduced with kind permission from RCOG²)

since asymmetrical IUGR may progress to generalised growth restriction in particularly severe cases.

The extent of investigation is in part determined by the GA of onset severity. All women diagnosed with SGA should receive more regular blood pressure and urine surveillance for the presence of pre-eclampsia. If severe SGA is identified at the mid-trimester anomaly scan, a detailed fetal anatomical survey and UA Doppler by a fetal medicine specialist may be required. Karyotyping may also be offered in this setting, particularly for women with structural anomalies, GA <23 weeks, a high Down's syndrome screening risk (>1 in 150), or polyhydramnios. This may be particularly relevant when Doppler studies are normal since a placental pathology is less likely [C].^{49,50}

Considering aberrant liquor volume, albeit strongly associated with SGA and adverse perinatal outcome, the predictive strength of the amniotic fluid index (AFI) in this setting is limited by its poor predictive accuracy (LR 2.77 [1.93, 3.96] and LR 0.58 [0.48, 0.69]), and significant heterogeneity. Thus, oligohydramnios should be used in conjunction with other prognostic factors and should not be used as an independent diagnostic or surveillance tool in the setting of SGA [A].⁵¹

As the IUGR fetus is at increased risk of mortality, as well as hypoxia and metabolic acidosis during labour, meticulous surveillance of fetal growth and wellbeing is essential for the SGA fetus (Fig. 38.1). When Doppler flow indices are normal it may be reasonable to repeat surveillance every 14 days [B].⁵² The relationship between increased placental vascular impedance and the shape of the UA velocity waveform is not entirely linear, however; as the placental abnormality expands the likelihood of adverse fetal outcome increases. At least a 50 per cent reduction of terminal placental vessels is required before the PI becomes abnormal.⁴⁴ An increasing RI is also strongly correlated with adverse fetal outcome.⁵³ When UA Doppler flow indices are abnormal therefore (PI >+2 standard deviations above mean for GA) and delivery is not indicated, surveillance is required twice weekly if end-diastolic velocities remain present [C].^{54,2} Doppler abnormalities such as absent or reversed end-diastolic flow (AREDFV) are significantly associated with suboptimal fetal outcome and daily Doppler indices are required unless delivery is imminent [C]⁵⁴ (summarised in Fig. 38.1).

Further investigation of the fetal circulatory system by Doppler examination of the MCA, DV and umbilical vein (UV) may be considered in certain instances such as AEDFV. This should be a consultant-based decision by a professional with significant fetal medicine expertise.

A decrease in the Doppler indices of the MCA (reduced MCA PI or MCA PI/umbilical artery PI [cerebroplacental ratio]) signifies 'brain sparing' and cerebral vasodilatation. The predictive accuracy of MCA Doppler for SGA is, however, limited and should not be used as a 'high-risk' screening test like UA Doppler [A].⁵⁵ However, in view of its association with adverse fetal outcomes, if MCA Doppler is abnormal, delivery should be delayed no later than 37 weeks of gestation. In the term SGA fetus with normal UA Doppler, an abnormal MCA

Doppler (PI <5th centile) has a moderate predictive value for acidosis at birth and is therefore used to guide timing of delivery.⁵⁶ In the preterm SGA fetus, MCA Doppler has limited accuracy and is not used to time delivery.⁵⁷

DV Doppler also has a moderate predictive value for acidemia and adverse fetal outcome and is considered a late sign of severe IUGR.⁵⁸ Chronic hypoxia causes increased blood flow through the DV (cardiovascular diversion), with a concomitant reduction in hepatic blood flow via the UV. In severe IUGR, decreased or absent DV flow may be observed and has a moderate predictive accuracy for compromise of fetal/neonatal wellbeing overall and perinatal mortality in high-risk pregnancies with placental insufficiency. As such, DV Doppler is used for surveillance in the preterm SGA fetus with abnormal UA Doppler and subsequently used to inform decisions regarding delivery [A].⁵⁸

Controversially, recent findings from the Prospective Observational Trial to Optimise Paediatric Health in IUGR (PORTO) study, which evaluated multi-vessel Doppler in 1116 non-anomalous IUGR fetuses, raise important questions regarding the usefulness of multi-vessel Doppler assessment with regard to fetal surveillance and timing of delivery. Although they confirmed that the classic pattern of progression from abnormal UA to MCA to DV was evident, this occurred no more frequently than the multiple other potential patterns of Doppler deterioration. Importantly UA and MCA Doppler remained the most useful and practical tool for identifying fetuses at risk of adverse perinatal outcome, identifying 88 per cent of all adverse outcomes [C].⁵⁹

MANAGEMENT OF SGA

Significant challenges exist regarding both the prevention and the management of SGA. At present no proven preventive or therapeutic strategies other than delivery truly exist. This in part reflects both the diverse range of maternal, fetal and placental aetiologies, and their poorly understood pathogenic associations with SGA. Furthermore, in many cases the underlying cause remains unknown even in those women for whom pathologically restricted growth is identified.

Timely detection of SGA remains crucial since this will inform both the clinician and the mother that the pregnancy is at increased risk, and also enable more detailed investigation to inform timing for delivery. Introduction of a structured antenatal surveillance programme is also found to significantly reduce the risk of adverse fetal outcomes, such as stillbirth and neonatal mortality secondary to preterm birth, compared with cases of SGA fetuses that failed to be detected antenatally.^{38,54}

The antenatal interventions that may improve perinatal outcomes in SGA prior to delivery are limited. For women at high risk of pre-eclampsia antiplatelet agents (e.g. aspirin) may be effective in preventing SGA birth. Although the effect size is small, a systematic review which included 1317 women

with abnormal UA Doppler has concluded that aspirin if started before 16 weeks of pregnancy reduces the incidence of both pre-eclampsia and neonatal SGA. Aspirin started after 20 weeks is not, however, effective in reducing the risk of an SGA infant and is therefore not of value [A].⁶⁰ NICE recommends that women either at high risk of PET or with more than one moderate risk factor take 75 mg aspirin daily from 12 weeks' gestation until birth.⁶¹

A single course of antenatal corticosteroids is also given to any woman diagnosed with an SGA fetus between 24⁺⁰ and 35⁺⁶ weeks of gestation, if delivery is considered imminent. This serves to promote fetal lung maturation and reduce neonatal death and morbidity. Appropriate timing of delivery is determined by the gestational age and fetal condition, and the presence of fetal lung maturity in a preterm fetus will help facilitate this decision.⁶²

There is also evidence to suggest that magnesium sulphate before birth may be neuroprotective for the fetus and may reduce the incidence of cerebral palsy among preterm infants. A recent Cochrane systematic review (including five eligible trials of women threatening or likely to give birth at less than 37 weeks (6145 babies)) concluded that a significant neuroprotective effect is observed. The number of women who need to be treated to benefit one baby by avoiding cerebral palsy is 63. A significant reduction in the rate of substantial gross motor dysfunction is also achieved [A].⁶³

Interventions to promote smoking cessation may prevent delivery of an SGA infant and improve birthweight. The overall health benefits of smoking cessation certainly support intervention, and all women who are pregnant and smoke should be offered this option [A].⁶⁴

TIMING OF DELIVERY IN SGA

One of the most important aspects of SGA management is an understanding of the decisions relevant to delivery. The main consideration needs to be appropriate timing, as the balance between the risks of iatrogenic morbidity due to prematurity and continued exposure to an unfavourable intrauterine environment requires careful evaluation.

Since delivery outcomes for SGA fetuses with an AREDV in the UA primarily follow caesarean section, the risks associated with induced/spontaneous labour are uncertain. For this reason any SGA fetus diagnosed with AREDV in the UA after 32 weeks is normally delivered by caesarean section before 37 weeks [C].⁶⁵ Delivery may, however, be considered promptly following detection of AREDV if determined safer by a senior obstetrician. For those SGA fetuses at or near term without an AREDV on UA, induction of labour with continuous FHR monitoring may be offered by a senior obstetrician.⁶⁶ However, women should be aware that the risk of pathological decelerations in labour, emergency caesarean section for suspected fetal compromise, and metabolic acidaemia at delivery are higher compared with an appropriate-for-gestational-age (AGA) grown fetus [C].⁶⁵ If the growth velocity is normal the

RCOG recommend that delivery should still be considered by 37 weeks due to the stronger association with adverse perinatal outcome compared with those with AGA [C].^{65,2}

The randomised, multicentre Growth Restriction Intervention Trial (GRIT) compared the effects of early and delayed delivery for such babies. The study included 587 babies and the median time-to-delivery intervals were 0.9 and 4.9 days for the immediate and delayed groups respectively. Mortality prior to discharge was not significantly different (10 per cent immediate group, 9 per cent delay group [OR 1.1, 95% CI 0.61–1.8]). Although in the delay group a higher stillbirth rate was observed, an almost equal number of additional perinatal deaths occurred in the earlier delivery group. As expected this group also had more acutely ill babies at delivery, who required increased mechanical ventilator support, and suffered major complications such as intraventricular haemorrhage and necrotising enterocolitis. Whether these babies would have died *in utero* had intervention been delayed is unknown [B].¹ Given the significant risk of neonatal morbidity and mortality, particularly among those born very preterm, a senior obstetrician should be responsible for ensuring that a comprehensive, individualised surveillance and delivery plan is made in close consultation with both the parents and the neonatal team.

For the preterm SGA fetus with AREDV detected prior to 32 weeks' gestation, delivery is appropriate if the DV Doppler becomes abnormal or umbilical vein pulsations appear, provided that the fetus is viable and received steroids. Even when the DV Doppler is normal, delivery should still be strongly considered before 32 weeks since early delivery in this setting is not shown to significantly increase overall perinatal mortality or long-term neurodevelopmental outcomes [B].^{1,67}

SGA PROGNOSIS

Low BW remains a major cause of morbidity and mortality in early infancy and childhood [B, C].^{1,68} It is important to recognise the clinical significance of SGA and IUGR independently, as most adverse outcomes are concentrated in the growth-restricted group, and the majority of term SGA infants have no appreciable morbidity or mortality [D].⁶⁹ For IUGR, the overall perinatal mortality rate has improved to approximately 8 per cent, with 70 per cent surviving without severe neonatal morbidity [B].⁷⁰

More reliable distinction of IUGR has also enabled the inclusion of growth restriction into the 'Classification of stillbirth by relevant condition at death' (ReCoDe) system. The study included 2625 stillbirths and 451,197 total births, representing an average stillbirth rate of 5.82 per 1000. Using the ReCoDe classification only 398 cases (15.2 per cent) remained unclassified as 'no relevant condition identified', with the largest category of stillbirths 'fetal growth restriction' (43.0 per cent) [C].⁹ The significance of this is clear and renews focus towards antenatal identification of IUGR in the prevention of stillbirth.³⁸

Prematurity is an additional factor that significantly contributes to this risk of morbidity and mortality in IUGR [B].^{1,8} GA is by far the most powerful predictor of survival to term in very preterm babies of 22–31 weeks. However, weight also has a powerful, non-linear effect on survival ($P=0.006$) [C].⁷⁰ The recent prospective multicentre randomised management study of fetal growth restriction (Trial of Randomised Umbilical and Fetal Flow in Europe or TRUFFLE) investigated perinatal morbidity and mortality rates following early onset IUGR. The study group comprised 503 women with a singleton fetus of 26–32 GA, AC <10th centile and UA Doppler PI >95th centile. Overall, 81 per cent of deliveries were indicated by fetal condition and 97 per cent were by caesarean section. Of the 490 liveborn babies with follow-up data, 27 (5.5 per cent) deaths occurred with 118 (24 per cent) suffering severe morbidity [B].⁷¹

The acute neonatal complications of SGA and growth restriction include an increased risk of hypothermia, hypoglycaemia, respiratory distress and birth hypoxia, hypocalcaemia, polycythaemia, intraventricular haemorrhage and necrotising enterocolitis [C].⁶⁸ Cerebral palsy (CP) is also more common in term babies whose BW is low for their GA at delivery. A comparison of 10 European registers for 4503 singleton children with CP was examined. They identified that babies of 32–42 weeks' gestation with a BW for GA <10th percentile were four to six times more likely to have CP than children between the 25th and 75th percentiles. In babies of less than 32 weeks' gestation, the relationship between weight and risk was less clear due to the adverse outcomes associated with early preterm birth [C].⁷²

At-2 year follow-up the GRIT Study reported no overall difference in the rate of death or severe disability between the immediate or deferred delivery group (19% vs 16%). Despite adjustment for GA and UA Doppler category, the OR (95% CI) remained 1.1 (0.7–1.8). Importantly, their results do not support early delivery as a useful measure to prevent terminal hypoxaemia and improve long-term brain development. An extremely fine balance between the risk of *in-utero* death and stillbirth does, however, clearly exist, and decisions regarding timing of delivery should be judged on an individual case basis by an expert obstetrician [B].⁶⁷

Regarding childhood and long-term sequelae, IUGR is thought to elicit a fetal programming process that has long-term implications. The neurodevelopmental deficits are often mild, such as changes in muscle tone, coordination deficits, visual deficits, lower verbal skills and intellectual competence, attention disorders and emotion regulation difficulties. An increased risk for learning disability is also noted [C].⁷³ Neurodevelopmental outcome is mediated primarily by growth catch-up velocity.⁷⁴ Those without catch-up in height and/or head circumference have the worst outcome [C].⁷³

Children born SGA are also shorter during childhood and as adults, with heights on average 1 standard deviation below the population mean. Those born very prematurely and with more severe degrees of growth restriction are less likely

to achieve a stature within the normal range. Endocrine and metabolic disturbances in the SGA child are also recognised, but there is no evidence to recommend routine investigation of all SGA children [C].⁷⁵

The 'developmental origins of adult disease' hypothesis states that adverse influences early *in utero* can result in permanent changes in physiology and metabolism, which result in increased disease risk in adulthood. This hypothesis originally evolved from observations by Barker and Osmund.⁷⁶ The 'Barker hypothesis' which reported that in England those regions with the highest rates of infant mortality also had the highest mortality rates from coronary heart disease. Since low BW was the commonest cause of infant death, they postulated that those babies who survived were at increased risk of coronary heart disease later in life.⁷⁶ Epidemiological studies have since demonstrated this and further relationships between BW and type 2 diabetes, insulin resistance, hypertension and cerebrovascular disease. A modest positive association between BW and subsequent BMI and waist circumference is also reported.⁷⁷ The most widely accepted theory underlying the developmental origins hypothesis is programming, which is the process whereby a stimulus or insult during a sensitive or critical period has irreversible long-term effects on development.⁷⁸ Potential mechanisms include altered fetal nutrition and increased glucocorticoid exposure. Changes in the intrauterine environment, including nutrient availability, may also alter gene expression via alterations in DNA methylation, and thereby increase susceptibility to chronic disease in adulthood. Moreover, such epigenetic changes, if they do occur in the gametes, may be heritable. This 'intergenerational effect' may account for the association between maternal and paternal SGA and subsequent second-generation SGA.^{2,79}

CONCLUSION

The accurate and timely detection of SGA remains a significant challenge in obstetrics. Differentiation of IUGR is particularly important given the increased associated perinatal morbidity and mortality. As a consequence of the diverse range of underlying pathogeneses, current proven strategies to prevent and treat SGA are limited. Timely delivery therefore remains at the forefront of SGA management, with accurate detection and comprehensive fetal surveillance fundamental to reducing perinatal morbidity and mortality. Given the consequences of severe IUGR and preterm birth, and furthermore the implications for future antenatal care, postnatal follow-up is essential.

Chapter 39 Aberrant liquor volume

Jennifer A Tamblin and R Katie Morris

MRCOG curriculum (antenatal care module 8)

- Understand the epidemiology, aetiology, pathogenesis, diagnosis, prevention, management, delivery and complications of aberrant amniotic fluid volume (polyhydramnios, oligohydramnios).
- Trainees should demonstrate that they can competently manage oligohydramnios and polyhydramnios.

INTRODUCTION

Amniotic fluid (AF) is essential for appropriate fetal growth and development. It provides a 'low resistance' environment for the fetus, allowing freedom of movement and hence musculoskeletal development while providing protection from external forces and infection. Any disruption in AF homeostasis will lead to either insufficient (oligohydramnios) or excess (polyhydramnios) AF. A finding of aberrant liquor volume (LV) on US is associated with increased perinatal morbidity and, in the case of oligohydramnios, increased perinatal mortality. In order to systematically investigate and manage pregnancies complicated by aberrant liquor volume, a broad understanding of AF dynamics is required.

AMNIOTIC FLUID HOMEOSTASIS

The total amniotic fluid volume (AFV) is the sum of the inflow and outflow into the amniotic space, reflecting total extracellular fetal fluid balance. Up until approximately 33 weeks AF production increases at a non-linear rate. For each week of gestation, a wide variation in AFV can be seen.¹ From 36 weeks, a reduction in total AFV is observed, with a particularly rapid decline from 41 weeks. Quantitatively, at 22 weeks the median AFV is approximately 600 mL, reaching 800 mL at its peak, before declining to 700 mL by 40 weeks.² Importantly, from approximately 22–39 weeks, the AFV

remains unchanged despite a significant gain in fetal weight. Clearly a fine balance exists to regulate AFV, particularly in late gestation when approximately 1000 mL fluid flows into and out of the amniotic compartment daily.¹ If abnormalities in flow continue over a prolonged period of time then this will result in abnormal LVs.

The mechanism underpinning AF regulation is not fully elucidated, and during early gestation the exact source of production and composition of AF remain unclear. Before 16 weeks, AF has the same osmolality as maternal plasma and it is most likely to be a transudate that passes from the maternal circulation. Since coelomic fluid is similar to maternal plasma and is located within the extra-coelomic space alongside the amniotic sac, this is the probable solute source during early development. Fetal urine is present in the amniotic space from 8–11 weeks but only becomes a major contributor in the latter half of pregnancy, reaching 1000–1200 mL/day at term.³ This fundamental source of AF is demonstrated by the almost complete lack of AF in fetuses with renal agenesis.⁴ Respiratory tract secretions, transfer of fluid across the chorionic plate and umbilical cord, and direct movement of fluid from maternal blood across the wall of the uterus into the amniotic cavity also contribute to AF production.

Maintaining AFV requires removal of AF and the fetal skin provides a major osmotic pathway for AF shifts until it becomes keratinised after 22–25 weeks.⁵ After this time oral and nasal mucosae continue to exchange fluid but this is no longer a major source of AFV regulation.⁵ Other mechanisms of removal include fetal swallowing, removing 200–1500 mL/day,⁶ and intramembranous transport (exchange between AF and fetal blood across the fetal placental surface) responsible for 200–500 mL/day. Transmembranous flow, which is the exchange between AF and maternal blood within the uterine wall, also contributes to this process (10 mL/day).⁶

AFV ASSESSMENT

Clinical assessment of AFV by palpation is unreliable. As such, AFV measurements have become standard in fetal surveillance, especially in the evaluation of high-risk pregnancies.

Due to its three-dimensional (3D) structure, absolute AFV is not routinely measured. Instead two-dimensional (2D) prenatal US is used and surrogate measures are employed to assess AF levels. However, it is recognised that these measures have a poor correlation with actual AFV, as determined by the 'gold-standard' dye-dilution method, due to the influences of fetal position, transducer pressure, maternal hydration status and observer inconsistency. More sophisticated methods include dye-dilution tests, 3D magnetic resonance imaging and 3D US; these are rarely performed outside the research setting due to their invasive nature (dilution techniques), being technically time-consuming by nature and high cost.⁷

Four principle sonographic methods are used to define AF levels with 2D ultrasound: subjective assessment, 2 × 2 measurement, single deepest pocket (SDP) and amniotic fluid index (AFI). SDP represents the deepest pocket measured vertically in the anterior–posterior plane at any location in the amniotic cavity as long as the umbilical cord or fetal parts are excluded. This parameter is also recognised as the 'deepest vertical pocket' (DVP), 'maximum pocket depth' (MPD) or 'maximum vertical pocket' (MVP). AFI is measured after 20 weeks by dividing the amniotic cavity into four quadrants using the maternal linea nigra as the midline. The DVP without fetal parts or cord is ascertained for each quadrant and then the four measurements are summed. For clinical purposes a single set of cut-offs for abnormal AFVs is used throughout pregnancy. To determine the threshold for normal and abnormal LVs, normograms with 5th and 95th percentile cut-offs have been defined for AFI, SDP, 2D pocket and dye-directed techniques across individual gestational ages.

Despite multiple studies and trials, no single sonographic method has emerged as superior in predicting adverse pregnancy outcome.⁸ In fact, it has been suggested that AFI may characterise more women as having oligohydramnios, leading to an increase in obstetric interventions without a concomitant measurable improvement in pregnancy outcome.⁹ Since effectiveness evidence supports the use of MVP, this is recommended until more robust evidence is available [A].⁸ In the case of a twin pregnancy, MVP is the preferred technique since AFI measurements for each individual fetal amniotic sac can be technically difficult and inaccurate, particularly in the case of MC multiple pregnancies [C].¹⁰

POLYHYDRAMNIOS

Any increase in the AFV surrounding the fetus is termed 'hydramnios'. Once a pre-defined sonographic value has been exceeded this is classified as 'polyhydramnios', which effects approximately 1–2 per cent of pregnancies.¹¹ In late second and third trimester for both singleton and multiple pregnancies, an MPD >8 cm, AFI ≥25 cm, or above the 95th centile for gestational age, is diagnostic of polyhydramnios. Further sub-categorisation to mild (MVP 8–12cm, AFI >24 cm and <30 cm), moderate (MVP 12–15cm, AFI ≥30 cm and <35 cm), and severe (MVP >15 cm, AFI ≥35 cm) may be of

value with regard to the investigation and management of polyhydramnios. Initial suspicion of polyhydramnios in low-risk women may be achieved clinically following identification of a discordantly high SFH. Additional symptoms and signs include a distended, uncomfortably tense abdomen, difficult palpation of fetal parts, and excessive FM. Despite its own inherent inaccuracies, 2D US detection of polyhydramnios is, however, more reliable, and as such represents the primary diagnostic modality.

Causes of polyhydramnios

Excess AFV results from either an increase in AF production or abnormal AF regulation and removal. Consequently, a diverse range of maternal and fetal conditions may adversely disturb fluid balance (Table 39.1). One of the most common causes is poorly controlled maternal diabetes mellitus, with the excess fluid most probably developing secondary to osmotic diuresis and fetal polyuria. Rarer causes of fetal polyuria include TTTS and Barter's syndrome.^{3,12}

Table 39.1 Causes of polyhydramnios

Maternal disease	Diabetes mellitus
Fetal	TTTS (increased amniotic fluid in the recipient twin and decreased amniotic fluid in the donor twin)
	Barter's syndrome
Structural	Tracheal atresia
	Duodenal and oesophageal atresia
	Mediastinal/thoracic mass
	Diaphragmatic hernia
Neuromuscular	Anencephaly
	Muscular dystrophy
	Fetal akinesia
Genetic	Chromosomal anomalies (aneuploidy [trisomies 21, 18 and 13])
	Non-immune hydrops
Cardiac failure	Sacroccoccygeal teratoma, vein of Galen aneurysm, fetal anaemia, maternal alloimmunisation, glucose-6-phosphatase deficiency, alpha-thalassaemia, fetomaternal haemorrhage
Infectious	Congenital syphilis
	Viral hepatitis
Idiopathic	

Decreased AF absorption results from either a failure of fetal swallowing and/or intestinal reabsorption, e.g. tracheal atresia, intestinal obstruction (oesophageal or duodenal atresia), extrinsic intestinal compression (diaphragmatic hernia or masses within the thorax and mediastinum) and neurological disorders (anencephaly, muscular dystrophy, fetal akinesia syndrome). In the presence of additional complications such as fetal growth restriction, an underlying chromosomal aberration such as aneuploidy (trisomies 18 and 21) should be considered.^{3,12} Other important causes of increased AFV include non-immune hydrops and cardiac failure, which may occur secondary to underlying reduced fetal vascular resistance (sacrocoxygeal teratoma, vein of Galen aneurysm) or fetal anaemia (maternal alloimmunisation).^{3,12} Parvovirus B19, CMV¹³ [D], congenital syphilis¹⁴ and viral hepatitis infection¹⁵ should be included in the differential diagnoses for polyhydramnios only when there is clinical suspicion or other suggestive sonographic findings such as non-immune hydrops.

As the liquor volume increases so does the likelihood of an underlying congenital anomaly. In severe polyhydramnios (AFI ≥ 35 cm) almost 80 per cent of pregnancies were found to be associated with a prenatally diagnosed structural fetal anomaly.¹¹ This was also the case in a retrospective cohort study of 672 singleton pregnancies with hydramnios ($P < 0.001$), which also found that 11 per cent of neonates had one or more congenital anomalies (US anomaly detection was 79 per cent). In those with a normal US evaluation, the risk of a major anomaly was 1 per cent in mild cases, 2 per cent with moderate and 11 per cent with severe hydramnios ($P < 0.001$). Of those anomalies eluded, cardiac septal defects, cleft palate, imperforate anus, and tracheo-oesophageal fistula were the most common.¹⁶

The timing of sonographic detection of polyhydramnios may also be useful in predicting fetal outcome. In 138 cases with polyhydramnios presenting prior to 26 weeks' gestation (21 severe, 18 moderate and 92 mild do not = 131); congenital abnormalities were noted in 86 per cent of severe, 72 per cent of moderate and 17 per cent of mild polyhydramnios cases. In the cases of mild polyhydramnios with no associated anomalies, in 91 per cent the polyhydramnios resolved but for those with associated anomalies there was resolution in only 13 per cent. For moderate polyhydramnios the corresponding figures were 80 per cent resolved and 0 per cent if associated with other anomalies or maternal conditions. No cases of severe polyhydramnios resolved. Thus second-trimester polyhydramnios that persists is associated with an increased risk of congenital anomaly [D].¹⁷

In a large proportion of cases the cause of polyhydramnios however, remains idiopathic. A prospective case-control study which included 6492 pregnant women diagnosed polyhydramnios in 251 (3.9 per cent) cases: 81.5 per cent mild and 18.5 per cent moderate. Of the 231 pregnancies for which complete follow-up data were available, idiopathic (no evidence of congenital or placental abnormalities, diabetes mellitus or isoimmunisation) polyhydramnios occurred

in 65.4 per cent. Diagnosis of idiopathic polyhydramnios occurred any time between 20 and 40 weeks' gestation (mean 33 weeks). Of these cases, most were mild (AFI > 24 cm); (81.5 per cent) with only 18.5 per cent classified as moderate (AFI ≥ 30 cm)¹⁸ [C].

Investigation of polyhydramnios

The investigation of cases of polyhydramnios should be individualised based on gestational age, polyhydramnios severity, and maternal and past obstetric history. A detailed review of maternal history, with an emphasis upon maternal symptoms and potential risk factors for increased AFV, such as diabetes, should initially be performed. Serological testing to exclude underlying alloimmunisation and a 75-g glucose tolerance test (repeated if completed previously) should be routinely performed. In those cases in which an underlying infectious aetiology is suspected, specific serological testing may be indicated.

Sonographic evaluation of the fetus will in the first instance include fetal number, chorionicity, severity of hydramnios and fetal growth. It would seem appropriate that a case of polyhydramnios diagnosed at < 30 weeks' gestation should be referred to a fetal medicine unit for assessment for structural and chromosomal anomalies. For those diagnosed after 30 weeks consideration should be given to other risk factors for congenital or structural anomaly (e.g. previous obstetric and family history, findings at the detailed US, risk factors for karyotypic anomaly) when deciding whether a fetal medicine referral is necessary [C].¹¹ This, however, remains contentious and certainly more clear guidance regarding the indications for more detailed investigation of polyhydramnios is warranted.

Complications of polyhydramnios

The maternal complications of polyhydramnios relate primarily to excessive uterine distension, and as such are determined by the extent and rate of AF accumulation. In mild cases, minimal maternal symptoms such as general abdominal discomfort and slight dyspnoea may develop. In moderate-to-severe polyhydramnios marked respiratory distress and severe abdominal symptoms may ensue. An increased risk of preterm rupture of membranes and labour is also observed [C].¹⁹ Interestingly the underlying cause (increased in those with an underlying congenital anomaly and maternal diabetes), as opposed to the severity of aberrant AFV, appears significant with regard to the timing of preterm labour onset [C].¹⁹ The incidence of placental abruption and cord prolapse also appears higher when there is sudden uterine decompression following membrane rupture; the exact risk of this, however, remains unknown [C].²⁰ Postnatally, the incidence of maternal haemorrhage secondary to uterine atony is also significantly higher in those women with pregnancies complicated by polyhydramnios.²¹

Operative delivery rates are higher when polyhydramnios exists due to labour dystocia secondary to excessive uterine size and poor contraction quality [C] and an increased risk of unstable lie [C].²⁰ Associations between idiopathic polyhydramnios and perinatal morbidity are poor apart from a strong positive association between polyhydramnios and birthweight >90th centile. The predictive ability of aberrant AFV to predict outcome is generally poor due to its poor sensitivity [A].⁸

A prospective study examining fetal outcomes in 200 pregnancies complicated by aberrant AFV found the perinatal mortality rate (PMR) (42.25 per cent) to be significantly higher compared with both the normal and the low AFV groups ($P < 0.001$). It was concluded that a higher rate of congenital anomalies was primarily responsible [C].²³ Again these findings are not supported after systematic review of the literature demonstrated no association between idiopathic polyhydramnios and fetal mortality (total of 144,681 fetuses). Whether this discrepancy is due to the inclusion of mild and moderate polyhydramnios is, however, uncertain and requires further clarification [A].⁸

Management of polyhydramnios

Management should be guided by the underlying cause of the polyhydramnios and the severity of maternal symptoms. In those cases secondary to maternal diabetes, polyhydramnios is associated with poor glycaemic control, and increased birthweight [C].²⁴ Importantly, aberrant AF has been shown to improve in response to optimisation of glycaemic control with oral/subcutaneous anti-diabetic therapy. Women with a pregnancy affected by diabetes should be under the care of a joint obstetric/diabetic team to optimise outcome for mother and baby. The management of specific disorders such as TTTS, and maternal diabetes, are discussed in greater detail in their relevant chapter.

Considering idiopathic polyhydramnios, mild asymptomatic cases may be managed expectantly. No proven benefits for fluid and salt restriction or diuretic agents have been reported, and are not routinely advised.¹² If moderate-to-severe polyhydramnios results in pronounced maternal distress (in the setting of an appropriately grown, sonographically normal fetus) a more aggressive approach may be indicated. Decisions regarding induction of labour and delivery should be made by a senior obstetrician taking into account aetiology, gestation and maternal considerations, and in an environment with the facilities to manage the potential complications relating to sudden uterine decompression, including abruption, fetal malposition, umbilical cord prolapse and PPH.

In those cases for which the risks of preterm delivery are too high, active treatment may be required, particularly in the setting of significant maternal compromise (respiratory or uterine activity). Treatment should be guided by the underlying aetiology and may include amnio-reduction and indometacin. Therapeutic amnio-reduction involves trans-abdominal aspiration of AF under indirect sonographic vision and is reported

to prolong gestation and improve perinatal outcomes [D].²⁵ However, significant risks, which develop in 2–3 per cent of pregnancies, include preterm pre-labour rupture of membranes, infection, placental abruption and membranous detachment [C].²⁶ Furthermore, re-accumulation may develop rapidly and serial re-treatments may be indicated up to every 2–3 days. For these reasons amnio-reduction should be reserved for only particularly severe cases of polyhydramnios, and should be performed only in a centre with sufficient expertise to perform the procedure safely, and only when prolongation of gestation is required [C].

Indometacin, a prostaglandin synthetase inhibitor, may also be considered as a treatment for severe polyhydramnios at less than 32 weeks to reduce maternal symptoms and prolong gestation [D].²⁷ Albeit more widely recognised for its role as a tocolytic in the prevention of preterm labour, it also reduces fetal urine production and subsequent AFV. The dose required is determined according to total AFV, ranging from 50 mg/day to 200 mg/day. Since there is a potential delay in treatment onset (4–20 days), therapy is often commenced after an initial amnio-reduction, but subsequently avoids the need for serial invasive procedures.³ This has also been successfully utilised in twin gestations (not TTTS) to successfully reduce AFV.²⁸ The main fetal risks of treatment include premature closure of the ductus arteriosus, intraventricular haemorrhage and renal failure. Prior to 34 weeks, the effect on the ductus is usually not significant. Meta-analyses within the setting of preterm labour have found that indometacin treatment at <34 weeks' gestation for tocolysis does not increase the risk of PDA. Treatment should be used with caution and once AFV has returned to the upper range of normal, treatment is to be stopped immediately [B].^{3,29}

KEY POINTS

- Polyhydramnios prevalence is 1–2 per cent.
- For late second to early third trimester, MPD >8 cm, AFI \geq 25 cm, or >95th centile for gestational age is diagnostic.
- Idiopathic polyhydramnios remains the most common aetiology.
- Polyhydramnios is positively associated with an increased fetal birthweight.
- Maternal complications relate primarily to excessive uterine distension.
- Polyhydramnios severity is positively associated with an increased risk of an underlying congenital anomaly.

OLIGOHYDRAMNIOS

An aberrantly low AFV surrounding the fetus is termed 'oligohydramnios'. Typically, diagnosis usually occurs at the second-trimester anomaly scan, a fetal growth US scan in the setting of high-risk pregnancy surveillance or following an acute clinical presentation such as reduced fetal movements.

Quantitatively, oligohydramnios may be defined as an MVP <2 cm. An AFV <200 mL or 500 mL,⁵ AFI <5 cm, or an AFI below the 5th percentile for gestational age, or a subjectively low AFV is also diagnostic.⁶

Importantly, oligohydramnios is associated with a number of adverse antepartum, intrapartum and perinatal pregnancy outcomes. This has led to an almost uniform recommendation for delivery following its diagnosis at term.⁶ Albeit more common in the third trimester, aberrantly low AFV may occur at any stage of pregnancy. Furthermore, the earlier oligohydramnios develops the more severe both fetal morbidity and mortality outcomes become.³⁰ As discussed below, the decisions regarding antenatal management are therefore also more complex.

Causes of oligohydramnios

Oligohydramnios may result from excessive AF loss, underproduction or excretion. Consequently, a diverse range of maternal and fetal conditions may again adversely disturb fluid balance (Table 39.2). The exact cause is often gestational dependent; however, a significant proportion remains idiopathic. In some cases oligohydramnios may be a transient finding, simply reflecting maternal dehydration.⁶

Persistent AF underproduction may be secondary to absent or dysfunctional kidneys, or urinary tract obstruction. Congenital abnormalities of the fetal urinary tract such as bilateral renal agenesis, lower urinary tract obstruction, cystic dysplasia, Meckel–Gruber syndrome or VACTERL (vertebral,

anal, cardiac, tracheo-oesophageal, renal, limb association) may be responsible.^{3,12} In a structurally normal fetus, oligohydramnios may reflect impaired uteroplacental blood flow and be associated with IUGR or fetal hypoxia. Central redistribution of oxygenated fetal blood towards essential organs while there is a concomitant reduction in peripheral renal perfusion and total urine output is one mechanism by which the fetus adapts to chronic hypoxia.⁶ Maternal disease, e.g. hypertension and chronic kidney disease, and iatrogenic causes, e.g. angiotensin-converting enzyme inhibitors and prostaglandin synthase inhibitors, may result in oligohydramnios for this reason. Other causes of low AFV include preterm premature rupture of the membranes (PPROM), spontaneous rupture of the membranes (SRM), TTTS, CMV infection and post-dates maturity (>42 weeks).^{3,12,31}

The commonest cause of oligohydramnios is PPRM, which complicates 1–2 per cent of pregnancies and is associated with 30–40 per cent of preterm births (<37 weeks), and 18–20 per cent of perinatal deaths [A].³² Sonographic detection of oligohydramnios in second-trimester PPRM is associated with a particularly poor prognosis and as such is recognised as a predictor of poor fetal survival [D].³³ The management of PPRM is discussed in the relevant chapter.

Investigation of oligohydramnios

Given the range of potential diagnoses prior to term, the detection of persistent oligohydramnios should prompt detailed review of maternal history, sonographic assessment

Table 39.2 Causes of oligohydramnios

Maternal disease	Hypertension
	Chronic kidney disease
	Diabetes insipidus
	Maternal dehydration
Pregnancy complications	Spontaneous membrane rupture
	Preterm pre-labour rupture of membranes
	Post-dates (>42 weeks)
Fetal	IUGR
	TTTS
Structural	Bilateral renal agenesis or dysplasia
	Urethral obstruction
	Cystic dysplasia
	Meckel–Gruber syndrome
	VACTERL
Uteroplacental insufficiency	
Infectious	Congenital viral infection – CMV
Iatrogenic	Angiotensin-converting enzyme inhibitors
	Prostaglandin synthase inhibitors
Idiopathic	

for evidence of membrane rupture, anatomical evaluation of the renal system and bladder, and assessment of placental function and fetal growth. The extent of investigation is in part guided by the gestational age of detection since, in those near term, induction of labour is indicated. Given the range of maternal and fetal conditions associated with low AFV, however, the validity of oligohydramnios as a diagnostic tool for PPRM is restricted by its poor sensitivity.³¹ In part this is because US is unlikely to detect minor leakages in AFV. As such within this setting AFV should be interpreted in collaboration with maternal history and clinical findings.³¹

Complications of oligohydramnios

Classically, oligohydramnios is considered an indicator of adverse perinatal outcome. Regardless of underlying aetiology, the earlier oligohydramnios develops the poorer the prognosis. As reported by Shipp *et al.*, who evaluated the significance of severe oligohydramnios and anhydramnios in 250 singleton pregnancies between 13 and 42 weeks, second-trimester-onset oligohydramnios compared with third-trimester onset was associated with a significantly increased rate of congenital anomalies (50.7 per cent vs 22.1 per cent) and poorer fetal survival (10.2 per cent vs 85.3 per cent) [D].³⁰ In part this is due to its association with lethal conditions including renal agenesis and early IUGR, but also reflects an increased severity of pulmonary hypoplasia, limb malformations and poor fetal growth. A significant association of oligohydramnios and poor fetal growth (birthweight <2500 g and <10th centile), neonatal death and perinatal mortality is also demonstrated [A].⁸

AF is critical for the canalicular phase of lung development occurring between 17 and 26 weeks. Severe oligohydramnios in early pregnancy results in underdevelopment of this fetal lung tissue and can result in fetal lung hypoplasia. Kilbride *et al.*³⁴ prospectively investigated whether sequential US assessment of AFV (<1 cm vertical pocket) could predict the occurrence of pulmonary hypoplasia and neonatal mortality in pregnancies complicated by second-trimester PROM. They found that both the duration of severe oligohydramnios and the timing of PROM were independent significant predictors of increased neonatal risk. In cases of severe oligohydramnios greater than 14 days following PROM at <25 weeks' gestation, the predicted neonatal mortality was in excess of 90 per cent [C].³⁴

Maternal implications depend on aetiology with chorioamnionitis secondary to PPRM being the most serious. Perinatal morbidity is not shown to be increased once congenital anomalies have been excluded [A].³⁵

Management of oligohydramnios

Oligohydramnios is not routinely treated during pregnancy and decisions regarding management are often dependent upon gestational age at diagnosis. A key priority is first to identify the underlying aetiology, since within the context of fetal growth restriction or maternal disease, severe oligohydramnios is considered an indication for delivery if >37 weeks. In uncomplicated post-dates pregnancies (>40 weeks) delivery is also

advisable; whether a significant improvement in perinatal outcome is achieved however is contentious.³⁶ In those women less than 37 weeks, the frequency and intensity of fetal surveillance and management should principally be guided by the underlying aetiology, gestational age and aberrant AFV severity.

Specifically considering the SGA fetus, the use of umbilical artery Doppler has been shown to reduce perinatal morbidity and mortality and is therefore the recommended primary surveillance tool [A].³⁷ Further management of the SGA fetus is discussed in Chapter 38.

There is some evidence that maternal hydration can temporarily increase AFV; however, the actual clinical benefits of this are not determined [A].³⁸ Within the context of PPRM, amnio-infusion has been described as a method of temporarily reversing low AFV. The procedure involves infusion of isotonic fluid by a needle inserted into the uterine space surrounding the fetus, thus directly increasing AFV. Current evidence regarding the safety and efficacy of therapeutic amnio-infusion is presently insufficient and is therefore not routinely recommended in women with PPRM. For those cases determined appropriate for amnio-infusion, therefore, this must be performed in a specialist fetal medicine centre within the context of a multidisciplinary team [A].^{31,39} The recently published prospective multicentre amniocentesis in preterm premature rupture of membranes (AMIPROM) RCT compared short- and long-term outcomes for participants with very early rupture of membranes (between 16⁺⁰ and 19⁺⁶ weeks' gestation and 20⁺⁰ and 23⁺⁶ weeks' gestation) randomised to either serial amnio-infusion (MPD <2 cm) or expectant management until 37 weeks. It found no significant differences in maternal, perinatal or pregnancy outcomes. A larger definitive study to evaluate amnio-infusion for improvement in healthy survival is still required since only 56 pregnancies were reviewed (28 serial amnio-infusion, 28 expectant management) [B].⁴⁰

When there is isolated oligohydramnios in the presence of an AGA non-compromised fetus with no evidence of maternal disease, guidance regarding appropriate management is uncertain. Currently a propensity towards antenatal fetal surveillance and induction of labour is observed. A randomised case-control study has concluded that increased AFV surveillance in low-risk pregnancies at late gestation does not significantly improve perinatal outcome [B].⁴¹ Further research is required in this area.

KEY POINTS

- Oligohydramnios is defined as MVP <2 cm, AFV <200 mL or 500 mL, AFI <5 cm, or AFI <5th centile for gestational age.
- Detailed review of maternal history, fetal sonographic assessment for membrane rupture, anatomical evaluation, placental function and fetal growth is routinely performed.
- Oligohydramnios duration and severity are independent predictors of increased neonatal mortality secondary to pulmonary hypoplasia in the setting of PROM.

- Oligohydramnios is associated with poor fetal growth, neonatal death and perinatal mortality.
- Management is primarily determined by the underlying aetiology.
- At <37 weeks the frequency and intensity of fetal surveillance and management are guided by aetiology, gestational age at onset and severity.

CONCLUSION

Sonographic detection of aberrant liquor volume is a common situation. Understanding gestation-dependent AFV dynamics is empirical given the numerous causes of both low and high AFV. Given the associated morbidity and mortality associated with certain aetiologies, comprehensive, informed investigation and subsequent parental counselling are essential in this setting. What remains to be ascertained is the clinical significance of idiopathic, uncomplicated, aberrant AFV. At present it is therefore essential that AFV measures are considered within the clinical context and in conjunction with other investigations.

Chapter 40 Fetal hydrops

Caroline Fox and Sailesh Kumar

MRCOG standards

Epidemiology, aetiology, pathogenesis, diagnosis, prevention, management, delivery, complications, prognosis with regard to the following:

Fetal haemolysis

- Relevant antigen–antibody systems
- Prevention
- Fetal pathology
- Diagnosis
- Assessment of severity
- Intrauterine transfusion (indications, techniques, referral)
- Delivery (timing, method)
- Counselling

Non-haemolytic hydrops fetalis

Demonstrate an ability to explain correctly and place in context for the woman: effects upon fetus and neonate of infections during pregnancy, including HIV, measles, chickenpox, rubella, cytomegalovirus, parvovirus and toxoplasmosis.

INTRODUCTION

The term ‘fetal hydrops’ describes the accumulation of fluid in two or more serous cavities, e.g. pericardium, pleura, abdomen or subcutaneously, and may also be associated with polyhydramnios.¹ It represents a non-specific, end-stage disorder of a broad range of conditions, where there is an imbalance in fluid movement between the interstitial and vascular spaces.² Fetal hydrops can be better understood by first dividing it into its traditional classification of immune hydrops (IH), i.e. red cell alloimmunisation involving fetal haemolysis, or non-immune hydrops (NIH). As fetal hydrops represents a significant degree of fetal compromise it is associated with high rates

of perinatal morbidity and mortality, although these will be discussed further as, not unsurprisingly, the outcome is variable depending on the aetiology.³ However, rates are usually higher (up to 98 per cent)³ in NIH than in IH (25 per cent).⁴

PREVALENCE AND EPIDEMIOLOGY

Fetal hydrops affects approximately one in 3000 pregnancies.¹ In the past IH, predominantly due to rhesus isoimmunisation, was a major contributor; however, since the introduction of effective rhesus prophylaxis in the 1970s there has been a significant decline in its prevalence.⁵ Currently 90 per cent of all fetal hydrops cases are NIH. A recent systematic review reported the following associations with NIH, in order of frequency of occurrence:⁶

- Cardiovascular, e.g. structural anomalies, arrhythmias, tumours – 21.7%
- Chromosomal abnormalities or syndromes – 17.8%
- Haematological, e.g. haemoglobinopathies, congenital leukaemia/transient myeloproliferative disorders, red cell aplasia – 10.4%
- Infection, e.g. toxoplasmosis, rubella, CMV, herpes simplex, enterovirus, syphilis, varicella zoster, Lyme disease (*Borrelia burgdorferi*), HIV, parvovirus B19 – 6.7%
- Thoracic, e.g. cystic adenomatoid malformation, extrapulmonary sequestration, diaphragmatic hernia, hydro-chylothorax, mediastinal tumours, lethal skeletal dysplasias – 6.0%
- Lymphatic dysplasia – 5.7%
- Placental, e.g. TTTS, umbilical/chorionic vein thrombosis, placental chorioangioma – 5.6%
- Urinary tract abnormality, e.g. structural anomalies, tumours – 2.3%
- Inborn errors of metabolism, e.g. lysosomal or glycogen storage disorders – 1.1%
- Extra-thoracic tumours, e.g. sacrococcygeal teratomas – 0.7%
- Gastrointestinal, e.g. duodenal/jejunoileal atresia, volvulus, meconium peritonitis – 0.5%

- Miscellaneous, e.g. maternal non-steroidal use – 3.7%
- Idiopathic, 17.8%.

This illustrates the wide range of disorders that can present with hydrops and reinforces the message that hydrops is a non-specific symptom rather than a diagnosis in itself.

CAUSES

Fluid movement across the vascular and interstitial spaces is regulated by their relative hydrostatic and osmotic pressures, as well as by the permeability of the intervening capillary wall. According to the Starling equation, fluid movement will occur when the hydrostatic pressure gradient across the capillary wall is greater than the osmotic pressure gradient. Therefore any mechanism that results in increased hydrostatic pressure, e.g. increased central venous pressure due to outflow tract obstruction as seen in pulmonary stenosis, or decreased osmotic pressure, e.g. decreased hepatic production of proteins in infection-induced liver dysfunction, can result in the accumulation of fluid in the interstitial space and thus fetal hydrops.² The other element that can contribute to increased interstitial fluid accumulation is reduced lymph flow. This is because lymph usually returns albumin to the circulation, thereby reducing the osmotic pressure of the interstitial space, but if this flow is reduced then excess fluid can also accumulate in tissues.⁷ Although lymph flow can be disturbed in isolation, as occurs in lymphatic dysplasia, it is more common for this to be a repercussion of an increase in central venous pressure, where a slight increase can result in a marked decrease in lymphatic flow.² The pathophysiology resulting in fetal hydrops therefore can be summarised to include conditions resulting in congestive heart failure, which would include all cases of immune hydrops, conditions with obstructed lymphatic flow, and conditions characterised by decreased plasma osmotic pressure or increased capillary permeability, but may represent a combination of these.²

COMMON CONDITIONS CAUSING FETAL HYDROPS

Immune hydrops

The rhesus blood group consists of five major antigens, D, C, c, E and e, although in total more than 50 different red cell antigens have been associated with haemolytic disease of the fetus or newborn.⁸ However only three antibodies seem to be associated with severe disease, namely anti-RhD, anti-Rhc and anti-Kell.⁸ Rhesus disease may occur when fetal red cells enter the maternal circulation via a fetomaternal haemorrhage, known as maternal sensitisation or alloimmunisation. However, the sensitising event in relation to other antibodies, i.e. Kell may not be pregnancy related but occur at the time of

a previous blood transfusion,⁸ making Kell typing of blood transfusions for women of reproductive age very important. Where the antigens displayed by the maternal and fetal erythrocytes differ, e.g. a mother is RhD negative but her fetus is RhD positive, then the mother will produce antibodies to the fetal genotype. In general this first alloimmunised pregnancy involves minimal fetal or neonatal disease; however, subsequent pregnancies are associated with worsening haemolytic anaemia.⁹ This occurs when maternal IgG crosses the placenta and binds to the fetal erythrocytes, which are then sequestered in the fetal spleen and undergo haemolysis. The fetal liver responds to this increased red cell turnover by stimulating erythropoiesis, leading to hepatomegaly, but where demand outstrips supply the fetus will become severely anaemic and will develop cardiac failure and hydrops. Kell sensitisation is thought to differ slightly from other red cell alloimmunisation in that fetal anaemia is exacerbated by erythropoietic suppression from the outset.⁸

Although fetal haemolysis is thought to be associated predominantly with anti-RhD, anti-Rhc and anti-Kell, numerous other antibodies including anti-k, anti-RhcE, anti-Fya, anti-Jka, anti-CCw, anti-RhE and anti-Rhe can be associated with a need for *in-utero* transfusion.⁸ However, the majority of these other antibodies are more commonly associated with haemolytic disease of the newborn rather than the fetus.⁸ This is significant because these babies need monitoring after birth as they can develop increasingly severe hyperbilirubinaemia, requiring exchange transfusion to prevent bilirubin encephalopathy (kernicterus).

The widespread use of anti-D immunoglobulin has resulted in a major reduction in the incidence of RhD alloimmunisation. In the UK, the introduction of postnatal immunoprophylaxis with anti-D in 1969, which has since been extended to include anti-D use for any potentially sensitising event, has led to a fall in the number of deaths attributable to RhD alloimmunisation from 46/100,000 births in 1969 to 1.6/100,000 in 1990.⁵ However, full coverage of immunoprophylaxis has not been achieved, and no such prophylaxis exists for the other red cell antibodies, therefore maternal alloimmunisation continues to contribute to perinatal mortality and morbidity.

Non-immune hydrops

Cardiovascular anomalies

Cardiovascular anomalies are the most frequent cause of NIH. The mechanism for this is most commonly congestive heart failure leading to increased central venous pressure. This can occur due to: obstructed outflow tracts, e.g. in pulmonary or aortic stenosis; diverted blood flow, e.g. transposition of the great arteries; abnormal venous return, e.g. in anomalous pulmonary venous return; abnormal ventricular filling, e.g. hypoplastic left heart; decreased inotropic force, e.g. fetal arrhythmias; and reversed flow in the inferior vena cava, e.g. seen in atrial tachycardias such as atrial flutter.

Cardiac dysrhythmias, both tachyarrhythmias, i.e. supraventricular tachycardia, and bradyarrhythmias, i.e. complete heart block, are associated with fetal hydrops through disturbance of the cardiac diastolic function but also by the effect of hypoxia directly on the myocardium.

Placental anomalies such as chorioangioma, sacrococcygeal teratomas and vein of Galen aneurysms can act as a large peripheral arteriovenous shunt and induce hydrops by decreasing peripheral vascular resistance and therefore cardiac afterload.

Chromosomal and genetic disorders

Chromosomal and genetic disorders are strongly associated with hydrops, particularly if this is diagnosed prior to 24 weeks when they account for 45 per cent,³ in either the presence or absence of coexistent structural anomalies. Turner's syndrome and trisomy 21 account for the majority of cases, although genetic syndromes and in-born errors of metabolism can also present in this way.^{3,6} Karyotyping is therefore indicated in the initial investigation of hydropic fetuses, with more detailed genetic testing if indicated from the history. The diagnosis should be considered based on ultrasound findings and family history. It is important to make the diagnosis as many of these conditions carry a significant recurrence risk, and genetic counselling is needed.

Haematological disorders

On some continents, such as south-east Asia, haemoglobinopathies and particularly alpha-thalassaemia zero are the most common cause of fetal hydrops; however, these causes are unusual in most other populations.¹⁰ Haematological causes in general result in fetal anaemia and pregnancy can therefore be prolonged with *in-utero* transfusion, although this cannot be viewed as curative.³

Infection

A multitude of viruses can be associated with fetal infection by causing dysfunction of bone marrow, myocardium and vascular endothelium leading to the development of fetal hydrops.⁶ In practice the most common causative organism is parvovirus B19 (also known as slapped cheek syndrome or erythema infectiosum).³ Transplacental infection of the fetus occurs in approximately 35 per cent, usually 1–3 weeks after maternal infection, and may resolve spontaneously but is also associated with inhibition of erythropoiesis and therefore fetal anaemia.¹¹ This is due to the presence of cellular receptors and co-receptors for parvovirus on erythroid progenitor cells, allowing them to be infected with parvovirus, as is also the case in fetal endothelial and myocardial cells.¹¹ The risk of hydrops after parvovirus infection ranges from 3.9 per cent to 12 per cent, with the risk being highest during the hepatic stage of haematopoietic activity, between 8 and 20 weeks' gestation.¹² The interval between infection and hydrops is usually 2–6 weeks; however, intervals of 10–12 weeks and even 20 weeks have been reported.¹²

Thoracic anomalies

Any disorder that causes increased intrathoracic pressure, such as a space-occupying lesion in the fetal thorax, e.g. diaphragmatic hernia, cystic adenomatoid malformation, chylothorax or rarely mediastinal teratoma, or that limits the space the usual organs have to occupy, e.g. skeletal dysplasias, can result in hydrops.² This is because venous return will be impaired, as may fetal swallowing if the oesophagus is compressed, resulting in increased central venous pressure with eventual hydrops and polyhydramnios respectively.

Other causes of NIH

TTS complicates 10–15 per cent of MC/DA twin pregnancies and if this is severe (stage IV), hydrops will be evident in the recipient twin due to high-output cardiac failure.

Structural anomalies of the urinary tract (i.e. urethral atresia) more commonly cause isolated ascites, due to bladder or renal pelvis rupture, rather than true hydrops although this has been reported.

MATERNAL RISKS AND COMPLICATIONS

'Mirror' syndrome can be associated with fetal hydrops in association with oedema of the placenta. It is characterised by an unusual form of pre-eclampsia, which can be extremely quick to develop and deteriorate. For this reason mothers with hydropic fetuses require regular review for their own health as well as that of their fetus. An increased risk of PPH and amniotic fluid embolus has also been reported.¹³

MANAGEMENT

Immune hydrops

Red cell alloimmunisation remains an important problem but due to its infrequent occurrence there is a lack of RCT evidence, so management is based largely on expert opinion. Thus although the RCOG and NICE guidelines,^{5,14} as well as a Health Technology Assessment systematic review and economic evaluation,¹⁵ exist on routine immunoprophylaxis for women who are RhD negative, these do not include management advice for affected pregnancies. The general principles, however, include routine testing for red cell antibodies associated with haemolytic disease of the fetus and newborn in all pregnant women. The further principles outlined below are taken from a recent systematic review of cohort studies of red cell alloimmunisation in pregnancy and recommend that management is undertaken by maternal–fetal medicine specialists [C].⁹ If antibodies are detected the titre should be calculated and then repeated, usually monthly to 24–28 weeks and then every 2 weeks thereafter. If the titre always remains

low, e.g. less than 16, then the pregnancy can be allowed to progress to 38 weeks. However, if the titre is above a critical value, usually taken as 32 for antibodies other than Kell, or 8 for Kell, then surveillance for fetal anaemia in the form of MCA Doppler scans is indicated every week or fortnight. If the peak systolic velocity of the MCA is indicative of fetal anaemia (≥ 1.5 MoM) then fetal blood sampling to determine fetal haematocrit is warranted with intrauterine transfusion (IUT) if fetal anaemia is confirmed. IUT has not only dramatically improved survival for fetuses affected by IH, to in excess of 90 per cent,^{16,17} but also reduced the occurrence of neurological morbidity in survivors,⁹ although experts agree that it is likely the best outcome will be achieved by avoiding hydrops in the first place [E].¹⁶ Timing of delivery is based on the level of antibody titres and fetal wellbeing but for any pregnancy with significant antibody titres delivery would be expected to be by 34–35 weeks' gestation if IUT has been needed [E].¹⁸

If the patient has had a previously affected pregnancy titres are not necessarily predictive of the degree of fetal anaemia, which is known to worsen in subsequent pregnancies.⁹ Therefore MCA scanning to detect likely recurrence of fetal anaemia is required. Where fetal anaemia presents in the early second trimester perinatal mortality is much higher and intravascular transfusion is not feasible, but management can involve intraperitoneal transfusion as well as IV immunoglobulin and plasmapheresis.^{9,16,17}

Treatment advances have made a vast difference to the prognosis of red cell alloimmunised pregnancies but the other area of significant advance has been the advent of non-invasive prenatal diagnosis of RhD status by analysis of cffDNA.⁹ It is now possible to reliably determine the fetal RhD genotype in the late first or early second trimester for both male and female fetuses (sensitivity 100 per cent, specificity 98.3 per cent)¹⁹ and hopefully non-invasive testing for other red cell antigens will soon be possible.

Non-immune hydrops

General management

Patients whose fetuses are affected with hydrops should be referred to a fetal medicine centre where the necessary expertise and experience are available [E]. A detailed ultrasound scan, including Doppler insonation of the fetal cerebral vasculature and liquor volume, is mandatory [C]. The ultrasound scan must also include careful evaluation of the fetal anatomy and, particularly if skeletal dysplasia is suspected, all the long bones, hands, feet, skull shape and thoracic circumference must be examined.²⁰ Fetal echocardiography should also be performed, to exclude cardiac malformations, and noting normal atrial and ventricular rate and rhythm. Some indication of the cause of hydrops may be obtained from the sites of fluid collection, e.g. parvovirus usually presents with cardiomegaly and ascites.

Karyotyping should be offered in all cases. Samples should be sent for cytogenetics and infection screen. The placenta and umbilical cord should be carefully examined to exclude

a chorioangioma or other vascular abnormalities. More recently, the finding that fetal anaemia can be predicted with up to 100 per cent sensitivity using the peak systolic velocity in the middle cerebral artery has significantly improved the assessment of these fetuses.²¹ Invasive fetal assessment in hydrops almost always involves fetal blood sampling [C]. This enables fetal blood to be obtained for a variety of investigations (FBC, karyotype, virology, enzyme studies, liver function tests, acid–base status and protein concentrations). The volume of blood required for these tests is small and should not compromise the fetus. Some of the investigations, such as karyotype or viral studies, can also be carried out on amniotic fluid or chorionic villi; however, fetal blood is preferable for complete haematological, biochemical and metabolic information. The risks of fetal blood sampling in a hydropic fetus are significantly greater than in the non-hydropic state. However, this risk must be balanced against the high mortality inherently associated with fetal hydrops [E].

Maternal blood should also be checked for atypical antibodies (indirect Coombs' test), FBC and Hb electrophoresis, viral serology and, in selected cases, glucose-6-pyruvate dehydrogenase (G6PDH) and pyruvate kinase carrier status. Other tests, such as for the presence of anti-Ro and anti-La antibodies, should be performed if the hydropic fetus is severely bradycardic. Many of the tests are selected depending on the clinical picture and family history. If more evidence emerges of unusual viral infections causing hydrops, specific tests to detect these organisms may be necessary.

Fetal anaemia is treated by *in-utero* intrauterine transfusions, irrespective of the cause of hydrops. Fetal tachyarrhythmias can be treated by administering specific cardiotrophic drugs either indirectly to the mother or directly to the fetus [C,E]. Although the transfer of drugs through an oedematous placenta is believed to be impaired, cardioversion is certainly possible in many instances.²² Hydrops secondary to fetal bradyarrhythmias is frequently associated with structural heart abnormalities. The mortality in this group of fetuses is significantly worse.²³

Pleural effusions can be treated by pleuroamniotic shunting [C] and large fetal tumours can be treated either fetoscopically *in utero* or occasionally by open surgery [C,E]. Hydrops in the recipient fetus in stage IV TTTS may be treated with fetoscopic laser ablation, or less commonly serial amnioreduction [E].²⁴ As fetal hydrops in this setting may be a pre-terminal event selective feticide may be the only option if the co-twin donor is to survive [C].

Human parvovirus B19

Maternal infection is diagnosed by the detection of parvovirus IgM and IgG antibodies, although neither is detectable for the first week, with IgM antibodies detectable first at about 7–10 days. IgM antibodies peak at 10–14 days and then decline within 2–3 months. Conversely IgG antibodies start to increase from 14 days, then reach a peak at about 6 weeks, after which they plateau, but are thought to persist to provide lifelong immunity.¹² Antibody levels are usually detected by enzyme immune assays but these can be falsely negative so

if there is a high clinical index of suspicion either these can be repeated after 14 days or PCR analysis can be requested for parvovirus DNA as well.¹² Fetal ultrasound to assess for signs of fetal anaemia or hydrops, in the context of maternal diagnosis, is usually sufficient to support the diagnosis of fetal parvovirus infection.¹² However, to provide definitive diagnosis of fetal infection parvovirus DNA detection from either amniotic fluid or fetal blood sampling is required.¹² If maternal infection is confirmed then regular, for example weekly fetal surveillance with ultrasound including MCA Doppler, is required for at least 12 weeks but possibly even 20 weeks. Where fetal anaemia and hydrops do develop these can be treated with IUT and, in contrast with IH-related anaemia, because the infection is transient one IUT is often sufficient, although less commonly the fetus may remain hydropic, and there is still a risk of neurological damage in survivors, making it important to follow these babies up.¹²

OUTCOME

Overall, the perinatal mortality rate in cases of NIH is high (>98 per cent)³ despite improvements in diagnosis and management. Early development of hydrops has a particularly poor prognosis. The mortality rate is highest among neonates with congenital anomalies (60 per cent) and lowest among neonates with congenital chylothorax (6 per cent). Mortality is higher in premature infants and those delivered in poor condition (lower 5-minute Apgar scores, higher levels of inspired oxygen support, and more often treated with high-frequency ventilation during the first day after birth). Once the diagnosis is made, urgent referral to a fetal medicine unit is essential.

The outcome in cases of IH treated by serial intrauterine transfusions is much better (>90 per cent survival).^{16,17} In severe TTTS the outcome is poor, especially in stage IV disease when the recipient is hydropic.²⁴

KEY POINTS

- Fetal hydrops represents an accumulation of interstitial fluid that is a symptom of an underlying disorder rather than a diagnosis in itself.
- Fetal hydrops carries a high rate of perinatal morbidity and mortality, so referral to a maternal-fetal medicine specialist is advised [E].
- Non-immune hydrops accounts for 90 per cent of all cases of fetal hydrops.
- Immune hydrops is most commonly related to anti-D, anti-C and anti-K antibodies, but all pregnant women should have red cell antibody detection undertaken routinely and if antibodies are detected should be monitored with serial titres and recourse to MCA Doppler and *in-utero* transfusion if indicated [A].

- Management of non-immune hydrops is dependent on the cause, but is largely supportive; however, if fetal anaemia is present *in-utero* transfusion is indicated [C].
- Timing of delivery is based on the degree of fetal compromise and the risks of prematurity but patients should be in a unit with level 3 neonatal care [E].

Chapter 41 Malpresentation

Alexander M Pirie

MRCOG standards

Module 1: Clinical skills

- Communicate effectively.
- Take notes concisely and accurately.

Module 5: Core surgical skills

- Demonstrate an understanding of the issues surrounding informed consent, including knowledge of complication rates, risks and likely success rates of different operations.

Module 8: Antenatal care

- Demonstrate skill in listening and conveying complex information (e.g. concerning risk).
- External cephalic version.

Modules 10 and 11: Management of labour and management of delivery

- The exam may test certain aspects of practical skill relating to normal and abnormal delivery. (MRCOG syllabus 2013)

INTRODUCTION

In cases of tragic outcome, junior obstetricians cast a shadow of suspicion upon themselves when their witness statements mix up the specific obstetric terms *presentation*, *position* and *lie*. This is usually by referring to the *breech position* rather than the correct *breech presentation*. This is not mere pedantry, but vital clear thinking which defines the baby's *presentation* as being the leading part of the baby which is lowest in the birth canal.^{1,2}

- *Presentation* is most commonly *cephalic*, *breech*, *face*, *brow*, *arm*, *shoulder*, *foot* or *compound*.
- *Position* refers to the relationship of the denominator of the presenting part to the maternal pelvis. So for cephalic presentations, the denominator is the occiput, and the positions can be *occipito-anterior*, *occipito-posterior*, *occipito-lateral*. For a breech presentation, the denominator

is the sacrum, so the positions can be *sacro-lateral*, *sacro-anterior*, *sacro-posterior*, etc.

- *Lie* refers to the relationship between the long axis of the baby and the long axis of the mother. So lie can either be *longitudinal*, *transverse*, *oblique* or *unstable*.
- A *malpresentation* is any presenting part which is not cephalic. Breech is the commonest malpresentation, followed by the much rarer face, brow and compound. The MRCOG candidate should know that malpresentation has its own specific complications and traditional management strategies. Other than for breech presentation, evidence quality to guide management for face and brow is low, partly because these are relatively uncommon.

BREECH PRESENTATION

This is the commonest malpresentation, which affects 3 per cent of babies at term. There is extensive evidence, debate and technique regarding breech presentation which is fully covered in Chapter 57.

FACE PRESENTATION

Prevalence and causes

The prevalence of face presentation is generally quoted at around 1 in 500–1250;³⁻⁵ it will vary with the local population as it relates to parity, prematurity and uterine obstructions such as fibroids and placenta praevia. The use of mid-trimester anomaly scanning probably decreases the term frequency of face presentation by reducing anomalies associated with the face such as anencephaly and iniencephaly. Macrosomia and polyhydramnios are also associated with face presentation, and so it may be commoner in obese populations with more diabetes. Seventy-five per cent of face presentations are mento-anterior position.²

Clinical examination

The diagnosis should always be suspected with premature labour, failed induction or slow progress. Vaginally, the bony

landmarks of the chin, malar and orbital ridges can be felt, and the soft opening of the mouth and nares. It is rarely confused with a vertex but more commonly confused with a breech. It is important to distinguish between mento-anterior and mento-posterior positions of the face, as the latter is less likely to deliver vaginally.

Abdominally, with a vertex presentation there is a smooth curved line between the fetal back and the occiput, with very little depression between them. With a face presentation, however, the extended head can be felt as a deep depression between the back and the head.

Management

- Explanation to the patient of need for further assessment and her consent.
- Discussion of risks and options including risks of facial oedema impairing initial feeding and also risk of contusions or lacerations to the face.
- Ultrasound and notes review to exclude placental, uterine or fetal anomaly.
- If mento-anterior position and pelvis feels adequate (see Chapter 57 for clinical pelvimetry), the deep curve of the sacrum allows the head to flex forwards and vaginal delivery is possible. This can be assisted with forceps and appropriate analgesia.
- If mento-posterior, unless baby is small or premature, vaginal birth is less likely as the full length of the mento-vertical diameter descends. If after a full discussion the mother is keen to try for vaginal birth, sometimes the mento-posterior face rotates to mento-anterior in the second stage of labour and then flexes for vaginal birth.
- The maternal risks include perineal injury with the larger diameters and also second-stage caesarean section.⁶

BROW PRESENTATION

Prevalence and causes

The prevalence of brow was found to be 1 in 775 in a modern series,⁵ but older estimates quote figures of 1 in 1500–3500.^{1–4} As with face presentation, there is a causal link with prematurity, contracted pelvis and fetal anomalies (such as fetal goitre). The incidence can also appear variable because there is no clear distinction of when a ‘deflexing brow’ becomes a face presentation. Increasing rates of caesarean section for slow progress will also mask a number of brow presentations.

Clinical examination

Brow presentation tends to be a labour phenomenon rather than an antenatal finding. The clinician may be surprised by the relatively high station of the head abdominally, as well as

the deep depression between occiput and fetal back, rather than the usual smooth curved line. Vaginally, the supraorbital ridges are felt and the frontal bones with anterior fontanelle. However, a deep caput succedaneum can mask the landmarks in later labour.

Management

- Brow is the least favourable of cephalic presentations because the full mento-vertical diameter of 13–14 cm presents to the birth canal.
- Full discussion with the woman regarding risks and options will help determine how to proceed.
- If the woman values vaginal birth over caesarean section, a short trial of further labour with appropriate fetal monitoring may allow spontaneous correction, either by flexion or further deflexion to a mento-anterior face presentation.
- Beware the growing *caput succedaneum* as this can become very deep with a brow presentation and give the impression that the head is lower than it really is.
- Uterine rupture has been described with brow presentation, particularly if oxytocin is used.
- Ultimately caesarean section is performed with due attention to the particular risks of second-stage caesarean section.⁵

TRANSVERSE LIE, OBLIQUE LIE AND UNSTABLE LIE

Prevalence and causes

Transverse, oblique and unstable lie are essentially the same thing, and probably most accurately referred to as oblique lie. The prevalence has been variously quoted at 1 in 150–350 births.^{1,2} Oblique lie has a strong association with prematurity, multiparity, polyhydramnios, placenta praevia, multiple pregnancy and uterine or fetal anomaly and so the prevalence will vary with the availability of mid-trimester scanning and population characteristics.

Clinical examination

When the Leopold manoeuvres are performed abdominally, the pelvis will feel empty, with the head high or in one of the iliac fossae. Vaginally, the pelvis will feel empty, or a presenting part may be felt bouncing at the very tip of a long finger. Care must be taken not to precipitate a cord prolapse.

Complications

- Cord prolapse at membrane rupture;
- Arm prolapse or compound presentation at membrane rupture;
- Difficulty delivering the baby at caesarean section.

Management

- Ultrasound to exclude placenta praevia, lower pole fibroids, fetal anomaly, polyhydramnios, etc.
- Full discussion with woman, explanation of risks of cord prolapse etc. and support informed choice.
- Explanation of 'First Aid' measures in event of spontaneous rupture of membranes and cord prolapse.
- Explain all-fours position with bottom up, call 999, keep bladder full, stay in position until delivery.
- Give information letter for ambulance crew or family with above information.
- Many obstetricians recommend admission to hospital from 37 weeks until delivery, although there are arguments for and against (see below) and documentation of informed choice is essential.
- At term, 'stabilising induction' can be performed where patient is taken to theatre, clinical pelvimetry, prepared for caesarean section and membranes undergo controlled rupture with view to immediate caesarean section if cord prolapses, or proceed to immediate oxytocin and careful maternal positioning after amniotomy, followed by continuous electronic fetal monitoring.
- If caesarean section is performed, transverse lie is one of the indications for classical caesarean section (with a vertical uterine incision but low transverse skin incision). Otherwise, the inexperienced obstetrician sometimes enters the lower segment to find an empty cavity with the baby being high above and impossible to bring down. If a lower-segment approach is possible, then a hand should be inserted in the uterus, then a foot grasped and checked for a heel to confirm it is a foot, and then gentle traction will usually bring the baby as a uterine breech extraction.
- The above advice is based on opinion, experience and small historical cohort studies, but there is no high-quality trial evidence to guide practice beyond this.

HOSPITAL VERSUS HOME MANAGEMENT FOR UNSTABLE LIE

An unstable lie is defined as the lie being mobile after 37 weeks. Many obstetricians recommend hospital admission from that gestation until delivery because of the small risk of cord prolapse. Planned caesarean section or stabilising induction is usually delayed until 39 weeks to promote fetal lung maturity.

Many of these women have an unstable lie because of their high parity, and therefore have children at home. The benefits of minimising the harms of cord prolapse by recommending hospital admission have to be balanced against the emotional and financial harms of being in hospital for a fairly long time and having to arrange alternative childcare. Ideally this question could be answered in part by comparative cohort studies, or by a randomised trial to include cost effectiveness and patient-reported outcomes.

Whether home or hospital management is decided, an honest discussion of the risks is required using the 'three-domain' decision model (see Chapter 57 for details) where the woman's values, intuition and understanding of risks can be evaluated to enable skilful support and informed choice. This must be documented in detail.

I will leave the reader with a legal case in England for reflection. In *Lorraine versus Wirral University Teaching Hospital NHS Trust*, Lord Justice Plender was asked to determine liability where the claimant had an unstable lie due to a fibroid, but was not admitted to hospital.⁷ The debate for most obstetricians would be whether home management risks a cord prolapse. However, in this case, the patient didn't have a cord prolapse, but sadly had a placental abruption at home with ongoing consequences for her son. Although the Court accepted that the abruption was not related to the unstable lie and high head, it was argued that had she been admitted for the high head, then the abruption would have happened in hospital with a probable better outcome with more rapid caesarean section.

The Judge explains that he is being asked to find on a difficult point of law on causation:

'I must determine whether the Defendant, and any other person in a similar position, is liable to compensate an individual who suffers an unforeseeable manifestation of a foreseeable danger arising from a breach of a duty of care owed to such an individual.'

The Judge found as follows:

'Even in the absence of such complicating factors as an obstructing fibroid and footling presentation, the leading medical textbooks in circulation at the time indicated that hospital admission might be an appropriate course for a lady at this advanced stage of her pregnancy. Turnbull's Obstetrics 1995 at 263 stated "Many units will feel happier if they can admit her [the mother] two or three weeks before term for daily observation." Dewhurst's Textbook of Obstetrics and Gynaecology, 1999 at 288 stated "Patients with transverse lie should not be allowed to labour because of the risks of uterine rupture and cord prolapse ... Recurrent unstable lie justifies hospital admission at 37 weeks to await labour." Steer's High Risk Pregnancy, 1999 at 305 stated "This approach [i.e. the interventionist approach] involves hospital admission from 37 weeks onwards."

On that argument, the Judge determined that the Claimant should have been admitted to hospital for the unstable lie and, had that happened, the entirely unfortunate coincidence of the placental abruption would probably have had a better outcome for her son, and so the case was settled against the hospital.

As a practising obstetrician in one of the largest maternity units in Europe, I am not sure that all experienced obstetricians interpret the quotes from those textbooks to mean that every patient with an unstable lie MUST be admitted to hospital. Rather, we would interpret those textbooks to mean that

we should give serious consideration to hospital admission for such a patient, and discuss (and document) the pros and cons on an individual basis, empowering each woman to a personal choice. But we must defer to the fact that case law is made by the Courts and not by doctors. On that sobering note, I will close this chapter with the words of the Glasgow hands-on obstetrician who pioneered obstetric ultrasound; he began his trusty old obstetric textbook with the humbling dedication:

*'To all who have known doubt, perplexity and fear as I have known them, to all who have made mistakes as I have, to all whose humility increases with their knowledge of this most fascinating subject... I dedicate this work'*¹

Chapter 42 Prolonged pregnancy

Devender Roberts and Rajeshwari Myagerimath

Standards

The recommendations on prolonged pregnancy from NICE guidelines 62, Induction of labour and 70, Antenatal care are summarised below:

- At the 38-week antenatal visit, all women should be offered information about the risks associated with pregnancies that last longer than 42 weeks, and their options should be discussed.
- Women should be informed that membrane sweeping makes spontaneous labour more likely, and therefore reduces the need for formal induction of labour to prevent prolonged pregnancy.
- Women with uncomplicated pregnancies should usually be offered induction of labour between 41⁺⁰ and 42⁺⁰ weeks. The exact timing should take into account the woman's preferences and local circumstances.
- Women who decline induction of labour from 42 weeks should be offered increased antenatal monitoring consisting of at least twice-weekly CTG and US estimation of the maximum amniotic pool depth.

INTRODUCTION

Prolonged pregnancy is defined as a pregnancy that continues beyond 42 weeks (294 days),^{1,2} the gestational age having been established by an ultrasound scan in the first trimester (or no later than 16 weeks of gestation).¹ This is the standard international definition accepted by WHO and FIGO. The terms *prolonged pregnancy* and *post-term pregnancy* are often interchanged but refer to the same condition.³

EPIDEMIOLOGY

Prevalence and incidence

The prevalence of prolonged pregnancy varies depending on population characteristics and local management practices.

Population characteristics that affect prevalence include: the percentage of primigravidas in the studied population, the prevalence of obesity, the number of women with a prior prolonged pregnancy and the number of women with a genetic predisposition.⁴ The proportion of women with pregnancy complications and the frequency of spontaneous preterm labour also influence the rate of prolonged pregnancy. Some studies have looked at the link between ethnicity and overall duration of pregnancy, but it is not well established.^{5,6} Local management practices such as scheduled induction of labour (IOL), differences in the use of early ultrasound for pregnancy dating, and elective caesarean section rates will affect the overall prevalence of prolonged pregnancy.⁷

Incidence of prolonged pregnancy occurs in 5–10 per cent of all pregnancies.⁸ The use of ultrasound in early pregnancy for precise dating significantly reduces the number of prolonged pregnancies compared to dating based on the last menstrual period and/or second-trimester ultrasound.^{9–12}

Causes and risk factors

The most common cause of prolonged pregnancies is inaccurate dating.^{13,14} When prolonged pregnancy truly exists the cause is usually not clear. It may represent simple biological variation. Prolonged pregnancy is common in primigravidas. Women with a single previous prolonged pregnancy have a 27 per cent chance of recurrence and those with two prior prolonged pregnancies a 39 per cent chance.¹⁵ Male fetuses, hormonal factors, genetic predisposition and obesity are all associated with increasing the risk for a prolonged pregnancy.^{10,16}

Fetal adrenal insufficiency and fetal adrenal hypoplasia are associated with prolonged pregnancies. This is thought to be secondary to their effect on circulating hormones that play a role in spontaneous labour. Similarly, placental sulphatase deficiency, a rare X-linked recessive disorder, can prevent spontaneous labour due to a defect in placental sulphatase activity and the resulting decreased oestriol (E3) levels.¹⁰

There is evidence to suggest that genetic factors may have a role i.e. women who themselves were results of a prolonged pregnancy are at higher risk of prolonged pregnancy (relative risk is 1.3).¹⁷ Twin studies also support a genetic predisposition. Rates of prolonged pregnancy are increased in women whose twin sister has had a previous prolonged pregnancy.

This association is greater in monozygotic than in dizygotic twins.¹⁸

In a retrospective cohort study of 29,224 deliveries over four years, it was found that high pre-pregnancy BMI is associated with an increase in the prevalence of prolonged pregnancy. Prolongation of pregnancy was seen in 30 per cent of women with BMI 30–34.9 kg/m² compared to 22.3 per cent of normal-weight women, and women with BMI 35–39.9 kg/m² and >40 kg/m² had further increased incidence of prolonged pregnancy (32.4 and 39.4 per cent respectively) [C].^{19,20} The association of obesity with prolonged pregnancy, but not pre-term labour, implied that obesity is associated with uterine quiescence or a suppression of myometrial activity. This study adds to the previously reported findings of an association between obesity and reduced myometrial contractility by both clinical and laboratory markers.²¹ However, the lack of association between increasing BMI and length of first and second stages of labour, higher caesarean section for failure to progress and higher incidence of retained placenta mitigates against an underlying aetiology of poor myometrial contractility in obese women with prolonged pregnancy in established labour. Hence the suggestion is that the effect of obesity on myometrial activity is more important in delaying the onset of labour than in reducing myometrial function once labour is established.¹⁹

Diets rich in n-3-polyunsaturated fatty acids (PUFA) are thought to be associated with a higher incidence of prolonged pregnancy by interfering with uterine production of prostaglandins, possibly by inhibiting the production of dienoic prostaglandins, primarily PGF₂α and PGE₂, which are mediators of uterine contractions and cervical ripening. An RCT by the Danish group on the effect of fish-oil supplementation in the third trimester showed prolongation of pregnancy by an average of 4 days (95% CI 1.5 to 6.4 days p=0.006) when compared to olive oil or placebo, without any detrimental effect on the growth of the fetus or on the course of labour.²²

FETAL AND NEONATAL RISKS OF PROLONGED PREGNANCIES

Continuation of pregnancy beyond 41 weeks increases the risk of adverse outcomes for the woman and the fetus. Prolonged pregnancy is associated with post-maturity syndrome. In this syndrome there is IUGR, association with meconium-stained amniotic fluid, oligohydramnios and fetal distress, evidence of loss of subcutaneous fat and dry cracked skin reflecting placental insufficiency.²³ Approximately 20 per cent of post-term fetuses have fetal post-maturity syndrome. It is apparent that not every prolonged pregnancy is complicated by post-maturity syndrome, but it is likely that the majority of morbidity and mortality associated with prolonged pregnancies arises because of post-maturity.

A retrospective study of over 170,000 singleton births demonstrated a 6-fold increase in stillbirth rates in prolonged pregnancies, from 0.35 at 37 weeks to 2.12 per 1000 ongoing pregnancies at 43 weeks.²³ The perinatal mortality rate at 42 weeks' gestation is twice as high as that at 40 weeks, 4-fold at 43 weeks and 5–7-fold at 44 weeks. There is evidence that when calculated per 1000 ongoing pregnancies, perinatal mortality rates increase sharply after 40 weeks.^{10,11,23,24}

A number of key morbidities are greater in infants born beyond 41 weeks' gestation including meconium aspiration, neonatal acidaemia, low Apgar scores, fetal macrosomia and shoulder dystocia with resultant risks of orthopaedic or neurological injury.^{11,25,26} Prolonged pregnancy is an independent risk factor for low umbilical artery pH at delivery and low 5-minute Apgar scores, neonatal encephalopathy, and infant death in the first year of life. Meconium aspiration syndrome is seen at higher rates in post-term neonates.^{16,23,27-30}

While preterm delivery is a well-established risk factor for cerebral palsy, a population-based follow-up study from 1967–2001 in Norway suggested that delivery at 42 weeks or later is also associated with increased risk of moderate to severe cerebral palsy, requiring entitlement to benefit for disability (RR 2.4, 95% CI 1.1 to 5.3) when compared to delivery at 40 weeks' gestation.³¹

MATERNAL RISKS OF PROLONGED PREGNANCY

The maternal risks of prolonged pregnancy are often underestimated. These include an increase in labour dystocia (9–12 per cent vs 2–7 per cent at 40 weeks), an increase in severe perineal injury (3 and 4 degree perineal lacerations) related to macrosomia (3.3 per cent vs 2.6 per cent at 40 weeks) and operative vaginal delivery, and a doubling in the rate of caesarean delivery (14 per cent vs 7 per cent at 40 weeks).^{30, 32-34} These risks are even higher in obese women with prolonged pregnancies.¹⁹ In addition to the medical risks, the emotional impact (anxiety and frustration) of carrying a pregnancy 1–2 weeks beyond the estimated due date should not be underestimated.

MANAGEMENT

Accurate dating of pregnancy

Accurate pregnancy dating is crucial in the diagnosis and management of prolonged pregnancy.³⁵ Routine ultrasound examination for pregnancy dating demonstrated a reduction in the rate of false-positive diagnosis and thereby the overall rate of prolonged pregnancy from 10–15 per cent to approximately 2–5 per cent, and thereby minimised unnecessary intervention.^{3,6} Due to the lower margin of error

first-trimester ultrasonography seems to be superior to mid-trimester ultrasound for pregnancy dating.³⁵

Prevention of prolonged pregnancy

Several minimally invasive interventions have been recommended to avoid formal induction and encourage spontaneous onset of labour at term. This includes membrane sweeping, unprotected sexual intercourse, nipple stimulation and acupuncture.

Sweeping of the membranes, also named stripping of the membranes, is a relatively simple technique usually performed in an outpatient setting. It has the potential to initiate labour by increasing local production of prostaglandins and, thus, reduce pregnancy duration. Sweeping the membranes at or beyond 40 weeks appears to significantly reduce not only the incidence of prolonged pregnancy but also the frequency of using other methods for induction of labour. There is no evidence that sweeping the membranes increases the risk of maternal and neonatal infection, or of premature rupture of the membranes. However, women's discomfort during the procedure and other side effects must be balanced with the expected benefits before submitting women to sweeping of the membranes.^{1,36-38}

A systematic review evaluating interventions aimed at prevention, or improvement of outcomes of delivery beyond term, showed sweeping the membranes performed as a general policy from 38 to 40 weeks onwards decreased the frequency of prolonged pregnancy: pregnancy continuing beyond 42 weeks (RR 0.28, 95% CI 0.15 to 0.50, NNT 11) and beyond 41 weeks (RR 0.59, 95% CI 0.46 to 0.74, NNT 9). Sweeping the membranes in women at term generally reduces the delay between randomisation and spontaneous onset of labour, or between randomisation and delivery, by a mean of three days. It increased the likelihood of either spontaneous labour within 48 hours (RR 0.77, 95% CI 0.70 to 0.84) or of delivery within one week (RR 0.71, 95% CI 0.65 to 0.78). A reduction in the frequency of using other methods to induce labour ('formal induction of labour') in women allocated to sweeping was reported in most trials (RR 0.60, 95% CI 0.51 to 0.71). The overall risk reduction was 14 per cent. About eight women need to have sweeping of membranes to avoid one formal induction of labour [A].³⁸

Membrane sweeping is the only evidence-based intervention known to reduced prolonged pregnancy.

Cochrane reviews on the role of other interventions designed to reduce the incidence of prolonged pregnancy, including sexual intercourse, nipple stimulation and acupuncture, are uncertain and that further studies of sufficient power are needed to assess their value.^{14,39-41}

Induction of labour

The data from 22 RCTs comparing elective IOL were analysed in a systematic review, which has governed policy for many units in the UK over the past decade.^{14,42} The conclusions

of the analysis favoured a policy of IOL at 41 completed weeks and beyond, to reduce perinatal mortality, decrease meconium staining of the amniotic fluid and cause a small decrease in caesarean section, compared to conservative management. [A]

Compared with a policy of expectant management, a policy of labour induction was associated with fewer (all-cause) peri-natal deaths; 17 trials, 7407 women (RR 0.31, 95% CI 0.12 to 0.88). There was one perinatal death in the labour induction policy group compared with 13 perinatal deaths in the expectant management group. The number needed to treat to benefit (NNTB) with IOL in order to prevent one perinatal death was 410 (95% CI 322 to 1492). For the primary outcome of perinatal death and most other outcomes, no differences between timing of induction subgroups were seen; the majority of trials adopted a policy of induction at 41 completed weeks (287 days) or more. Fewer babies in the labour induction group had meconium aspiration syndrome (RR 0.50, 95% CI 0.34 to 0.73; eight trials, 2371 infants) compared with a policy of expectant management. There was no statistically significant difference between the rates of NICU admission for induction compared with expectant management (RR 0.90, 95% CI 0.78 to 1.04; 10 trials, 6161 infants). For women in the policy of induction arms of trials, there were significantly fewer caesarean sections compared with expectant management in 21 trials of 8749 women (RR 0.89, 95% CI 0.81 to 0.97).⁴²

The recommendations of the Society of Obstetricians and Gynaecologists of Canada for management of pregnancy at 41 to 42 weeks are broadly in agreement with these findings.¹¹

The American College of Obstetricians and Gynecologists recommendations on management of prolonged pregnancy also support a policy of IOL.

While much of the work has been conducted in prolonged pregnancies, evidence from one of the retrospective cohort study showed that some of the fetal risks such as presence of meconium, increased risk of neonatal acidaemia and even stillbirth have been described as being greater at 41 weeks and even at 40 weeks as compared with 39 weeks of gestation.^{43,44} In addition to stillbirth being increased prior to 42 weeks, another retrospective cohort study found that the risk of neonatal mortality also increases beyond 41 weeks' gestation.⁴⁵ Thus, 42 weeks does not represent a threshold below which risk is uniformly distributed. Indeed, neonatal morbidity (including meconium aspiration syndrome, birth injury and neonatal acidaemia) appears to be lowest at around 38 weeks and increase in a continuous fashion thereafter.⁴⁶ Similar to neonatal outcomes, maternal morbidity also increases in term pregnancies prior to 42 weeks' gestation. Complications such as chorioamnionitis, severe perineal lacerations, caesarean delivery rates, PPH and endomyometritis all increase progressively after 39 weeks of gestation.^{35,44,47-50}

Current guidance for the management of prolonged pregnancy in the UK is based on NICE guidelines on induction of labour and antenatal care.^{1,2} Based on the evidence from epidemiological data, trial data and health economic analysis, the guideline development group (GDG) reached a consensus

that, on balance, induction of labour should be offered from 41⁺⁰ weeks onwards. The guideline found that IOL became more acceptable to women as gestation advanced (45 per cent wanted expectant management at 37 weeks vs 31 per cent at 41 weeks, $p < 0.05$).⁵¹

There is evidence to suggest that this policy is acceptable to women. In a Scandinavian RCT of women at 41 weeks' gestation, 74 per cent of women who were induced desired the same management, whereas only 38 per cent of women with serial antenatal monitoring desired the same management.⁵²

One of the common dilemmas in the management of the obese pregnant woman with prolonged pregnancy is how to balance the maternal risks of IOL, including caesarean section and PPH, with the fetal risks of perinatal morbidity and mortality associated with prolonged gestation. A retrospective (historical) cohort study looked at the effect of higher maternal BMI on delivery outcome following induction for prolonged pregnancy and demonstrated that IOL for these women was associated with increased rates of caesarean section delivery (28.4 per cent for obese women compared with 18.9 per cent for normal-weight women). Although this 28.4 per cent caesarean section rate is high, it is also important to realise that over 70 per cent of obese pregnant women with prolonged pregnancy delivered vaginally, and with rates of labour and neonatal complications also comparable to normal-weight women. The results of this study suggest that IOL in obese women with prolonged pregnancy is a reasonable and safe management option.¹⁹

Monitoring prolonged pregnancy

The NICE antenatal guideline recommends increased antenatal fetal surveillance consisting of at least twice-weekly CTG and US estimation of maximum amniotic pool depth in women who decline induction of labour. These recommendations are supported by both the American College of Obstetricians and Gynecologists and the Society of Obstetricians and Gynaecologists of Canada, despite lack of evidence that it improves perinatal mortality. This recommendation is based on the evidence that perinatal morbidity and mortality increase as gestational age advances.

It has been suggested that AFI is preferable to MPD liquor volume assessment in these pregnancies. However, there is still debate about what constitutes the best cut-off values for both measurements, as liquor volumes fall after term. An RCT comparing the two methodologies showed that use of AFI did not improve perinatal outcomes but was associated with an increase in the intervention rate. Thus MPD is probably the tool of choice for assessing liquor in these prolonged pregnancies [B].^{53,54} More complex fetal monitoring with a formal biophysical scoring system has been suggested, but an RCT shows that it holds no advantage over simple monitoring with NST-CTG and liquor assessment [B].⁵⁵

CTG monitoring is usually applied on the basis of observational data, although it is of no proven benefit [C].⁵⁶

It has been suggested that computerised CTG may be superior to conventional CTG, but this has yet to be tested in clinical trials. The use of Doppler analysis of various fetal arterial systems has also been advocated in the assessment of prolonged pregnancies, but again this has not been evaluated by RCT. In addition, complex arterial Doppler assessment is not suitable as a screening tool in standard practice. The use of umbilical artery Doppler is claimed to be of benefit; however, the alterations in the waveforms are subtle.⁵⁷

In a prospective questionnaire-based survey, only 31 per cent of women at 41 weeks' gestation opted for conservative management despite this being the unit's policy [C].⁵¹ Many women will see induction as interference with a natural process, and loss of maternal choice is a major determinant of maternal dissatisfaction with the management of pregnancy and labour. It is therefore vital that each woman is treated on an individual basis and counselled regarding the risks of prolonged pregnancy, to allow her to make her own decision about induction of labour.³

KEY POINTS

- Prolonged pregnancy is a condition associated with increased risk of stillbirth, post-maturity syndrome and perinatal mortality and morbidity.
- Induction of labour should be offered between 41 and 42 weeks.
- Women who opt for conservative management beyond 42 completed weeks should have fetal surveillance with twice-weekly CTG and US measurement of the MPD.

CONCLUSIONS

- The use of early ultrasound dating reduces the incidence of prolonged pregnancy [A].
- Induction of labour after 41 weeks reduces perinatal mortality rates without increasing caesarean section rates. Nevertheless some will opt for conservative management with fetal surveillance [A].
- Sweeping the membranes significantly reduces the incidence of prolonged pregnancy and the need for other methods of induction of labour, with no evidence of increase in the risk of maternal or neonatal adverse outcomes [A].
- No clear evidence exists to support the hypothesis that fetal monitoring can reduce the perinatal mortality in prolonged pregnancy but it is suggested as good practice by the NICE antenatal guideline. Therefore IOL seems the best policy to avoid perinatal risks [C].
- Lower-grade evidence [B,C] supports the use of NST-CTG and liquor assessment using MPD in monitoring prolonged pregnancy.

Chapter 43 Routine intrapartum care: an overview

Mary Higgins

MRCOG standards:

Clinical skills: Take an obstetric history, communicate effectively, and take notes concisely and accurately.

Teaching: Demonstrate aptitude in teaching common practical procedures in labour.

Management of labour and delivery: Have the knowledge, skills, understanding and judgement to be capable of initial management of intrapartum problems without direct supervision, including knowledge and understanding of normal labour, data and investigation interpretation, clinical judgement and prioritisation, management of a team, communication skills, insights and knowing one's limits, emotional and cultural awareness, and appropriate use of protocols and guidelines.

The exam may test certain aspects of practical skill relating to normal delivery.

Curriculum covered:

Theoretical skills

- Review labour definitions.
- Understand the endocrinology and pharmacology governing labour.
- Understand the biochemistry controlling corpus and cervix in labour.
- Know the stages of labour.
- Understand fetal response in labour.

Practical skills

- Be able to interpret routine data collected in labour.
- Be able to define normal and abnormal progress in labour.
- Know the principal indications and methods for managing delay in labour.
- Understand the effects of labour on the fetus and their implications for fetal monitoring.

Definitions

Dystocia: Failure to progress within any stage of labour based on either total time or rate of progress based on a partogram.

Lie: Orientation of the fetal long axis with respect to the long axis of the mother (longitudinal, oblique or transverse).

Malpresentation: Any position of the fetus other than occiput anterior.

Normal birth: A birth without surgical intervention, use of instruments, induction, epidural or general anaesthesia.

Partogram: A graph demonstrating the dilatation of the cervix as a function of time – can also record station, maternal vital signs and fetal heart rate.

Position: The position of the fetal presentation in relation to the maternal pelvis (occiput anterior, posterior, transverse; mento anterior or posterior, sacrum anterior posterior or transverse).

Presenting part: Fetal part at the pelvic outlet (cephalic, breech, compound).

Stages of labour:

First stage: Time from diagnosis of labour to full dilatation of the cervix.

Second stage: Time from full dilatation of cervix to delivery of the fetus.

Passive second stage: Full dilatation of the cervix prior to or in the absence of involuntary expulsive contractions.

Active second stage: Full dilatation with expulsive contractions, baby visible, active maternal effort following confirmation of full dilatation of the cervix in the absence of expulsive contractions.

Third stage: Time from delivery of the fetus to delivery of the placenta.

Station: Relationship between the presenting part and the ischial spines. May be described either based on centimetres or 'thirds', or based on distance from lowermost portion of the presenting part or bi-parietal diameter.

INTRODUCTION

Just under half of the 729,624 births in the UK in 2012 were normal – that is, without surgical intervention, use of instruments, induction, epidural or general anaesthesia.¹ If one includes the women who had epidural anaesthesia but a normal vaginal delivery then this percentage increases. Ninety percent of women in the UK will give birth to a single baby, presenting head first, after 37 weeks' gestation, and most women (75 per cent) will go into labour spontaneously. If the delivery and birth progress normally these women will not need the support of the obstetric team, other than as a supportive service to the midwifery team should problems arise. It is important that obstetricians be aware of the physiological processes of normal labour and delivery, both as a method of early recognition of pathology and in acknowledgement of the stellar work of midwifery staff. Recognition by obstetricians and midwives of early problems can prevent emergencies happening in women who were previously deemed normal – a central theme in the Active Management of Labour,² and a key responsibility of the consultant on call.³

ONSET OF LABOUR

Aristotle proposed that labour began once the infant had outgrown maternal supplies and therefore needed to be able to function independently of its parent. More recent theories include changes in the progesterone-to-oestrogen ratio, or in the sensitivity of progesterone receptors, secretion of steroids from the fetus and changes in the uterine wall tension as well as changes in cytokines. Prostaglandins and inflammatory markers may play a part. The complexity of possible causes is shown in Fig. 43.1.

DIAGNOSIS OF LABOUR

Internationally there are several different definitions of when to make a diagnosis of labour, from cervical effacement with pains² to cervical dilatation greater than 6 cm.⁴ In the UK, labour is defined as either latent (painful contractions and some cervical change up to 4 cm dilatation) or established (regular painful contractions and progressive cervical dilatation from 4 cm).

Notes On Labour

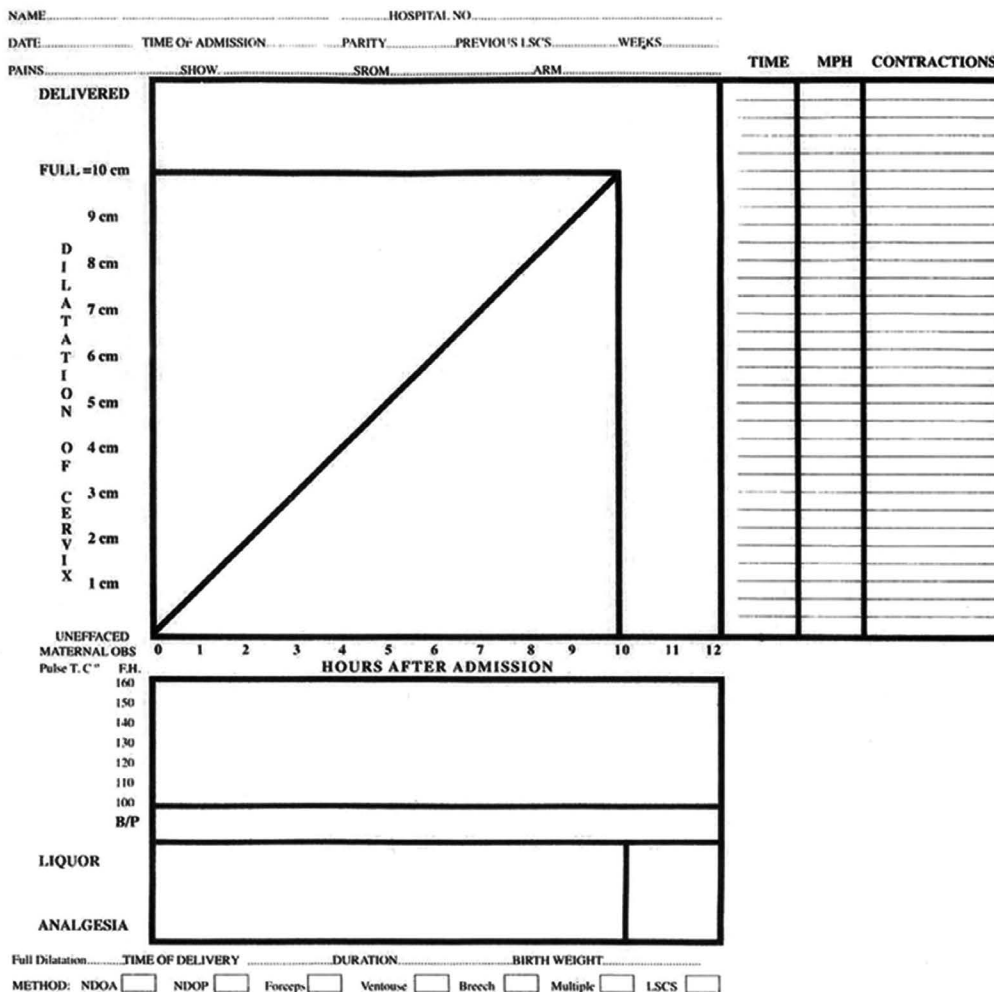

Fig. 43.1 Partogram

LABOUR IN PRIMIPAROUS WOMEN COMPARED TO LABOUR IN MULTIPAROUS WOMEN

The differences between first and subsequent labours are so significant that in our unit, like many others, two different colour partograms are used to distinguish between the two [E]. In a first labour a woman, no matter how well informed, has yet to experience the emotional and physical experience of labour. With this in mind the care and experience of her healthcare provider are invaluable to provide her with the support she requires at this, one of the most profoundly emotional experiences of her lifetime. It is continuously astonishing how acutely women and their partners remember everything that happens to them and everything that is said to them at this time. As first-time labours are often longer and more uncertain of outcome as the functional capacity of the pelvis is unknown, this highlights the need for high standards of care and attention. In contrast, labour in a multiparous woman is different: the pelvis has been tested, the uterus is more efficient, labour is normally shorter and the woman has personal experience to give her confidence in her own ability. One major concern is the risk of uterine rupture and the need for great caution in the use of oxytocin as a result; though the labour is different, excellent midwifery and obstetric care are still required.

CARE OF THE WOMAN IN LABOUR

Place of birth

In the UK, women may choose to deliver at home, in a midwife-led unit or in an obstetric-led unit (Box 43.1).

Box 43.1 Recommendations regarding place of birth (adapted from the NICE Guidelines on Intrapartum Care)

Home/Midwife-led Unit

Advantages: Higher likelihood of a normal delivery without intervention.

Disadvantages: If something does go unexpectedly wrong during labour the outcome may be worse than in an obstetric-led unit.

Women choosing to labour at home or in a midwifery-led unit should be informed of the locally available services, the likelihood of being transferred into the obstetric unit and the time this may take.

Obstetric-led Unit

Advantages: Immediate access to obstetricians, anaesthetists, neonatologists and other specialist care including epidural anaesthesia; women with a pre-existing medical condition or previous complicated birth should be advised to give birth in an obstetric-led unit.

Disadvantages: More likely to have intervention.

The NICE Guidelines on Intrapartum Care⁵ outline medical conditions and other factors indicating increased risk and suggesting planned delivery in an obstetric unit as well as conditions and factors indicating individual assessment when planning place of birth. Should an obstetric opinion be required, either by the woman or her midwife, regarding the place of birth this should be obtained from a consultant obstetrician and clearly documented in the hand-held maternity notes. Examples of conditions or factors suggesting delivery in an obstetric unit include: diabetes, BMI >35 at booking, epilepsy, multiple birth, recurrent antepartum haemorrhage, previous obstetric complication (including retained placenta requiring removal in theatre), anaemia (Hb <8.5 g/dL at onset of labour), SGA infant or previous myomectomy. Individual assessment can be used for women with conditions such as ulcerative colitis, hepatitis B or C with normal liver function tests, previous intrauterine death due to a non-recurrent cause, age over 40 at booking or BMI between 30 and 34 or single antepartum haemorrhage of unknown origin [D].

In labour, circumstances may change so that consideration may be given to transferring the woman from her home or midwifery unit to an obstetric unit. In making this decision, the clinicians need to bear in mind the likelihood of birth during transfer. Such indications include need for electronic fetal monitoring, delay in first or second stage of labour, maternal request for epidural, obstetric emergency, retained placenta, maternal pyrexia or hypertension, significant meconium-stained liquor or malpresentation first diagnosed at the onset of labour. Twenty-five per cent of intended home deliveries required hospital delivery in 2012, of which half of the transfers occurred prior to the onset of labour.¹

There is not enough information on the possible risks to the woman or her baby relating to the planned place of birth – a recent Cochrane Review identified only two small randomised trials, of which only one (involving 11 women) contributed data to the review [A].⁶

Communication in labour

A woman in labour should be treated with respect and be involved in what is happening to her – this includes establishing her wants and expectations for labour, supporting her in one-on-one care, and only offering clinical intervention when it is warranted. One-on-one care does not merely mean a physical presence, but also requires the emotional support of a trained companion – especially valuable in first labours. Lack of such support can significantly affect both the morale of the woman and her confidence in her care provider [D,E], best described as follows:

‘As human consciousness is seldom more open to impression than during the momentous hours of labour, a casual approach to just another routine assignment may leave a mother with a burning sense of resentment. Apparently trivial episodes such as a curt tone of voice, a bloodstained glove, a mindless exposure in the lithotomy position or a failure to convey the result of pelvic examination,

*though not seemingly of great consequence in themselves, still portray an often deplorable lack of sensitivity in professional staff who should know a great deal better.*²

When additional expertise is being requested, such as when a midwife requests the opinion of an obstetrician, the woman should be involved in this and the obstetrician should be of sufficient expertise to provide that opinion.

In order to continue with efficient communication the woman should be greeted with an introduction of who the person is and what their role is in her care. Knocking and waiting prior to entering her room shows respect for her personal space and should be standard in all but the most pressing emergencies.

Different women need different approaches to labour – some require quiet support and others boisterous encouragement. Therefore the clinicians and attendants need experience and sensitivity to match the type of support they give to the needs of the mother;⁷ often the partner (usually forgotten) can advise on this.

If the woman has a written birth plan it is important to read it and discuss it with her. Despite popular opinion in obstetrics, women with written birth plans do not have an increased rate of episiotomy or delivery by caesarean section, and may have a decreased incidence of epidural use [C].⁸

In the case of an acute emergency it is even more necessary that staff maintain a calm and confident approach so that the woman is reassured of their support.

Pain relief in labour

Pain relief in labour has proven to be one of the most controversial areas of labour management, with women themselves being divided between ‘natural’ and ‘medicalised’ labour. While a low-risk woman is unlikely medically to need regional anaesthesia (compared to a woman requiring a caesarean delivery where it would be inhumane to deny regional or general anaesthesia to her) it is nearly universally recognised that women should have several options available to them in labour so that they can choose, in discussion with their care provider, what form of pain relief they may wish. Thousands of studies have been published on options for pain relief for parturients, the reviews of which are beyond the scope of this chapter.

What is obvious is that options other than regional analgesia alone are reasonable and may work perfectly well for some women, especially if their labour is progressing normally. Women choosing to use breathing or relaxation techniques should be supported in their choice, and the playing of music of their choice should be supported. Aromatherapy may be used for pain relief, though a review of two trials showed no difference in pain intensity or the rate of subsequent use of epidural anaesthesia [A].⁹ The opportunity to labour in water is recommended for pain relief, as it has been shown to significantly reduce the rate of analgesia (OR 0.84, 95% CI 0.7 to 0.98) without increasing the rate of maternal infection [A].¹⁰

Other options for pain relief include:

- Transcutaneous electrical nerve stimulation (TENS): research is inconsistent whether TENS will reduce pain scores, but many women said that they would use it again in future labours and no obvious harm has been identified. NICE guidelines suggest TENS should not be offered in established labour. Given the limited evidence base and absence of adverse events, midwifery literature has recently supported offering women in labour the choice of TENS [A].¹¹
- Inhalational analgesia (e.g. Entenox) should be made available as it reduces pain intensity and gives pain relief during labour. Flurane derivatives appear to cause more drowsiness and nitrous oxide more nausea [A].¹² As an example of cultural differences in labour ward management, inhalational analgesia tends to be used in Western Europe for management of pain relief in early labour, and only used in advanced labour in North America.
- Intramuscular or intravenous opioids provide some relief from pain in labour but the effect appears to be moderate and is associated with a higher rate of maternal nausea, vomiting and drowsiness [A].¹³
- Remifentanyl patient-controlled analgesia provides a superior analgesia and patient satisfaction compared to pethidine but lower pain relief compared to epidural [A].¹⁴ One-on-one midwifery care, appropriate monitoring and experience in both the medication and its possible complications are required in order to maintain patient safety when administering remifentanyl due to the serious complications that have been described with its use [E].¹⁵
- Regional anaesthesia: while epidural (or combined spinal epidural) analgesia appears to be effective in reducing pain in labour there is an increased risk of instrumental delivery (A, RR 1.42).¹⁶ Before choosing epidural anaesthesia, the risks and benefits should be explained as well as the implications of epidural anaesthesia for labour.⁵

Eating and drinking in labour

Following Mendelson’s work in the 1940s (showing an increased risk of aspiration in those who had recently eaten and then underwent general anaesthesia) oral intake has been restricted in labouring women. Since that time, however, anaesthesia has improved considerably with increased rates of regional anaesthesia. A recent Cochrane review of 3130 women over five trials concluded that there are no benefits or harm in restricting foods and fluids to women at low risk of anaesthesia; no studies were identified investigating women at higher risk of anaesthesia [A].¹⁷ Women in low-risk established labour should be encouraged to eat a light diet and drink isotonic drinks, unless they have been administered opioids or developed risk factors making general anaesthesia more likely.

PROGRESS IN LABOUR

One of the most common questions asked by labouring women is at what point should they deliver. It is recommended that women should be told that first-time mothers deliver, on average, within 8 hours (rarely past 18 hours) and subsequent labours last on average 5 hours (rarely past 12 hours). This knowledge is important for the woman's psychological well-being as well as for decisions she may make about analgesia in labour.

The diagnosis of delay in labour is more than a simple line on a partogram. While delay in the first stage of labour is based on cervical dilatation less than 2 cm in 4 hours (or slowing of progress in non-primiparous women), other factors such as strength, duration and frequency of contractions as well as descent and rotation of the fetal head may play a part. As an example, a multiparous woman whose cervical dilatation increases from 2 cm to 3 cm may be considered to have delay in labour, but if the fetal position has changed from OP to OA and from station minus 3 to the spines, with an increase in strength and frequency of contractions, then this is more reassuring of normal labour and therefore care may be individualised to whether amniotomy or oxytocin is truly required in her case, rather than patience.

It is recommended that a partogram should be used when labour is established. Various types of partograms have been published in the literature, and no one type has been exclusively recommended within the UK. At its simplest, a partogram is a graph demonstrating the dilatation of the cervix as a function of time, though many also report fetal position, station, FHR and maternal vital signs. The classic Friedman curve was said to be developed by Friedman in the 1950s as he sat in a hospital waiting room anticipating the birth of his first child – as information was relayed to him on the progress of his wife in labour he drew a graph on mathematical paper in order to predict when the delivery would occur. Friedman went on to develop a graph based on nulliparous¹⁸ and multiparous¹⁹ women. The partogram was further adapted to add an 'action line' in order to determine either when a woman needed to be transferred to an obstetric unit²⁰ [D] or else have some intervention aimed to correct dystocia [B].²¹ The value of Friedman's work is that

he introduced the concept of latent and active phases of labour, and gave an intellectual approach to labour which went on to inform both the Active Management of Labour and modern care of the labouring woman.

One concern is the applicability of the Friedman curve to the modern care of the parturient – of the 100 women studied initially,¹⁸ four underwent induction of labour, 68 were delivered by forceps and one by caesarean section. Cervical assessment was performed at the peak of a contraction (only 22 received 'caudal anaesthesia' – mostly for delivery) and examinations were performed *per rectum* rather than vaginally. With this in mind, other partograms have been developed, some using similar populations to Friedman but different statistical methods²² and others using modern populations of parturients [C].^{20,21} Interestingly, partograms have also been developed based on individual patient factors: the influence of the fetal gender on progress in labour²⁵ (male fetus increasing the active first phase by 0.6 hours), and the influence of maternal BMI^{26,27} (with average length of labour increasing by 1.7 hours in women with a BMI >30) [C].

No one partogram is recommended for use in the UK, and it is advisable that clinicians be aware of which partogram is in use in their unit. It is recommended that if an action line is to be used [E], it should be the WHO action line, which is set at 4 hours to the right of the alert line.²⁸

FETAL MONITORING

Intermittent auscultation, whether by handheld Doppler or Pinard, is recommended for every low-risk woman in spontaneous labour. Admission CTG is not recommended as it is associated with a higher rate of continuous electronic fetal monitoring (CEFM), fetal blood sampling and delivery by caesarean section [A].²⁹

The frequency of fetal monitoring as recommended is outlined in Table 43.1. Monitoring of the FHR should be converted to CEFM when an abnormal heart rate is auscultated, there is meconium staining of liquor, maternal pyrexia or fresh bleeding or oxytocin is required. CEFM can also be used if the mother requests it. Otherwise intermittent auscultation

Table 43.1 Recommendations regarding maternal and fetal observations in labour (adapted from the NICE Guidelines on Intrapartum Care)

First stage of labour	
Maternal observations	Fetal observations
<ul style="list-style-type: none"> • 4-hourly temperature and BP • Hourly pulse rate • Half-hourly documentation of frequency of contractions • Frequency of emptying of bladder • Vaginal examination offered every 4 hours, or if concerns regarding progress, or in response to the woman's wishes 	<ul style="list-style-type: none"> • Fetal heart rate auscultation after every contraction • At least every 15 minutes • Lasting at least 1 minute • Fetal descent, station, position • Liquor

(continued)

Table 43.1 Recommendations regarding maternal and fetal observations in labour (adapted from the NICE Guidelines on Intrapartum Care) (continued)

Second stage of labour	
Maternal observations	Fetal observations
<ul style="list-style-type: none"> • 4-hourly temperature • Hourly pulse rate and BP • Half-hourly documentation of frequency of contractions • Frequency of emptying of bladder • Vaginal examination offered every hour (active stage), or in response to the woman's wishes 	<ul style="list-style-type: none"> • Fetal heart rate auscultation after every contraction • At least every 5 minutes • Lasting at least 1 minute • Fetal descent, station, position • Liquor
Third stage of labour	
Maternal observations	Neonatal observations
<ul style="list-style-type: none"> • Based on her general physical condition and degree of blood loss 	<ul style="list-style-type: none"> • Apgars recorded at 1 and 5 minutes routinely • Minimal separation from the mother within the first hour: encourage skin to skin • Head circumference, birthweight and temperature after 1 hour

should be used as a preference in low-risk women as CEFM increases the risk of instrumental and caesarean delivery [A].³⁰

Should there be abnormalities on the CTG suggestive of fetal distress, there are a number of options available. Further information may be obtained either by fetal blood (scalp) sampling (measuring either fetal pH or fetal lactate, which requires smaller blood volumes than pH) or STAN monitoring (monitoring elevation of the ST segment of the ECG, requiring specialist equipment not universally available in the UK). Options also include changing clinical circumstances (stopping oxytocin, change of maternal position, amnio-infusion) or consideration of delivery. Each of these options can be considered in the context of the individual situation, available equipment and the wishes of the parents to be, but should be discussed with senior obstetric and midwifery personnel.

Other maternal and fetal monitoring recommendations are shown in Table 43.1.

CAUSES OF DYSTOCIA

The mnemonic of the '3 Ps' relates to the relative incidence of the common causes of dystocia in labour. The first P (**powers**) relates to uterine contractions, or inefficient uterine activity, and may be corrected using amniotomy or oxytocin. Inefficient uterine action rarely occurs in a multiparous woman in spontaneous labour and therefore great care needs to be taken when considering the use of oxytocin to correct slow progress in labour, especially in the second stage of labour. The obstetrician would be wise to consider why a woman would not make progress in the second stage

when her pains have been sufficient until then to achieve full dilatation.

The second (**passenger**) relates to the position of the fetus, with an OP position being a relatively common cause of delay in both the first and second stage. Correction of malposition needs to be individualised to both the type of malposition and the individual patient, and to the experience of the clinician. Recently there have been several papers published assessing the use of ultrasound to diagnose malposition in labour, especially as part of the assessment for instrumental delivery.

The final P refers to the **passage** – or the relationship of the fetus to the pelvis. Only when both the powers and the passenger have been corrected can the diagnosis of dystocia due to the passage (or cephalo-pelvic disproportion, CPD) be made. In the National Maternity Hospital in Dublin great care is taken to make the correct indication for delivery so as not to over-diagnose CPD due to the possible implications for further deliveries. Here a woman being delivered by CS for 'dystocia – unable to treat' (as oxytocin caused decelerations on the CTG) is different to the woman delivered by CS for 'dystocia – unsuccessful treatment' (following a full course of oxytocin in an infant with an OA position), and as such would receive different recommendations regarding future deliveries.

A fourth P can be added to the mnemonic to consider a cause of slow progress in the second stage – the **perineum**.

DELIVERY

The NICE Guidelines distinguish between a passive and active second stage of labour and recommend that birth should take place within 3 hours of start of the active second stage

(2 hours in multiparous women). Prolongation of the second stage of labour is associated with increased maternal and neonatal morbidities. Interestingly, prolongation of the active second stage, but not the passive stage, is associated with an increased risk of PPH (adjusted OR 10.6 compared to baseline <10 minutes) [C].³¹ Prolongation of the second stage is also associated with a higher risk of long-term complications such as urinary incontinence³² and cervical insufficiency in a future pregnancy (OR 24.9) [C].³³

It is recommended that a diagnosis of delay in the second stage should be made when it lasts more than 2 hours (1 hour in multiparous women) and the woman transferred to the care of a healthcare professional who is competent in performing an instrumental delivery [E]. Once the decision is made that an instrumental delivery may be required, the decision itself does not protect against the risks of an unintentional further prolonged labour, with one study showing that 74 per cent of prolonged second stages occurred while waiting after a decision had been made to perform an instrumental delivery [C].³⁴

Women may choose to labour in the second stage in a supine, lateral, upright or 'all-fours' position. A systematic review showed several benefits (reduction in assisted births, episiotomies and abnormal FHR patterns) to women labouring upright but a possible increase in blood loss >500 mL. As the methodological quality of the papers varied the authors recommended that the results be interpreted with caution³⁵ [A] but that at present women should be allowed to make choices about which birth position they assume, which in turn can affect the woman's sense of control during labour [D].³⁶

POSTNATAL CARE

Active management of the third stage of labour involves administration of prophylactic uterotonic, early cord clamping and controlled cord traction for delivery of the placenta. Active management reduces the risk of PPH, the need for further uterotonics and the need for blood transfusion³⁷ [A] but increases maternal vomiting after birth, after-pains and use of analgesia.

One area of active management of the third stage causing much recent controversy relates to the timing of cord clamping. Advocates of delayed cord clamping cite increased birth-weight and neonatal Hb due to the placental transfusion of blood after delivery, whereas others have concerns regarding the risk of maternal haemorrhage. Assessment of late clamping (>1 minute after birth or after the cord has stopped pulsating) as an individual component of the active management of the third stage showed no difference in the rate of severe PPH in early versus late clamping, with increased neonatal Hb and iron stores, and an increased requirement for phototherapy for jaundice in the late group [A].³⁸

Following delivery, it is recommended that observations be based on the woman's general physical condition and her

degree of blood loss. This is based on a lack of high-level evidence on maternal observations in the third stage of labour, but lack of evidence does not imply lack of effect. At least one set of vital observations should be taken in this time so as to provide objective measurement of maternal wellbeing, especially when there has been an abnormality detected in the first or second stage of labour [E].

CONCLUSION

The majority of women will conceive spontaneously, have a normal pregnancy and deliver vaginally without incident. Despite this normality, labour and delivery are among the most profound physical and emotional times in a woman's life, and it is our privilege to work as a team in caring for women and their families at this time.

Chapter 44 Preterm labour

Myles Taylor and Stuart Rundle

MRCOG standards

Candidates are expected to:

- Be conversant with the appropriate use of tocolysis and steroids in preterm labour.
- Be able to manage preterm labour and in-utero transfer of the mother.
- Be able to recognise and manage intrauterine infection.

In addition, we would suggest the following:

Theoretical skills

- Understand the contribution of spontaneous preterm delivery to overall perinatal morbidity and mortality.
- Have access to and utilise mortality and morbidity figures, stratified by gestation.
- Be aware of the aetiologies behind spontaneous preterm labour and how they vary with gestation.
- Recognise major and minor risk factors for spontaneous preterm birth.
- Be aware of specialised screening tests for predicting preterm delivery.

Practical skills

- Formulate a plan for the antenatal management of asymptomatic women recognised to be at increased risk of spontaneous preterm birth.
- Be able to manage women in threatened preterm labour with regard to obstetric interventions and counselling regarding neonatal prognosis.
- Perform an ultrasound scan to confirm presentation and gestation.
- Be able to use tocolytic agents safely, with regard to dosage, route of administration, side effects and contraindications.
- Be able to undertake a preterm delivery, including delivery by caesarean section.

INTRODUCTION

There are two major clinical subtypes of preterm births. *Indicated preterm deliveries*, undertaken for maternal or fetal reasons, make up approximately one third of all such births. The remaining two thirds are classified as *spontaneous preterm births* and have two subdivisions: spontaneous preterm labour and preterm pre-labour rupture of the membranes (PPROM).

DEFINITION

In the UK, preterm birth includes all deliveries between 24⁺⁰ and 36⁺⁶ weeks. Many developed countries now officially register all deliveries with a birthweight above 500 g. In 2011, 7.1 per cent of UK livebirths were preterm with 5.6 per cent of singletons and 53.1 per cent of multiple pregnancies delivering before 37 completed weeks of gestation. For reasons related to aetiology, outcome and recurrence risk, the WHO divides preterm deliveries into three gestational periods:

- moderate to late preterm births at 32⁺⁰ to 36⁺⁶ weeks (incidence 5.5 per cent);
- very preterm births at 28⁺⁰ to 31⁺⁶ weeks (incidence 0.7 per cent);
- extreme preterm births at 24⁺⁰ to 27⁺⁶ weeks (incidence 0.4 per cent).

Significantly higher rates of preterm birth of up to 12 per cent are reported from the United States. Conversely, many Nordic countries quote rates below 5 per cent. This must reflect differing aetiological, socio-economic and cultural factors.

NEONATAL OUTCOMES

Survival

When counselling parents, doctors must use perinatal statistics that are up to date and, where possible, reflect local outcomes. The UK Office for National Statistics (ONS) produces an

annual report providing accurate, high-quality and up-to-date data regarding gestation-specific neonatal and infant mortality in England and Wales. In 2011, the overall infant mortality for preterm babies born between 24 and 37 weeks of gestation was 25.4 deaths per 1000 livebirths, compared with 1.5 deaths per 1000 livebirths for babies born at term, though the rates of mortality for preterm births are not linear (Fig. 44.1). Predicted survival can be modified by accurate estimates of fetal weight or antenatal assessments of fetal wellbeing.

Morbidity

The risks of later neurodevelopmental impairment, disability and handicap are especially significant within the 24–26-week gestational window. The UK-based EPICure Study reported that 50 per cent of the survivors at 23–25 weeks' gestation were impaired, half with severe disability.¹ In another study, up to 40 per cent of survivors born before 26 weeks' gestation were found to have a head circumference below the third centile at two years of age, after which little 'catch-up' growth is possible.² Follow-up of very-low-birthweight children to school age has also shown later educational difficulties.³ Additional concerns relate to social behaviour, as well as subsequent influences on adult health.

AETIOLOGY AND PATHOGENESIS

Several mechanisms are described for the pathogenesis of preterm birth. With the possible exception of true cervical weakness or incompetency, these mechanisms seem to share a final common pathway that involves up-regulation of prostaglandin production and the production of uterotonic agents and enzymes that weaken the fetal membrane and degrade cervical stroma. Activation of the fetal hypothalamic–pituitary–adrenal axis, long hypothesised as a potential initiating mechanism in normal labour, may also be implicated in preterm labour.

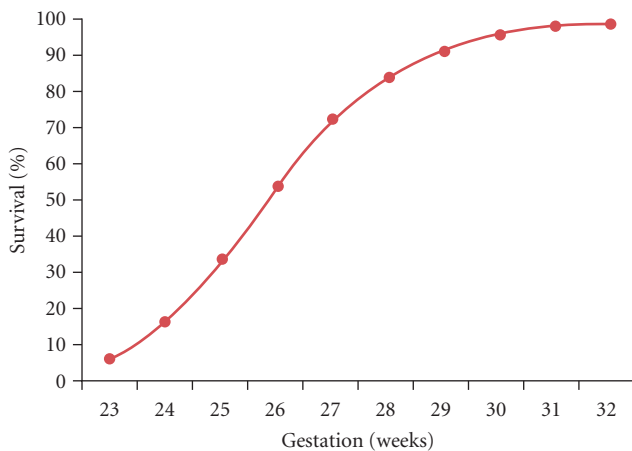

Fig. 44.1 Percentage predicted survival for European infants known to be alive at the onset of labour

Infection

Subclinical infection of the choriodecidual space and amniotic fluid is the most widely studied aetiological factor underlying spontaneous prematurity. Many indirect lines of evidence support the role of subclinical infection in human preterm labour, including the following:

- Vaginal colonisation with a variety of micro-organisms has been associated with an increased risk of spontaneous prematurity. However, it is plausible that the presence of such pathogens may simply be markers for other socio-economic, sexual or behavioural factors that ultimately lead to preterm labour.
- If an amniocentesis is performed in preterm labour with intact membranes, 10–15 per cent of amniotic fluid samples result in positive cultures.
- Histological chorioamnionitis is much more common after spontaneous preterm birth, with lower gestational ages having a higher likelihood of infection [A]. Of note, most cases are subclinical, with only 10 per cent of histologically proven cases of chorioamnionitis having overt clinical signs of infection.

Vascular

Spontaneous prematurity has been associated with an increase in membrane haemosiderin deposits, thought to reflect decidual haemorrhages. The link between placental abruption and either uterine activity or PPRM is well recognised.

Uterine over-distension

Multiple pregnancy and polyhydramnios are the most common causes of uterine distension. Myometrial stretch has been shown to result in up-regulation of oxytocin receptors and prostaglandin production. Stretch of the fetal membranes may also result in the formation of prostaglandins and other cytokines that are key to the initiation of labour.

Multiple pregnancy

In 2011, 1.6 per cent of all maternities in the UK involved multiple pregnancies, mostly twin pregnancies. The median gestation at delivery for twins is approximately 35 weeks and for triplets 33 weeks. Presently, assisted reproduction techniques (ART) are responsible for up to one third of twin pregnancies and three quarters of triplets, leading to an increasing burden of preterm births. The UK HFEA has strategies in place for reducing the number of multiple pregnancies resulting from ART to no more than 15 per cent of assisted conceptions. In those pregnancies affected by higher-order multiples, multifetal reduction has been shown to reduce the risk of preterm birth and should always be considered.

Polyhydramnios

Fetal anomalies, such as atresias of the gastrointestinal tract, are the most common cause of polyhydramnios leading to preterm delivery.

Intercurrent illness

Serious infective illnesses such as pyelonephritis, appendicitis and pneumonia are associated with preterm labour. This association is presumed to be due either to direct blood-borne spread of infection to the uterine cavity or indirectly due to chemical triggers, such as endotoxins or cytokines. Many other medical complications, such as cholestasis of pregnancy and any surgical procedures, are associated with preterm labour, although the mechanisms remain obscure. Intercurrent illness may also result in iatrogenic indicated preterm birth for maternal or fetal reasons.

Cervical weakness

This remains a notoriously difficult diagnosis to make, either within or outside pregnancy. Even a careful review of the clinical events leading up to preterm labour and delivery does not necessarily show correlation with the aetiology.

Relationship between gestation and aetiology

Studies involving the use of amniocentesis in threatened preterm labour found most positive amniotic fluid cultures to be from pregnancies presenting before 30 weeks' gestation. The incidence and severity of histological chorioamnionitis also show an inverse relationship with gestational age. Thus, the earliest births carry the highest risk of an infectious aetiology. Intrauterine infection has also been associated with an increased risk of various neonatal morbidities, independent of gestation at birth. These include:

- periventricular leukomalacia;
- cerebral palsy;
- bronchopulmonary dysplasia.

These pathologies are presumed to be secondary to high circulating levels of inflammatory cytokines. This leads to the paradox of prematurity; namely, those fetuses who stand to gain most by delaying delivery also carry the greatest risk from prolonged exposure in a potentially hostile uterine environment.

RISK GROUPS

Owing to limited resources and a paucity of beneficial interventions in low-risk women, most aspects of prematurity prevention should be targeted at women with major risk

factors for preterm birth. These major risk factors include the following.

Epidemiological and personal factors

There are a variety of minor risk factors for spontaneous preterm birth that carry importance in epidemiological terms. The relative risk attributable to each factor is small. Some minor risk factors carry importance because they are potentially modifiable. These include:

- smoking;
- low BMI;
- interpregnancy interval of less than one year.

Other minor risk factors that are not amenable to influence include:

- maternal age (teenage multiparae);
- parity (nulliparous or grandmultiparous);
- ethnicity (black women);
- socio-economic deprivation;
- unemployment;
- low levels of education.

Reproductive factors

Preterm birth shows a tendency for recurrence. After one preterm birth, the risk in the next pregnancy is approximately 20 per cent. After two preterm deliveries, this risk increases to 35–40 per cent. Where the most recent birth was at term, but the penultimate delivery was preterm, recurrence risks are intermediate. As well as a tendency for preterm births to recur in the same gestational age group, the earliest births have the highest recurrence risks. This presumably reflects differing aetiologies predominating at different gestations. Recent epidemiological evidence suggests that a history of preterm birth in a twin or higher-order pregnancy is a risk factor for preterm birth in a subsequent singleton pregnancy and that the risk is greatest if the twin birth occurred at less than 34 weeks.⁴ The risk of preterm birth in a twin pregnancy following prior singleton spontaneous preterm birth is considerable at up to 67 per cent, compared to 21 per cent if the previous singleton was delivered at term.⁵

Anatomical factors

Although there is little evidence upon which to estimate either individual risk or the total contribution to preterm births, the malformed uterus has long been associated with spontaneous prematurity. Uterine and cervical abnormalities may be congenital or acquired: unicornuate uterus has been reported to result in a preterm birth rate of 17 per cent, though other minor uterine abnormalities may be amenable to surgical correction before conception, thus lessening the risk. The role of fibroids in preterm delivery remains controversial;

considering their frequency, their influence is probably minimal in the absence of cervical involvement.

Cervical surgery, such as cone biopsy, remains a classic risk factor. A 2006 meta-analysis⁶ and more recent studies have also implicated large-loop excision of the transformation zone in an approximate doubling of the rate of preterm births in women having undergone this procedure. The evidence associating large-loop excision with preterm birth, however, remains contradictory and it is likely that variables such as the number of treatments or depth of cervical tissue excised are important determinants of the absolute risk. In addition to cervical excision surgery, epidemiological evidence casts doubt on the benign nature of surgical cervical dilatation, the risk of subsequent preterm delivery increasing with the number of previous cervical dilatations.

Current pregnancy factors

Uterine over-distension secondary to multiple pregnancy or pregnancies known to be at risk of polyhydramnios requires careful monitoring. Intercurrent illness, surgery during pregnancy and recurrent vaginal bleeding are all risk factors for preterm birth.

MANAGEMENT OF ASYMPTOMATIC HIGH-RISK WOMEN

A careful analysis of events surrounding the previous birth should be undertaken. The risk of recurrence may be adjusted if there were non-recurring phenomena, such as fetal anomaly or intercurrent illness.

Investigation and treatment outside pregnancy

Ideally, women should be seen in the postnatal period and the events leading to their preterm birth reviewed. Following this, a clear management plan for any subsequent pregnancy should be made [E]. The importance of smoking cessation should be stressed [C] and the potential benefit of leaving 12 months between pregnancies should be discussed [C]. Dietician referral may be appropriate for women with a low BMI.

Investigation and treatment during pregnancy

Early dating scan

A first-trimester dating scan is essential to time subsequent investigations. It also ensures precise gestational age assessment should preterm labour recur near the limits of neonatal viability [E].

Bacterial vaginosis

Bacterial vaginosis (BV) has been associated with an increased risk of preterm birth in many observational studies. Randomised studies, such as that of Hauth *et al.*,⁷ have demonstrated that oral metronidazole significantly lowers the risk of preterm birth, by 60 per cent in high-risk women positive for BV [A]. As there is concern that BV may reflect chronic intrauterine infection, 5–7 days of oral therapy at standard doses seems appropriate. A large trial using briefer therapy has not shown benefit. Several randomised, placebo-controlled studies have suggested an increase in moderately preterm birth (32–34 weeks) in BV-positive women randomised to vaginal clindamycin cream. One hypothesis is that topical therapy adequately treats vaginosis, but fails to affect pre-existing intrauterine infection.

Asymptomatic bacteriuria

This carries an increased risk of preterm birth. Although it may simply be a marker for heavy vaginal microbial colonisation, a meta-analysis of many trials confirms that risk is reduced by appropriate antibiotic treatment [A]. An alternative explanation for the association with preterm birth may be an increased risk of pyelonephritis in women presenting with asymptomatic bacteriuria.

Group B streptococcal colonization

Group B streptococcal (GBS) colonisation has been linked to prematurity. Preterm infants are certainly more susceptible to early-onset GBS infection, acquired during passage through the birth canal. However, evidence that it is one of the major causal organisms behind spontaneous prematurity remains weak. GBS is a commonly found organism in asymptomatic bacteriuria. RCOG currently do not recommend screening for GBS and only intrapartum treatment should be given [A], as antenatal antibiotics have not been shown to lower perinatal transmission. It is, of course, very common for women who know they are colonised to request antenatal treatment. Women should be advised that several studies from North America have reported that over-aggressive prophylactic treatment of GBS has led to an increase in neonatal infections with penicillin-resistant *Escherichia coli*. In pregnancy, as elsewhere, antibiotics have the potential for harm.

Other organisms

Organisms such as *Chlamydia trachomatis*, *Neisseria gonorrhoeae* and *Trichomonas vaginalis* have been associated with preterm delivery but, again, a causal link has not been established. Antenatal treatment of chlamydia has not been shown to lower prematurity rates, although it may prevent perinatal transmission. Treatment of chlamydia and gonococcus must always include contact tracing and treatment of the partner. These are best accomplished in conjunction with the department of genitourinary medicine.

Cervical ultrasound

Cervical length can be accurately and repeatedly measured by ultrasound. The risk of prematurity is inversely related to cervical length [C].⁸ These measurements should only be made by transvaginal scanning, as the full bladder necessary for visualisation transabdominally leads to false lengthening and can obliterate gross funnelling. Transvaginal ultrasound has been shown to be more accurate than digital measurements for assessing cervical length. The test has predictive ability in all groups of women (low risk, high risk, twins, symptomatic, etc.). In asymptomatic women with a short cervix, the risk of moderately preterm delivery rises only slightly, to 4 per cent, with lengths of 11–20 mm. At 10 mm, the risk is 15 per cent and it increases dramatically as length decreases further. RCOG's Green-top guideline Cervical Cerclage (2011) recommends that serial sonographic cervical length measurements may be offered from 14 weeks' gestation for women who have previously undergone one or more second-trimester losses or preterm delivery. Other groups that are considered at increased risk of preterm delivery, including multiple pregnancy, uterine abnormality and previous cervical surgery or dilatation, do not have sufficient evidence for benefit of cervical cerclage to allow recommendation of serial cervical length scans in the absence of previous preterm birth [B].

Cervical cerclage

After documentation of a shortened cervix on ultrasound, randomised trials of cerclage versus observation have shown contradictory results. Perhaps more importantly, cervical ultrasound is able to exclude weakness – if the cervix is long, surgical intervention can be avoided. The Medical Research Council Randomised Trial of Cervical Cerclage highlighted over-intervention based on simple clinical assessment, suggesting benefit in only 4 per cent of cases.⁹ In a more detailed analysis, cerclage without ultrasound-documented shortening led to improved outcomes only after three or more previous very early deliveries [B]. Current RCOG guidance is that women with a history of three or more second-trimester pregnancy losses or preterm deliveries may be offered a history-indicated cerclage. Women with a history of one or more losses or preterm deliveries may be offered serial cervical ultrasound with the option of cerclage if the ultrasound-measured cervical length falls to 25 mm or less before 24 weeks' gestation. In clinical practice, however, many clinicians have lower history-related thresholds for both serial cervical measurement and cerclage.

The relative merits of McDonald versus Shirodkar transvaginal cerclage have long been debated and remain unresolved. Some authors have advocated transabdominal sutures, particularly when a previous transvaginal cerclage has failed. These are placed at the level of the internal os via a Pfannenstiel incision or performed laparoscopically. They are permanent and necessitate caesarean section for delivery. Their use has not been subjected to rigorous testing. They have a number of theoretical disadvantages, including the need for abdominal delivery if preterm labour occurs regardless of

gestation, and they are associated with the operative morbidity of any abdominal procedure. They are probably only rarely required and their use should be restricted to clinical trials.

Progesterone supplementation

There is increasing evidence suggesting that progesterone supplementation can reduce the incidence of preterm delivery, particularly in high-risk groups. Progesterone is available in two forms – natural, usually administered vaginally, and synthetic, 17-alpha-hydroxyprogesterone administered intramuscularly. In singleton pregnancies with a history of previous preterm delivery, a 2013 meta-analysis of 36 RCTs¹⁰ concluded that exogenous progesterone is protective against recurrent preterm birth, with administration of antenatal progesterone associated with a reduction in the risk of birth before 34 weeks' gestation (RR 0.31, 95% CI 0.14–0.69) and before 37 weeks (RR 0.55, 95% CI 0.42–0.74). The two most important trials showing benefit used different formulations, routes and doses of progesterone. Furthermore, the same meta-analysis reported a reduction in the incidence of a number of adverse neonatal outcomes including neonatal death (RR 0.45, 95% CI 0.26–0.76) and a potential beneficial effect in women identified as having a short cervix on ultrasound examination. Intriguingly, progesterone supplementation does not appear to prevent preterm birth in multiple pregnancies. Further studies are required to define the optimum preparation, dose, timing, route of administration and indications for progesterone supplementation. Currently, the American College of Obstetricians and Gynaecologists recommends progesterone supplementation be restricted to women with a singleton pregnancy and a previous history of spontaneous preterm birth,¹¹ while RCOG recommends its use be restricted to clinical trials until the short- and long-term fetal effects of therapy become clearer.

Vaginal pessaries

Vaginal pessaries have been proposed as a non-invasive alternative to cervical cerclage in women with a short cervix and at risk of spontaneous preterm birth. A 2013 Cochrane review¹² included just one well-designed RCT that showed a beneficial effect of cervical pessaries in reducing preterm birth, but concluded that more trials in different settings and with different risk factors were needed.

Cervico-vaginal fibronectin testing

This is undertaken after 22 weeks, as levels are often high prior to this gestation. Fetal fibronectin (fFN) is a 'glue-like' protein binding the chorio-decidual membranes. It is rarely present in vaginal secretions between 22 and 34 weeks. Any disruption at the chorio-decidual interface results in fFN release and possible detection in the cervico-vaginal secretions. A bedside test is available that has improved upon clinical ability to predict preterm labour. Technique is important in performing the test. Digital examination of the cervix should not have been performed prior to fFN testing and no lubricating jelly used. Only the swab supplied with the testing kit should be used

and it should be immersed in the pooled vaginal secretions from the posterior fornix for 15–20 seconds. Endocervical swabbing should not be undertaken and it should be noted that sexual intercourse within the 24 hours prior to testing or recent vaginal bleeding might lead to a false-positive result.

Qualitative testing kits return a positive or negative result with fFN concentrations of 50 ng/L used as a threshold for positivity. For high-risk asymptomatic women with a positive fFN test at 24 weeks' gestation, 46 per cent will deliver before 30 weeks' gestation.¹³ Conversely, the risk of preterm delivery is less than 1 per cent with a negative test.

Presently, clinicians can use the high negative predictive value of fFN testing to either withhold or optimise the timing of therapies such as antenatal steroid administration. There is no specific treatment for a positive fFN result in asymptomatic women.

Salivary oestriol

A salivary oestriol surge has been reported up to 3 weeks before onset of labour. Its usefulness in predicting preterm birth has not been proven.

Home uterine activity monitors

An increase in painless uterine activity may precede the onset of labour. However, the early detection of this increased activity has not been found to reduce the incidence of prematurity. This is not surprising, as no effective prophylactic treatment has yet been found that suppresses contractions. Many studies, meta-analyses and reviews have shown no evidence of benefit from oral ritodrine. At present, the conclusions for other maintenance tocolytics, such as nifedipine or GTN patches, must be similar, given the paucity of well-controlled studies supporting their use.

Lifestyle modification

Women at high risk should be counselled about smoking [C]. Work from France suggested that increased social and economic support for women believed to be at risk of preterm delivery led to a reduction in early births. Such results have not been replicated elsewhere. Randomised trials of social support in the UK failed to improve pregnancy outcomes [B]. In some situations, hospitalisation for bed rest led to an increase in preterm births [A]. The roles of sexual abstinence and/or psychological support are no clearer and should not be recommended as a universal or general measure in high-risk women.

MANAGEMENT OF SYMPTOMATIC WOMEN

History

The diagnosis of preterm labour remains notoriously difficult in the absence of advanced cervical dilatation or ruptured membranes. A detailed review of current symptoms

is necessary. Symptoms such as low backache or cramping are often cyclical. Vague complaints, such as pelvic pressure or increased discharge, are common. The coexistence of vaginal bleeding should always be taken seriously. In a woman presenting with contractions, the risk of delivery within 7 days if she has vaginal bleeding and a closed cervix is actually greater than if she presented with no bleeding, but 2 cm of cervical dilatation.

Examination

Abdominal examination may reveal the presence of uterine tenderness, suggesting abruption or chorioamnionitis. A careful speculum examination by an experienced clinician can yield valuable information. Pooling of amniotic fluid, blood and/or abnormal discharge should all be commented on. A visual assessment of cervical dilatation is usually possible and has been shown to be as accurate as digital examination findings. Medical staff should try to limit digital examinations to cases in which speculum assessment is inconclusive, as they are known to stimulate prostaglandin production and may introduce organisms into the cervical canal. When undertaken in cases of PPRM, digital examinations are associated with a significant reduction in the latent interval before labour.

Further investigation

Repeat vaginal examination

Repeat vaginal examination in 1–4 hours should be considered essential in the absence of secondary tests. The interval between assessments should be guided by the severity of the symptoms.

Bedside fibronectin testing

This offers a rapid assessment of risk in symptomatic women who do not have advanced dilatation. If done correctly, these tests have a greater predictive value than digital examination. In one study, 30 per cent of women with a positive fibronectin test delivered within 7 days, compared with only 10 per cent of women who were 2–3 cm dilated.¹⁴ Quantitative testing kits are now available that return an fFN concentration for interpretation by the clinician. A recent publication, in association with the manufacturer, reports increasing positive predictive values for spontaneous preterm birth with incrementally increasing fFN concentrations from 10.9 per cent to 46.2 per cent for concentrations of 10 ng/L and 500 ng/L, respectively, in women with symptoms of preterm labour.¹⁵

Cervical length measurement

Cervical length measurement by transvaginal ultrasound in symptomatic women has also been shown to improve diagnostic accuracy. Although measurements can be repeated frequently and with little expense, skilled ultrasonographers and suitable machines with transvaginal probes are required.

Post-assessment risk

This should be based on the complete picture. A realistic end-point should be the chance of delivery within the next 7 days. If this risk is judged to be low, serial observation and review are appropriate. If the risk is high, treatment strategies to optimise perinatal outcome should be implemented.

In symptomatic women, a positive fibronectin test carries a risk of delivery within 28 days of up to 70 per cent, regardless of initial cervical length. Combination testing refines the prediction of deliveries in the next 7 days. In the group with a positive fibronectin test but a normal cervical length, only 5 per cent will deliver within 1 week.¹⁶ However, if the cervix is also short when tested, the risk of delivery within 7 days climbs to 50 per cent. This is particularly useful, as many interventions (tocolytics, steroids and in-utero transfer) should be based on this end-point.

THERAPY

Transplacental therapy

Steroids

Current evidence shows that a single course of maternal steroids given between 26 and 34 weeks' gestation and received within 7 days of delivery results in markedly improved neonatal outcomes [A], with a significant reduction in the risk of:

- respiratory distress syndrome (44% reduction in risk, 95% CI 31–57%);
- neonatal death (31% reduction in risk, 95% CI 19–42%);
- intraventricular haemorrhage (46% reduction in risk, 95% CI 31–67%).

Maximum benefit from the injection is seen between 24 hours and 7 days after administration of the second dose of antenatal corticosteroid. In the most recent Cochrane review (2006) of this subject, treatment over a wide gestational range (26–34⁺⁶ weeks) resulted in clinical benefit. On the other hand, courses received less than 24 hours and more than 7 days before delivery did not produce a significant reduction in respiratory distress syndrome. In general, no convincing difference is seen between betamethasone and dexamethasone as long as a total dose of 24 mg of either drug is administered over a 24- to 48-hour period. There is considerable reassuring evidence about the long-term safety of single courses of maternal steroids from paediatric follow-up into the teenage years. However, clinicians should only cautiously employ repeat courses, as there is growing concern about adverse consequences and little evidence of improved outcome.^{17,18} Published examples of potentially harmful effects of repeated doses include:

- increased sepsis in PPRM;
- restricted fetal body and brain growth;
- adrenal suppression.

Most worrying is the increased risk of neonatal death seen when three or more courses of antenatal steroids were given in the American TRH Study.¹⁹ Any extensions to the accepted gestational window should also be made cautiously. There may be limited steroid responsiveness in fetuses at or below 25 weeks' gestation. As there is little proof that steroids are beneficial, their use may lead to overoptimism. Although RCOG's Green-top guideline Antenatal Corticosteroids to Reduce Neonatal Morbidity and Mortality (2010) recommends steroids from 24 weeks' gestation, this recommendation is not based on evidence from randomised trials. More worryingly, using steroids when inappropriate may hinder later use, particularly when clinicians are wary of multiple courses. The upper gestation at which steroids should be used is also controversial. In comparison to PPRM and preterm labour, elective caesarean deliveries after 34 weeks are at increased risk of respiratory difficulties and administration of prophylactic steroids has been shown to reduce the risk of neonatal unit admission for babies born by caesarean section before 39 weeks of gestation [A]. In addition, there is some evidence that growth-restricted fetuses may derive benefit from antenatal steroid administration up to the 36th week of gestation [C] if planned late preterm birth is indicated.

Although there is a paucity of evidence that steroids are beneficial in multiple pregnancy, most expert opinion supports their use. Even more caution should be used before embarking on repeat courses in this situation. Corticosteroids can cause significant glycaemic disruption in diabetic women. They should be used in conjunction with increased glucose monitoring and adjusted insulin doses. The effects can last up to 24 hours after the second dose of steroids.

Magnesium sulphate

Antenatal magnesium sulphate is gaining increasing utility as a strategy to reduce the rates of cerebral palsy (CP) associated with preterm birth [A]. In children born preterm, a larger proportion (49 per cent) of CP will have perinatal aetiology when compared to children with CP born at term (35 per cent). To date, five RCTs have investigated the neuroprotective effects of magnesium sulphate when administered antenatally to women at high risk of preterm birth. A Cochrane review of these trials²⁰ concluded that antenatal administration of magnesium sulphate reduced the risk of cerebral palsy (RR 0.68, 95% CI 0.54–0.87) and gross motor dysfunction (RR 0.61, 95% CI 0.44–0.85). It is recognised that the magnitude of the beneficial effect is likely to be higher at earlier gestations and limited at gestations above 32 weeks. For this reason and due to concerns over adverse neonatal outcomes reported in an earlier trial, its use above 32 weeks' gestation is not advocated.

Dosing and administration should be according to locally agreed guidelines. In general, antenatal magnesium sulphate should be considered when spontaneous or iatrogenic preterm birth is likely to occur within 24 hours. The University of Adelaide guideline panel has proposed a bolus and maintenance regime with cessation of the maintenance infusion at

birth or after 24 hours, whichever is sooner.²¹ If birth does not occur following initial treatment with magnesium sulphate and delivery is again considered imminent prior to 32 weeks' gestation, re-treatment is not recommended due to inadequate data regarding benefit or harm.

Tocolytics

The use of tocolytics is usually inappropriate if steroids have been given and intensive care cots are available. They should not be used if there is a contraindication to prolonging pregnancy, for example in cases of intrauterine infection or severe pre-eclampsia. There is no clear evidence that tocolytic drugs improve outcome [A] and they have no impact on the rate of preterm birth or clear effects on perinatal or neonatal morbidity. Their use is, however, associated with prolongation of pregnancy by up to 7 days and so it is reasonable to use them in uncomplicated women in suspected early preterm labour needing transfer to a hospital which can provide suitable neonatal care or in those who have yet to complete a course of antenatal steroids or in whom antenatal magnesium sulphate is indicated.

Beta-agonists

The Canadian trial remains the most influential tocolytic trial to date.²² This trial concluded that ritodrine (a beta-agonist) was able to reduce the number of women delivering within 48 hours by 40 per cent [A]. These drugs have significant maternal side effects, including hypotension, tachycardia, anxiety and palpitations. Maternal deaths from acute cardiopulmonary compromise are described, with greatest risks:

- if beta-agonists are given in large fluid volumes;
- in multiple pregnancy;
- in women with cardiac disease.

In women with diabetes, significant extra glycaemic disruption additional to that caused by steroids occurs with beta-agonists. As such the use of ritodrine for tocolysis has declined, though it is still licensed for this indication in the UK.

Oxytocin antagonist

The oxytocin antagonist atosiban is now widely used in the UK, mainly because of the significantly reduced frequency of side effects compared to beta-agonists. It is the only drug apart from ritodrine to be licensed for tocolysis in early preterm labour. Its clinical effectiveness is no greater than that of the beta-agonists or calcium channel blockers and costs are higher [B].

Calcium channel blockers

Although the use of nifedipine for tocolysis in early preterm labour is an unlicensed indication, it has the advantages of oral administration and relatively low cost in comparison to atosiban. Nifedipine and atosiban have comparable clinical

effectiveness in delaying birth for up to 7 days [A]. Compared with ritodrine, nifedipine has a favourable side-effect profile and it is associated with improvement in neonatal outcome compared to other tocolytic agents [B].

Other agents

Other smooth-muscle relaxants used to treat preterm labour include magnesium sulphate and GTN. There is little evidence to suggest increased efficacy or improved outcomes [B] and none has a licence for use in pregnancy. As prostaglandins appear to be one of the pivotal chemicals involved in parturition, NSAIDs such as indomethacin and COX-inhibitors have attracted considerable interest as tocolytics. There are potential fetal side effects such as premature closure of the ductus arteriosus and consequent fetal pulmonary hypertension, but these can be limited by restricting their use to less than 72 hours and only below 30 weeks' gestation. Maternal gastrointestinal side effects are less marked with selective COX-inhibitors; however, there is evidence of excess cardiovascular morbidity when these drugs have been used in other settings. Their use is not widespread at present.

Antibiotics

The UK Oracle II Study found no evidence of benefit for the use of antibiotics in uncomplicated preterm labour²³ [A] and seven-year follow up showed a significant increase in the incidence of cerebral palsy.²⁴ On the other hand, significant advantages are obtained when antibiotics are prescribed to women with preterm pre-labour rupture of membranes without an associated increase in cerebral palsy in the long term.²⁵

Emergency cervical cerclage

Occasionally, women present in the mid-trimester with relatively minor symptoms (pelvic pressure, watery discharge, etc.) and, when examined, are found to have membranes bulging into the upper vagina. If considering emergency cerclage, clinicians need to be aware that there is no randomised evidence for guidance and few reports of the outcome after expectant management. Two clinical issues must be considered. First, is this a reflection of marked cervical weakness or is the cervix responding to uterine activity? A history of significant cervical surgery may be helpful. If symptomatic contractions are present, the answer is clear. Otherwise, all clinicians can do is reassess the cervical dilatation after several hours. This can be precisely and repeatedly measured non-invasively using transperineal ultrasound. Second, is there any evidence of intrauterine infection? Only 10 per cent of cases of chorioamnionitis are clinically obvious but, if it is present, cerclage is doomed to fail. A suggested way to assess this is by amniocentesis, but this is rarely performed in practice.

In-utero transfer

In-utero transfer to a unit with adequate neonatal facilities is recommended where these are not available in the admitting unit [D]. It would seem logical that this will improve

outcome for babies. It should certainly be considered where neonatal stabilisation would be difficult or impossible. It may also help to keep mother and baby together where transfer of the mother after delivery is likely to be difficult. All units should have guidelines for referral and communication.

FETAL ASSESSMENT

Maternal steroid therapy can suppress both fetal activity and heart rate variability. Umbilical artery Doppler studies can also be influenced. In fetuses with absent/reversed end diastolic flow (EDF), a short-term return of EDF is commonly observed.

When labour has started or is thought to be imminent:

- Whenever possible, the presentation in preterm labour should be confirmed by ultrasound, as clinical palpation is notoriously unreliable;
- An accurate estimated fetal weight, particularly below 28 weeks, can aid parental counselling.

There are considerable difficulties surrounding the interpretation of the FHR in preterm infants, particularly at extremely early gestations. Simply applying the criteria used at term is inappropriate. Some work has suggested that the baseline rate is more important than either decelerations or variability. Of note, RCTs have failed to show any benefit from continuous as opposed to intermittent monitoring in moderately preterm births [B].²⁶ Decisions regarding monitoring in labour at very preterm gestations must be discussed with parents. Intervention on the basis of FHR monitoring may not be justifiable near the limits of viability.

MODE OF DELIVERY

Many clinicians feel that fetal morbidity and mortality, the difficulty in diagnosing intrapartum hypoxia/acidosis and the maternal risk do not justify caesarean section for fetal indications below 26 weeks. At this early gestation, intrapartum caesarean section has not been shown to improve neonatal outcomes. As gestation advances, both neonatal outcomes and the ability to diagnose fetal compromise improve, and intervention for fetal reasons becomes universally appropriate. The safety of breech vaginal delivery is often questioned based on observational data suggesting an increased mortality and morbidity in the preterm breech born vaginally. However, there are recent similar studies that conclude the opposite.²⁷ Although the obstetric community agreed on the need for a well-conducted RCT to answer this question, this was not translated into recruitment when trials were attempted. A careful attempt at vaginal breech delivery, preferably under epidural analgesia, is not absolutely contraindicated [C].

Type of caesarean section

At the earliest gestations, the lower segment is poorly formed, often leading to vertical uterine incisions. A classical uterine incision carries up to a 12 per cent risk of uterine rupture in subsequent pregnancies, some of which will occur antenatally. The modified DeLee vertical lower segment incision does not appear to carry any greater risk than a conventional transverse incision and should be used in preference [D]. Alternatively, it is often possible to perform an en-caul delivery through a transverse incision if the membranes are left intact.

ANALGESIA

In terms of intrapartum analgesia, the use of epidural anaesthesia is frequently advocated. There has been little research on the subject. Postulated benefits include avoiding expulsive efforts before full dilatation or a precipitous delivery, a relaxed pelvic floor and perineum, and the ability to proceed quickly to abdominal delivery. Concerns are often expressed about the prolonged effects of narcotic analgesia on a preterm infant with limited metabolic capacity.

COMMUNICATION

There are two vital areas of communication in the management of women with threatened preterm labour:

- 1 communication with the woman and her family and
- 2 communication with the neonatal paediatricians.

Where possible, a clear management plan should be discussed with the parents. This should include monitoring in labour, potential interventions and what will happen to the baby afterwards. Involvement of the neonatal paediatricians is helpful, especially where there are difficult issues to cover, such as the management of an extremely preterm infant. Even when resuscitation would not be appropriate, parents often appreciate the opportunity to have discussed the care of their baby with the paediatricians. When labour does occur, it is vital to alert the neonatologists. Outcomes in very preterm infants have been shown to be improved if there is a senior paediatrician present at delivery. This can usually only be accomplished with some advanced warning.

SUMMARY

- Oral metronidazole significantly lowers the risk of preterm birth, by 60 per cent in high-risk women positive for bacterial vaginosis.
- Asymptomatic bacteriuria carries an increased risk of preterm birth; the risk is reduced by appropriate antibiotic treatment.

- Intrapartum antibiotics should be offered to women who are known to be colonised with GBS. Antenatal screening or treatment is not recommended.
- When based on historical factors alone, cervical cerclage improves outcomes only in women with three or more previous very early deliveries.
- Hospitalisation for bed rest leads to an increase in preterm births.
- Tocolytics have no significant benefit on perinatal mortality or the prolongation of pregnancy to term, but do reduce the number of women delivering within 48 hours by 40 per cent.
- A single course of maternal steroids given between 26 and 34 weeks' gestation and received within 7 days of delivery results in markedly improved neonatal outcomes.
- Maternal magnesium sulphate is beneficial in reducing the risk of cerebral palsy due to very or extreme preterm birth.
- There is no evidence of benefit and some evidence of harm associated with the use of antibiotics in uncomplicated preterm labour with intact membranes.

KEY POINTS

- Beneficial antenatal treatments for high-risk women include metronidazole for bacterial vaginosis, antibiotics for asymptomatic bacteriuria, cerclage for three or more second-trimester losses or very preterm births and progesterone supplementation.
- In symptomatic women, the following factors are associated with a high risk of delivery within 7 days: cervical dilatation >3 cm, ruptured membranes or any vaginal bleeding.
- A single course of corticosteroids should be given when delivery before 34 weeks is likely within the next 7 days. In general, repeat courses should be avoided, as they may carry risk without conferring benefit.
- Fetal fibronectin and cervical-length scanning can aid decision making in determining appropriate timing of maternal corticosteroid administration.
- After the diagnosis of preterm labour is confirmed, consideration should be given to the issues of neonatology consultation, fetal monitoring, mode of delivery and intrapartum antibiotics if a known GBS carrier, as well as administration of maternal magnesium sulphate.

Chapter 45 Pre-labour rupture of the membranes

Myles Taylor and Stuart Rundle

MRCOG standards

- Candidates should be able to diagnose and manage rupture of the membranes in term and preterm pregnancies.

In addition, we would suggest the following:

Theoretical skills

- Understand the changes in amniotic fluid volume at different gestational ages.
- Understand the physical and biochemical properties of amniotic fluid that can be used diagnostically.
- Be aware of the risks associated with pre-labour rupture of the membranes (PROM), both at term and preterm.
- Have a thorough knowledge of the management options for PROM at term.
- Know the organisms likely to cause chorioamnionitis along with their appropriate antibiotic therapies.

Practical skills

- Be able to confirm membrane rupture using clinical history, examination and specialised tests.
- Assess amniotic fluid volume using ultrasound.
- Be able to diagnose clinical chorioamnionitis by examination and additional testing.

INTRODUCTION

PROM is a common clinical problem, and the assessment of women with possible membrane rupture is a management issue faced in everyday practice. When PROM occurs, the fetus loses the relative isolation and protection afforded within the amniotic cavity. In general, PROM refers to rupture of the membranes with leakage of amniotic fluid in the absence of uterine activity. Pre-term PROM (PPROM)

occurs when rupture of membranes occurs before 37 weeks' gestation. At term, approximately 75 per cent of women will labour within 24 hours of membrane rupture. The latency period tends to be longer with decreasing gestational age: at 26 weeks, only half of women are in labour within 1 week; at 32 weeks, half will labour within 24–48 hours.

INCIDENCE

PROM occurs in approximately 8 per cent of term pregnancies and complicates 2–3 per cent of pregnancies that have not reached 37 weeks' gestation. PPROM is associated with approximately one third of all deliveries before 37 weeks' gestation. It is important to make a distinction between term PROM and PPROM, as the conditions have different aetiologies, risks and recommended management plans.

AETIOLOGY

The pathophysiology of PROM is not well understood but probably includes a variety of mechanical, infective and constitutional mechanisms.¹ The main risk factors for PPROM include a history of PPROM in a previous pregnancy, genital tract infection, antepartum bleeding and smoking.²

Term PROM

Rupture of the membranes at term usually reflects physiological (as opposed to pathophysiological) processes. Apoptosis (programmed cell death) refers to the natural deterioration and breakdown of cells and cellular structure over time. The role of apoptosis in PROM has attracted considerable research interest. As term approaches, uterine activity is known to increase and Braxton–Hicks contractions are prominent. Such repetitive stretching of the membranes may lead to weakening via several mechanisms. First, it induces focal thinning of the membranes. Second, it leads to strain hardening, a biomechanical phenomenon associated with materials

becoming less elastic and less able to withstand stress. Such stretch-induced weakening will be most likely at the internal cervical os, where physiological ripening of the cervix will allow a degree of membrane prolapse.

PPROM

In contrast to the 'natural' phenomenon occurring at term, PPRM usually has pathological origins. Ascending infection appears to be one of the major causes and appears to be a more frequent aetiology than in preterm labour with intact membranes. That chorioamnionitis can be associated with preterm PROM is easily understood. As with preterm labour, the majority of these infections are subclinical and give few signs or symptoms until fluid loss has occurred.

Another factor strongly linked with PPRM is antepartum haemorrhage, particularly when it occurs recurrently. A weak cervix can also predispose to early membrane rupture. It will fail as a barrier to ascending infection and, by allowing membrane prolapse, will allow localised biomechanical weakening, as described for term PROM.

There is a strong epidemiological link between maternal smoking and PPRM, which is dose dependent. As smoking is a modifiable behaviour and a reduction in smoking has been shown to reduce risk, this should be pointed out to women, particularly those with a history of PPRM in a previous pregnancy.

CLINICAL ASSESSMENT

The correct diagnosis of PROM, either preterm or at term, is crucial. Many interventions will be based upon the diagnosis. If undertaken unnecessarily, these interventions will undoubtedly increase maternal and fetal morbidity.

History

A history from the mother of 'a gush of fluid' followed by recurrent dampness will correctly identify over 90 per cent of cases of pre-labour membrane rupture.³

Examination

PROM should be confirmed by a sterile speculum examination, performed after the mother has rested supine for 20–30 minutes. Amniotic fluid can be seen pooling in the posterior fornix, either spontaneously or after fundal pressure. The presence of meconium should be noted. At preterm gestations, meconium is suggestive but not diagnostic of intra-amniotic infection; at term, it is a relative contraindication to expectant management. The absence of any pooling is an equally important finding. The cervix can usually also be seen, allowing assessment of length and dilatation.

A digital examination must be avoided unless the patient is thought to be in established labour, as it is known to increase the incidence of:

- chorioamnionitis;
- postpartum endometritis;
- neonatal infection.

A digital examination also decreases the length of the latent period before the onset of labour, with the greatest decreases seen at the earliest gestations.⁴

Point-of-care testing

Concern about the consequences of misdiagnosing true PROM has led investigators to seek secondary tests that can be used at presentation. Two common tests use either nitrazine sticks (relying on the higher alkaline pH of amniotic fluid) or the ferning pattern seen when amniotic fluid is dried onto a glass slide and then viewed under a microscope. Importantly, neither of these tests has been shown to be more reliable than a basic history and examination.³ Both have appreciable false-positive and false-negative rates, which appear to be further increased in women with prior negative speculum examinations. While potentially useful as an adjunct in the diagnosis of PROM in resource-poor settings, their use has largely been superseded by the introduction and commercial availability of more specialised and technologically advanced tests that are rapidly able to detect amniotic fluid proteins present in cervico-vaginal discharge at the point of presentation.

The two most commonly used bedside tests able to detect the presence of amniotic fluid proteins utilise the high concentration of either insulin-like growth factor binding protein-1 (IGFBP-1) or placental alpha micro-globulin-1 (PAMG-1) within amniotic fluid compared to other body fluids. Both tests have appreciably lower false-positive and false-negative rates than that achievable with history and examination alone. A recent meta-analysis of prospective cohort studies comparing IGFBP-1 and PAMG-1 in the diagnosis of PPRM reported a sensitivity and specificity of 96.0 per cent and 98.9 per cent respectively for the PAMG-1 test.⁵

Fetal fibronectin is a protein found at the chorio-decidual junction rather than being found in high concentration in amniotic fluid. Testing for presence of fFN is commonly used to determine the risk of preterm labour in women with intact membranes and has been postulated for use in the diagnosis of PROM. fFN testing has been shown to become negative in some women after membranes have been ruptured for more than 12 hours if liquor is not seen on speculum examination. It should be noted that none of these technologically advanced tests for the detection of PROM have been evaluated against the true gold standard for the detection of PROM: the amniodye test.

If diagnostic uncertainty remains following presentation, clinical assessment and point-of-care testing, repeated dry

pads argue against the diagnosis while the use of pads which change colour when in contact with fluids with a pH >5.2 are now available.⁶

Ultrasound

Amniotic fluid volume can be assessed by ultrasound. Even at term, the normal variation in directly measured AFV is considerable, ranging from 250 to 1200 mL, making ultrasound diagnosis of reduced AFV a non-specific test for the detection of PROM. As the variation in AFV can be much greater in preterm gestations, the diagnostic role of ultrasound in PPRM is very limited. Despite this, the ultrasound assessment of AFV has been reported to correlate with latency in PPRM and with neonatal mortality and morbidity in mid-trimester PROM.

Misdiagnosed PROM

The improvement in detection of PROM in clinically equivocal cases brought about by specialised bedside tests is likely to result in a fall in the incidence of misdiagnosed PROM. Ladfors *et al.*⁷ have studied the outcome of women presenting with possible PROM after 34 weeks' gestation in whom amniotic fluid could not be seen on speculum examination. Vaginal samples were taken and blindly analysed later for diamine oxidase, an enzyme that is absent from urine or vaginal secretions but present in large amounts in amniotic fluid. Of the women with negative speculum examinations, 12 per cent tested positive for diamine oxidase. Nearly 90 per cent of these diamine oxidase-positive women went into labour within 48 hours, compared to only 45 per cent of the diamine oxidase-negative women. Crucially, no difference in maternal or neonatal outcome was seen between the two groups. This suggests that a delay in the diagnosis of PROM in women with an initially negative speculum examination is of no clinical consequence [C].

CLINICAL MANAGEMENT

Term PROM

A clinician with experience of diagnosing membrane rupture should assess women reporting a history suggestive of PROM at or beyond 37 completed weeks of gestation. Whether this assessment should take place immediately or after a suitable delay, in which labour may establish, has not been the subject of extensive research. The predominant risk to the fetus after PROM at term is ascending infection. The risks to the mother are of uterine infection, via either chorioamnionitis or postpartum endometritis.

A 2006 systematic review of 12 randomised or quasi-randomised trials of women with term PROM compared immediate intervention to expectant management⁸ and found that the former was associated with a reduction in the rate of maternal infection and neonatal unit admission without an increase in the risk of caesarean section or operative vaginal delivery [A]. The results were limited by the heterogeneity of the included studies, the largest of which was the Canadian TERMPROM Study.⁹ This study and subsequent secondary analyses¹⁰⁻¹⁴ have provided considerable evidence to share with prospective parents.

The trial compared four management policies, namely immediate induction with intravenous oxytocin, immediate induction with vaginal prostaglandins, expectant management for up to 4 days followed by induction with oxytocin, or expectant management followed by induction with vaginal prostaglandins. The absolute risks associated with any policy were found to be small. Table 45.1 outlines the differences in labour outcome among the four management policies. None reached statistical significance. In Table 45.2, the risks of maternal and neonatal infection are reviewed. Although clear trends are obvious in these tables, readers are referred to the original publication for tests of significance. Four points from the original trial are worthy of separate mention.

Table 45.1 Delivery outcomes after membrane rupture at term, TERMPROM Study⁹

	Immediate induction		Expectant management	
	Oxytocin (%)	Prostaglandin (%)	Oxytocin (%)	Prostaglandin (%)
C-sect (overall)	10.1	9.6	9.7	10.9
C-sect (multiparous)	4.3	3.5	3.9	4.6
C-sect (nulliparous)	14.1	13.7	13.7	15.2
C-sect (nulliparous, unfavourable cervix)	14.8	14.1	15.0	14.9
SVD, nulliparous	60.8	60.8	58.0	58.9
Use of oxytocin	91.9	43.1	49.9	43.8
PROM-delivery interval	17.2 hours	23.0 hours	33.3 hours	32.6 hours

● C-sect, caesarean section; SVD, spontaneous vaginal delivery; PROM, pre-labour rupture of membranes.

Table 45.2 Perinatal infectious morbidity after membrane rupture at term, TERMPROM study⁹

	Immediate induction		Expectant management	
	Oxytocin (%)	Prostaglandin (%)	Oxytocin (%)	Prostaglandin (%)
Fever before or during labour	3.8	5.8	8.7	6.7
Antibiotics before or during labour	7.5	9.0	11.9	11.6
Postpartum fever	1.9	3.1	3.6	3.0
Neonatal infection	2.0	3.0	2.8	2.7
Neonatal antibiotics	7.5	10.9	13.7	12.2
NICU stay >24 hours	6.6	9.2	11.6	10.2

- NICU, neonatal intensive care unit.

- 1 The use of prostaglandins did not reduce the subsequent need for oxytocin; this was no different between the two groups randomised to prostaglandins and the expectantly managed group randomised to induction with oxytocin.
- 2 Only a minority of women (approximately 18 per cent) randomised to expectant management waited 4 days before induction.
- 3 The four babies that unexpectedly died in the trial were all in the expectant management arms. Two were antepartum stillbirths and two were related to fetal distress in advanced labour, both of which started spontaneously.
- 4 The views of the women participating in the trial showed a preference for immediate induction, as opposed to expectant management.

A more recent, large retrospective cohort study¹⁵ examining dichotomised time thresholds for significant increases in the risk of infective sequelae of PROM at term found that a latency of greater than 12 hours was associated with a significantly increased risk of chorioamnionitis (OR 2.3, 95% CI 1.1–4.4); however, once again it should be emphasised that the absolute risk remained small (1.3% incidence before 12 hours vs 3.3% after). Similar small risk increases were demonstrated for maternal endometritis at a threshold of 16 hours and PPH at a threshold of 8 hours.

Later publications from the TERMPROM investigators showed that the least expensive policy was immediate induction of labour using oxytocin.¹⁴ In terms of where to undertake expectant management, the evidence suggested an increased risk of infection and caesarean section when women were allowed home. If this was translated into clinical practice, and women needed to remain in hospital, it would clearly increase the cost of expectant management further. In contrast, maternal satisfaction, particularly amongst multiparous women, was greater with management at home.¹²

Regardless of whether a policy of immediate induction or expectant management is pursued, factors linked with perinatal infection include an increasing number of vaginal examinations after membrane rupture, an increasing interval

between membrane rupture and labour onset, and an increasing duration of active labour.^{10,11} There is also clear evidence that immediate induction of labour using oxytocin should be recommended for women who are known to be colonised with GBS [B].¹³ Expectant management in this situation was associated with a 3–4-fold increase in risk of neonatal infection, and even immediate induction with prostaglandins failed to lower this.

In general, the evidence suggests that immediate induction is associated with less maternal and neonatal infection and a shorter interval from membrane rupture to delivery [A] but given the small risk differences personal preference should be given considerable influence. There is no evidence that mode of delivery is influenced by induction of labour in the context of term PROM. When oxytocin is used initially, health-care costs are lower and the interval to delivery is shortest. However, meta-analysis has suggested that the use of epidural analgesia is increased [A]. When prostaglandins are used initially, infection risks may be marginally greater, the interval to delivery slightly increased, and oxytocin required subsequently in nearly half of the women [A].

Preterm PROM

The major risks in preterm PROM are:

- chorioamnionitis;
- abruption;
- preterm delivery.

Other risks include cord prolapse and operative delivery. Many tests have been used to predict chorioamnionitis, which is usually subclinical. Serum markers, such as white cell count and C-reactive protein, have a poor predictive ability and should principally be used to support a clinical diagnosis. Oligohydramnios, as assessed by ultrasound, can select a group at higher risk of infection and/or earlier delivery, but again is not diagnostic. Amniocentesis can give valuable information but remains technically difficult when little

amniotic fluid remains and is not recommended practice in the UK.

In contrast to preterm labour with intact membranes, transvaginal ultrasound measurements of cervical length are not predictive of early delivery. As well as PPRM being a common sequela of antepartum haemorrhage, early membrane rupture carries a 5 per cent risk of subsequent abruption. However, this risk varies inversely with gestational age and is reportedly as high as 50 per cent below 24 weeks.¹⁶

Although neonates born after PPRM are reported to have lower incidences of respiratory distress syndrome when compared to preterm labour without PROM, maternal steroids still appear to reduce the risk further [A]. There does not appear to be any significant increase in maternal sepsis after single steroid courses. Despite the fetal and maternal risks associated with PPRM there is evidence that intentional delivery prior to 34 weeks of gestation does not reduce maternal or neonatal morbidity and may be associated with additional risks to the fetus.¹⁷ Tocolytics are relatively contraindicated in this situation and are known to be less effective.

Antibiotic therapy for PPRM

The UK ORACLE I Trial demonstrated a role for oral erythromycin in PPRM.¹⁸ In this study, women with PPRM were randomised to one of four oral regimens:

- 1 Erythromycin (250 mg qds);
- 2 Co-amoxiclav (325 mg qds);
- 3 Both erythromycin (250 mg qds) and co-amoxiclav (325 mg qds);
- 4 Placebo.

The antibiotics were taken for 10 days. In singleton pregnancies, erythromycin alone was associated with a significant reduction (from 14.4 to 11.2 per cent) in the composite primary outcome, a measure of neonatal mortality and major morbidity [B]. The reductions with either co-amoxiclav or both antibiotics failed to reach significance. Unfortunately, the 10-day course of co-amoxiclav led to a significant increase in proven neonatal necrotising enterocolitis, from 0.5 to 1.9 per cent. Once again, antibiotics have been demonstrated to have the potential for harm. In contrast to those in preterm labour with intact membranes, 7-year follow-up of those children prescribed antibiotics for PPRM in the Oracle I Trial did not show any functional impairment.¹⁹ Thus the prophylactic use of erythromycin is currently recommended when PPRM is diagnosed (RCOG guideline number 44).

Chorioamnionitis remains a notoriously difficult diagnosis. For research purposes, it requires:

- maternal pyrexia (>38°C), and at least two of either:
- maternal tachycardia >100 bpm;
- fetal tachycardia >160 bpm;
- uterine tenderness;

- raised C-reactive protein;
- offensive vaginal discharge.

When clinically suspected, delivery is almost always appropriate, as antibiotic therapy is rarely curative. Based on the culture results after amniocentesis in PPRM, anaerobes are the most common isolate, followed by GBS and then other streptococci.

The care of women known to be GBS carriers has been simplified by the ORACLE Trial, as the organism is usually sensitive to erythromycin. After completion of a 10-day course, further antibiotics should probably be withheld until labour starts.

There are two gestational age ranges that require special consideration.

Pre-viable PROM below 23–24 weeks' gestation

Lung development has reached a critical stage and appears to be at least partly reliant on normal amniotic fluid volumes. There are significant risks of lethal pulmonary hypoplasia, a condition that cannot be reliably predicted on prenatal ultrasound. These risks are highest early in the mid-trimester and when severe oligohydramnios is found on serial ultrasound monitoring. As there are additional risks of chronic pulmonary morbidity, fetal limb contractures and extreme preterm birth with consequent co-existent morbidity and mortality, many parents will opt for termination of pregnancy.

Researchers have investigated the role of minimally invasive surgery and membrane sealants in this situation, as the prognosis is otherwise very poor, but results have proved disappointing.

PPROM at 34–37 weeks' gestation

This is another controversial area. Randomised trials have failed to reach a consensus on whether a policy of IOL versus expectant management may lead to fewer adverse pregnancy outcomes such as hospitalisation, perinatal infection and neonatal morbidity. A 2010 Cochrane review concluded that there was insufficient evidence to guide practice on the benefits and harms of immediate delivery versus expectant management in late preterm PROM.²⁰ Two recent large randomised trials have sought specifically to address the question of IOL versus expectant management between 34 and 37 weeks' gestation. The Dutch PPRMEXIL (PPROM Expectant Management versus IOL) trial group failed to show a reduction in adverse neonatal outcome following IOL versus expectant management between 34 and 37 weeks' gestation.²¹ The international multicentre PPRMOT (Preterm Pre-labour Rupture of Membranes Close to Term) trial has yet to report its findings.

Inpatient versus outpatient care

For some women who rupture membranes early, without immediately ensuing labour, the dilemma of best place of management must be considered. There are no good trials to inform practice. As it is recognised that 48–72 hours is a critical time during which many women will labour or develop clinical chorioamnionitis, it is recommended that all women with PPRM be managed as inpatients during this time. After this, a decision to change to outpatient management must be taken at consultant level. Women must know the potential risks and be educated in measurement of their temperature and signs and symptoms of developing chorioamnionitis. It is suggested that women measure their temperature twice daily (RCOG guideline 44).

Neither umbilical artery Doppler analysis nor biophysical testing has proven effective at early identification of the infected fetus. However, given that PPRM is associated with growth restriction, monitoring of fetal growth by ultrasound seems reasonable.

ACKNOWLEDGEMENT

This chapter has been revised and updated. The authors and editors acknowledge the contribution of Griff Jones to the chapter on this topic in a previous edition of the book.

KEY POINTS

- At term, the outcomes for women with PROM are as good in women induced immediately as in those managed conservatively. Where possible, women should be offered the choice.
- At term, women known to be colonised with GBS should be encouraged to allow immediate induction of labour using oxytocin after PROM.
- At term, early induction using oxytocin appears to reduce perinatal infection and shorten hospital stay without increasing operative intervention. It should be strongly recommended to women known to be GBS positive.
- Immediate induction is associated with increased use of epidural analgesia.
- Maternal steroid use in PPRM reduces the risk of respiratory distress syndrome.
- Erythromycin used for 10 days after PPRM is associated with a significant reduction (from 14.4 per cent to 11.2 per cent) in neonatal mortality and major morbidity.
- Co-amoxiclav when used for PPRM leads to a significant increase in proven neonatal necrotising enterocolitis, from 0.5 per cent to 1.9 per cent.
- Term PROM is usually a reflection of normal physiology, whereas pathological processes, such as infection and antepartum haemorrhage, often underlie PPRM.

- Accurate diagnosis of membrane rupture is essential and can usually be achieved by simple history and speculum examination alone.
- Diagnostic uncertainty following clinical examination can be resolved with the use of specialised bedside tests that detect amniotic fluid proteins in cervico-vaginal secretions.
- A digital vaginal examination should always be avoided after PPRM unless advanced labour is suspected.

Chapter 46 Antepartum haemorrhage

Lucy Kean

MRCOG standards

Candidate expectations:

Theoretical skills

- Be familiar with the relevant RCOG guidelines: Antepartum haemorrhage and placenta praevia, placenta praevia accreta and vasa praevia: diagnosis and management^{1,2}
- Understand the mechanisms of disseminated intravascular coagulation.
- Safe use of blood products.

Practical skills

- Be competent in the management of antepartum haemorrhage and major obstetric haemorrhage.
- Be able to localise the placenta using ultrasound in the third trimester and be confident in assessment of fetal heart activity.
- Have assisted at a caesarean section for placenta praevia.
- Have attended skills drills on obstetric collapse.

INTRODUCTION

Definitions

Antepartum haemorrhage (APH) is variously described as bleeding from the genital tract in pregnancy before the onset of labour at gestations from 20 to 24 weeks. Between 20 and 24 weeks management may be broadly the same, except delivery will rarely be expedited. The recent guideline produced by the RCOG uses 24 weeks as a starting gestation.¹ For the purposes of this chapter, the threshold of 20 weeks will be used, as this is often the gestation at which women will be admitted to the labour suite rather than the gynaecology ward.

APH is one of the commonest reasons for admission in pregnancy. It affects approximately 4 per cent of all

pregnancies and is associated with increased rates of fetal and maternal morbidity and mortality.

Minor bleeding is defined as less than 50 mL that has settled; major bleeding is 50–1000 mL with no sign of clinical shock; massive haemorrhage is blood loss of >1000 mL and/or signs of clinical shock.

Recurrent APH is bleeding on more than one occasion.

Aetiology

The causes of APH can be divided into three main groups:

- Placenta praevia;
- Placental abruption;
- Local causes:
 - friable cervical ectropion/cervical trauma
 - local infection of the cervix/vagina
 - genital tract tumours
 - varicosities;
- Others:
 - marginal placental bleeding
 - show
 - vasa praevia;
- Undetermined.

Placenta praevia and abruption together account for 50 per cent of bleeding and represent the greatest threat to the fetus and mother. However, despite the other causes appearing to be more minor (with the exception of vasa praevia) these carry an increased perinatal mortality of at least 3 per cent, and must therefore represent a group of pathological conditions. When the cause is unexplained, there remains an increased risk of fetal growth being poorer. Thus all APH must be fully investigated and evaluated.

PLACENTA PRAEVIA

The incidence of placenta praevia is variable depending on the population and background caesarean section rate, with rates from 0.4 to 0.8 per cent reported. In the UK rates are rising as the CS rate rises and the age of mothers increases.²

Definitions

Placenta praevia is defined as a placenta partially or wholly situated in the lower uterine segment. It is most usefully graded as minor or major depending on whether the placenta covers the internal os or not.

- Grade 1: the placental edge is in the lower segment but does not reach the internal os.
- Grade 2: the placental edge reaches but does not cover the internal os.

These grades represent a minor degree of placenta praevia.

- Grade 3: the placenta covers the internal os and is asymmetrically situated.
- Grade 4: the placenta covers the internal os and is centrally situated.

These grades represent a major placenta praevia.

Aetiology

Uterine surgery

Placenta praevia is strongly associated with previous uterine surgery. Its incidence increases with the number of procedures performed (Table 46.1) [C].²

Women with two or more previous abortions have a 2.1 (95% CI 1.2–3.5)-times increased risk of subsequently developing placenta praevia. Other procedures such as curettage and submucous myomectomy also increase the risks of praevia.

Maternal age

Placenta praevia increases dramatically with advancing maternal age, with women older than 40 years having a nearly 9-fold greater risk than women under the age of 20, after adjustment for potential confounders, including parity [C].

Smoking

The relationship between smoking and placenta praevia is not clear but there does appear to be a small but significant increase in risk in smokers.

Assisted conception

The risk is significantly higher in assisted-conception pregnancies with an odds ratio of 5.6 (95%CI 4.4–7) reported [C].³

Multiparity appears to increase the risk, as does a multiple pregnancy.

Associations

- Fetal abnormality: the rate of fetal abnormality is approximately doubled in women with placenta praevia [C].
- IUGR is common in women with multiple bleeds from a placenta praevia. The overall rate is 15 per cent [C].
- Ten per cent of women with a bleeding placenta praevia will have a coexistent abruption [C].

Diagnosis

- In most women, the placental site will have been determined at the anomaly scan, and may be known to be low-lying at the time of bleeding. Placenta praevia usually presents with painless bleeding (though 10 per cent will have concurrent abruption).
- Often a small bleed or number of small bleeds will precede a much larger one (though this is not always the case).
- The presenting part is usually high, being prevented from engaging by the placenta lying in the lower segment.
- The fetal condition generally remains good until the maternal blood loss causes compromise, or an abruption coexists.

It is difficult to diagnose a placenta praevia until the lower segment begins to form at about 28 weeks; however, a low-lying placenta can cause bleeding from the second trimester onwards.

Placental-site location is now a recommended part of the fetal anomaly screening examination in the UK, and cases are now detected on routine ultrasound at 18–21 weeks. Five per cent of women have ultrasound evidence of a low placenta at 16–18 weeks, but only 0.5 per cent have a placenta praevia at delivery. Transabdominal ultrasound is usually the test first performed, although it can be very difficult to determine the placental edge with a posterior placenta.

Table 46.1 The relationship between placenta praevia and caesarean section

Number of previous caesarean sections	Incidence of placenta praevia (%) [total 0.3%]	Incidence of placenta accreta in those with placenta praevia (%)	Overall risk of placenta accreta (%)
0	0.26	5	0.01
1	0.65	24	0.16
2	1.8	47	0.85
3	3	40	1.2
4	10	67	6.7

Transvaginal imaging is better and the woman does not need a full bladder, thus avoiding maternal discomfort. Also there is less distortion of the anatomy of the lower uterine segment and cervix. Transvaginal ultrasound (TVS) does not appear to provoke vaginal bleeding [B].² TVS should be performed at the routine anomaly scan at 18–21 weeks as it will reduce the need for third-trimester repeat scanning in 20–60 per cent of women.

MRI has also been used to identify placenta praevia, though it is expensive and not superior to TVS performed by an experienced person.

The following factors on second-trimester ultrasound are associated with the persistence of a placenta praevia in the third trimester:

- The placenta covers the internal os with an overlap of more than 1.5 cm [C].⁴
- The leading edge of the placenta is thick [C].⁵
- The placenta is posterior.
- There is a uterine scar.

Morbidly adherent placenta

Morbidly adherent placentae occur in approximately 1 in 200–400 deliveries in the USA and 1 in 800 deliveries in the UK. The major risk factor is uterine scarring, and thus the incidence is increasing with the increasing caesarean section rate. However, prior manual removal, submucous myomectomy or uterine curettage may also cause scarring and an increase in risk. A short caesarean section-to-conception interval has also been causally related.

Three degrees of adherence have been described: accreta, increta and percreta, where the placenta adheres to or invades into or through the uterine wall because of abnormal development of the decidua basalis.

Accreta is the most common, comprising 80 per cent. PPH will occur in most cases, particularly if the accreta is partial, where non-contracted portions of myometrium are adjacent to adherent placenta. Diagnosis in an increasing number of cases is made antenatally⁶ but still many are only diagnosed in the third stage. Antenatal diagnosis using colour flow or power Doppler ultrasound and MRI has been described. It is important to determine whether an accreta is present in women at most risk (previous caesarean section with an anterior placenta praevia), as it is crucial in forward planning and discussion of options with the woman.

The NPSA in conjunction with RCOG have formulated a patient safety bundle that lists the requirements for good management of a potential placenta accreta. All women undergoing caesarean section at high risk of placenta accreta should be managed in line with this care bundle. This will include:

- Women with one or more previous caesarean sections and placenta praevia.
- Women with a previous scar where imaging of placental localisation has found the placenta to be lying over the previous scar, even if it is well clear of the internal cervical os.

The elements of the care bundle are:

- 1 Consultant obstetrician planned and directly supervising delivery.
- 2 Consultant obstetric anaesthetist planned and directly supervising anaesthesia at delivery.
- 3 Blood and blood products available on site.
- 4 Multidisciplinary involvement in pre-operative planning.
- 5 Discussion and consent includes possible interventions (such as hysterectomy, leaving placenta *in situ*, cell salvage and interventional radiology).
- 6 Local availability of level 2 critical care bed.

NICE guidance also recommends having a senior haematologist available for discussion.

Imaging modalities for placenta accreta include ultrasound and MRI.

Ultrasound imaging using greyscale, colour and power Doppler entails looking for loss of the usual sonolucent zones between the placenta and myometrium and between the myometrium and bladder, evidence of placenta within the bladder and abnormal vascular patterns. MRI features are of uterine bulging, placental bands on T2 weighted images and signal heterogeneity within the placenta.

Positive predictive values of 75–88 per cent have been reported. However, these are research studies, and in clinical practice there is often less experience with both ultrasound and MRI, such that the positive and negative predictive values are likely to be less. NICE recommend both ultrasound and MRI for suspected accreta. However, in the end the diagnosis is always made surgically.

MANAGEMENT OF PLACENTA PRAEVIA

Management of the woman who does not bleed or in whom bleeding is minor and settled

Maternal risks

Bleeding

APH is the cardinal sign of placenta praevia and it is unusual for a woman with placenta praevia to reach the late third trimester without vaginal bleeding. Bleeding becomes more likely as the frequency and strength of contractions increase, causing shearing of the placenta at the level of the internal os. The bleeding is said to be painless, though a considerable number (10 per cent) of women who bleed from a placenta praevia will have a coexistent abruption. It is also reported that most women experience a minor bleed before any major bleeding. Whilst this is true for many women, some will have a significant haemorrhage as their first event.

Hospitalisation

There are few data on which to base the management of placenta praevia. One reasonably large observational study involving 161 women demonstrated that the risk of bleeding

was not related to the degree of praevia.⁷ Only one small randomised study has been performed which showed only reduced hospital stay in the home care arm.⁸

Management decisions regarding women who have not bled are difficult and must be made individually. Important factors may include:

- where the woman lives in relationship to the hospital and whether she has an adult with her at home;
- other factors that may make a placenta praevia more difficult to manage, such as a scarred uterus.

Because there have been no trials on this aspect of management, the decision to manage as an outpatient must be made at a senior level and fully discussed with the woman and her partner. It is important to remember that long-term hospitalisation carries significant financial and psychological implications for women and their families and may not be justified for women who have never bled.

For women who have had bleeding, most obstetricians would recommend inpatient management from 34 weeks. However there may be exceptions, such as a placenta that migrates enough for vaginal delivery to become an option. Women who are managed as inpatients show a trend towards later delivery.

Recent transfusion guidance in the UK means that blood can only be cross-matched on a sample that is less than 72 hours old. This may pose particular problems for women with complex cross-matching, such as those with multiple antibodies. Where this situation exists, close communication with the transfusion laboratory is essential.

Surveillance

The rate of fetal abnormality is approximately double the background rate in women with placenta praevia. When a diagnosis of placenta praevia is made, a careful reassessment of the fetal anatomy must be undertaken.

There is a considerable false-positive rate of diagnosis of low-lying placenta at 18–20 weeks using transabdominal (TA) scanning. A repeat transvaginal (TV) scan at 20–24 weeks will reduce the number of women who require follow-up and minimise anxiety for these women. Where the placenta appears to cover the internal os, a re-scan at 32 weeks is recommended as these women have a lower chance of placental migration, and require more careful management in the third trimester.² In women with a minor praevia, a full assessment should take place at approximately 36 weeks. If the placenta is >2 cm from the os a vaginal delivery is more often achieved. The thickness of the placental edge is also important; a thin leading edge is a more favourable finding for vaginal delivery. If the placenta is still low, a further scan in a week or two may show some changes as the lower segment continues to develop.

Tocolysis

Tocolysis for the treatment of uterine activity has been used to good effect in some studies [C].⁹ It appears to be safe to

use, gaining on average 13 days when compared to women in whom it was not used. It must be used judiciously to settle uterine activity that is causing bleeding. It must never be considered in women who show signs of cardiovascular instability or where there is evidence of fetal compromise. Studies have mainly used beta-sympathomimetics, which have a physiological disadvantage. Where tocolysis is considered agents other than beta-agonists should be considered first. Given the lack of cardiovascular side effects, an oxytocic antagonist would probably be the first choice.

Planning for delivery

In the woman who has not bled or in whom bleeding has been minor, there are a number of factors that need to be taken into account. These include:

- making a final decision about how to deliver for women with minor praevia;
- timing in relationship to the gestation of the pregnancy;
- ensuring a fully experienced and prepared team is assembled for delivery.

Deciding when to attempt a vaginal delivery

There has been much debate about when a vaginal delivery can be expected and when it is unlikely to occur. RCOG guidelines suggest that the decision regarding mode of delivery should be made on clinical grounds, supplemented by sonographic assessment.²

One large observational study has shown that if the placenta is within 2 cm of the internal os, the vast majority of women will require caesarean section [C].¹⁰ This is therefore accepted as a reasonable cut-off for expecting to need to perform a caesarean section. However, where the leading edge of the placenta is thick, the placenta may still have an impact at this distance. Once the placenta is more than 4.5 cm from the internal os, it is unlikely to be problematic. The grey area of 2–4.5 cm must be managed clinically and will depend on features such as the station of the fetal head and the position of the placenta (anterior or posterior, anterior being slightly less problematic as the anterior lower segment tends to retract more in labour).

Ideally all women will have had a planned third trimester with repeat scanning, admission where necessary and plans made for delivery if this occurs earlier than anticipated. Where plans have been made for vaginal delivery, but heavy bleeding occurs in labour, the situation must be evaluated clinically as CS may be required.

If a woman presents in late pregnancy either for planned CS or in labour with the head engaged, it is reasonable to scan transvaginally to reassess the relationship between the placenta edge and head. A decision to proceed to vaginal birth must then be based on the relationship between the head and placenta and the wishes and expectations of the woman. If a vaginal delivery occurs, uterotonics may be needed to ensure adequate uterine contraction for a few hours.

PLANNED CAESAREAN SECTION FOR PLACENTA PRAEVIA

Timing of caesarean section

Pre-labour CS carries an increased risk of respiratory complications in the newborn. Occasionally these are severe enough to require intensive intervention. Table 46.2 shows the incidence of respiratory morbidity for each week of gestation in babies delivered prior to labour from 37 to 41 weeks [D].¹¹

It has also been noted that the incidence of respiratory distress syndrome is higher amongst infants born to mothers delivered by elective CS for placenta praevia and relates to lower cortisol levels in these infants [C].¹² This suggests that the maturing processes in these infants are not accelerated. The RCOG guideline 'Antenatal Corticosteroids to Reduce Neonatal Morbidity and Mortality' (2010) states that antenatal corticosteroids should be given to all women for whom an elective CS is planned prior to 38⁺⁶ weeks of gestation [A].

When bleeding is occurring, the risks and benefits of delivery versus conservative management can only be assessed on an individual basis. However, there is often pressure to deliver earlier because of hospital inpatient management. If there are no compelling medical reasons for delivery before 38 weeks, the risks to the fetus must be fully discussed with the mother before delivery.

Planning the caesarean section

The degree of technical difficulty of CS for placenta praevia will be related to:

- gestation;
- the degree of praevia;
- whether the praevia is anterior;
- the presence of other risk factors making a morbidly adherent placenta more likely;
- the sonographic or MRI appearances of the placenta;
- previous abdominal procedures, which may make access to the uterus more difficult;
- morbid obesity.

Where placenta accreta is suspected, planning using the NPSA care bundle is vital.^p

Table 46.2 Respiratory morbidity amongst infants delivered by elective caesarean section

Gestation	Respiratory morbidity per 1000 (95% CI)	Odds ratio compared to vaginal delivery at term (95% CI)
37 1 0–37 1 6	73.8 (49.1–106.1)	14.3 (8.9–23.1)
38 1 0–38 1 6	42.3 (31.1–56.2)	8.2 (5.5–12.3)
39 1 0–39 1 6	17.8 (8.0–33.5)	3.5 (1.7–7.1)

Autologous blood transfusion is not recommended in the management of placenta praevia, as when blood is needed it is often required in very large amounts.² Haemoglobin should be optimised before delivery. Cell salvage should be considered. Where blood or blood products are declined thorough discussion of the available options such as cell salvage must be undertaken and full informed consent gained as far in advance as possible.

Discussion regarding the prophylactic placement of uterine artery embolisation catheters should take place in advance where an accreta is suspected. Women who have declined the use of blood or blood products should be delivered in a unit where interventional radiology is available.

A planned CS must enlist the help of all those thought to be necessary. This will include at the very least:

- senior obstetrician;
- senior anaesthetist;
- experienced midwives, anaesthetic assistants and theatre staff.

Where a morbidly adherent placenta is a strong possibility, discussion with a surgical/urological team may be necessary as bladder involvement is not uncommon. Because of the risk of ureteric injury when a hysterectomy is required for an accreta, ureteric stent placement has been suggested prior to CS, as this reduces the risk of ureteric damage; this should be evaluated on a case-by-case basis.

When a CS is likely to involve significant haemorrhage, the haematology staff (medical and laboratory) should be alerted. The appropriate amount of blood should be cross-matched in advance, with cryoprecipitate and fresh frozen plasma urgently available. The laboratory should be warned if there is likely to be a need for more blood or blood products.

Consent

It is important that the potential outcomes are discussed with the mother before delivery. This must include a discussion of management in the presence of continued or heavy bleeding and the possibility of the need for hysterectomy or other techniques.

Type of anaesthetic

The type of anaesthesia used is the ultimate responsibility of the anaesthetist. The final decision can only be made when the anaesthetist has all the facts at his or her disposal. Good communication before the delivery is vital.

There is evidence that blood loss at CS for placenta praevia is less when regional anaesthesia is used and that this does not compromise mothers [C].¹³ (Elective delivery is different from delivery of the cardiovascularly unstable woman with acute bleeding, as discussed below.) When procedures are likely to take slightly longer, a combined spinal–epidural approach may be undertaken. If a hysterectomy is required many women will require conversion to general anaesthesia.

Surgery

Accountability

The surgery must be performed or supervised by an experienced obstetrician. The CEMD in the UK 1994–1996 recommended that a consultant be present during surgery for a placenta praevia. The main reason for this recommendation is that a decision to proceed to life-saving hysterectomy is likely to be made earlier by a senior person. Death of a woman from haemorrhage at elective CS has been defined by the NPSA as a ‘never event’. This excludes women who have declined blood products and in whom a placenta accreta is found, but does include death after major placenta praevia.

The surgeon must avail him/herself of all the available information before commencing the CS. It is prudent to try to plan how the uterine incision will relate to the placenta before starting. Careful ultrasound mapping of the placental site prior to operation will help the surgeon to know where the placenta lies and the best route to deliver the baby.

It is also the responsibility of the surgeon to ensure that appropriate consent has been gained, that all the team members are aware the procedure is about to commence, and that the blood is available in theatre. These vital steps should not be delegated to anyone else in an elective situation and should form part of the usual WHO safe-surgery checklist undertaken before surgery commences. The surgeon should have a clear idea of the views of the woman regarding management in the face of haemorrhage with regard to uterine preservation or hysterectomy. Uterine artery catheter placement will be more advantageous where uterine preservation is important.

Technique

Uterine incision

Caesarean section is usually performed through a transverse skin incision and through the lower segment of the uterus, but if there is an anterior placenta praevia, the vessels may cover the entire anterior lower segment and the placenta will be encountered underneath the uterine incision. Some authors have recommended a classical CS in this situation, but this may make any repeat CS even more hazardous, and lower segment bleeding can be difficult to see and secure in this case. In cases of a centrally implanted praevia with the potential for an accreta, an upper segment incision, avoiding the placenta entirely with the aim of leaving the placenta in-utero or performing a planned hysterectomy, can be considered [D].

Delivery

The baby may be delivered by the obstetrician passing a hand round the margins of the placenta, or by incising the placenta. It is often easier to bring down one of the baby’s feet and perform breech extraction than to try to deliver a very high head past the placenta that occupies the uterine incision. Prolonged delay in delivery can lead to fetal exsanguination if the placenta has been cut. Some authors have recommended clamping the cord as soon as the uterine incision is made, to prevent

fetal bleeding if the placenta is cut. However, in many cases this is not easy and can add unnecessary delay.

Third stage

Oxytocics should be administered (5 units syntocinon IV) as soon as the baby is delivered. An oxytocin infusion or long-acting oxytocin analogue should then be commenced to continue uterine contraction. The uterine angles should be secured with Green–Armytage clamps before delivery of the placenta, and any large bleeding venous sinuses in the incision can also be secured.

The placenta should be delivered by controlled cord traction.

If the placenta does not separate, there are different choices depending on whether the accreta is total or partial. If the whole placenta is adherent, bleeding is usually minimal. The placenta can be left *in situ* and the uterus closed. This carries future risks of sepsis, haemorrhage or need for placental removal, but successful cases of placental passage followed by a future pregnancy have been described. Using methotrexate does not speed the passage of the placenta. The safest option is hysterectomy. Where this is chosen the uterus should be closed and then removed.

If the placenta is partially adherent (the more common scenario in a scarred uterus), the issue is usually that the non-adherent parts separate, but the adherent parts prevent efficient contraction, and so heavy bleeding ensues. The options are to a) perform a hysterectomy (safest) or b) remove the separated parts and attempt to control the bleeding. Various strategies have been described, including over-sewing of bleeding areas, re-section of the placenta and the portion of uterine segment it adheres to (possible if this is a small portion of lower segment scar), removal of as much placenta as possible then using brace sutures, or radiological embolisation techniques to reduce blood flow to bleeding areas.

In all strategies successful pregnancies afterwards have been reported, but also ultimate recourse to hysterectomy is often required.

If the placenta separates the lower segment must be examined. Delivery of the uterus may improve visualisation. Bleeding with a placenta praevia at this stage is most troublesome from the lower segment as this contracts poorly. Various strategies have been employed to improve haemostasis. These include:

- over-sewing individual bleeding sinuses;
- packing the uterine cavity;
- siting a balloon device, which can be inflated to provide uterine compression and removed later per vaginam;
- extra ecobolics, including prostaglandin PGF2 α , intramyometrial vasopressin, misoprostol;
- radiographic embolisation techniques;
- uterine or internal iliac artery ligation.

What is most important is that if haemorrhage is continuing and excessive, early recourse to hysterectomy is the safest strategy and the abdomen should not be closed until haemostasis is assured.

Post-delivery monitoring

Women delivered with a major placenta praevia or who have had significant intra-operative haemorrhage must be carefully monitored in a high-dependency setting until continuing loss has been excluded.

The management of major PPH is discussed in Chapter 64. Again it is vital that if haemorrhage is continuing, early recourse to hysterectomy is undertaken.

If all or part of the placenta is retained, follow-up with weekly serum hCG and interval ultrasound (determined by clinical features) should be undertaken.

Postnatal counselling

When haemorrhage has been severe, women will need the opportunity to go through events with the senior member of the team. The anaesthetist may wish to be involved. It is important that women understand what implications there may be for future deliveries, especially where there has been particularly difficult surgery.

The management of women with severe antepartum bleeding with placenta praevia utilises the steps above. Further management of the woman with severe bleeding is discussed below.

VASA PRAEVIA

Vasa praevia (VP) occurs when fetal vessels cross or run within the membranes between the amnion and chorion close to the internal cervical os, and are thus at risk of rupture during labour, either as a result of shearing at membrane rupture or from compression from the fetal head. It has been variously reported as occurring in 0.015–0.04 per cent of all pregnancies and has a high perinatal mortality. If the diagnosis is made antenatally the perinatal loss rate is substantially reduced. The presentation is usually bleeding at the time of membrane rupture, followed by fetal bradycardia. The two main types of VP occur when:

- 1 The umbilical cord inserts directly into the membranes rather than the placenta (a velamentous insertion) (Type I);
- 2 There is an additional separate (succenturiate) placental lobe with vessels crossing over from one portion of the placenta to the other (Type II).

Risk factors for vasa praevia are:

- Bilobed placenta or succenturiate lobe;
- Velamentous insertion;
- Low-lying placenta in the second trimester;
- Multiple pregnancy;
- In-vitro fertilisation.

Placenta praevia, low-lying placenta and bilobed or succenturiate placenta account for 89 per cent of pregnancies

complicated by VP. Antenatal diagnosis is usually only made if there is the suspicion of a higher risk and TVS performed.

If an antenatal diagnosis is made, delivery by elective CS is recommended, though the timing of delivery is not based on evidence. Delivery is recommended between 35 and 37 weeks following a course of steroids for fetal lung maturation [D].² Whether admission prior to this is needed is debatable and each case should be individually assessed.

VP does not form part of the National Screening programme in the UK at present. A recent re-evaluation of the available evidence by the NSC suggested that women with identifiable risk factors should undergo TVS after the 20-weeks scan, repeated later if VP is suspected. However, this has not yet been fully evaluated from either a feasibility or cost perspective.¹⁴ The review also noted that many practitioners did not consider themselves experienced enough to know what is abnormal. It is likely that the NSC will eventually recommend some form of screening for VP. In the meantime, it seems reasonable to consider a TV ultrasound after the 18–20-weeks scan if there is a bilobed or succenturiate placenta, and if a velamentous insertion is noted, and perhaps to offer women who have more than one of the other risk factors a scan. As RCOG recommend that TV ultrasound should be done to reduce the need for follow-up for women with a low-lying placenta at the detailed scan, then this whole group could be screened for VP with no extra effort. That would leave the last two risk groups. Perhaps it would be reasonable to consider TV scanning all women with IVF multiple pregnancies. It would not be many women and these women will be attending for additional ultrasound anyway, so the increase in workload is likely to be small.

PLACENTAL ABRUPTION

Definition

Abruption is defined as bleeding following premature separation of a normally sited placenta.

It occurs in as many as 5 per cent of pregnancies, though the majority of these are small and only visible on placental examination after delivery. It can most easily be graded as follows.

Grade 0: An asymptomatic retroplacental clot seen after placental delivery.

Grade 1: Vaginal bleeding and uterine tenderness; visible retroplacental clot after delivery.

Grade 2: Revealed bleeding may or may not be present but placental separation is significant enough to produce evidence of fetal compromise and retroplacental clot visible after delivery.

Grade 3: Revealed bleeding may or may not be seen but there are significant maternal signs (uterine tetany, hypovolaemia, abdominal pain), with late-stage fetal compromise or fetal death. Thirty per cent of these women will develop disseminated intravascular coagulopathy (DIC).

Abruption has historically been associated with very poor fetal and maternal outcomes. Perinatal mortality rates vary widely as the diagnostic criteria are generally clinical and broad. The minimal perinatal mortality rate is at least 4 per 1000 and maternal mortality continues to be a risk.

Aetiology and associations

The aetiology of placental abruption is unclear, but there are a number of recognised associations.

The risk factors for abruption include:

- previous abruption;
- family history of abruption;
- fetal abnormality;
- rapid uterine decompression (rupture of membranes with polyhydramnios);
- trauma;
- chorioamnionitis/premature rupture of membranes;
- smoking/illicit drug use (cocaine and amphetamines especially);
- abnormal placentation (circumvallate placenta etc.);
- pre-eclampsia;
- underlying thrombophilia;
- first-trimester bleeding (especially if a haematoma is seen).

Women with a low BMI, who have undergone assisted reproductive techniques, multiparous and older women are also at increased risk.

A history of previous abruption carries the greatest risk, with an increase in risk of about 8 times above the background rate. Women who have a sister who has had a significant abruption are at increased risk themselves (odds ratio 2).¹⁵

Debate surrounding the role of thrombophilia continues. There does appear to be an increased risk in women who are heterozygous for factor V Leiden or the prothrombin gene.¹⁶ What is as yet unproven is whether there are any effective interventions to prevent abruption in women with underlying thrombophilia.

Given that placental abruption is associated with disturbed placentation, any factor seen in these cases will be associated with an increased risk of abruption. These include pre-eclampsia, growth restriction, oligohydramnios, fetal abnormality (especially aneuploidy) and pregnancies with abnormal umbilical artery Doppler velocities.

Diagnosis

The diagnosis of placental abruption is primarily a clinical one. There may or may not be revealed bleeding. The woman may have had pain preceding or during the bleed and the uterus may be irritable; alternatively, if a large abruption is present, the uterus may be hard and tender.

In grades 2 and 3, the clinical picture is usually clear and the management will be dictated by the fetal and maternal condition. Grades 0 and 1 may be much more difficult to diagnose. There will be much overlap between women with marginal bleeding and bleeding due to other causes. This is

largely irrelevant clinically, as all women with APH represent a high-risk group for whom surveillance in pregnancy needs to be increased.

Ultrasonography is not a good method of diagnosing placental abruption. Small areas are difficult to visualise and, in the acute phase and in large abruptions, can be isoechoic and look like placenta. When an abruption is clinically suspected, it is prudent to manage with that as the diagnosis. Ultrasound should be used to:

- confirm fetal viability;
- assess fetal growth;
- measure liquor volume;
- perform umbilical artery Doppler velocities;
- confirm fetal normality as far as possible;
- exclude placenta praevia.

Kleihauer testing should be performed in women who are rhesus negative. This will ensure that an appropriate dose of anti-D is given should a large fetomaternal haemorrhage be detected. Kleihauer testing as a diagnostic tool has not been shown to be of clinical value in determining whether pain or bleeding is secondary to abruption.¹⁷

Management specific to abruption

When to deliver

The main management decision to be made with abruption is whether to deliver the fetus. This will of course depend on the clinical picture and the gestation. Approximately 50 per cent of women who abrupt will present in labour, and the decision then must be how to deliver the fetus.

When fetal compromise is confirmed at viable gestations, the aim should be to deliver the fetus. Studies comparing neonatal outcomes at gestations of viability suggest that CS is a better choice for the fetus; however, even when CS is performed, perinatal mortality rates of 15–20 per cent are reported in this group. At very low gestations, a vaginal delivery should be the aim. Labour is often quick and although prostaglandins and oxytocin can be used, they are rarely needed.

It is important when performing CS to alert the haematology laboratory and to arrange to have blood cross-matched as soon as possible (see below). Whether there is time to delay to await the results of clotting screens and cross-matching will depend on the degree of maternal bleeding and the condition of the fetus.

It is important to:

- remember that there may already be considerable unrevealed bleeding which may increase the blood loss well above that which has been revealed;
- be as prepared as possible;
- seek senior help if this is thought likely to be necessary;
- expect heavy postpartum bleeding.

If the fetus is already dead, a vaginal delivery should be the expectation. At least 30 per cent of women will develop DIC with placental abruption and delivery should be expedited. The management is discussed further below.

The time taken to achieve delivery will depend entirely on the rate of bleeding, the rate of change in the clotting studies and the clinical condition of the mother. Fortunately, delivery is usually rapid and after delivery the DIC will usually begin to resolve.

If the abruption is small, the fetus uncompromised and the mother well, a conservative approach may be utilised. There can only be gains for the mother and fetus if there are benefits in terms of maturity and the option to give steroids. If abruption is thought to be the diagnosis and the fetus is mature, delivery in a controlled manner is probably the best management plan. After 38 weeks in most cases of suspected abruption, delivery should be considered. Between 34 and 38 weeks, cases must be managed on an individual basis. When a conservative approach is undertaken, increased surveillance is essential. In the acute phase, a period of inpatient management with twice-daily CTG until stability is confirmed is warranted. Fetal growth must be serially assessed, and umbilical artery Doppler waveform analysis is also helpful.¹⁸

Bleeding of other causes

The group of other causes comprises a wide range of conditions. As a group, these causes carry an approximately 5-fold increased risk of perinatal mortality and therefore warrant careful consideration.

Management will depend on the individual cause, but there are some general principles:

- It is preferable to err on the side of caution, and safer to increase surveillance rather than to assume that the cause must be benign.
- There is no evidence to support a policy of delivery at term in the well fetus, but steps to ensure fetal wellbeing must be continued if a conservative approach is adopted.

MANAGEMENT OF THE WOMAN PRESENTING WITH ANTEPARTUM HAEMORRHAGE

Management at initial presentation

A rapid assessment of the condition of both the mother and the fetus is a vital first step.

A clinical history can be quickly taken in an acute situation. A more detailed history can be taken once the immediate clinical picture is established. When taking the initial history, questions should be asked regarding:

- dates by previous scan;
- amount of bleeding;
- associated or initiating factors;
- abdominal pain;
- coitus;
- trauma;

- leakage of fluid;
- previous episodes of bleeding;
- previous uterine surgery (including induced abortions and surgically managed miscarriages);
- smoking and use of illegal drugs (especially cocaine);
- fetal movements;
- blood group;
- position of the placenta, if known from a previous scan.

Smoking increases the risk of placenta praevia, placental abruption and marginal bleeding. This is a dose-dependent effect. Fetal growth restriction is associated with both marginal placental bleeding and placental abruption. The mother may have noticed a reduction in fetal movements. The use of cocaine and crack cocaine is strongly associated with placental abruption.

Maternal assessment

In the initial stages, this should include:

- pulse;
- blood pressure;
- uterine palpation for size, tenderness, presenting part.

A vaginal examination must not be performed until a placenta praevia has been excluded.

Fetal assessment

It should be established whether a fetal heart can be heard, making sure it is fetal not maternal (the mother may be very tachycardic). If a fetal heart is heard and the gestation is estimated to be 26 weeks or more, FHR monitoring should be commenced.

These initial steps take very little time. Following this initial assessment, women will fall into one of two categories.

- 1 The bleeding is minor or settling and neither the mother nor fetus is compromised.
- 2 The bleeding is heavy and continuing and the mother or fetus is or soon will be compromised.

Group 1: bleeding is minor or settling and neither the mother nor fetus is compromised

This is the most common group. It is usually clearly apparent that neither mother nor fetus is in danger on admission. Time can then be taken to conduct a full and thorough history and examination.

Once it is clear that the placenta is not low, a vaginal examination can be undertaken with the following aims:

- to assess the degree of bleeding;
- to ascertain cervical changes, which may be indicative of labour;
- to assess local causes of bleeding (trauma, polyps, cervical lesions, etc.);
- to take bacteriological samples if infection is suspected (high vaginal and endocervical swabs, urine PCR or endocervical swabs for chlamydia, plus viral swabs if herpes is suspected).

After a careful history and examination, it should be possible to use selected investigations to help establish a diagnosis.

Further investigations

- Full blood count.
- Kleihauer testing in women known to be rhesus negative or in women with unknown blood group.
- Grouping and saving of serum, with blood cross-matched if there is continuing or severe bleeding.
- Clotting screen in cases of suspected abruption or heavy bleeding.

Ultrasound is useful for:

- measurement of fetal size;
- assessment of liquor volume;
- location of the placenta in relation to the internal cervical os;
- establishment of fetal wellbeing:
 - biophysical profile;
 - umbilical artery Doppler velocimetry.

Ultrasound is not generally helpful in diagnosing abruption. Acute abruptions can be difficult to see as they may have the same echogenicity as placenta. It should be made clear that the ultrasound examination is primarily to assess the position of the placenta and the wellbeing of the fetus. Women are often disappointed if they have been led to believe the ultrasound will identify the cause of the bleeding.

If the source of bleeding is fetal, the fetus is usually quickly compromised. This may present with a fetal tachycardia progressing rapidly to a sinusoidal CTG and finally a terminal bradycardia. Point-of-care testing is usually too slow to be helpful in these cases.

A Kleihauer test is mandatory for all rhesus-negative women. All RhD-negative women will require 500 IU anti-D (unless they are already sensitised). The Kleihauer test must be done to determine whether there has been a large fetomaternal haemorrhage, in which case more anti-D will be needed.

The Kleihauer is not a useful test to differentiate small abruptions from bleeding of other causes [C].¹⁷ Fetal cells may appear in the maternal circulation in as many as 15 per cent of women at some time in pregnancy, and a lack of fetal cells in the maternal circulation does not preclude an abruption.

When any pregnant woman complains of episodes of vaginal bleeding in pregnancy, other than confirmed causes of haemorrhage, cervical cancer must be excluded by direct observation of the cervix and a cervical smear taken. This should be undertaken irrespective of her past medical history or reports of normal past cervical smears [E].

Surveillance after a limited APH

Although some units admit women who have had APH for 24 hours, there is no evidence to suggest that this improves outcome once fetal and maternal wellbeing has been established [D]. Management must be individualised, taking into account the suspected cause of bleeding, gestation, fetal assessment and continuing maternal risk factors.

The following must be borne in mind.

- No bleeding, however light, should be dismissed without full investigation.
- Once APH has occurred, the pregnancy becomes high risk, and a management plan for ongoing fetal surveillance must be formulated and discussed with the mother.
- Women must be advised to watch for warning signs such as a decrease in the frequency of fetal movements, further bleeding or pain, and should be assessed again should any of these occur.

Planning for the rest of pregnancy

If bleeding settles and the mother is discharged, a clear plan for the remainder of the pregnancy should be made. Even if the cause is thought to be minor, extra fetal surveillance is needed as a higher fetal mortality rate is seen compared with background. Fetal surveillance for growth and wellbeing should be instituted, as guided by the clinical picture. If all remains well, induction of labour at term is not needed, but the degree of surveillance after the due date may need to be increased.

Group 2: severe ongoing bleeding, compromised mother and/or fetus

Delivery must be expedited if the mother is compromised. If the fetus is compromised, the decision to deliver will be based on the gestational age. In most cases, delivery will be indicated.

The method of delivery will be determined by the cause and severity of the bleeding, the fetal gestation and status. Women with major haemorrhage from a placenta praevia will need delivery by CS.

Placental abruption causing maternal or fetal compromise necessitates delivery. If the fetus is already dead, vaginal delivery after stabilisation of the mother is usually the safest option. However, if the bleeding continues, and the mother's condition cannot be stabilised, delivery should be achieved by the quickest method, which may be CS. Coagulopathy will only begin to resolve once the placenta is delivered, and may be severe enough to warrant replacement with FFP, cryoprecipitate and platelets. These women usually labour very quickly. Epidural or spinal anaesthesia must not be used if the clotting studies are abnormal or not available. CVP lines can be useful, but should be sited through an antecubital long line, and not sited or removed until clotting is normal.

It can be difficult to measure antepartum blood loss accurately, as the loss may be concealed (placental abruption) or diluted by amniotic fluid.

Major haemorrhage can be defined by blood loss and/or vital signs:

- blood loss >1000 mL;
- disturbance of conscious state;
- systolic pressure <100 mmHg;
- blood pulse >120 bpm;
- reduced peripheral perfusion.

Disturbances of coagulation due to loss or consumption of platelets and clotting factors may occur during haemorrhage. DIC is the coagulation problem most often encountered in obstetric patients. This and the other complications – fetal or maternal death, adult respiratory distress syndrome, renal and hepatic failure – are more likely to occur if adequate replacement of blood volume is not instigated rapidly.

Aims of treatment of major haemorrhage

- Rapid restoration of the circulating blood volume and oxygen-carrying capacity.
- Cessation of further blood loss.
- Restoration/maintenance of normal blood coagulation.
- Delivery of the live fetus (where appropriate).

Resuscitation should aim to keep the Hb concentration above 8 g/dL, the pulse rate below 100 bpm, and the systolic blood pressure above 100 mmHg. Four units of cross-matched blood should be available at all times. BCSH recommend aiming to keep the platelet count above 75×10^9 , the prothrombin and activated prothrombin times $<1.5 \times$ mean control, and fibrinogen >1 g/L [E].¹⁷

The success of treatment is dependent on careful organisation as well as prompt treatment and the use of appropriate blood products and non-blood volume expanders. The patient, her partner and relatives must be kept fully informed.

When major haemorrhage is identified

- 1 Call for help. The immediate team will consist of:
 - the obstetric specialist registrar;
 - the obstetric senior house officer;
 - the anaesthetic registrar;
 - the senior midwife.

The consultant obstetrician and anaesthetist should be informed.

A member of staff should be nominated to run samples and record events.
- 2 Start facial oxygen 10–15 L/min (hypoxia will reduce uterine contractions).
- 3 Insert two intravenous cannulae (14 gauge brown/orange), one into each antecubital fossa.
- 4 Take 30 mL of blood for:
 - FBC;
 - clotting screen (including fibrinogen and fibrin – degradation products or D-dimers if DIC is suspected);
 - cross-match 6 units;
 - urea and electrolytes, liver function.
- 5 Commence the following infusions:
 - up to 2 L 0.9% saline/Hartmann's solution;
 - colloid (up to 1.5 L);
 - uncross-matched Rh-negative blood or group-specific blood (if clinical condition is critical);
 - cross-matched blood as soon as available.

Cross-matched blood is the ideal but crystalloid first and colloid second should be used until blood is available. Group O RhD-negative blood should only be used as a last resort, but can be life saving when haemorrhage is severe. Group O RhD-negative blood **must not** be given to patients known to have anti-c antibodies from their antenatal records [E].

Fluids should be warmed, as cold injury exacerbates DIC.

- 6 Site an indwelling catheter to monitor urine output and aim to keep output above 30 mL/h.
- 7 One member of staff should be assigned to record the following:
 - pulse;
 - blood pressure;
 - CVP (half-hourly) if a line is present (see below);
 - continuous FHR (where appropriate);
 - fundal height (abruption/PPH);
 - any drug administration (time, type, dose);
 - measured blood loss.
- 8 The senior obstetrician present should coordinate and manage the clinical situation i.e. prompt treatment of the cause of haemorrhage, adequate fluid replacement and regular checking of FBC and clotting status in order to prevent and treat DIC.

A major haemorrhage box is an asset on any acute unit. It should contain everything needed for the initial resuscitation (fluids, cannulae, tourniquet, blood bottles and forms, oxytocics, etc., Fig. 46.1).

Fig. 46.1 A major haemorrhage box

BLOOD TRANSFUSION CONSIDERATIONS

The goals of haematological management are to maintain:

- Hb above 80 g/L;
- Platelet count $>75 \times 10^9/L$;
- Prothrombin time $<1.5 \times$ control mean;
- Activated prothrombin times $<1.5 \times$ control mean;
- Fibrinogen >1 g/L (remembering that 4 g/L is the lower limit of normal in pregnancy).

Packed cells and stored blood lack platelets and clotting factors. Fresh whole blood is not available because of potential hazards of viral transmission. FFP and sometimes cryoprecipitate are usually necessary to compensate after transfusion of 4–6 units. Stored blood also is a source of thromboplastins and can lead to or exacerbate DIC when large amounts are transfused. In most units, up to 4 units of FFP may be issued before the coagulation screen result is known for a patient in critical condition (usually 6 units already transfused and blood loss continuing), provided that coagulation studies are being processed.

Thrombocytopenia can also occur during massive transfusion, but in DIC a platelet transfusion is rarely required unless the platelet count falls below 50×10^9 and there is continued blood loss.

Blood should be administered through blood-warming equipment and rapid administration of warmed fluid should be achieved by the use of a compression cuff on the infusion bag. The use of a blood filter is not necessary. Cold injury increases the risk of DIC.

Extra blood and products should be ordered early – the amount of each will depend on the clinical situation and FBC and coagulation screen results. In established DIC, extra FFP or cryoprecipitate and platelets may be needed, according to instructions from the haematologist.

Recombinant factor VIIa (NovoSeven) has been used in cases of severe continuing haemorrhage. It does not work where there is hypofibrinogenaemia or thrombocytopenia (fibrinogen <1 g/L, platelets less than 20×10^9) so should be given after cryoprecipitate and platelets if needed in cases where continued bleeding is thought to be secondary to thrombostatic failure [C].¹⁹ The prothrombotic properties of recombinant factor VIIa necessitate careful postnatal precautions for thromboembolism deterrence. In the immediate post-haemorrhage period, good hydration and compression devices should be used, with heparin added when clinically safe.

Once bleeding has been stopped, the patient should be managed in an obstetric high-dependency setting or adult intensive therapy unit.

Central venous pressure monitoring

CVP monitoring can be helpful where there has been massive haemorrhage, concealed blood loss or when blood loss is continuing.

A long line should be used if there are concerns regarding clotting.

A pressure between 3 and 7 cmH₂O, using the angle of Louis as the reference zero, should be established.

- Ensure that the rate of transfusion at least equals the rate of continuing blood loss and is, in addition, adequate to replace the loss already measured.
- Do not over-transfuse the patient with cell-free colloid as this will result in a severely anaemic patient, with a high CVP, preventing further blood transfusion.
- Do not exceed a CVP of 7 cmH₂O (this leads to a high risk of pulmonary oedema due to low colloid oncotic pressure).
- Do not use or rely on increasing the CVP excessively to correct oliguria.
- Consider using a fluid challenge test if you are unsure of the adequacy of fluid replacement:

Infuse 250 mL Hartmann's or 0.9% saline rapidly (2 minutes). Observe the CVP changes over the following 5–10 minutes.

- *Hypovolaemia*: rapid rise and fall back to previous CVP level.
- *Isovolaemia*: rise and fall back to slightly higher CVP level.
- *Hypervolaemia*: rise to higher CVP level sustained for more than 10 minutes.

MAJOR HAEMORRHAGE AND SPECIFIC ANTEPARTUM CONDITIONS

Placenta praevia

It is unusual for the placental site to be unknown, as most women have a detailed fetal anomaly scan. Bleeding significant enough to cause maternal hypotension requires delivery.

If the placenta is known to be praevia, delivery by CS is needed. If the placental site is unknown, the following strategy is helpful.

- Is the presenting part engaged? If so, a placenta praevia is less likely.
- Ultrasound scan can be performed to confirm the leading edge of the placenta, but only if the practitioner is trained to do so.
- If the presenting part is high and delivery is needed, an examination in theatre should be considered if the diagnosis is still unclear.
- The consultant must be informed prior to delivery and should be present for delivery or as soon as possible.

Major abruption

Large abruptions can lead on to DIC in 30 per cent of women. Management must be directed at ensuring the safety of the mother and fetus. Abruption is associated with a high risk for PPH.

- Usually presents with pain and vaginal bleeding with a woody, hard, tender uterus.
- If fetal heart is detected, continuous monitoring is needed.
- Vaginal examination should be performed with due caution.
- Follow the guidelines for massive obstetric haemorrhage, above.
- Prevent PPH and monitor for renal failure.
- Discuss with consultant haematologist.
- If no fetal heart is detected, ultrasound confirmation should be performed, membranes should be ruptured and syntocinon commenced to empty the uterus.
- FBC and clotting must be monitored at least 4-hourly as these can deteriorate quickly.

DIC

This is defined as inappropriate activation of the clotting cascade, leading to widespread coagulation, increased fibrinolysis and end-organ failure.

The obstetric causes can be divided into three areas.

- 1 Injury to vascular endothelium:
 - pre-eclampsia;
 - hypovolaemic shock;
 - septicaemia;
 - cold injury (large amounts of cold fluid).
- 2 Release of thrombogenic tissue factors:
 - placental abruption;
 - amniotic fluid embolism;
 - prolonged intrauterine fetal death.
- 3 Production of procoagulant phospholipids:
 - incompatible blood transfusion;
 - septicaemia.

Disseminated intravascular coagulation represents a cascade of events which can vary in severity, and range from a compensated state with only laboratory evidence of increased coagulation and fibrinolytic factor turnover, through to massive uncontrollable haemorrhage with very low concentrations of plasma fibrinogen, raised fibrin degradation products (FDPs) and thrombocytopenia. The evolution of events leading to DIC is shown in Fig. 46.2. End-organ damage is caused by hypotension, fibrin–platelet clump deposition in small vessels, and persisting endothelial damage leading to increased vascular permeability.

The following organs are most susceptible to damage.

- Kidneys:
 - acute tubular necrosis;
 - glomerular damage.
- Lungs:
 - pulmonary oedema;
 - adult respiratory distress syndrome/systemic inflammatory response syndrome.

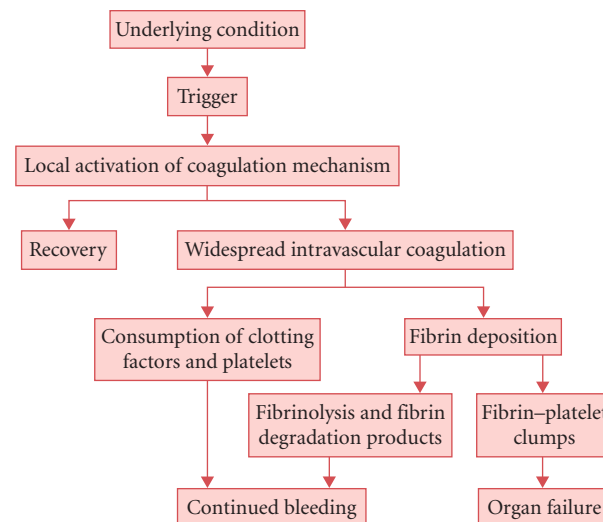

Fig. 46.2 Evolution of disseminated intravascular coagulation

- Central nervous system:
 - infarcts;
 - cerebral oedema.

The principles of management are:

- maternal resuscitation;
- treatment of the cause;
- replacement of blood and clotting factors;
- intensive monitoring until resolution.

Prompt and aggressive fluid replacement will limit damage to the endothelium and allow rapid clearance of fibrin–platelet clumps.

A full coagulation screen should be obtained for any patient at risk of DIC (this should include FDPs or D-dimers and fibrinogen; a thrombin time is useful if fibrinogen testing cannot be done). In DIC, all aspects of the routine clotting study are deranged (activated partial thromboplastin time, partial thromboplastin time and thrombin time). In pregnancy, the normal range for fibrinogen is increased, with the lower limit of normal being 4 g/L. In any woman in whom the fibrinogen falls to 1 g/L, a cryoprecipitate infusion (which is rich in fibrinogen) should be considered. Measurement of fibrin degradation products can be useful; D-dimers that are more specific may also be measured when other indices of coagulation are abnormal.

Management of DIC

Senior haematological advice should always be sought if DIC is suspected. The mainstay of the management of massive haemorrhage is to stop further loss of blood and resuscitate with appropriate blood products. Mild DIC may be controlled by adequate transfusion with stored blood and FFP. More FFP will be required in severe cases. FFP provides factors V and VIII, other labile coagulation factors and some antithrombin IIIa and fibrinogen. Cryoprecipitate (with a higher concentration of fibrinogen) and platelets may also be needed.

After initial resuscitation, management will be dependent on repeated checks of the haemoglobin, platelet count and coagulation status.

- Remember that stored blood contains thromboplastins and can exacerbate DIC once 6 units have been given.
- Remember the fibrinogen reference range in pregnancy is >4 g/L. Any woman with a fibrinogen of <1 g/L requires cryoprecipitate if there is active bleeding.

Treatment of the cause

DIC will not settle until the cause resolves. The urgency of treatment will be determined by the severity of the DIC and other factors such as maternal and fetal condition.

In general, following abruption and intrauterine fetal death, vaginal delivery should be the aim. Usually this will be accomplished within 4–6 hours. If DIC becomes uncontrollable during this time, more rapid delivery will be needed. Although it is considered that transfusion of replacement clotting factors may add fuel to the fire of DIC, it is recommended that replacement is aggressively pursued whilst delivery is being accomplished.

After delivery, steps to avoid PPH should be instituted.

Post-delivery surveillance

The aims are to:

- ensure adequate blood and clotting factor replacement;
- prevent further bleeding;
- monitor renal function and urine output until resolution;
- be vigilant for signs of impending lung involvement.

Fortunately, most women make a rapid recovery following delivery. It is important to ensure that the patient and her partner have the opportunity for a full debriefing.

SUMMARY

Antepartum haemorrhage increases the risk of perinatal death regardless of the cause. All women with APH therefore warrant careful fetal and maternal evaluation. In many cases a cause cannot be found, but the increase in perinatal mortality requires careful fetal surveillance for the remainder of all such pregnancies. Abruption carries the largest fetal and maternal risk. Women with underlying placental disease carry the highest risk for abruption.

Placenta praevia is becoming increasingly prevalent. As repeated caesarean sections are performed, the risk of a placenta praevia with a morbidly adherent placenta increases. A multidisciplinary approach is needed to ensure good maternal outcomes in the most difficult cases.

- Transvaginal ultrasound provides the most information and is safe in the diagnosis of placenta praevia.
- The risk of placenta praevia and accreta increases with each subsequent caesarean section.

- Regional anaesthesia for elective caesarean section for placenta praevia is safe and is associated with less maternal bleeding than general anaesthesia.

KEY POINTS

- The major causes of APH are abruption, placenta praevia and a mixed category of other causes.
- APH of any cause carries an increase in the risk of perinatal death for that pregnancy.
- Maternal deaths related to abruption and placenta praevia continue to be reported. Senior involvement is needed in the delivery of women with placenta praevia.
- Placenta praevia and accreta are likely to become more common as the CS rate rises.
- Increased surveillance is required for all ongoing pregnancies complicated by APH.
- Large abruptions carry a high risk of DIC and require a multidisciplinary approach to optimise care.

Chapter 47 Intrauterine fetal death

Lucy Kean

MRCOG standards

Theoretical skills

- To be able to manage intrauterine fetal death (IUFD) in a labour ward setting.
- To be able to counsel for postmortem.
- To have attended perinatal mortality and morbidity meetings.
- To understand the legalities of registration and disposal of fetal tissue.
- Be familiar with the RCOG Green-top Guideline Late intrauterine fetal death and stillbirth 2010.
- Be familiar with the RCOG Good Practice Guideline: Disposal following pregnancy loss before 24 weeks of gestation (RCOG Website)

Practical skills

- Be able to confirm fetal death using ultrasound.
- Role-play counselling after IUFD.
- Candidates are encouraged to attend postmortem examinations in cases they have personally managed.

INTRODUCTION

Intrauterine fetal death or stillbirth is variously defined in different countries, by gestation or birthweight. In England and Wales, stillbirth is defined as a baby delivered with no signs of life known to have died after 24 completed weeks of pregnancy. This definition allows fetuses known to have died before this time, but not expelled from the uterus until after 24 weeks, to be categorised as fetal losses or miscarriages. Therefore parents are not required to notify the registrar of births and deaths of these earlier losses. Most of these are co-twin deaths, which remain in-utero. The WHO uses birth after 28 weeks, or of a baby weighing 1000 g or more. This definition is most useful for international comparisons.

Globally, stillbirth affects 2.6 million families each year, with 98 per cent occurring in low- and middle-income countries. Stillbirth reduction remains a global challenge, with many countries not recording stillbirths at all.¹

There has been much recent criticism of the lack of progress in reducing the rate of stillbirth in the United Kingdom. In 2011 the stillbirth rate rose slightly to 5.2 per thousand total births from 5.1 in 2010, as rates in the rest of Europe appear to be falling. However, recent data produced from areas with a high uptake of the use of customised growth charts has demonstrated a clear fall in the rates of stillbirth, though recognising that these areas often had higher rates of loss prior to intervention. However, a clear downward trend in these areas has been matched by no movement in other areas without the intervention.² The rationale is that early recognition of small babies or those with plateauing growth allows for intervention before catastrophic placental failure. These data have led to the recommendation that customised fetal growth charts are used in the routine antenatal care of women (RCOG Investigation and management of the SGA fetus 2013) [C].

For the purposes of this chapter, fetal death after 20 weeks' gestation is taken as the focus, as these women are generally managed on the labour ward.

STILLBIRTH CLASSIFICATION SYSTEMS

The ability to determine the cause of an IUFD will be related to the rate of uptake of postmortem (PM) examination, the quality of the examination and the experience of the examiner.

Various methods of designation and classification of stillbirth have been used. The aims of each system are to retain important information towards understanding the causes of stillbirth, to be easy to apply and have high inter-observer agreement. There are six contemporary systems, the Extended Wrigglesworth and Amended Aberdeen systems, CODAC (Cause of Death and Associated Conditions), PSANZ-PDC (Perinatal Society of Australia and New Zealand – Perinatal Death Classification), ReCoDe (Relevant Conditions at Death) and Tulip. Recent studies

have suggested that the two older systems (Wrigglesworth and Aberdeen) perform less well in terms of the proportion of unexplained stillbirths and inter-observer agreement. Wrigglesworth and Aberdeen systems lead to a higher proportion of unexplained stillbirths (52 and 44 per cent) with CODAC and Tulip having the lowest rate of unexplained stillbirth (9.5 and 10 per cent). ReCoDe and PSANZ-PDC report unexplained loss rates of 15 and 14 per cent. It can be seen, therefore, that the ability to determine a cause of death will be at least in part related to the system that is used to analyse the pathology.

At present there is no international consensus on the best system to use and so causes of stillbirth will remain difficult to compare. The RCOG guideline of 2010³ still states that parents should be told that no specific cause is found in almost half of stillbirths, a fact that we can see is now no longer the case if newer methods of pathological classification are used.

Box 47.1 Causes of IUFD

Fetal

- Cord accidents
- Feto-fetal transfusion
- Feto-maternal haemorrhage
- Chromosomal and genetic disease
- Structural abnormality
- Infection
- Anaemias of fetal origin e.g. alpha-thalassaemia

Direct maternal effects

- Obstetric cholestasis
- Metabolic disturbance e.g. diabetic ketoacidosis
- Reduced oxygen states e.g. cystic fibrosis, obstructive sleep apnoea
- Uterine abnormalities e.g. Ashermann's syndrome
- Antibody production e.g. rhesus disease, platelet alloimmunisation, congenital heart block

Maternal placental effects

- Pre-eclampsia
- Renal disease
- Antiphospholipid syndromes
- Thrombophilia
- Smoking
- Drug abuse e.g. cocaine

Primary placental disease

- Placental villous dysmaturity (Stallmach changes)

CAUSES

The causes of fetal death are many (Box 47.1). An understanding of the aetiology and associations can better direct investigations.

These individual conditions and the fetal effects they cause are discussed in greater detail in the relevant chapters.

ASSOCIATIONS

It is recognized that IUFD is more common amongst certain groups, though the exact aetiology for the increase in risk is uncertain. Advanced maternal age, obesity, advanced gestation and social deprivation are all associated with increased risk. Non-white ethnic origin and booking after 12 weeks are also associated with higher risk [C]. Multiple pregnancies have an increased risk, as do women with diabetes and hypertension. Women who experience intimate partner violence have an increased risk of stillbirth and miscarriage. Reducing the disparity in stillbirth rates between disadvantaged groups and more affluent populations remains a major goal for developed countries.

The contribution of each of the above factors to fetal death may be variable. Many of these diseases or conditions are common and yet fetal death is uncommon. It is vitally important not to ascribe causation to associations without investigation, as this may lead to important further information being missed and may inappropriately ascribe causation. Although abruption may lead to fetal demise, it may not be the whole story, as abruption is commoner with fetal abnormality, thrombophilia, growth restriction, smoking and illicit drug use. Equally, thrombophilia is common (affecting more than 5 per cent of the population), and whilst some types have been shown to contribute to fetal death in some women, they may also be an incidental finding after a fetal death of another cause. There is still much controversy regarding the role of thrombophilia in stillbirth. Large randomised trials of management have not been performed and thrombophilia is not a single entity. Association is strongest amongst women who deliver a very growth-restricted baby, but there is little guidance on future interventions to reduce risk, though increased surveillance will obviously be important.

Diabetes is associated with stillbirth as gestation increases. Current guidance advises delivery at or after 38 weeks in women with diabetes A].⁴

Obstetric cholestasis (OC) is discussed further in Chapter 15. The association with fetal death once the condition is recognised is probably small, with rates similar to the background rate of 5.7/1000 being reported in recent studies. That OC is associated with higher rates of meconium passage, fetal compromise in labour and CS shows that there is an association with reduced fetal resilience. It is a difficult diagnosis to make at PM, as the features are very non-specific

in the fetus (generally just an anoxic mode of death). Direct questioning about itching may point to the diagnosis, which can be confirmed by measurement of maternal bile acids.

Cord accidents are often attributed as the cause of death, as the finding of a cord knot or tight nuchal cord is easily seen at delivery and is often seen as a clear demonstration of the cause of death which parents can understand. However, it is rare for knots or cord entanglement to cause antepartum stillbirth, though these may be implicated intrapartum. These findings are seen as often in pregnancies resulting in live births. Only if pathological confirmation is obtained should these be deemed causal. Many parents decline PM because causation is erroneously ascribed to a cord accident.

MANAGEMENT

Diagnosis of the death

IUFD presents with decreased fetal movement in as many as 50 per cent of cases. Others present with an unexpected finding at a routine ultrasound or antenatal visit or with signs of an acute event such as abruption, ruptured membranes or the onset of labour. In the developing world, intrapartum stillbirth accounts for nearly half of all losses, with 1.2 million babies being lost each year.¹

When an IUFD is suspected, it is vitally important to establish the diagnosis as soon as possible. It is natural for parents to cling on to every shred of hope for as long as possible, and delay in diagnosis can lead to a false elevation of hope.

Fetal death must be diagnosed by ultrasound. CTG and auscultation can be very misleading. The heart rate tracing of an anxious mother can be identical to that of a fetus. Even heart rate tracings achieved by scalp electrode can record the maternal heart rate when the fetus is dead.

The ultrasound must be performed by a trained practitioner and a second opinion is recommended if practicably possible. Colour-flow mapping can be very useful, especially in the obese woman. It is sometimes, but not always, helpful for the parents to be shown the still fetal heart.

Ultrasound can also confirm features that may be helpful in further investigation. There may be:

- Spalding's sign (overlapping of the fetal skull bones when the fetus has been dead for some time);
- oligohydramnios;
- signs of fetal hydrops;
- intrafetal gas.

Once the ultrasound has confirmed fetal death, it is very important that the news is given to the parents in an unambiguous and sensitive way. Phrases such as 'I cannot see a fetal heartbeat' can be taken by parents to mean that the operator cannot be sure or is not sufficiently trained. It is much better to explain that the baby has died and to express your sorrow.

Offer to call a supporter (partner, friend) if the woman has attended unaccompanied. It may be necessary to repeat the

scan when the partner arrives. It is also worthwhile doing a repeat scan if the woman reports passive fetal movement, as many do, as this can be important for the parents in knowing that the diagnosis is correct.

The initial reaction of parents will vary according to their prior suspicions, and many parents will initially feel anger. It is helpful for parents to be able to express their distress freely and without interruption. Do not try to challenge anger expressed against medical or midwifery staff at this time. If the pregnant woman has family with her, they should be allowed time together to come to terms with the findings.

All units should have a clear protocol for the management and investigation of women with fetal death. It should encompass lines of responsibility so that steps are not inadvertently omitted or repeated.

It is important to establish the events leading up to the fetal death, as there may be factors that will impact on the next pregnancy. It does not take long to take a history of events, and mothers may forget important factors later. It is an important process for the mother; she may feel the need to go through events preceding the admission. Although some of the information that parents volunteer is not relevant, it should be listened to sympathetically and never dismissed as irrelevant.

Establishing the safety of the mother and providing choice

At this point it is important to accede to mothers' choices in regard to management and to carefully advise if her choices may compromise safety. Empathy, choice and continuity of carer are three of the most valued aspects that parents report. The provision of written information is also helpful, as parents remember little of what they are told in the acute period.

Measurement of blood pressure and urinalysis should be undertaken to rule out significant pre-eclampsia. Where the fetal death is due to an abruption, clinical signs are usually apparent from the outset. If it is felt that the fetus has been dead for some time, a clotting screen should be performed to ensure that there is no coagulopathy (unlikely if the fetus is recently demised, but a 30 per cent risk after 4 weeks). Signs of maternal infection should also be recorded, as the presence of chorioamnionitis will alter management [C].

PREVENTION OF RHESUS (D) ISOIMMUNISATION

Massive fetomaternal haemorrhage is one cause of fetal death and may have occurred hours or even days before clinical presentation. If the woman is RhD negative, blood for Kleihauer testing should be taken soon after the diagnosis for an estimation of the volume of fetal-maternal transfusion. Anti-RhD immunoglobulin should be given as soon as possible after presentation and not delayed. Delivery may not occur until after the 72-hour watershed beyond which immunoprophylaxis is

less effective. A further dose of anti-RhD immunoglobulin might be necessary once the Kleihauer result is known and clearance of fetal cells should be rechecked at 48 hours where a large fetomaternal haemorrhage has been encountered. If it is deemed important to know the fetal blood type and this cannot be ascertained from a fetal blood sample after birth, testing of the rhesus status can be undertaken by using free fetal DNA analysis from a maternal sample. This result will not usually be available within the 72 hours required for anti-D prophylaxis, and so all rhesus-negative women should receive at least a standard dose of anti-D when the fetal blood type is unknown [C].

HOW TO DELIVER

If the mother is well, the next step is to decide how and when to deliver her. Many women are horrified that a vaginal delivery is often recommended. This must be approached in a sympathetic manner. Most women will understand that a straightforward vaginal delivery will minimise the length of postnatal inpatient time and speed their general recovery. There may be circumstances in which CS has to be considered. These will include women for whom this management was previously planned, women with a major placenta praevia and women who simply cannot bear the concept of a vaginal delivery. There can be no set rules and each case must be individually managed. There have been no studies that have assessed the psychological impact of different delivery strategies in this context [D].

TIMING OF DELIVERY

Women should be offered the choice of when they would like to deliver. Clearly if there are conditions that pose a risk to maternal safety (abruption, pre-eclampsia, infection) then advice on expediting delivery needs to be given.

The risk of coagulation problems secondary to a retained dead fetus is small. Estimated risk is 30 per cent if the fetus has been retained for 4 weeks. Therefore, given that over 85 per cent of women will deliver spontaneously within 3 weeks following IUD, conservative management is an option that can be offered, though testing for DIC twice weekly is recommended. Prolonged time before delivery will limit PM evaluation in some cases. Some women will want to spend time at home before commencing induction and others will want to start the process as soon as possible.

Women should be cared for within an environment that allows for supporters to stay but in which maternal safety is not compromised. In many units, a dedicated room is set aside for their management. Experienced midwifery care should be provided.

Women should have full access to analgesia as required. Diamorphine or morphine is a better option in this setting (compared to pethidine) as both have a longer half-life. Epidural analgesia should be available for women with normal

clotting, and patient-controlled analgesia may be useful for those who cannot receive epidural analgesia.

INDUCTION OF LABOUR

If the woman appears to be physically well, her membranes intact and there is no evidence of infection or bleeding, she should be offered a choice of immediate IOL or expectant management. If there is evidence of ruptured membranes, infection or bleeding, immediate IOL is the preferred management option.

There are various strategies that have been used for IOL after fetal death. Whichever method is used, it is important to remember that complications such as uterine rupture and shoulder dystocia can occur and management must be safe. Until relatively recently, third-trimester induction was generally achieved with standard prostaglandin E2 preparations. This was because of their safety profile in relation to uterine rupture. Now, the combination of the anti-progesterone mifepristone and the prostaglandin analogue misoprostol is recommended. The advantage of this protocol is that the induction to delivery time is shorter (median 8.5 hours, and about 7 hours shorter than if mifepristone is not used). However, in order for the process to work efficiently, the mifepristone needs to be given 24–48 hours before starting misoprostol [B]. Although this time can be spent at home, many women do not wish to delay starting. Higher rates of anxiety have been reported in women in whom the diagnosis to commencement of induction time is greater than 24 hours. In women who do not wish to wait, misoprostol alone or prostaglandin E2 may be used. There is usually a longer time from induction to delivery in these cases. Misoprostol is not licensed for this indication and informed consent should be documented.

A standard protocol for mifepristone/misoprostol induction is shown below.

- Mifepristone: 200 mg 24–48 hours before induction.
- Misoprostol: 50–100 mcg pv 6 hourly for 24 hours.

Vaginal use of misoprostol is associated with fewer side effects of pyrexia and shivering than oral use [B].

In gestations of 34 weeks or more, doses of 50–100 mg of misoprostol appear to be effective but require breaking the tablets in half or dissolving in water.

Oxytocin augmentation will be required for some women.

Mechanical methods are rarely required now that misoprostol is widely available.

Where possible, membranes should be left intact for as long as possible, as ascending infection can rapidly develop.

For women who have IUD and who have had a previous CS, the risk of uterine rupture is increased in IOL. After a single CS, induction is reasonable, but consent must be taken by a senior person (RCOG recommend a consultant), and the risk of uterine rupture discussed. Mifepristone alone (200 mg tds for 2 days) has been shown to lead to labour in two thirds of women.

Vaginal prostaglandin E2 can be used with the caveats on safety that increased rates of uterine rupture are seen in labour with a live baby (0.7–1.25%) [C]. If misoprostol is used a reduced dose is recommended, but the exact dose profile of greatest safety is not yet known. Smaller doses need to be specially prepared as tablets cannot be accurately cut into quarters.

Women with more than one previous CS or a previous non standard uterine incision require individualised management. After one previous CS there are still slightly increased risks of rupture and so careful surveillance must be undertaken during induction, but vaginal birth should be considered as the primary option.

Mechanical methods have been used for women with previous CS. There are no large trials and safety data are limited. It is recommended that these are used in the context of clinical trials only.

Immediate postnatal care

PPH is not uncommon, especially where there is pre-eclampsia, abruption, prolonged fetal death or infection. Prolonged chorioamnionitis and repeated small abruptions predispose to retained placenta. When this occurs it should be dealt with quickly and antibiotic prophylaxis given.

An assessment of thrombosis risk should be made for each woman using standard tools. IUFD does not itself constitute an increased risk, but associated factors (pre-eclampsia, infection, immobility) will do. LMWH should be prescribed along normal guidelines [D].

INVESTIGATIONS

It is important not to make assumptions about the cause of the IUFD that may deny parents full investigations. This is

particularly so when a true knot or placental abruption is seen. Parents may wish to have a clear cause quickly identified, but it is the role of the medical and midwifery team to explain that only complete information can provide real answers.

The fetus should be carefully examined after birth. The birthweight and length should be recorded and the placenta weighed. If possible the birthweight centile should be calculated using customised centile charts as this will give a better idea of unidentified growth restriction.

Any dysmorphic signs should be noted and if there is a suspected abnormality at this stage, an examination by a clinical geneticist or interested paediatrician can be helpful (this is particularly important if PM is declined) [E].

Sexing the baby is important for identity and naming, but may be very difficult in early fetal deaths and hydropic babies. Also, where there are dysmorphic features, there may be ambiguity. There must be no attempt to guess the sex by obstetricians or midwives, as this may prove very damaging if the assessment is wrong. If necessary, it may be better to await the result of the initial PM findings or karyotype which can often be determined using rapid methods such as PCR, and available within a day or two. If the sex is not determined and parents do not wish any investigation, it is possible to register the baby as indeterminate sex. Alternatively a consensus can be reached by two experienced practitioners (a senior midwife, obstetrician or neonatologist) and if appropriate the parents can be invited to examine the baby and give their own assessment.

Investigation needs to be tailored to the individual case and thought should be given to include only those tests that are going to help inform or manage.

Investigation of the mother

See Table 47.1

Table 47.1 Investigation of the mother

Investigation of the mother	Aim
Kleihauer	Fetal-maternal haemorrhage/determine dose anti-D
FBC with platelets	
Clotting studies/fibrinogen	Baseline in case of bleeding; abnormalities may suggest pre-eclampsia or DIC
Blood group, antibody screen	Isoimmunisation
Anticardiolipin antibodies (IgG, IgM), lupus anticoagulant screen	Antiphospholipid syndrome
Thrombophilia screen	This is debatable: consider if IUGR or placental pathology; care in counselling as association may be weak. (recommended in RCOG guideline)
Protein S measurement should be deferred until at least 6 weeks postnatally	
Haemoglobin A1c	Diabetes
Urea and creatinine	Renal disease/pre-eclampsia

<i>Investigation of the mother</i>	<i>Aim</i>
Liver function tests	Pre-eclampsia/obstetric cholestasis/acute fatty liver
Bile acids	Obstetric cholestasis
Maternal serology for: syphilis, parvovirus B19, CMV, herpes simplex, rubella (if not immune), toxoplasmosis	
(Consider others if history of travel or symptoms e.g. influenza, malaria)	Transplacental transmission of infection
High vaginal/cervical swabs	Transcervical ascending infection (only relevant if confirmed histology of chorioamnionitis)
Blood cultures	If signs/symptoms suggest maternal sepsis
Parental platelet typing	If USS or PM shows intracranial haemorrhage
Thyroid function	Occult maternal thyroid disease
Anti-Ro/La	If hydrops or PM evidence AV node calcification
Red cell antibodies	If fetal hydrops
Urine screen for cocaine metabolites	If consent given and high index of suspicion
Parental karyotype	If fetal karyotype fails and there is a high index of suspicion of chromosomal disease

Investigation of the fetus

Postmortem examination

Investigation of the fetus and placenta is outlined in table 47.2. Fetal investigation is likely to help with diagnosis and future pregnancy management. Parents should be provided with written and verbal information that covers the aim of PM examination, the extent of the examination, how samples of tissue are dealt with afterwards and whether samples are kept for research or audit. They also need to know how long the process will take and whether there will be any delay in releasing the baby for burial or cremation. Perinatal pathology services should offer a rapid service where there is a cultural need to release a baby for burial quickly, but parents do need to know that some information may not be obtained accurately if the process is speedy (for instance careful examination of the fetal brain usually requires fixation which takes some days). Written consent must be obtained for each part of the process, including the fetal tissues sent for karyotyping.

Parents should have time to consider whether they wish a PM to be done and once they have signed the form there should be at least 12, and in the view of the Human Tissue Authority (HTA), 24 hours until the start of the PM.

Parents should always know that, even after they have signed the consent form, they can change their minds about anything they have agreed to.

What is postmortem examination and how it is performed?

Parents need to know that the person performing the examination is a dedicated perinatal pathologist. Some

regions perform their perinatal pathology in a main centre. When this is the case, parents should be told that the baby will need to be transferred and will be rapidly and safely returned. Babies classified as stillborn under UK law must be transferred by the undertaker.

Postmortem examinations may take up to 5–7 working days to complete when the brain needs to be fixed for proper examination. Examinations should be completed within 3 days after receipt of the body if no special examination is required. There will then be additional time for histopathological analysis, microbiology, metabolic studies, etc., which can add significant delays to the final report. It is recommended that at least 60 per cent of reports are issued within 42 days and 90 per cent within 56 days.

The baby is always treated with dignity and respect. The incisions are closed and do not involve the face or limbs. In most cases the baby when dressed will look no different from the way it did before the PM. The exception may be the very small macerated fetus whose skin is so thin that suturing is not possible. In these cases, the baby is wrapped.

Fetal and placental investigation

What tissues are kept?

In general, the pathologist will not need to keep any organs. Samples for histology may be retained, but even these can be returned should the parents wish. Where a postmortem is performed in the first trimester, organs are so small that occasionally whole organs need to be retained to make microscope slides. Again, these can be returned if wished.

Where there is a suspected CNS abnormality, the brain needs to be fixed before examination ideally. This can take 5–7 days, especially in a large term fetus. If this is an important

Table 47.2 Fetal investigation

If potential for fetal abnormality take fetal and placental genetic material for karyotype. Discuss consideration of microarray analysis or single gene testing with pathologist and genetics team (fetal blood, skin, chondrocytes, placenta)	Use more than one site and use more than one method. Solid tissue better for array analysis
Fetal and placental swabs	Bacterial infection
Fetal blood for bacteriology and virology	Culture, serology for viral infection if suspected; if no cord sample available, cardiac blood should be taken; parental consent required
Placental pathology	Infection, infarction, abruption, trophoblast invasion failure, maternal or fetal vessel thrombosis
PM examination of fetus Limited investigation if PM declined: examination/X-rays/MRI	Structural fetal abnormalities, growth restriction, infection, metabolic syndromes

aspect of the postmortem (usually if there has been antenatal suspicion of abnormality), parents have three options:

- 1 to forgo this extra information;
- 2 to delay funeral arrangements until this process is complete;
- 3 to allow the pathologist to retain the fetal brain and to proceed with funeral arrangements without the brain being returned.

Most parents who have given consent for postmortem will want to wait, and to delay arrangements until the baby can be returned intact.

What other investigations might be needed?

Other information may become available later, which may require further investigations. These would include parental karyotype if a fetal translocation were found or if the fetal karyotype failed but a chromosomal cause were suspected, or antiplatelet antibodies if intracranial haemorrhage is seen.

Karyotype analysis often fails. Where there are specific concerns, the genetic laboratory may be able to help with specific diagnoses by utilising other techniques such as FISH or PCR. Fetal chondrocytes provide the most prolonged cell viability, and a small sample from the iliac crest or patella can sometimes provide a diagnosis. Some have recommended performing a fetal karyotype by transabdominal CVS or amniocentesis to avoid problems associated with delay and infection of the placenta during delivery. Whereas this may be ideal, it may be unacceptable to many mothers at this time. Fetal deaths where there are known abnormalities and no previous karyotype has been taken are the group most likely to benefit from this; however, as alternative techniques increase in the number and type of chromosome problems detectable, the need for this will diminish. A search for single gene problems and consideration to whole genome array analysis will be directed to fetuses where a structural abnormality is seen that may point in the direction of a chromosome or genetic issue, undetected

by karyotype analysis. Array analysis is a science in its early stages. Where copy number variants are seen these will be categorised as varying degrees of likelihood as causative, depending on the findings, parental testing and the current body of knowledge. Array analysis is progressing quickly, but is not yet widely used in the management of stillbirth.

The Kleihauer test will become negative very quickly if there is ABO incompatibility. This test must therefore be performed as soon after confirmation of fetal death as possible and should not be delayed until after delivery. Mothers who have experienced huge fetomaternal transfusion may describe an episode of shivering, feeling unwell or rigors that may pinpoint the event; transfusion reactions have been described in this context.

Maternal glucose metabolism returns to normal almost as soon as the fetus dies. Blood sugar estimation is therefore generally unhelpful. Also, as the derangement is generally mild, HbA1c measurements are usually normal. A suspicion of disordered glucose metabolism may arise if the fetal weight is excessive and islet cell hyperplasia is confirmed (though other diagnoses such as Beckwith syndrome can also present in this manner). Women with unexplained stillbirth have a four-fold increase in glucose abnormalities in subsequent pregnancies. Therefore, if this diagnosis is suspected, formal glucose testing should be undertaken in the next pregnancy [C]. It is established that APS can lead to IUFD, and there is evidence that low-dose aspirin and LMWH improve pregnancy outcome amongst those women who present with recurrent miscarriage (see Chapter 89). Thrombophilia may be associated with stillbirth in growth-restricted fetuses and there may be placental features that point to an underlying thrombophilia. It must be recognised that there are no studies to guide management in the subsequent pregnancy.

Obstetric cholestasis carries at most a marginal increase in the rate of stillbirth, but as it is a recurrent condition, screening for bile salts is worthwhile [E].

It is possible to screen maternal urine for the presence of illegal drugs. This should only be done with the consent of the mother and, in this author's experience, is unhelpful. Most

mothers feel guilty enough if they think they have contributed to the death of their baby without needing concrete evidence. Those who divulge information about illicit drug use do not need the additional burden of proof. Those who do not provide this information are unlikely to consent to urine testing.

Can anything else be offered to parents who do not want a PM?

Placental pathology should be offered regardless of whether a full PM is to be performed. However, it is important to be realistic about what information this can yield. Up to 48 hours after fetal death placental morphology does not change very much, but after this time placental morphology changes such that it can be difficult to differentiate pre-existing from PM changes. After 14 days from fetal death placental pathology is unlikely to yield any useful information. It is important that the placental pathology is undertaken by an experienced perinatal pathologist, as ascribing causation based on placental changes is not a straightforward task.

Fetal MRI can provide some information, but cannot replace a full PM yet as a specific skill set is required to ensure accurate diagnoses. However, up to 87 per cent concordance has been seen when used to determine major structural abnormalities, compared with PM examination [C].⁵

Parents need careful counselling by someone who is experienced in dealing with this situation and who understands the processes involved. It is important that obstetricians are trained to seek consent in these cases and understand fully the issues involved. An excellent leaflet explaining PM to parents is produced by the HTA at <http://www.hta.gov.uk/policiesandcodesofpractice/modelconsentforms.cfm>.

The final facet of obtaining good information at PM is to give the pathologist all the relevant information. Where there are specific suspicions, the pathologist should be informed of these. It is usually helpful to speak directly with the pathologist about the case. This will also enable the doctor responsible for the case to attend the PM if possible.

AFTER DELIVERY

After delivery there are many processes that need to be completed before discharge. The first and most important is to allow the parents as much (or as little) time with the baby as they need. Parents should be allowed to express their own wishes with regard to seeing and holding the baby. Some parents will want to come back to the hospital on a few occasions before they feel able to finally part from their lost baby.

Evidence on whether psychological outcomes are better or worse in women who have close contact with their stillborn infant is conflicting and so it is imperative to be guided by what the parents feel is best for them.

Depression, which can become post-traumatic stress disorder (PTSD), is common and women, their partners and children may need considerable support, access to good-quality counselling and in some cases the support of the perinatal mental health team and GP.

Parents should be offered the opportunity to have photographs taken and, if these are not wanted at the time, they can be kept, as many parents request them later (sometimes a long time later). The parents may want footprints or handprints of the baby to be taken.

Importantly, having a funeral and keeping mementoes is not associated with additional adverse outcomes. Photographs should only be taken after seeking the parents' wishes, as in some cultures taking photographs of the dead is unacceptable.⁶

All units should have a bereavement team to take on the care of parents. These teams are usually acutely aware of cultural requirements and may provide an important liaison between the family and the pathologist, especially where there is a need for funeral arrangements to proceed without delay. Unfortunately, it is often those who have the most to gain from PM who feel the most cultural pressure not to delay burial. Sympathetic discussion can often provide a way forward, and many pathologists will provide an out-of-hours service so that delays can be minimised.

Parents should be provided with the telephone numbers of organisations that may also offer support, such as SANDS, as they sometimes need to talk to people unconnected with the hospital. The bereavement team will also provide a contact number.

LEGAL ISSUES

The law in the UK states that a stillborn baby is one delivered after the 24th week of pregnancy, showing no signs of life.

Further guidance issued by the Department of Health and accepted in Scotland and Northern Ireland states that a baby delivered after 24 weeks, but known or able to be proved by examination to have died before 24 weeks, does not need to be registered. Most often this applies to a co-twin, retained for some time after death; however, occasionally a woman will present with a singleton loss, where it is clear that the death was many weeks earlier. In these cases it must be provable by examination of the development of the fetus that the baby was less mature at the time of birth. In some cases this will require PM examination. In others it may be very obvious, by external examination by an experienced person. Where a PM is needed to establish the potential maturity but this is not wished, the baby should be registered in the normal way.

The parents need the stillbirth certificate in order to register the baby. The attending doctor or midwife can issue the certificate.

When the certificate is completed, it is important not to use abbreviations, or attempt to guess the cause of death. It

is extremely difficult to have death certificates changed and parents can be deeply upset to find that a baby has a registered cause of death that is not accurate. The Registrar's office may need to contact the doctor or midwife signing the death certificate, so it is always important to sign and print the name, and important information such as recognised GMC qualifications must not be omitted. The less well the form is completed, the more time the bereaved parents will have to spend at the Registrar's office while he or she tries to contact the doctor or midwife involved.

The mother, or father if the couple were married at the time of the loss, can register the stillbirth. This has to be done within 42 days (21 days in Scotland) and only in exceptional circumstances will this be extended to 3 months. Registration can be delegated to the delivering doctor, midwife or bereavement officer if they have the appropriate supporting information and documentation (most Registrars' websites will have the requirements).

Responsibility for funeral arrangements lies with parents, but can be delegated to the hospital.

The sex of the baby can be added later after PM, but changing the name can be more difficult and will not be permitted in many cases.

The law does not recognise fetal deaths before 24 weeks. The lack of legal recognition means that parents will not have a death certificate for these early fetal losses. It does not mean that they cannot arrange a funeral or cremation if they wish.

Mothers who have delivered a stillborn baby are entitled to normal maternity benefits and payments. Mothers delivering before this time will not be so entitled.

The Coroner has the discretion to be involved where there has been a criminal act, such as assault, and can request a PM. Cases of unattended fresh stillbirth should also be discussed with the coroner.

If there is a suspicion of a criminal act to cause a stillbirth, the police should be informed.

SUPPRESSION OF LACTATION

The onset of lactation often catches women by surprise and is a source of considerable distress when it starts in earnest at about 48 hours. Although not all women need or want lactation suppression, discussion should take place so that advice can be given about how to cope. For some women, simply a good supportive bra, NSAIDs if there is discomfort, and time will be enough. However, about a third of women experience distressing breast pain and so pharmacological measures should be offered to all suitable women. A single dose (1 mg) of cabergoline, a long-acting dopamine agonist, is highly effective. Dopamine agonists for the inhibition of lactation should not be used in women with pre-eclampsia or hypertension [B].⁷

CONTRACEPTION

This subject is best covered by the GP or consultant later, but women do need to know that they can conceive before their first period. A pregnancy conceived quickly may delay the grieving process and, before women go home, it does no harm to include a leaflet on contraception that will meet their needs.

GOING HOME

Although every effort is made to ensure women go home quickly, premature discharge must be avoided. It is undoubtedly more painful for women to have to return with problems, and safety is paramount. Many units have a bereavement suite or family room so that other family members can stay for support until discharge can safely be achieved.

Contact telephone numbers should be given to the woman or a companion, and there should be a contact who knows what has happened and who is easily available should problems occur. The community team will play a central role in the care of the family, and detailed communication with the GP and community midwife is of paramount importance. They must be informed by telephone on the day of the woman's return to the community, and all antenatal appointments must be cancelled. There is a notification process so that mailing regarding baby products which may have been signed up to antenatally can be suppressed.

BEREAVEMENT CARE

As perinatal death becomes less common, couples can feel increasingly isolated in their grief. The bereavement team and the community midwife and GP need to be aware of the situation and to react quickly when problems appear to be mounting. It is particularly those couples with high expectations and little family or social support who can be most vulnerable at this time. It is helpful to ensure before discharge that provision is made for the partner to have some time off work, as he will often be forgotten at this time. Also, if the fetal loss has occurred early (20–24 weeks), the patient will need a statement of fitness to work (previously termed a sick note), as maternity leave will not be applicable.

Parents who have other children often wish to receive guidance about explaining the death of the baby to them. Children's books about stillbirth are available. Self-help groups (such as SANDS) also offer support that may sometimes be lacking from professionals. The couple's response to bereavement cannot be predicted by whether they already have children, or the gestation of the fetal loss. Couples respond in different ways and take different amounts of time to heal. The loss of

a baby with a severe malformation should not be interpreted as a blessing; it may leave parents with significant fears for the future.

The death of one twin with the survival of the other is especially distressing for parents, who are faced with contradictory psychological processes. It is very difficult to celebrate the birth of one healthy baby and to grieve the death of the other. In this situation, mourning may get postponed or give rise to symptoms of failed grieving, which include the inability to care for and relate to the surviving child appropriately and may contribute to postnatal depression. The Twins and Multiple Births Association (TAMBA) has an excellent parents' leaflet on dealing with the loss of one baby in a multiple pregnancy.

FOLLOW-UP

The obstetrician involved in the antenatal care is the usual choice to conduct the follow-up. However, there may be occasions when the woman requests follow-up by a different practitioner, and when this occurs it should not be questioned. It has traditionally been arranged for follow-up to take place at around the time of the usual postnatal visit. In general it is reasonable to try to schedule a visit once all information is available. Reporting times for PM vary and so it is important to know these before attempting to set a date for review.

Women often experience extreme anxiety coming back to the hospital where they have had such a devastating experience. If possible, a neutral venue should be chosen. In every case, there should be enough time to discuss events.

Ideally, the name of the baby should be ascertained before the interview. The bereavement team should be able to supply this. Not all parents will have named the baby.

Generally, parents need to have time to go through events as they recall them, to ask questions that are important to them, and to receive and understand the results of any tests that have been performed.

Often the issues that are most troubling parents are not those that the medical team see as important, so it is vital to keep an open mind, to encourage parents to talk spontaneously and to be honest in replies. Parents may want to apportion blame to individuals or actions. When this occurs, it is important to be honest and to offer apology where this is deemed necessary. Where there has been a failure of care, parents need to receive sincere apologies and reassurance that action to prevent a similar occurrence will take place. Being half-truthful or dishonest will not prevent or reduce litigation. However, where there has been no failure of care, it is important to support other colleagues' management in discussion with parents.

When an underlying cause for the fetal death has been identified, this must be clearly explained. There may be the need to involve other professionals, such as clinical geneticists, at a later date.

When no cause has been found, parents are often very frustrated. This is always difficult for professionals, as the wish to provide answers is one of our most ingrained rationales. It is important not to try to provide unfounded reassurance, but in all cases a clear plan of management for the next pregnancy should be outlined.

Parents often ask when they can try for another pregnancy. It must not be assumed that all couples will wish to do so, and this issue must be covered sensitively.

Early conception may be associated with very marginally higher risks of preterm birth and SGA babies, but these risk increases are not great enough to recommend delayed conception [C].⁸ However, it is important that the grieving process is complete (as much as can ever be so) before the next child. Mothers who conceive quickly may have more problems with anxiety during pregnancy, depression, PTSD and disordered bonding after the next birth. Interestingly, fathers experience greater depression if conception is delayed. Postpartum depression following the birth of the next baby is common and professionals should be alert to this.

It is helpful for parents if the issues discussed can be provided for them in a letter. Many women will not wish to book their next pregnancy at the same hospital, and a clear letter will help the future team to understand events. It is also helpful for parents as an *aide memoire*, as they may not clearly remember some of the points covered. Finally, parents must be given the opportunity to come back if they are unclear about certain aspects and, for some, a pre-conceptual visit is helpful.

Where possible lifestyle adjustments should be recommended prior to conception. These may include weight loss, smoking cessation and drug and alcohol interventions. Stillbirth is commoner in relationships where there is domestic violence. Whilst there is still no clear recommendation regarding effective intervention during pregnancy, if possible the opportunity to enquire and offer help should not be missed. This information must be appropriately shared to help to protect the woman and any existing children, and to protect any baby born in the future.⁹

MANAGEMENT OF THE NEXT PREGNANCY

Management in the next pregnancy will depend on the circumstances of the loss and the results of the investigations.

Some aspects are common to all women who have lost babies in these circumstances. A means of identifying that a baby was lost so that professionals are all aware quickly that there has been a previous loss is important. This may include stickers on notes and icons on computer records.

It is beyond the remit of this chapter to discuss the potential management plans after fetal loss as the causes are very diverse and management must be individualised. The most

important facet of management is to try to adhere to the plans that were formulated after the loss of the baby. It is unusual for professionals to disagree to such an extent that a previously agreed plan has to be changed. There may be minor differences of opinion, but it is better to put these aside in the interests of maintaining the faith of the patient in their care when at all possible. When the plan needs to be changed (such as may occur when new information comes to light), it is important to explain clearly why the changes need to be made and how this will improve the prospects of a healthy pregnancy.

After the birth of the next child, parents may require much reassurance that the baby is healthy. An examination by a senior paediatrician can do much to allay fears.

Postnatal depression is common and both families and professionals need to be aware of this.

KEY POINTS

- Confirm fetal death quickly by ultrasound.
- Offer parents choice wherever possible.
- Do not make assumptions regarding the cause of death.
- Offer a full range of investigations tailored to the circumstances of the death.
- The support of a bereavement team is an integral part of care.
- Do not discharge the mother home until it is safe to do so.
- Do not forget lactation suppression and thromboprophylaxis.
- Information should be provided at all stages in a form that parents can understand.
- Management of the next pregnancy should try to follow previously set plans.

SECTION FIVE

First Stage of Labour

This page intentionally left blank

Chapter 48 Induction of labour

Nina Johns

MRCOG standards

- Candidates are expected to have the knowledge and skills to perform an induction of labour.
- Candidates should be able to evaluate the clinical need and make the decision for induction of labour.
- Candidates should be able to appropriately counsel women and their families regarding the methods of induction, the risks and benefits.

Theoretical skills

- A revision of the knowledge and understanding of normal labour.
- An understanding and judgement of the different indications and methods for induction of labour.
- Demonstration of the use of appropriate protocols and guidelines and knowledge of national guidance on induction of labour (NICE CG070).

INTRODUCTION

Induction of labour is the process by which labour is started prior to its spontaneous onset by artificial stimulation of uterine contractions and/or progressive cervical effacement and dilatation, leading to active labour and birth. The clinical need for IOL occurs when it is perceived that the outcome of the pregnancy will be improved if it is interrupted by induction, labour and birth.

IOL has considerable impact on women's experience of labour and birth, as it may be less efficient, more painful and more likely to require epidural analgesia and assisted birth.^{1,2} Therefore a well-defined clinical indication is needed, with careful consideration of the benefits and risks, together with a clear explanation to the woman prior to the decision being made.

The indications for IOL need to take into account the level of urgency for birth and suitability of vaginal birth. If the clinical situation necessitates urgent birth prior to the likely completion of an IOL process or vaginal birth is contraindicated, then

an emergency caesarean birth may be required. If a woman declines the offer of IOL, a plan for monitoring maternal and fetal wellbeing needs to be made and an opportunity provided for her to discuss the risks and benefits again during her continuing care.

The management of IOL is subject to clear national and international guidance with NICE clinical guidelines (CG070)^{1,2} and WHO recommendations.³ Local pathways of care and clinical decisions should therefore reflect this guidance and be based on the evidence available.

INCIDENCE

IOL is a common obstetric intervention, occurring in approximately 20 per cent of all births in the UK. The rates of IOL vary but have been rising over the last 30 years in most developed countries. The RCOG *Patterns of Maternity Care* report found the mean induction rate for primiparous women was 27.5 per cent and 21.4 per cent for multiparous women in the UK (Fig. 48.1). The report highlights that the wide variation in induction rates is not explained by demographic or clinical risk factors.⁴

Increasing rates of IOL also have an impact on the workflow in maternity departments. The increasing elective workload has to be balanced with the emergency care required for women in spontaneous labour or with pregnancy-related complications. At times of peak activity, this workload can exceed capacity and lead to delays and increase the risk to these women and their babies.

INDICATIONS FOR IOL

The primary indication for IOL is when the outcome for mother and baby will be improved by interrupting pregnancy rather than awaiting spontaneous onset of labour. The decision to proceed with IOL must also take into account the attitude and wishes of the woman, provided her understanding of the risks of induction and the risks of continuing the pregnancy are established.

There are many recognised indications for IOL and for most there is a potential risk of perinatal mortality. The following indications are discussed in further detail where

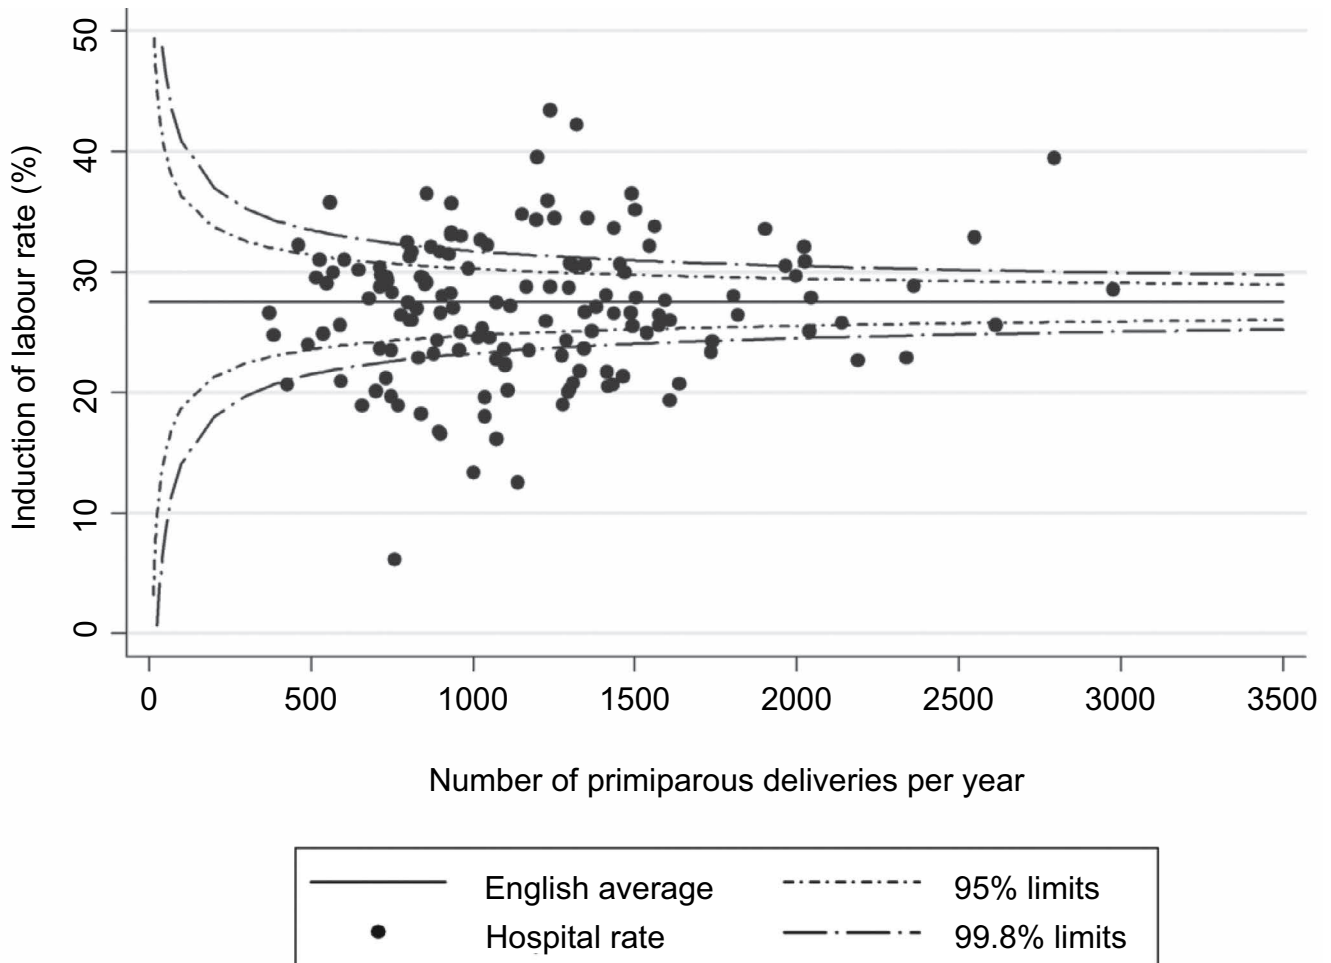

Fig. 48.1 Funnel plot showing rates of induction of labour among primiparous women. RCOG *Patterns of Maternity Care in English NHS Hospitals 2011/12*.

evidence is available to inform decision making or for which recent national guidance has changed.

Prolonged pregnancy

There is established evidence that the risk of perinatal mortality increases with gestational age beyond 40 weeks (Fig. 48.2). Systematic review of RCTs shows that expectant management compared to IOL after 41 weeks' gestation is associated with higher rates of perinatal death, despite the overall incidence being low (2–3/1000 pregnancies). Further, births after 42 weeks' gestation are associated with increased risk of intrapartum and neonatal deaths.^{1,2} It is recommended that IOL is offered from 40⁺⁷ weeks onwards to avoid prolonged pregnancy. As approximately 20 per cent of women will still be pregnant at 40⁺⁷ weeks, local pathways may delay IOL until 40⁺¹² weeks, to facilitate more women to attend in spontaneous labour.

Women who choose not to have IOL should be offered additional antenatal monitoring, which should include as a minimum EFM and ultrasound examination for liquor volume measurement twice weekly.¹

Pre-labour rupture of membranes at term

Approximately 8–10 per cent of women present with spontaneous rupture of membranes at or beyond 37 weeks' gestation; of these 60 per cent will labour spontaneously within 24 hours. Women should be offered the choice of expectant management following spontaneous rupture of membranes, with the offer of IOL after 24 hours to reduce the risk of serious neonatal infection. (Incidence is 1 per cent with PROM compared to 0.5 per cent in women with intact membranes.) During the period of expectant management women should be advised to check their temperature, report any change in vaginal loss and have fetal movements and heart rate assessed every 24 hours.

Premature pre-labour rupture of membranes

PPROM prior to 37 weeks' gestation occurs in approximately 3 per cent of pregnancies. The resulting risk of preterm birth, maternal and neonatal infection is associated with significant morbidity and mortality. Evidence from RCTs shows

Fig. 48.2 Risk of stillbirth for singleton births without congenital anomalies by gestational age, 2001–2002. U. Reddy *et al.* *American Journal of Obstetrics and Gynecology* 2006;195:764–70.

that immediate IOL is associated with reduced incidence of chorioamnionitis. However, the increased risk of neonatal morbidity due to prematurity prior to 34 weeks' gestation has led to the recommendation that induction is inappropriate unless there are clinical indicators of sepsis or fetal compromise.^{1,2}

Maternal conditions

Diabetes

Confidential Enquiry data have confirmed the higher still-birth rate for women with diabetes, which is approximately 5 times greater than the national rate. Evidence from RCT and cohort studies shows that IOL between 38–39 weeks' gestation results in reduction in late stillbirth and the intrapartum complications of macrosomia, such as shoulder dystocia. Therefore, IOL is recommended after 38 weeks.⁵

Hypertension

Pre-existing and gestational hypertension are both associated with increased risk of placental abruption, developing pre-eclampsia and increased perinatal mortality. In order to reduce this risk, recent NICE guidance recommends that for women with chronic hypertension whose blood pressure is lower than 160/110 mmHg after 37 weeks, with or without antihypertensive treatment, timing of birth, and maternal

and fetal indications for birth should be agreed between the woman and the senior obstetrician. Further, women with pre-eclampsia after 37 weeks' gestation should be offered IOL.⁶

Obstetric cholestasis

OC is associated with an unpredictable increased risk of still-birth at all gestations. Systematic review suggests that the uncertain risk to the fetus and the risks of the intervention of IOL should be balanced and discussed with the woman after 37 weeks' gestation. There is additional evidence suggesting that the decision to intervene should also be influenced by the severity of the biochemical abnormalities.⁷

Advanced maternal age

Epidemiological studies show that the average age of women having their first baby is increasing, particularly in women aged over 35 years. Women over 40 have increased rates of intrapartum CS and operative vaginal delivery rates. Their risk of stillbirth at 39 weeks' gestation is similar to that of a 25–29 year old at 41 weeks' gestation and is greater in nulliparous women. IOL is often offered at 39–40 weeks' gestation, particularly in a first pregnancy, after these risks have been discussed with the women, but there is currently no trial evidence that early induction reduces intrapartum complications or perinatal mortality.⁸

Maternal request

Maternal request for IOL is currently not supported by NICE guidance. However, it adds that this may be considered in exceptional circumstances and after discussion of the risks with the women. In practice, these women will often face frustrating delays in the process as their indication for induction will not be prioritised when there are issues of capacity.

Fetal conditions

Small for gestational age

The SGA fetus is defined as having an abdominal circumference or estimated fetal weight below the 10th centile on ultrasound examination and is at greater risk of perinatal mortality and morbidity, particularly if growth restricted.¹⁰ At present the only intervention for IUGR is birth. RCT evidence shows increased risk of adverse perinatal outcome in women offered expectant management versus IOL when SGA was detected beyond 36 weeks' gestation. Therefore it is recommended that IOL can be offered at 37 weeks' gestation. However, rates of emergency CS are increased in this group undergoing IOL and continuous FHR monitoring is recommended once regular uterine contractions commence.⁹

Reduced fetal movements

Women who present on two or more occasions with reduced fetal movements are at increased risk of a poor perinatal outcome compared with those who attend on only one occasion. There are currently no studies to determine whether intervention such as IOL alters perinatal morbidity or mortality in these women. NICE recommends that the decision to induce labour at term in a woman who presents recurrently with reduced fetal movements, when the growth, liquor volume and CTG appear normal, must be made after careful consultant-led counselling of induction on an individualised basis.¹⁰

Multiple pregnancies

Twin and triplet pregnancies more often present in preterm labour, with nearly 60 per cent of women with twin pregnancies giving birth spontaneously before 37 weeks' gestation. Evidence from studies reporting on all multiple pregnancies together (uncomplicated, spontaneous onset of labour or otherwise) showed an increase in the risk of fetal death per week at term gestations, with significant rise from 37 weeks' gestation. The risk of term perinatal mortality was greater in MC twin pregnancies. It is recommended that women with DC twins should be offered elective birth at 37 weeks, and MC twins at 36 weeks. For triplets there is an increased risk of spontaneous preterm labour and a significantly higher risk of fetal death after 34 weeks 6 days. It is recommended that women with triplet pregnancies should be offered birth at 35 weeks.¹¹

Suspected fetal macrosomia

Suspected fetal macrosomia is defined as a birthweight above 4000 g and occurs in approximately 2–10 per cent of births in the UK. Evidence from two systematic reviews comparing IOL versus expectant management showed no difference in maternal or fetal outcomes, such as CS rates or episodes of shoulder dystocia, with suspected fetal macrosomia.¹

METHODS OF IOL

Spontaneous labour is defined as the onset of regular painful contractions, leading to progressive dilatation of the cervix. The precise steps for the initiation of labour are unknown and methods for IOL aim to bring about dilatation of the cervix and start uterine contractions. Reviews of the available evidence for methods of IOL are summarised in Table 48.1 and discussed below.

Membrane sweeping

Membrane sweeping appears to result in increased local production of prostaglandins. Systematic review shows that membrane sweeping is associated with an increased rate of spontaneous labour and a reduction in need for formal induction, particularly in multiparous women.^{1,2} It is associated with an increased incidence of uncomplicated bleeding and pain at the time of examination, but similar maternal (CS rates, maternal infection) and fetal outcomes (compared to no membrane sweep) and appears acceptable to women. Review of the NNT show that to avoid 1 formal IOL, sweeping of membranes would need to be performed in 8 women in pregnancies of 38–42 weeks' gestation. Women should be offered membrane sweeping prior to formal IOL and at the 40- and 41-week antenatal visits.^{1,2}

Vaginal prostaglandins

Prostaglandins (PGs) are established in the role of stimulating uterine contractions and cervical change. Vaginal PGs can be administered via a number of preparations: controlled release pessaries, vaginal tablets or gel.

Evidence from systematic review and RCTs shows that, in women with an unfavourable cervix, all preparations of vaginal PGE₂ improve cervical status and reduce the need for oxytocin augmentation. In addition, in women with a favourable cervix, vaginal PGs are associated with high rates of achieving vaginal birth within 24 hours compared to placebo and reduced risk of PPH compared to amniotomy plus intravenous oxytocin.

It appears that maternal and fetal outcomes are comparable for all preparations of vaginal PGs and vaginal PGs should be the preferred method of IOL irrespective of cervical status. However, in women with an unfavourable cervix the use of controlled-release pessaries may be preferable because the induction time may be longer and repeated doses of tablet or gel would be required.^{1,2}

Table 48.1 Summary of methods of induction of labour

Method of IOL	Level of evidence	Benefit	Potential harm
Membrane sweeping	Systematic review & RCT	Increased spontaneous labour; reduction in IOL; same maternal and fetal outcomes	Increase in uncomplicated bleeding; pain
Vaginal prostaglandins	Systematic review & RCTs	Improved cervical status (unfavourable cervix); higher rates of birth by 24 hours (favourable cervix); less PPH	Uterine hyperstimulation; increased risk of scar rupture in previous CS
Oral PGE2	Systematic review	Similar maternal and fetal outcomes compared to other PGE2 preparations & ARM +/- oxytocin	Significant gastrointestinal side effects
Intravenous PGE2; extra-amniotic PGE2; intracervical PGE2	Systematic review	Similar maternal and fetal outcomes compared to vaginal PGE2 preparations	Increased uterine hyperstimulation with IV PGE2 and significant maternal side effects
Intravenous oxytocin alone	Systematic review	When compared to vaginal PGE2, less likely to achieve cervical change or birth within 24 hours	Increased rate of caesarean birth with intact membranes and unfavourable cervix
Amniotomy with intravenous oxytocin	Systematic review	Comparable to vaginal PGE2 to achieve birth within 24 hours and rates of caesarean birth	Increased PPH (favourable cervix); more invasive for women and requires CEFM
Misoprostol	Systematic review & RCTs	Comparable to vaginal PGE2 at low dose, increased rates of success at higher doses	Significantly higher rates of uterine hyperstimulation; maternal gastrointestinal side effects; not licensed for use in pregnancy in UK
Amniotomy (ARM)	Systematic review (1 RCT)	Similar maternal and fetal outcomes compared to vaginal PGE2 but increased need for oxytocin; no uterine hyperstimulation	Significantly increased need for oxytocin augmentation; risk of infection
Mechanical methods (balloon catheters)	Systematic review & RCTs	Comparable to vaginal PGE2 to achieve birth within 24 hours; less uterine hyperstimulation	Risk of infection; maternal satisfaction unclear
Castor oil	Systematic review & RCT	Small RCT shows improvement of Bishop's score; systematic review shows no difference	All women experienced nausea after ingesting castor oil
Homeopathy	Systematic review	Insufficient data to show benefit	Insufficient data to show harm
Acupuncture	Systematic review but poor quality studies & RCT	Insufficient data to show benefit	Insufficient data to show harm
Herbal supplements	No evidence	No evidence of benefit	Potential harmful effects due to active ingredients

Amniotomy and oxytocin

Amniotomy describes the artificial rupture of the membranes (ARM) and is only possible if the cervical os is open and the membranes are accessible. Systematic review of the RCT evidence for ARM only compared

to vaginal PGs showed a significant increased need for oxytocin use but with similar maternal and fetal outcomes at birth.¹ ARM alone is not recommended as a primary method of IOL, but may be considered if vaginal PGs are contraindicated or there is a history of uterine hyperstimulation.

Intravenous oxytocin has been used alone, in combination with ARM, or following cervical preparation with other agents. Systematic review has evaluated the effects of intravenous oxytocin alone compared to vaginal PGs and in combination with ARM. It shows that intravenous oxytocin alone was associated with an unchanged cervical status after 12–24 hours and an increased caesarean birth rate, in women with an unfavourable cervix and intact membranes. Women with ruptured membranes or with a favourable cervix given intravenous oxytocin alone were significantly less likely to give birth vaginally within 24 hours when compared with vaginal PGs.¹

Systematic review comparing ARM with intravenous oxytocin and vaginal PGs showed no significant differences in not achieving vaginal birth within 24 hours or in caesarean birth rate, but numbers of cases were small. However one RCT, with women with a favourable cervix, showed significant increases in PPH rates in those receiving ARM and intravenous oxytocin compared to those with vaginal PGs. It is recommended that ARM with intravenous oxytocin should not be used as a primary method of IOL, but may be considered if vaginal PGs are contraindicated or there is a history of uterine hyperstimulation. ARM with intravenous oxytocin continues to be the secondary process for IOL if vaginal PGs have not been successful.¹

Misoprostol

Misoprostol is a synthetic PG producing uterine contractions and can be given orally, vaginally or sublingually. It is not licensed for use in pregnancy in the UK.

Systematic review has compared different doses of oral and vaginal misoprostol with vaginal and intracervical PGs and shown that vaginal misoprostol at low doses is comparable with vaginal PGs, but at higher doses is associated with higher rates of successful IOL but also with greater risk of uterine hyperstimulation. However, the only available preparations of misoprostol are higher-dose tablets and the product is not licensed in the UK, therefore misoprostol should not be used for IOL except in cases of IUFD.¹

Mechanical methods

Mechanical methods studied for use in IOL include balloon catheters or laminaria tents, which are inserted into the cervical

canal or into the extra-amniotic space. Balloon catheters appear to be the most commonly used method in the UK. Systematic review has compared mechanical methods with placebo, vaginal or cervical prostaglandin, and with misoprostol and intravenous oxytocin; unfortunately the studies are small, with many different comparisons. It appears that, when compared with all PG preparations, mechanical methods do not change the rate of vaginal birth within 24 hours or the caesarean birth rate.¹ Mechanical methods may be associated with reduced rates of uterine hyperstimulation and may reduce the risk of uterine rupture in the presence of a previous CS scar, but require further evaluation.

CLINICAL PATHWAY AND PROCESS FOR INDUCTION OF LABOUR

The NICE guidance on the IOL care pathway can be found within the guidance and website link: <http://pathways.nice.org.uk/pathways/induction-of-labour#path=view%3A/pathways/induction-of-labour/performing-induction.xml&content=view-node%3Anodes-formal-induction>.

Monitoring during IOL

How close a woman is to the onset of spontaneous labour will influence the likelihood that IOL will be successful. This is assessed by vaginal examination and cervical status measured using the Bishop's score (Table 48.2). Prior to formal induction, this should be assessed and recorded and maternal and fetal wellbeing established with a normal FHR pattern with EFM and routine maternal observations.

Prior to IOL it is necessary to confirm that the indication for offering induction remains, confirm the fetal lie and presentation, confirm that placental site is not low-lying and inform the woman of the pathway and the risk of complications, including uterine hyperstimulation/tachysystole.

After administration of vaginal PGs, when contractions begin, fetal wellbeing should be assessed with continuous EFM.

Table 48.2 Cervical scoring using modified Bishop's score

Cervical scoring				
Score	0	1	2	3
Dilatation (cm)	<1	1–2	2–4	>4
Length (cm)	>4	2–4	1–2	<1
Consistency	Firm	Average	Soft	
Position	Post	Mid/Anterior		

Once this is confirmed as normal, intermittent auscultation should be used unless there are clear indications for continuous EFM. Bishop's scores should be reassessed 6 hours after vaginal PGE2 tablet or gel insertion, or 24 hours after vaginal PGE2 controlled-release pessary insertion, to monitor progress.¹

Place of IOL

Facilities should be available for continuous electronic fetal heart rate and contraction monitoring wherever IOL is carried out.

Cohort studies found that woman being induced in the morning were less likely to require intravenous oxytocin and had lower rates of operative vaginal birth and greater maternal satisfaction.¹

A recent Cochrane review of four studies of outpatient IOL showed no difference in success of induction or birth outcomes, and greater maternal satisfaction during outpatient IOL, but that total hospital stay was the same for inpatient and outpatient pathways.¹² NICE recommends that outpatient induction should be continuously audited and only carried out if safety and support procedures are in place.

SPECIAL CIRCUMSTANCES

Previous caesarean birth

A proportion of women who have had a previous caesarean birth will also have an indication for IOL in a future pregnancy. In addition to the risks of IOL, these women also have the increased risk of uterine rupture. Multiple systematic reviews have compared different methods of induction in women with previous caesarean births and UKOSS have reviewed rates of uterine rupture.^{1,13} Systematic review showed inadequate evidence for the preferred method for induction in these cases, though a small RCT showed that vaginal PGs followed by ARM was more effective than ARM alone.¹ However, UKOSS data show a higher risk of uterine rupture with labour induction and that the rate with vaginal PGs was greater than with ARM and intravenous oxytocin. Uterine rupture is more likely to be associated with IOL in women with no previous vaginal birth. It is recommended that women who have had a previous CS may be offered IOL with vaginal PG, CS or expectant management on an individual basis. Women should be informed of the increased risks with IOL, increased risk of need for emergency CS and increased risk of uterine rupture.¹

IUFD

IUFD after 24 weeks of gestation is estimated to occur in 1 per cent of all pregnancies. Though 90 per cent of women will spontaneously deliver within 3 weeks of the intrauterine death, expectant management is associated with risks of intrauterine infection if the membranes are

ruptured, and of DIC. Multiple RCT and observational studies have compared induction methods and shown that misoprostol is most effective and that the use of oral mifepristone reduced the dosage of prostaglandins required to induce labour.¹

COMPLICATIONS OF IOL

IOL has considerable impact on women's experience of labour and birth, as it may be less efficient, more painful and more likely to require epidural analgesia and assisted birth.¹ In addition to the impact on women's experience, there are additional specific complications.

Failed IOL

Failed induction is defined as failure to establish labour after one cycle of treatment, consisting of the insertion of two vaginal PGE2 tablets (3 mg) or gel (1–2 mg) at 6-hourly intervals, or one PGE2 controlled-release pessary (10 mg) over 24 hours, and is estimated to occur in 15 per cent of cases.¹

There is little evidence relating to management of failed induction and NICE recommends that each case is reviewed individually to consider whether a further attempt to induce labour can be considered or a caesarean birth is required.

Uterine hyperstimulation

Uterine hyperstimulation can appear as tachysystole (increased uterine contractions) or hypertonus (increased uterine activity with fetal distress), which leads to fetal heart rate changes and occurs in 1–5 per cent of cases depending on the methods of induction used. Systematic review shows low-dose PG preparations carry the lowest risk and that tocolytics can be used to reduce the uterine activity and reversible hyperstimulation. Terbutaline is recommended as first-line treatment; however, if FHR changes remain, emergency caesarean birth may be considered necessary.

Cord prolapse

Cord prolapse is a potential risk when the membranes rupture, especially when the membranes are ruptured artificially. To reduce this risk it is recommended that engagement of the presenting part should be assessed, umbilical cord presentation should be excluded during vaginal examination and ARM should be avoided if the baby's head is high.¹

Emergency caesarean birth

Patterns of maternity care in English NHS Hospitals 2011/12 show that among primiparous women with induced labours, the mean rate of emergency caesarean was 30.2 per cent.

Among multiparous women whose labours were induced, the mean rate of emergency caesarean was 13.2%.⁴ However recent meta-analysis to evaluate whether or not IOL increases the risk of CS in women with intact membranes showed that a policy of induction was associated with a reduction in the risk of CS compared with expectant management in women at term. The authors concluded that this effect may arise from non-treatment effects, and that additional trials are needed.¹⁴

Delays in care

Whilst there is qualitative evidence regarding the impact of IOL on a woman's experience, there are no data reviewing the impact of the increasing elective workload in maternity departments or the effect of delays in the induction pathway on a woman's experience.¹ It is difficult to justify delays in the elective induction pathway when the indication for induction is the increased risk of continuing the pregnancy. However, balancing the demands of ongoing emergency work with the additional demands of an increasing IOL rate and unpredictable individual response to the intervention continues to challenge maternity services. This also has an unknown impact on the emotional and psychological wellbeing of the mother and her family.

KEY POINTS

- The national and worldwide rates of induction of labour continue to rise occurring in approximately 28% of births in primiparous women in UK in 2011/12.
- Robust indications for the intervention are required which are evidence based and show that IOL will avoid potential harm.
- Pregnancy outcomes, incidence of complications and maternal experience of IOL should be monitored through research, audit and maternity dashboards.
- NICE recommends the method of choice to be two vaginal PGE2 tablets (3 mg) or gel (1–2 mg) at 6-hourly intervals, or one PGE2 controlled-release pessary (10 mg) over 24 hours.

SUMMARY

Induction of labour is one of the most common obstetric interventions. A clear clinical indication is needed to interrupt a pregnancy, with careful consideration of the benefits and risks, together with a full explanation to the woman and her family prior to the decision being made.

Chapter 49 Management after previous caesarean section

Lucy Kean

MRCOG standards

Theoretical skills

- Candidates must be familiar with the relevant guidelines (RCOG and NICE^{1,2}).
- Candidates should know the signs and symptoms of impending uterine rupture.

Practical skills

- Candidates are expected to be able to counsel women in the antenatal clinic regarding delivery after previous caesarean section.
- They should be able to manage the labour of a woman with a previous caesarean section, knowing how to advise accordingly regarding both induction and augmentation of labour.
- Be able to recognise a morbidly adherent placenta at manual removal and manage with senior assistance.
- Have attended skills drills on obstetric collapse.

In addition, we would suggest the following.

- Know the rates of vaginal delivery in women undergoing labour after prior caesarean section in your unit.

INTRODUCTION

Delivery by caesarean section accounted for 25.5 per cent of deliveries in England in 2012–2013, with rates ranging from 17–40 per cent. In many units, emergency CS rates for primigravidae of 24 per cent are seen. Consequently, the problem of management of women with a scarred uterus in subsequent pregnancies is one of the most common reasons for hospital referral in multigravida. It is a vital part of antenatal care that women are given a clear understanding of the plan of management from early in pregnancy, with the caveat that this may need to be adapted if the pregnancy presents unexpected problems.

UNDERSTANDING THE RISKS

Relative maternal morbidity and mortality

It is almost impossible to assess the relative mortality from CS, as the indication for the CS will undoubtedly have an impact on the outcome. There are no trials to instruct us in this, and adapting information from published reports such as the CEMD is fraught with difficulty. In the most recent CEMD 116 women died after CS, but in only one case was the CS performed for maternal request. In all of the other cases there were compelling maternal or fetal indications for the procedure. Three women died following uterine rupture, though one of these women had a placenta praevia accreta.³

Chapter 53 discusses the risks of CS in detail.

A good understanding of the risks of CS is vital in counselling women with regard to subsequent delivery. The risks of both placenta praevia and placenta accreta increase exponentially with each repeat CS, from a baseline risk of 0.26 per cent and 0.01 per cent respectively in an unscarred uterus to 10 per cent and 6.7 per cent after a fourth CS.

In comparing elective repeat caesarean section (ERCS) with vaginal birth after caesarean section (VBAC) it is clear that the main maternal morbidity is encountered by women who need an emergency CS for a failed VBAC. It is therefore vital that when discussing management with a patient, the individual risks and benefits must be considered.

The aim of this chapter is to attempt to quantify these risks in order that, for each individual, appropriate counselling can be undertaken in planning the next delivery.

It is important to realise that women make decisions for a variety of reasons and that their choices may not always be those that we would make ourselves. The recent change in guidance produced by NICE has provided extended choice for all women to choose delivery by CS if they wish.²

There is remarkably little evidence to inform practice with regard to the management of previous CS. There are only two small randomised trials comparing trial of labour with elective CS, and most of the available data relate to observational studies.⁴

Candidates should be conversant with the RCOG Green-top guideline *Birth after previous caesarean birth*,¹ the NICE guideline *Caesarean section 2011*² and research that has been published since the guidelines were produced.

Repeat elective CS: risks and benefits

Maternal benefits

Caesarean section avoids labour with its risks of:

- Perineal trauma (urinary and faecal problems);
- 5% risk of anal sphincter trauma and 39% risk instrumental delivery;
- The need for emergency CS;
- Scar dehiscence or rupture with subsequent morbidity and mortality.

It also has the advantage of allowing a planned delivery.

Maternal risks

- Prolonged recovery;
- Future pregnancies would probably require CS for delivery;
- Increased risks of placenta praevia and accreta in subsequent pregnancies;
- Wound infection risk of 10–20 per cent;
- Risk of death 13/100,000.

Fetal benefit

- No risk from intrapartum scar rupture.

Fetal risk

- Increased risk of transient tachypnoea/respiratory distress syndrome (1–3 per cent at 39 weeks, 6 per cent at 38 weeks).

Planned VBAC: risks and benefits

Maternal benefits

- Shorter hospital stay and convalescence (if a vaginal birth achieved);
- Potentially easier future deliveries.

Maternal risks

- Increased risk of transfusion (relative risk 1.7 due to increased need in women with failed VBAC);
- Increased risk of endometritis (relative risk 1.6 due to increased risk in women with failed VBAC);
- Risk of uterine rupture (0.22–1.0 per cent which is stratified by need for intervention i.e. highest risk with prostaglandin IOL, lowest risk for spontaneous delivery) [D];
- Risk of death 4/100,000.

Fetal benefit

- Reduced risk of transient respiratory morbidity.

Fetal risks

- 0.08 per cent risk of hypoxic ischaemic encephalopathy (similar to risk for nulliparous women);
- 0.04 per cent risk of delivery-related death.

A large observational study from Scotland suggested that women with a previous CS were at increased risk of stillbirth at term compared to women with an unscarred uterus. This study showed an absolute risk of 1.1/1000 women at or after 39 weeks for women previously delivered by CS compared to a risk of 0.05 per cent for women with an unscarred uterus. The absolute risk of stillbirth after CS is the same as that for the nulliparous population.⁵ A subsequent large Canadian study of similar size showed no significant differences in antepartum stillbirth between the previous CS and previous vaginal delivery groups.⁶ The latter paper attempted to control for obesity, a risk factor for both CS and stillbirth. It may be that obesity is the factor that increases the risk, rather than caesarean section [C].

Uterine rupture rate for women undergoing labour after a single prior CS

Uterine rupture is accurately defined as a disruption of the uterine muscle extending to and involving the uterine serosa or disruption of the uterine muscle with extension into the bladder or broad ligament. A uterine dehiscence is defined as disruption of the uterine muscle with intact uterine serosa.¹

Studies looking at rates of scar rupture are all observational. The most helpful study for informing UK practice reported 35,854 women with a single previous CS, giving birth by means other than elective CS at 37 or more weeks.⁷ Multiple births were excluded. This study showed that across the whole group the success rate for VBAC was 74.2 per cent. The uterine rupture rate was higher in women induced using prostaglandins, but not in women induced by other methods. The rupture rate was higher in women who had not previously also delivered vaginally. The overall risk of uterine rupture was 0.35 per cent. Women who had not previously delivered vaginally had a rupture risk of 1 in 210 if they did not undergo IOL with prostaglandins, and 1 in 71 if they were induced with prostaglandins. For women who had previously delivered vaginally the risks were 1 in 514 and 1 in 175 respectively.⁷

The National Institute of Child Health and Human Development (NICHD) has produced a large multicentre prospective cohort study encompassing around 16,000 women undergoing ERCS compared to 18,000 women undergoing planned VBAC, mostly women delivering in tertiary centres. This study gave an overall risk of uterine rupture in the VBAC group of 0.74 per cent. Unsuccessful VBAC had the highest rupture rates of 2.3 per cent [D].⁸

The RCOG Green-top guideline suggests that women know that the risk of rupture is 22–74/10,000 compared to almost no risk for ERCS and a composite risk of 0.5% should be discussed with women.¹

ADVISING WOMEN ABOUT INDIVIDUAL RISKS

When advising women on subsequent delivery, as much information about the previous CS as possible should be sought.

It is good practice to ask for a copy of the case notes of the previous surgery before making a final decision, as occasionally features may be seen that will alter management, such as extensions of the uterine incision that the woman may be unaware of. It is also important to gain any available information about the circumstances leading to the CS.

Good antenatal planning should individualise the risks and benefits for each woman for each type of delivery, allowing the woman to make the best choice for herself. Research suggests that most women do not have clear ideas about the best choice for delivery and want accurate information and advice individualised for their own set of circumstances. The composite success rate should be quoted at 72–75%.¹

Type of scar, method of closure and previous operative morbidity

It is recognised that vertical upper-segment uterine scars have a high risk of rupture, often with catastrophic results. Therefore, it is usual to recommend repeat pre-labour CS for women who are known to have undergone previous classical CS. However, despite this, some women will arrive in labour. A scar rupture rate of 12 per cent has been seen in this group.⁹ Lower-segment vertical scars are associated with lower rates of uterine rupture of 2 per cent, but it is often very difficult to be sure that the scar did not encroach into the upper segment. With a full discussion of the risks and necessary precautions, women with a low uterine scar should be considered for VBAC.¹ It should not be assumed that a vertical abdominal incision means that the uterine incision will also be vertical; indeed, in most cases a vertical abdominal incision is associated with a transverse uterine incision. Given the extremely high rates of uterine rupture with vertical upper-segment incisions, it is best to err on the side of caution whenever there is doubt. J-shaped and inverted-T-shaped incisions are associated with similar rupture rates to low vertical incisions of 1.9 per cent [D].

In the USA a single-layer uterine closure was the norm for some years. In the UK this trend was not universally adopted and most women continued to undergo a traditional two-layer closure. The evidence on whether a single-layer closure is associated with higher rates of subsequent rupture is conflicting. Because the only studies of rupture are either small or observational the real risks are difficult to quantify. The largest study suggested an increase in risk, with an OR 3.95 (95% CI 1.35–11.9).¹²

One study addressed the issue of rupture related to intrapartum or postpartum pyrexia in the previous caesarean delivery. This study suggested an OR of 4.02 in women experiencing both intrapartum and postpartum pyrexia. However, the study was small and the confidence intervals very wide (1.04–15.5) [D].

Indication for previous CS

The extent to which the reason for previous CS impacts on subsequent successful trial of labour has been evaluated in a meta-analysis of observational studies [D].¹³ The results are shown in Table 49.1.

Table 49.1 Successful vaginal delivery in subsequent labour by reason for previous caesarean section (CS)

Indication for previous CS	Success rate (%)
Malpresentation	85
Any reason one previous vaginal delivery	84
Fetal distress	75
Dystocia	67
Oxytocin in this labour	63

Table 49.2 Successful vaginal delivery related to dilatation at arrest of the previous labour

Dilatation at arrest (cm)	Vaginal delivery (%)
0–5	61
6–9	80
10	69

DOES CERVICAL DILATATION AT TIME OF PREVIOUS CS HAVE AN IMPACT ON DELIVERY?

This question has been addressed through observational studies. Only women whose prior CS was for ‘failure to progress’ were included (Table 49.2).¹²

These data accord with an overall rate of vaginal delivery for dystocia in the previous labour of 69 per cent, which compares well with the data from Rosen *et al.*,¹² and shows that dilatation at arrest does not signify who will achieve successful delivery next time, though CS for dystocia at any stage reduces the chance of successful VBAC[D].

TRIAL OF LABOUR IN WOMEN WITH MORE THAN ONE PRIOR CS

The NICHD study⁸ used a multivariate approach to assess the rupture risk for women who have undergone two or more previous sections. The rupture rate was not higher for these women compared to women with a single previous CS, but they did experience higher rates of transfusion and hysterectomy. Many other smaller observational studies have suggested an increase in risk of 2–3 in women with more than one previous CS. Many of these studies were uncontrolled. One relatively large observational study showed the risk of uterine rupture was increased 2-fold compared with women with only one uterine scar (rupture risk 1.8% vs 0.9%; adjusted OR 2.3, 95% CI, 1.37–3.85).¹¹ The most recent meta-analysis showed a 1.3 per cent rupture risk for women with two or more CS.¹² It is interesting to note that the VBAC rates between studies

vary hugely and it is very likely that there are differing criteria for selection for VBAC in the different participating centres, which may account for the different rupture rates seen.

Success rates vary but should be quoted as 62–75 per cent. Because of small numbers the real risk for rupture in women with three or more sections is difficult to quantify. Small observational studies suggest that the rupture risk may be increased by a factor of 2 or 3.¹

Women should therefore be counselled that a VBAC is an alternative after two prior lower-segment sections and an individualised risk given where possible based on all the available information.

TRIAL OF LABOUR IN WOMEN WITH OBESITY

In the case of women with a scarred uterus and obesity, decision-making is often difficult. It is recognised that fetal birthweight is usually larger than average, and the prior CS will often have been performed for poor progress in labour, as obesity appears to increase the risks of inefficient uterine activity. The wish to avoid a further abdominal delivery must be balanced against the increased morbidity that occurs if an emergency CS is required. Observational data suggest that for women weighing in excess of 135 kg, the chance of vaginal delivery is very low (13 per cent) and elective CS may be a better option in this very obese group.¹⁵

The rates of unsuccessful VBAC increase incrementally as BMI increases. Women with a BMI above 30 have an OR for failed VBAC of 2 (95% CI 1.2–3.3).

OTHER RISK FACTORS FOR UNSUCCESSFUL VBAC AND UTERINE RUPTURE

Other risk factors have been evaluated.

Interdelivery interval

The interdelivery interval has been the subject of three studies. All of the studies are retrospective and in all the analysis was limited to women with singleton pregnancies, at term, who had one prior caesarean birth and no prior vaginal births. This will therefore skew the data towards slightly higher rupture rates, as women with a previous vaginal birth form the lowest risk group for rupture. It is noted from these studies that high rupture rates are reported, varying from 0.9 per cent in the lowest rupture groups to 4.8 per cent in the highest rupture rate groups. These studies are all from the USA and all small. At most the OR increase in risk is 2–3 and likely to be most pronounced in the intervals of less than a year.

Maternal age

The success of vaginal birth in all women decreases as age increases, regardless of whether the woman has previously undergone CS. Studies have shown lower rates of successful VBAC in women over 35 but these studies have not controlled for confounding variables. Unsuccessful VBAC carries the highest rate of uterine rupture. It is not surprising therefore that a study has suggested a link between uterine rupture and maternal age.

Other risk factors

Almost every factor known to be associated with lower chances of successful vaginal birth in any setting has been examined in relationship to VBAC and unsurprisingly those factors associated with overall lower rates of vaginal delivery are also associated with lower rates of successful VBAC. These include fetal macrosomia, delivery after 41 weeks, cervical dilatation of <4 cm at admission, non-white ethnicity, male infant and short maternal stature. When discussing choices with women these can be borne in mind. Decision making may therefore vary depending on the circumstances at the time, as some of these factors are dynamic.

ANTENATAL MANAGEMENT

Counselling and documentation

Wherever possible, the records of the delivery leading to CS should be reviewed [E]. Occasionally, facts that the patient may be unaware of may come to light. It is especially important to review records where there is any doubt about the type of uterine scar used. Counselling the patient with regard to the likelihood of success is also important, and review of the previous labour is a necessary part of this counselling.

It is very important to document carefully the discussion of the risks and benefits of both vaginal delivery and CS with the patient. Women should be provided with as accurate information as possible pertinent to their particular set of circumstances. The role of the doctor is to advise and guide where requested. The final choice rests with the woman. Women should be advised that the safest place to labour, should she wish to labour, is in hospital. It is better to support a woman to labour in hospital, even if the clinician feels this is injudicious, than for her to feel unsupported and to choose to labour at home.

If a woman is able to make her choice early in the pregnancy her antenatal care can be tailored around this. If her choice is for VBAC and there are no other factors which place the pregnancy at risk then a scheduled visit at 40 weeks to discuss a strategy should she pass 41 weeks is reasonable. Women can be offered an open appointment to return should they have further questions, but the provision of antenatal care can rest with the community midwife. For women with no identifiable

pregnancy-related problems who choose ERCS a date can be provided for CS at 39 weeks so that the woman can prepare. This can be amended if circumstances change.

It is important to establish what choices women who choose ERCS would make should they labour before the date of planned CS. Many but not all women would consider VBAC if spontaneous labour ensues before the planned date.

Planning the delivery

Value of pelvimetry

Pelvimetry performed either clinically or radiographically does not provide any useful information [A]. Four trials of more than 1000 women were included in the most recent Cochrane Review. The trials were generally not of good quality. Women undergoing pelvimetry were more likely to be delivered by CS (OR 2.17, 95% CI 1.63–2.88). No impact on perinatal outcome was detected.¹²

Value of ultrasound for scar thickness

Ultrasound evaluation of the scar antenatally has been investigated as a method of determining women at higher risk of scar rupture during labour. Unfortunately, results do not give a high enough sensitivity for this modality to be used in everyday clinical practice.¹

Documenting the plan and setting limits

Women are generally keen to avoid a repeat of the previous labour, and so it may be reasonable to avoid the circumstances that led to problems in the previous labour, such as avoiding induction if the CS was for failed induction. Women who underwent CS for poor progress usually need reassurance that limits will be placed on their next labour so that they do not undergo a prolonged labour. Women are significantly more likely to request a repeat CS if they had their initial surgery because of failure to progress in labour than if their initial CS was because of suspected fetal compromise.

It is important when discussing delivery in the antenatal period to agree a clear plan of management with the patient and for this to be carefully documented and easily available to carers in labour. If the agreed plan is for delivery by elective CS, it is good practice to give the patient a date for this, assuming an uncomplicated pregnancy. This can be made with the proviso that if circumstances change, it can be amended, but it does allow women to plan in advance and minimises requests for early delivery later in pregnancy that can compromise neonatal wellbeing. In general, an elective CS should be performed in the 39th week of pregnancy. It is possible to apply a little common sense where women have persistently laboured at 38 weeks before, but it must be remembered that if women have a tendency to go well past their dates, even 39 weeks may be early for some babies.

Assessment of the risk of placenta accreta

This is particularly pertinent in the management of women undergoing delivery after repeated caesarean sections. The risk is highest in women with a coexistent placenta praevia.

Findings suggestive, but not diagnostic, of a placenta accreta on antenatal ultrasound include:

- loss of the normal hypoechoic rim of myometrial tissue beneath the placenta;
- loss of the normal hyperechoic uterine serosa–bladder wall interface;
- presence of tissue of placental echotexture extending beyond the uterine serosa, sometimes seen within the lumen of the bladder;
- sometimes multiple or large placental venous lakes are seen giving the placenta a ‘moth-eaten’ appearance.

MRI has been suggested as an adjunct to ultrasound. Much depends on the experience of the person performing the scans. False negatives and positives occur with both modalities. Currently, in experienced hands, ultrasound alone is as good as MRI. If an accreta is suspected then it is prudent to take precautions for major haemorrhage. Full consent and discussion of the potential outcomes should be undertaken.

Management of placenta accreta is discussed in Chapter 46, Antepartum haemorrhage.

MANAGEMENT OF LABOUR

All carers on labour wards must be trained in the identification of the signs and symptoms of scar rupture.

Signs and symptoms of scar rupture

The cardinal signs of imminent uterine rupture are:

- worsening CTG changes (especially prolonged variable or late decelerations);
- haematuria;
- secondary arrest;
- small amounts of vaginal bleeding;
- pain over the scar which persists between contractions.

Signs of uterine rupture are:

- fetal bradycardia;
- upward displacement of the presenting part;
- sudden loss of contractions;
- maternal hypotension;
- heavy vaginal bleeding;
- abdominal or shoulder pain.

If the fetus or placenta is extruded into the abdomen, there is very little time to salvage the fetus. Delivery needs to be accomplished within 10 minutes. Most fetuses in this situation are profoundly acidotic at the time of delivery.

The literature is conflicting with regard to signs of impending uterine rupture. Clearly the sign most commonly associated with uterine rupture is a fetal bradycardia. Studies that have examined the CTGs in cases of confirmed rupture have shown bradycardia in almost 100 per cent of cases.

This is however, unhelpful to the clinician on the labour ward as our aim is to intervene before the uterus ruptures.

Ridgeway *et al.* undertook a case–control comparison of the CTGs of women who had a confirmed uterine rupture with those women undergoing VBAC who had a successful vaginal birth. This study differs from others because it compares only women having VBAC. Comparing cases with uterine rupture in the 4 hours preceding the second stage and during the second stage there were no differences in the appearance of any type of deceleration.¹⁷

Sheiner *et al.*¹⁸ examined CTGs in the period before uterine rupture but compared them to the CTGs of women who did not have a scarred uterus. They demonstrated higher rates of severe fetal bradycardia (4.0% vs 1.0%, $p = .064$), fetal tachycardia (8.0% vs. 2.3%, $p = .042$), reduced baseline variability (24.0% vs. 12.5%, $p = .021$), uterine tachysystole (10.0% vs. 0.8%, $P < .001$) and disappearance of contractions (6.0% vs. 0, $p < .001$) in women with uterine rupture as compared to the controls.

Ayres *et al.*¹⁹ examined the CTGs of women who had a uterine rupture and showed that 100 per cent of CTGs showed late decelerations prior to the bradycardia seen with the rupture. They did not compare these to controls.⁶

Therefore, although an abnormal CTG is the most consistent finding in uterine rupture and is present in 55–87 per cent of cases, deciding who is at risk of rupture from who is not is not an easy undertaking, as it appears that CTG changes are commoner in women undergoing VBAC than in the population of women with an unscarred uterus.

Conduct of the labour

General management

Some general steps can be taken on admission in labour to minimise the risks to the mother and fetus. These include:

- Read the plan for labour in the notes and note any discussion points;
- Site intravenous access (though this can be capped and flushed);
- Group and save blood;
- Discuss active management of the third stage;
- Advise continuous EFM once labour is established.

The use of EFM

There are no trials assessing the various modalities of monitoring of the fetus in labour during VBAC. Because bradycardia is seen in uterine rupture, the consensus opinion of the Expert Committee recommends continuous fetal monitoring in labour for women with a uterine scar [E].

The use of oxytocin to augment labour

The use of oxytocin in labour in women with previous CS is contentious. There are no randomised studies to help and only observational data are available [D].

The potential for oxytocin to correct abnormal patterns of labour is the same in women with a previous CS as it is in women without. However, given evidence that in nulliparous

women oxytocin use does not reduce the rate of CS its use in the context of previous CS might be questioned.

The studies are all observational. One study attempted to control for dose and duration of oxytocin use and found a doubling in the rate of rupture which was most marked at doses of greater than 20 mu/min. Oxytocin augmentation appears to be associated with an increase in the risk of scar rupture of 2–3.^{8,11}

It is vital that, before considering syntocinon, all steps are taken to optimise labour progress. With the advent of small fetal monitors and more mobility with epidural analgesia, it should be possible to allow women the opportunity to mobilise without compromising fetal surveillance. Forty per cent of women will respond to simple measures such as rehydration (see Chapter 50). A more flexible approach should be adopted in women with a uterine scar, and consideration should be given for lower rates of progress before resorting to syntocinon. When syntocinon is thought to be necessary, the decision should be made at consultant level and the risks and benefits should be discussed with the mother [E]. Assessment of progress in labour should ideally be made by the same person and the frequency of vaginal examination may need to be increased as there is some evidence that early intervention for static progress over 2 hours after augmentation can be used to prevent uterine rupture.

INDUCTION OF LABOUR

There have been many concerns voiced about IOL in women with a scarred uterus. Only four small randomised trials assessing the method of induction have been performed. These trials are too small to provide any meaningful data. Several observational studies have been performed, but all of these have limitations.

Clearly success rates for VBAC are lower if IOL is needed. The NICHD study showed a 33 per cent CS rate in induced labours.⁸ Other studies have suggested successful vaginal birth in 50–70 per cent of women with a previous vaginal birth undergoing IOL compared to 44–61 per cent of women who have not delivered vaginally previously.

Membrane sweeping

Membrane sweeping is recommended for women where IOL is considered after 40 weeks. There are no trials assessing this approach in women with a previous CS, but it seems a reasonable option and may reduce the need for intervention.

Non-prostaglandin IOL

The NICHD study gave a risk for uterine rupture amongst women induced by non-prostaglandin methods of 89/10,000. This was almost exactly the same as the risk for women augmented in labour (87/10,000).⁸ The data from Scotland did not show a significant increase in uterine rupture in women

induced with ARM and oxytocin, with rates of 29/10,000.⁷ Mechanical methods also include use of hygroscopic dilators, foley catheters and specifically designed catheters when the cervix is not yet suitable for artificial rupture of membranes. These methods are associated with a lower risk for induction than prostaglandins (0.29%).

Prostaglandin IOL

The NICHD study did not show a significantly higher risk of uterine rupture with prostaglandin IOL compared to non-prostaglandin methods of induction (140 vs 89/10,000).⁸ The Scottish data showed a higher risk with prostaglandin IOL of 87 vs 29/10,000.⁷ Interestingly the figure for prostaglandin IOL in the Scottish study is identical to the risk for non-prostaglandin IOL in the NICHD study, and lower than the risk for prostaglandin IOL in the NICHD study.

Clearly, when deciding on the best strategy the reason for induction must be considered and weighed against the risks of the procedure. Induction at 41 weeks is recommended to prevent the risk of stillbirth after this time. The risk of stillbirth at 41 weeks from epidemiological studies is 2–3/1000 [B]. The risks of perinatal death following IOL in women with a previous CS is 1.1/1000 [D]. Given the possibility that stillbirth may be more common in women with previous CS the marginal benefit of induction past 41 weeks is still probably justified, but the benefits are not as clear cut as they are for women with an unscarred uterus.

An unfavourable cervix at the onset of induction is associated with higher rates of CS but not with any other adverse outcome [D].

Despite the potential increased risk of scar rupture with prostaglandin the guideline development group who produced the most recent NICE guideline on IOL recommend that intravaginal PGE2 be used as the preferred option in women with a previous CS [E]. There are no preparations of prostaglandin that are licensed for use in IOL. The data sheets for the commonly used preparations (PGE2 tablets, gel and slow-release pessaries) all state that use in induction is contraindicated. The NICE guideline (Induction of labour) states that informed consent should be sought and documented.

Documentation:

- Involve a consultant obstetrician in decisions regarding mode of delivery, the need for induction and any decision to augment labour.
- Management plans should be fully documented.
- EFM should be used once labour is established.
- Local guidelines should be developed.
- There should be adequate education of all staff, ensuring awareness of signs and symptoms of uterine rupture.

MANAGEMENT OF THE THIRD STAGE

PPH is commoner in women who have a scarred uterus, probably because of the inability of the scar tissue to contract and

increased placental adherence. Therefore, a low threshold for very active management of the third stage should be implemented. This should include:

- oxytocics at delivery of the shoulders;
- prompt delivery of the placenta after separation;
- consideration of continued syntocinon infusion for 4 hours after delivery or a long-acting syntocinon analogue.

If the placenta is retained, the possibility of a placenta accreta must be borne in mind. Therefore, before proceeding to a manual removal, important steps must be taken.

- 1 Establish the probable placental site from the previous scan reports. Accreta is much more likely if the placenta was noted to be anterior.
- 2 Cross-match 4 units of blood.
- 3 Obtain the patient's consent and note that the possibility of accreta has been discussed, with its potential problems and management options.
- 4 Ensure that senior staff are aware and, if you are inexperienced, ask for help *before* you go to theatre.

If at the time of manual removal a clear plane of cleavage cannot be defined, placenta accreta is likely.

Different treatment options for morbidly adherent placenta have been tried with variable success. These are fully discussed in Chapter 46.

CONCLUSIONS

The current rates of CS of 24 per cent in primiparae will inevitably lead to large numbers of women needing to choose the best method for delivery next time. Vaginal delivery after CS is a safe option if precautions are taken. IOL and augmentation lead to increased rates of scar rupture and must only be undertaken with caution. However, the risks of repeated CS must also be considered, as it is recognised that placenta accreta increases in incidence exponentially with each repeat CS (see Chapter 46). Keeping primary CS rates to a minimum will help to prevent the morbidity associated with both VBAC and repeated CS.

Key points

- A thorough history and examination of the notes should be made when booking a patient who has undergone a previous caesarean section.
- Where information is lacking, it should be sought.
- Vaginal delivery is a valid option after almost any prior lower-segment caesarean section.
- After classical caesarean section, vaginal delivery should be avoided.
- Repeated caesarean sections carry exponentially increasing risks of placenta praevia and accreta, with significant maternal morbidity.

- The risk of scar rupture in labour after a single caesarean section is approximately 22–74/10,000.
- Oxytocin use in labour probably increases this risk by two to three times.
- Induction of labour may lead to at least a doubling in risk of scar problems but it is possible that the magnitude of increase is higher if prostaglandins are needed.
- The risk of scar rupture may be 2–3 times higher after more than one caesarean section.
- Vigilance for scar rupture in labour is of paramount importance.
- Active management of the third stage should be standard.
- Placenta accreta must be considered if an anteriorly placed placenta is retained.

Chapter 50 Poor progress in labour

Graham Tydeman and Alexandra Rice

INTRODUCTION

There is a shortage of randomised evidence regarding poor progress in labour. This applies both in terms of diagnosis and management. As such, much of what is held to be normal is based on lower-quality evidence. The phrase ‘failure to progress’ (FTP) is used in the literature, which can be taken to mean the end stage of poor progression, although in reality in many situations where FTP is declared, there has actually only been a slowing of progression rather than no progression at all. The CS rate has been steadily increasing with FTP increasing in proportion. In 1985 the WHO declared there was ‘no justification for any region to have caesarean section rates higher than 10–15 per cent’. At that time, 15 per cent was an unusually high rate.¹ In a Scottish audit from 1995, the CS rate was 16 per cent and FTP was the sole indication in 50 per cent of emergency cases.² In 2012 the Scottish CS rate was 28 per cent.³ During the same time period, the perinatal mortality rate has remained largely unchanged.⁴

The question is whether there has simply been a greater tendency to diagnose FTP, or has the population changed with more fetuses becoming stuck and if so, why?

If FTP is considered as abnormal labour, then it is worth reviewing the evidence for what constitutes normal labour. Labour is typically separated into latent and active phases. Women are not in ‘established labour’ until the active phase. Only in the active phase is FTP relevant as there is no imperative to intervene before labour has become ‘established’. There is a general consensus that the latent phase carries no inherent risk of harm if it fails to progress. As will become apparent in considering this subject these are generally descriptive terms based on observational studies. Conceptually speaking, labour has become established when the process of delivery has no chance of stopping and will inevitably result in either delivery or fetal impaction. Finally, FTP is a description and whether it is also a diagnosis is debatable. Once FTP has been declared there are many factors influencing management and, particularly in the absence of other clear imperatives such as risk of fetal hypoxia, this should include the woman’s choice.

NORMAL LABOUR

Cervical dilatation

Much of what we consider normal labour was established in the 1950s by Friedman.⁵ His ground-breaking study published in 1955 involved 500 nulliparous women, at term, who arrived in early labour. As admitted in the paper, it was biased as it excluded those who presented already in advanced labour. Unlike previous studies that had focused on the total length of labour, Friedman plotted progress as a function of cervical dilatation. This work became the gold standard and it started the process by which an individual woman’s labour could be compared with normal. A 2003 review stated ‘What Friedman did was define labor in a way that lent itself to quantitation and thus to standardization.’⁶ He also introduced the idea of the two main phases of labour: latent (from labour onset to the point at which the rate of dilatation begins to change) and active (from that point until complete dilatation) and provided the opportunity to assess variations from normal objectively. On the other hand, Friedman’s work only involved women in their first labour and the mean age was only 20 years. In addition, over 50 per cent were instrumental deliveries; the occipito-posterior rate was unusually high at nearly 20 per cent but the caesarean section rate was 1.8 per cent. Cervical dilatation was assessed by both vaginal and rectal examination. Small numbers of women with breech, twins and stillbirth were also included (4 per cent of the total). Heavy sedation, which at the time usually involved a potent mix of opiates, was common. Variations of normal were defined as up to 2 standard deviations from the mean with latent phase having a mean of 8.6 hours \pm 6 hours and the active phase a mean of 4.9 \pm 3.4 hours. The active phase was when the rate of dilatation began to accelerate – at just under 3cm dilatation reaching a peak rate of 3 cm/h (\pm 2 cm/h) from about 4 cm. In the final stages, there was a slowing in rate of progress from 9 cm but once full dilatation was achieved, the average length of the second stage was 1 hour (\pm 0.8 hours). The high rate of instrumental deliveries probably explains the short second stage as routine practice in the unit was not to allow the

second stage to extend beyond 2 hours. Following the publication of this work, any individual woman's labour could then be compared with 'The Friedman Curve' (Fig. 50.1), an asymmetrical sigmoid curve that was an amalgamation of all labours studied. The introduction of the partogram and the active management of labour were direct consequences of the publication of the Friedman curve.

In the 1990s there were reviews of the Friedman curve from two perspectives – was it still relevant 40 years later and was the initial analysis valid? The original data were not normally distributed and were an amalgamation of 500 different curves but, perhaps most importantly, were never intended to be prescriptive – they were not intended to dictate care in labour. Between 1992 and 1996 and involving nearly four times as many nulliparous women as Friedman, a similar study was organised,⁷ but analysed with better statistical tools. This produced some of the first data suggesting Friedman's curve might either be inaccurate or no longer relevant. As a result but also largely in response to the rising CS rate, the US National Institute of Child Health and Human Development organised a very large study to describe contemporary labour. A retrospective review of the case notes of over 200,000 women between 2002 and 2008 was undertaken. This resulted in several important publications including a re-evaluation of the Friedman curve. Focusing on over 60,000 nulliparous women, one publication resulting from this study⁸ reported that labours took much longer than as predicted by the Friedman curve with many women not entering the accelerative phase until 6 cm (rather than 4 cm) and the normal rate of progress being up to 6 hours between just 4 and 5 cm and up to 3 hours between 5 and 6 cm. For the second stage, even without an epidural, second-stage 95th centiles were between 3.6 and 2.8 hours for nulliparous and parous women respectively: 3 times longer than from the Friedman data. For both nulliparous and parous women, progress to about 6 cm was similar but thereafter progress was much faster in parous women for the remaining first stage and the second stage. New graphs were produced to provide the basis for a new partogram for nulliparous and parous women (Fig. 50.2). Despite these data, many places still rely on the '1 cm/h after 4 cm' dictat from the accelerative phase of the original Friedman curve. New guidance from the UK acknowledges the uncertainty that 'Essentially there is huge normal variation in the length of time an individual women will be in labour. All we can advise is that first labours will last on average 7 hours and are unlikely to last more than 18 and that in subsequent pregnancies the average duration is 5 hours and unlikely to last more than 14'.^{9,10}

Descent of the head

Partograms not only include cervical dilatation but also plot the descent of the head during labour. The Royal College of Midwives describes the need to assess the descent of the head during each vaginal examination⁹ and it is commonly taught in midwifery and obstetrics; however, there is much less evidence of what is normal than there is for cervical dilatation. One study from India¹¹ looked at 100 cases of normal labour

Fig. 50.1 The Friedman curve

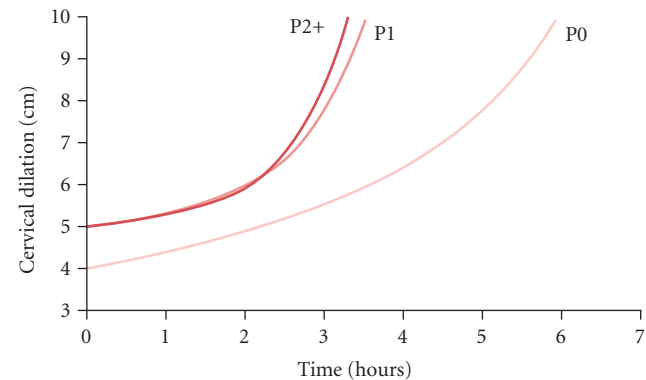

Fig. 50.2 Curves from 2002 to 2008 US data

and concluded that the course of labour was uninfluenced by the degree of engagement. Using a simulator that precisely defined the actual station of the head and using the classification of station from ACOG, another study found reliability poor between observers.¹²

Partograms

Finally, despite their widespread use in almost all labour wards, there is room for debate about the value of partograms in improving outcomes. RCOG promotes their use as 'they result in fewer operative births and less use of oxytocin';¹³ however, a Cochrane systematic review¹⁴ from 2008 that included six studies involving nearly 8000 women (two of which were randomised to partogram or no partogram) found no difference in CS or instrumental delivery rates unless the partogram included a latent phase, in which case CS rates were higher with the use of a partogram. The conclusion was: 'We cannot recommend routine use of partogram as part of standard management and care' although the authors did acknowledge that it was such an established part of normal practice that its use could be 'locally determined'.

ABNORMAL LABOUR – FAILURE TO PROGRESS?

First stage – problems with diagnosis

FTP inherently implies an abnormal labour. Its ‘diagnosis’ is on the increase in relative and absolute terms as the CS rate has risen. Evidence from the UK in 2000¹⁵ showed that with a CS rate of 20 per cent, FTP was the indication in 20 per cent of CS whereas a US study of nearly 40,000 women in 2013¹⁶ with a 30 per cent CS rate showed 35 per cent of CS being performed due to FTP. Of those having a CS for FTP, 40 per cent of nulliparous women and 33 per cent of parous women were at less than 5 cm cervical dilatation at the time of delivery, which begs the question, were they even in established labour?

As we have seen, there has been a strong focus on cervical dilatation as the single measure of progress in labour. For an individual woman being compared to population data, it needs to be considered whether she is a normal representative of that population. Partograms with an action line are commonly in use to aid these comparisons – if the rate of progress falls behind the action line, FTP can be considered to be occurring. Given the body of evidence that normal progress in labour is a sigmoid curve, it perhaps seems odd that action lines are of uniform slope. We have previously considered the evidence as to whether a partogram is of value but there appear to be no studies comparing a partogram with or without an action line. There are several RCTs comparing the effects of action lines of different fixed slopes^{17,18,19} and NICE¹⁰ concludes that a 4-hour action line should be used as the use of shorter intervals ‘increases interventions without any benefit to mother or baby’. Using a definition of up to 4 cm as the end of the latent phase, NICE goes on to define the diagnosis of delay as ‘cervical dilatation of less than 2 cm in 4 hours for first labours or cervical dilatation of less than 2 cm in 4 hours or a slowing in the progress of labour for second or subsequent labours’.

In addition to being nulliparous, a variety of factors have been identified that might make any individual woman’s progress differ from the norm. Perhaps it should be questioned whether the use of general population curves should apply to all women. In a manner akin to customised growth charts²⁰ perhaps there should be customised progress in labour charts. Factors that tend toward slower labour include: induction of labour, premature rupture of membranes, age, epidural, obesity and having been raped.^{21,22,23,24} Factors which shorten labour, other than being parous, include oxytocin use²⁵ and staying upright in the first stage.²⁶

Cervical assessment – is full dilatation 10 cm?

As we have seen, measuring the dilatation of the cervix is the standard way that labour is compared with normal but it

should be no surprise that there are errors in the assessment of cervical dilatation, particularly between different examiners. For an individual woman, error could be very significant if the conclusion is that she is failing to progress. There is some research evidence from simulators demonstrating significant inter-observer error.^{27,28} It makes sense (and is recommended) to minimise error with examinations performed by the same observer where possible⁹ but in situations where this good practice occurs, it is also common for a doctor to perform a single final examination prior to intervention. This also makes sense: that person may be taking responsibility for the decision whether to intervene, but they should be aware of the potential for error inherent in their single examination.

The technique of examination is another potential source of error: whether it is performed vaginally or rectally is not unified in the early research and even for vaginal examination there is no unified opinion as to the best way to perform the assessment. Where 10 cm comes from is also difficult to determine and there appears to be a lack of evidence as to the range of normal. The teaching from early obstetric and midwifery textbooks, 1903 to 1953,^{29–33} was to avoid unnecessary vaginal examinations – the recommendation was simply one examination at rupture of membranes (to confirm no cord prolapse) and only one more in the second stage, only if there was delay. A normal second stage, of 2–3 hours was quoted for nulliparous and 1 hour for parous. These figures are interestingly more similar to research from the 21st century⁸ than from Friedman in 1955.⁵ Earlier textbooks also focused on how much cervix was left before full dilatation was achieved rather than how dilated it had become. Not until 1953 is the idea introduced that 3¾ inches (9.5 cm) is the normal aperture for full dilatation³³ but in the same book it was also noted that full dilatation was different for different-sized babies: 3¾ inches for a 7 pound baby but 2½ inches was suggested as full dilatation for a 3 pound baby.

There is almost certainly biological variation with some women never achieving 10 cm despite full dilatation and others having several centimetres of cervix left at 10 cm. There appears to be no evidence as to what dilatation is the range of normal. There is an attraction in focusing attention on how much cervix is left before full dilatation is achieved, rather than how dilated it has become. Full dilatation is a clear end point: there is no cervix left and it has all become incorporated into the lower segment.

Midwives are often still taught using pocketbook cards with various-diameter holes in to learn what 10 cm feels like.³⁴ Anecdotally some observers simply try to determine how far apart their fingers are at all stages but others do this until there is not much cervix remaining, and then subtract what is left from 10. This is inherently illogical as if there are 3 cm left on one side, then there is likely to be another 3 cm on the other side, which should mean, by simple subtraction, that the dilatation is actually only 4 cm and not 7 cm. However the cervix is rarely perpendicular to the vagina (Fig. 50.3) so it may work in practice and, more importantly, focuses on what remains, which is arguably a more important end point.

Fig. 50.3 Cervical dilatation

The reality of vaginal examination is likely to be that during training we learn a consensus of what each dilatation ‘feels like’ in comparison with experienced teachers, rather than attempt to measure a precise reality at each examination. This adds a considerable element of judgement and error.

Second stage

The second stage is typically divided into the passive phase from full dilatation to the start of active pushing. If a normal second stage is up to 3.6 hours¹⁰ it needs to be considered what adverse effects there are of being at one end of the normal range. NICE recommends that it should be no more than 3 hours (1 hour passive and 2 hours pushing) for nulliparous women and 2 hours (1 hour passive, 1 hour pushing) for parous women.¹⁰ In a Canadian study³⁵ of over 150,000 uncomplicated women there was an increase in a combination of maternal and neonatal adverse outcomes, including PPH/ sepsis and lower Apgar scores/increased admissions to neonatal units, with second stages longer than 2 and 3 hours for parous and nulliparous women respectively.

Causes

Traditional teaching talks in terms of the three P’s – power, passage and passenger. In other words are contractions ineffective (power); is the pelvis (passage) insufficient to cope with the presenting part of the fetus (passenger); or is the presenting part too large, possibly as a result of position, to fit through an otherwise normal pelvis? There is a simple attraction to thinking in these terms but unfortunately there is also a lack of evidence that an understanding of the cause leads to any intervention that will alter management – except perhaps in extreme cases such as severe hydrocephalus, massive lower-segment fibroids or pelvic abnormalities when elective CS might prevent ‘inevitable’ FTP if labour were to commence. There is evidence of prolonged labour and higher

instrumental delivery rates in certain fetal positions such as occipito-posterior³⁶ but a lack of evidence as to what to do about it that might make a difference. This makes evaluation of these factors in any greater detail of debatable value. Investigations such as pelvimetry or estimation of fetal weight are insufficiently reliable to be of use in practice.³⁷ Cephalopelvic disproportion (CPD) is the description of a failure of two of the three Ps (passenger and passage). If CPD truly does occur then FTP is the inevitable consequence. The difficulty is that there are no precise ways of determining when CPD has occurred other than by allowing labour to continue long after a suspicion of FTP has been raised, such as occurs in situations where access to intervention is very limited. If the delivery then proceeds by CS then signs such as ballooning of the lower segment, free fluid in the abdomen and a deeply impacted head may confirm the diagnosis of FTP.¹⁰ As such, estimates as to its true incidence are difficult to establish but are reported to only be a few per cent.³⁸ On the other hand, if a CS for FTP is being performed where there is no absolute evidence of CPD, what is it being done for?

In addition to poor rates of cervical dilatation and failure of descent there are other signs that the head is becoming ‘stuck’. Increasing moulding and caput are traditional features along with a feeling of impaction – difficulty in getting a finger around the head due to a lack of room between it and the maternal pelvis. The more marked these features are, particularly if permanent saggital suture overlapping occurs, the higher the chance of true CPD occurring,³⁹ but again there is lack of evidence to support use of these features to guide management. Perhaps there should at least be an awareness that if these features are not present, it should prompt the person doing the examination to question whether there really is true FTP or whether one of the many sources of error highlighted above might be at play.

Prediction

A variety of parameters have been identified that appear to be associated with an increased chance of FTP, including maternal shoe size, maternal height, maternal pelvimetry and estimations of fetal weight. Unfortunately none of these has yet been found to be sufficiently robust to be useful in practice and NICE recommend they should not be used to guide management.¹⁰

Population change

Increasing age and obesity have been linked to an increased chance of CS for FTP. In the mid-1970s, 6 per cent of US pregnant women were over 35 years old compared to 20 per cent in 2012.⁴⁰ The incidence of obesity in women of child-bearing age has doubled in the same time,⁴¹ with studies on adolescents showing relative risk of 1.6 for FTP, even for the mildly overweight (BMI of over 25 kg/m²).⁴² A recent study from Scotland showed relative risks of up to 14 times higher for emergency caesarean in the most obese women.⁴³

MANAGEMENT

Having excluded all forms of error and having been robust in making the diagnosis, if the conclusion is reached that there has been significant FTP, management in the first stage is CS and in the second stage is either CS or instrumental delivery. Obviously it's not quite that simple and interventions can be tried to accelerate the rate of progress in an attempt to return it to normal but unfortunately none of these interventions has conclusively been shown to improve outcome.

First stage

The use of oxytocin is encouraged by NICE for nulliparous women and has been shown to shorten labour but not to reduce first-stage caesarean sections: 'Oxytocin will bring forward the time of birth but will not influence the mode of delivery or outcomes.'¹⁰ For parous women in particular, there is the concern that if the labour really is obstructed then forcing the uterus to contract more can result in rupture, massive haemorrhage and death. Again to quote NICE, 'Oxytocin should only be started in multiparous women once there has been a full assessment by the obstetrician. Continuous fetal monitoring is required with the use of oxytocin irrespective of the parity. Once oxytocin has been commenced vaginal examinations should occur at 4-hourly intervals; if there has been less than 2 cm of progress the decision should be made as to whether a CS is required.' And furthermore: 'Early use was associated with hyperstimulation as well as increased fetal heart trace concerns but no change in neonatal or maternal outcomes. Current guidelines do not recommend the use of syntocinon in the second stage whether or not regional anaesthesia is in place or not. The only exception to this would be subjectively poor contractions at the start of the second stage in nulliparous patients with regional anaesthesia.'¹⁰

The package known as the 'active management of labour' that includes early amniotomy and 2-hourly examinations also does not appear to make any difference.¹⁸ One-to-one care from a health professional has benefits in terms of length of labour and other markers such as postnatal depression rates but other than encouraging trends in the original observational studies from the 1970s⁴⁴ there remains little evidence that it affects CS rates.

Immobility in the first stage has been associated with longer labours and NICE¹⁰ discourages women from staying supine although encouraging women to mobilise doesn't seem to improve outcomes.

Second stage

Not lying supine and not being in the lithotomy position has been shown to be associated with a shorter second stage and lower rates of instrumental delivery.⁴⁵ In the second stage, oxytocin can be used but again without robust evidence that it alters outcome.

CONCLUSIONS

Failure to progress accounts for about a third of all emergency caesarean sections. CS rates are rising with minimal evidence of benefit. Despite much more powerful data from large studies in the 21st century, management of labour continues to rely on practices that emerged following publication of a small study in the 1950s. The key points from later research are that the active phase may not start until 6 cm and that slow progress before then may not be intrinsically harmful. The use of oxytocin may speed things up but not alter outcome. On the plus side there is plenty of room for research: we rely on assessing progress largely by cervical dilatation alone which has untested errors and not even a standardised technique. Research into establishing these errors, standardising technique and perhaps focusing on the amount of cervix until full dilatation is achieved may be interesting. There is evidence that the population is changing and as such it may be wrong to try to reverse the trend in rising caesarean sections for FTP.

A fresh look with new ideas and robust research as to how to tackle rising intervention rates is needed. Sixty years after Friedman, it will be interesting to see where we'll be in another 60.

Chapter 51 Fetal compromise in the first stage of labour

Jenny Blackman and Myles Taylor

MRCOG standards

- The ability to recognise, classify and act appropriately on CTG patterns.
- The ability to perform fetal blood sampling and to be able to interpret the results.

In addition, we would suggest the following.

Theoretical skills

- Know the risk factors for fetal compromise and how they can be recognised either antenatally or in early labour.
- Understand the alterations in placental blood flow during contractions.
- Know the acute intrapartum complications that can lead to fetal compromise.
- Be aware of the different techniques available for assessing fetal wellbeing in labour as well as their individual indications and limitations.
- Be able to quote the risk of serious neonatal morbidity and mortality.

Practical skills

- Be confident in your ability to interpret a CTG, particularly with regard to recognising those babies requiring immediate delivery.
- Be able to perform and interpret additional tests of fetal wellbeing for non-reassuring CTGs that do not necessitate immediate delivery.
- Be able to apply a scalp electrode or perform a real-time ultrasound scan when it is not possible to obtain an adequate fetal heart rate trace using conventional Doppler techniques.

INTRODUCTION

Members of the public, and indeed the legal profession, commonly relate childhood disability to a 'difficult' labour

and delivery. However, the Consensus Statement of the International Cerebral Palsy Task Force reported that intrapartum hypoxia could at most be responsible for only one in ten cases of cerebral palsy.¹ Nevertheless, as labour represents about 0.4 per cent (1/280) of the total duration of pregnancy, a 10 per cent contribution to sub-optimal neonatal outcomes reminds us that it is a relatively 'high-risk' period. The fact that uterine perfusion is dramatically reduced during each contraction emphasises the additional stress that labour places on the fetus.

AIMS

The aim of monitoring fetal wellbeing during labour is to prevent birth asphyxia and so reduce perinatal mortality, morbidity and long-term disability. Although all three of these outcomes are uncommon, the use of operative delivery for 'non-reassuring fetal status' remains an everyday occurrence on delivery suites in the UK. This is in part because of a wish to deliver on the downwards slope towards a poor outcome, before it actually occurs. The key question is, what are the poor outcomes that we are trying to prevent? Currently, efforts are focused on reducing intermediate adverse outcomes in the hope that long-term permanent adverse outcomes (death and disability) can be avoided. Such intermediate outcomes include NICU admissions at term, umbilical cord acidosis and base deficit, low Apgar scores and neonatal hypoxic ischaemic encephalopathy at term.

ABSOLUTE OUTCOMES

Perinatal mortality

This remains a widely accepted measure of maternity care, but such crude figures provide little help in assessing intrapartum monitoring. First, they are heavily distorted by very preterm births, in which fetal condition at birth is only one of many factors influencing outcome. Second, perinatal mortality rates also include stillbirths. It is self-evident that fetal monitoring can only be of use when the baby is alive at the onset of labour.

Intrapartum term stillbirths may be a more appropriate mortality figure, as they are often related to events occurring during parturition. The intrapartum stillbirth rate in term singleton pregnancies is reported as only 0.3 per 1000.² The influence of fetal monitoring on such a rare event will remain difficult to study.

Long-term morbidity

The achievement of normal long-term neurodevelopment is another major aim of intrapartum fetal assessment. The incidence of cerebral palsy is widely quoted as 2 per 1000. However, as mentioned previously, only in 10 per cent of cases (or 1 in 5000 births) are intrapartum events thought to have been of influence. Once again, the ability of fetal monitoring to impact on such a rarity is difficult to prove or disprove.

All obstetricians should therefore appreciate that intrapartum operative interventions carried out at term because of 'non-reassuring fetal status' are trying to prevent sub-optimal outcomes seen in approximately 1 in 2000 births. It is necessary not only for obstetricians to react appropriately but also to avoid over-reaction.

INTERMEDIATE OUTCOMES

Apgar scores

To improve the recognition of intrapartum factors contributing to the absolute outcomes referred to above, markers of potential long-term morbidity have been used.

The influence of the condition of the baby at birth using Apgar scores taken at 1 and 5 minutes has been widely investigated, particularly in the earliest studies. All now agree that the 1-minute Apgar score purely reflects the need for neonatal resuscitation, regardless of aetiology. Unfortunately, the 5-minute Apgar score also appears to provide little predictive ability for long-term complications unless very low (<4) or moderately low (<7) and remaining so beyond 10 minutes of age.

There is not yet enough evidence to support the use of other similar markers, such as the need for intubation or ventilation.

Arterial or capillary pH

Hypoxaemia will result when gas exchange across the placenta is impaired, with a gradual fetal accumulation of CO₂. This eventually leads to fetal acidaemia, which can be detected by analysing fetal capillary or neonatal arterial pH. The widely accepted lower limit of normal for fetal or neonatal pH is 7.20. This represents two standard deviations below the mean fetal pH seen from intrapartum studies. It must be stressed that this

value was chosen for statistical reasons, not primarily because of an association with neonatal morbidity. Clinical studies suggest that an umbilical arterial pH below 7.00 may be a more reliable marker of potential long-term problems, but the figure of 7.20 remains in everyday use to provide a wide margin of safety. The type of acidosis is also important. In a respiratory acidosis, the PCO₂ is elevated but the base excess is normal, a condition that will be easily resolved with the onset of neonatal respiration and gas exchange. Metabolic acidosis is associated with a transition to anaerobic metabolism and an accumulation of acids such as lactate. It is defined by a base deficit >12 mmol/L and is a marker of moderate to severe neonatal compromise in its own right.

Neonatal encephalopathy

Neonatal behaviour and early-onset medical complications also provide some prognostic information. Neonatal encephalopathy refers to disturbed neurological function in the first week of life. Signs include difficulty maintaining respiration, depressed tone and reflexes, altered level of consciousness and seizures. Moderate to severe neonatal encephalopathy will be seen in most cases of brain damage secondary to intrapartum complications. However, neonatal encephalopathy has poor sensitivity with 75 per cent of cases having no clinical signs of intrapartum hypoxia.

Criteria for intrapartum hypoxic events

No individual intermediate measure can precisely link intrapartum complications to absolute outcomes. Several groups have proposed pathways by which combinations of intermediate measures can help to define a causal intrapartum hypoxic event. The International Cerebral Palsy Task Force has listed criteria essential to link brain injury to an earlier intrapartum hypoxic event.¹ They include:

- evidence of a metabolic acidosis at birth (pH <7.00 and base deficit >12 mmol/L);
- early-onset moderate or severe encephalopathy;
- cerebral palsy of the spastic quadriplegic or dyskinetic type.

Other features that support an intrapartum hypoxic event include:

- a sentinel hypoxic event around the time of labour;
- a deterioration in the fetal heart rate pattern around the time of the sentinel event after a previously normal pattern;
- Apgar scores of <7 for longer than 5 minutes;
- early-onset multi-organ dysfunction
- early imaging evidence of an acute cerebral abnormality.

WHAT TYPE OF FETAL MONITORING IS BEST?

The Dublin Trial of Intermittent versus Continuous Monitoring remains the classic study in this field.³ Despite subsequent studies, the conclusions have been largely unchallenged. In low-risk pregnancies, electronic continuous monitoring was better at detecting fetal acidosis and led to a reduced incidence of neonatal seizures. However, it did not appear to have any influence on the absolute outcomes of mortality and long-term disability. Meta-analysis seems to support these conclusions, although it is recognised that the data are insufficient to detect a true difference in the rare absolute outcomes of death and disability [Ia]. Most authorities agree that continuous monitoring leads to an increase in operative intervention, although this can be at least partially mitigated by the use of secondary tests of fetal wellbeing.

WHAT IS A HIGH-RISK PREGNANCY?

The presence of any of the following risk factors at the onset of labour would label a fetus as being at 'high risk' of intrapartum hypoxia, for which the consensus is that continuous fetal monitoring should be offered:

- Hypertension/pre-eclampsia;
- Diabetes;
- APH;
- Significant maternal medical disease;
- IUGR;
- Preterm gestation;
- Isoimmunisation;
- Multiple pregnancy;
- Breech presentation;
- Previous caesarean section;
- Significant meconium staining of the amniotic fluid;
- Pre-labour rupture of membranes for >24 hours;
- Oligohydramnios;
- Abnormal umbilical artery Dopplers;
- Post-term pregnancy;
- Epidural analgesia;
- Induced or augmented labour.

Meconium staining of the amniotic fluid remains a marker of risk. In the Dublin trial, ARM was performed on admission, and the 5 per cent of women with either no fluid or significant meconium were excluded from the trial. Despite continuous monitoring and fetal blood sampling, the perinatal mortality rate in this group was 11 per 1000, compared to 2.1 per 1000 in the remaining trial participants. However, in the absence of fetal heart rate abnormalities, the presence of meconium is not an indication for fetal blood sampling.⁴

It is attractive to base intrapartum monitoring plans on a pre-labour assessment of risk. However, risk can change as labour progresses, for example with:

- the onset of vaginal bleeding;
- development of meconium staining of the amniotic fluid;
- maternal pyrexia (>38 degrees or 2 readings of >37.5 degrees 2 hours apart);
- slow progress in labour.

Ongoing risk appraisal can assist the clinician in deciding how long to tolerate a suspicious (but not pathological) CTG before employing secondary tests. It must be remembered that at least 40 per cent of cases of moderate to severe birth asphyxia in term pregnancies will occur to women in whom no antepartum risk factors were identified.⁵

ADMISSION TESTS

Equally attractive to the pre-labour assignment of risk is an early labour reassessment in low-risk pregnancies. In this situation, a screening test is applied to try to identify those fetuses that are more likely to develop intrapartum complications. Tools that have been used in this situation include CTGs, ultrasound assessment of AFV and umbilical artery Doppler. Research suggests that an abnormal admission test is associated with increased levels of obstetric intervention but no significant reduction in adverse perinatal outcomes [Ib].^{6,7} The NICE Guideline on Intrapartum Care does not recommend an admission test in women with uncomplicated pregnancies labouring at term.

INTERMITTENT AUSCULTATION

In the low-risk situation, intermittent auscultation, either by Pinard stethoscope or by handheld Doppler, is often advocated. Current guidelines suggest auscultating the FHR every 15 minutes in the active phase of the first stage of labour. This should be for 60 seconds following a contraction, in order to detect significant decelerations. Maternal pulse should also be recorded by palpation to avoid confusion, particularly when an FHR abnormality is suspected.

The main criticisms of intermittent monitoring are that:

- the above standards are often not achievable on busy delivery suites;
- gradual changes such as an increasing baseline or falling variability will be missed;
- there is no certification process for practitioners using intermittent monitoring;
- no hard record from the monitoring is generated and therefore it is impossible to audit any guidelines related to performing the technique.

CONTINUOUS ELECTRONIC FETAL MONITORING

The mainstay of 'high-risk' fetal assessment, EFM relies on several assumptions:

- that abnormal patterns in the FHR will be seen in the presence of compromise;
- that sufficient warning will be given to allow potentially beneficial interventions to be undertaken;
- that caregivers will recognise the abnormality and take appropriate action.

Many events, such as cord prolapse or abruption, may be so acute as to have no preceding period of deterioration in fetal wellbeing. Fetal monitoring may allow recognition of the problem but no advance warning. A similar rapid deterioration may be seen in fetuses with diminished reserves at the onset of labour, such as those babies with IUGR. Alternatively, it has been suggested that a chronically compromised baby may not exhibit the same type of FHR changes when acute compromise is superimposed. CTG abnormalities in this situation may be subtle or even atypical. *Low et al.* found that only 80 per cent of term births with metabolic acidosis exhibited a predictive fetal heart rate pattern.⁵ In other words, in one fifth of cases, the obstetrician would have found the CTG acceptable. The pathophysiology behind other causes of neonatal harm, such as infection, may not be associated with severe or typical 'non-reassuring' FHR abnormalities until almost pre-terminal. Finally, events related to the actual delivery (trauma, shoulder dystocia, problems during resuscitation) contribute to morbidity and mortality but cannot be predicted by intrapartum monitoring.

Some cases of abnormal intrapartum monitoring may have their roots in fetal development. Fetal cardiac anomalies are frequently undiagnosed antenatally and carry considerable morbidity and mortality. It is logical to assume that an abnormal heart will respond to the haemodynamic changes of labour atypically. Similarly, it can be difficult to disentangle prenatal neurological damage, occurring before the onset of labour, from that arising during labour. As the control of FHR involves higher centres, damage to these structures will lead to abnormal cardiovascular responses in labour. Thus, although it is tempting to assume that a poor neurological outcome is necessarily due to a stressful labour as reflected by an abnormal CTG, an alternative possibility needs to be considered, namely that pre-existing neurological damage led to an abnormal cardiovascular response to labour.

WHAT IS A NORMAL CTG?⁸

A useful approach that helps to avoid over-reaction is initially to extract those features of a CTG that are normal by systematically reviewing baseline rate, heart rate variability and accelerations.

Fig. 51.1 Rising baseline. It is sometimes difficult to see if a baseline is rising or is stable on a short piece of CTG but when a long episode of monitoring is folded and looked at in this manner then the rising baseline is obvious

- **Baseline.** The normal fetal baseline heart rate is 110–160 bpm. There is a small fall in baseline rate as gestation advances. A stable baseline over time is also important (Fig. 51.1). Many women will also have had recent admissions, generating earlier CTGs for comparison.
- **Variability.** FHR variability appears to result from a balance between sympathetic and parasympathetic influences. Therefore, a well-oxygenated nervous system is required for its full expression. Normal variability is >5 bpm. Short periods of reduced variability (particularly when associated with an inactive baby) can be entirely physiological, but in most cases variability will have recovered within 45 minutes.
- **Accelerations.** FHR accelerations represent a response to many minor stresses. Commonly, this is fetal movement, but it also includes palpation or noise. It implies a fetus responsive to external stimuli and, therefore, intact neurocardiac pathways. Most authorities agree that accelerations are the hallmark of fetal wellbeing.

WHAT IS AN ABNORMAL CTG?

- **Baseline.** A continuous and progressive fetal bradycardia indicates fetal hypoxaemia. Fetal bradycardia can arise with any acute reduction in fetal oxygenation, such as cord compression, abruption or uterine hyperstimulation. If the bradycardia is moderate to severe or associated with other CTG abnormalities and the cause cannot be corrected promptly, abdominal delivery will be necessary.
- An isolated tachycardia is rarely, if ever, associated with fetal compromise. Such a tachycardia may be appropriate

in some situations. If the baby is very active, the mother will know and the variability will usually be excellent. A fetal tachycardia may arise secondary to a maternal tachycardia, often in response to pain or maternal pyrexia. Clinicians must always be wary of an underlying diagnosis of chorioamnionitis as the fetus is in a hazardous environment that will not be reflected by scalp pH.

- **Variability.** A prolonged period of reduced variability, lasting >90 minutes, is clearly abnormal. The most concerning cause of decreased variability is fetal hypoxaemia, usually chronic, that has globally depressed CNS function. Other aetiologies include pre-existing neurological problems, maternal drugs and congenital heart block.
- **Accelerations.** These will rarely be seen in the presence of a compromised fetus.
- **Decelerations.** Decelerations arouse instant concern in many observers, particularly the less experienced. However, they should never be viewed in isolation, only as a part of the whole clinical picture. Decelerations are usually divided into one of three types, but this can only be determined after observing a pattern repeating over time.
 - **Early decelerations.** These decelerations begin with the onset of a contraction and mirror the shape of the contraction trace. They are usually thought to arise from vagal nerve stimulation secondary to cord compression. They are seen in approximately 1 in 20 first-stage CTGs and, in isolation, are rarely associated with fetal compromise (Fig. 51.2).
 - **Variable decelerations.** Variable decelerations are just that – variable. Each deceleration has a different shape and their timing with regard to contractions is unpredictable. They are the most common type of deceleration and are seen in up to 1 in 8 first-stage traces (Fig. 51.3). They are classically thought to arise from chemoreceptor stimulation secondary to cord compression. They may also result from head compression.
 - **Late decelerations.** Late decelerations begin after the contraction, with the onset, nadir and recovery occurring after the onset, peak and end of a contraction (Fig. 51.4). Only 1–2 per cent of labours demonstrate

Fig. 51.2 Early decelerations

Fig. 51.3 Variable decelerations

Fig. 51.4 Late decelerations

late decelerations in the first stage of labour. Late decelerations have been postulated to result from direct fetal myocardial depression secondary to hypoxaemia. There may be an additional contribution from chemoreceptor stimulation. Although isolated late decelerations with no other fetal heart rate abnormality are rarely associated with fetal compromise, the presence of any other coexisting abnormalities justifies secondary testing.

CTG INTERPRETATION AND DOCUMENTATION

RCOG and ACOG both recommend a three-tier system of interpretation of the CTG. In the UK, each CTG recording is interpreted as being either normal, suspicious or pathological (Tables 51.1, 51.2) and an appropriate management plan instigated in response. To assist this systematic approach, the use of a structured CTG *pro forma* has been advocated.

Table 51.1 Categorisation of fetal heart rate pattern (NICE Intrapartum Care Guideline 2007)

Category	Definition
Normal	A FHR* trace in which all four features are classified as reassuring
Suspicious	A FHR trace with one feature classified as non-reassuring and the remaining features classified as reassuring
Pathological	A FHR trace with two or more features classified as non-reassuring or one or more classified as abnormal

*Fetal Heart Rate

This encourages a thorough analysis of the CTG in the clinical context, documentation of CTG findings and proposed management plan.

No one element of the CTG should be interpreted in isolation. Regardless of how much intellectual activity is put into the interpretation of the CTG, it remains a screening test only. Even the most worrying pattern (late decelerations with reduced variability) is only associated with acidosis in 50 per cent of cases. Diagnostic or secondary tests are necessary to avoid unnecessary obstetric intervention.

SECONDARY TESTS OF FETAL WELLBEING

Vibro-acoustic stimulation

The use of VAS applied to the maternal abdomen in the presence of a non-reactive antenatal CTG is well documented.⁹ The healthy fetus responds with an acceleration in fetal heart rate. The same technique has been applied in the intrapartum

period. An acceleration evoked by VAS immediately prior to scalp sampling was never associated with a pH of <7.25. VAS cannot completely eliminate the need for scalp sampling, as only 30 per cent of non-responders will be found to be acidotic. However, it can reduce the need for scalp sampling by up to 50 per cent [B].

Fetal blood sampling

Fetal scalp pH studies remain the principal secondary test of intrapartum fetal wellbeing. It is recommended that all units offering continuous EFM have facilities for FBS. Fetal scalp pH lies between arterial and venous pH but it cannot be determined to which it is closer in advance. As mentioned previously, the lower limit of normal is accepted as a pH of 7.20 in order to allow a wide margin of error. The recommended classification of fetal scalp pH is shown in Table 51.3.

- After a normal result, FBS should be repeated no more than 60 minutes later if the CTG remains pathological, or sooner if there are further abnormalities.
- After a borderline result, FBS should be repeated no more than 30 minutes later.
- An abnormal result should prompt urgent delivery.

Ideally, the base excess should also be measured to distinguish metabolic from respiratory acidosis. There is interest in simply measuring the capillary lactate levels, which provide similar information.¹⁰ Testing systems have now been developed that require smaller volumes of fetal blood than conventional pH studies. This, in conjunction with the ability to sample at lesser dilatations, has led to a lower 'failure-to-sample' rate.

FBS should be performed with the woman in a left lateral position.

Contraindications to FBS include maternal infection with HIV, hepatitis and HSV, suspected fetal haemophilia and prematurity (less than 34 weeks of gestation).

Table 51.2 Classification of fetal heart rate trace features

Feature	Baseline (bpm)	Variability (bpm)	Decelerations	Accelerations
Reassuring	110-160	≥5	None	Present
Non-reassuring	100-109 161-180	40-90 minutes	Typical variable decelerations with over 50% of contractions, occurring for over 90 minutes Single prolonged deceleration for up to 3 minutes	The absence of accelerations with otherwise normal trace is of uncertain significance
Abnormal	<100 >180 Sinusoidal pattern ≥10 minutes	<5 for 90 minutes	Either atypical variable decelerations with over 50% of contractions or late decelerations, both for over 30 minutes Single prolonged deceleration for more than 3 minutes	

Table 51.3 Classification of fetal blood sample results (NICE Intrapartum Care Guideline 2007)

Fetal blood sample result (pH)	Interpretation
≥7.25	Normal
7.21–7.24	Borderline
≤7.20	Abnormal

Scalp stimulation

Most clinicians will have noted that fetuses that respond to scalp sampling with an acceleration almost always have a normal pH. This has been confirmed in formal studies, which showed that 93 per cent of fetuses with a scalp pH >7.20 respond with an acceleration, compared to none of those that are acidotic.¹¹ This can be useful information when technical difficulties preclude sample collection. However, clinicians should always be wary of scalps that do not bleed, as this may reflect peripheral vasoconstriction in a compromised fetus.

FETAL ECG

The knowledge that changes occur in both the fetal PR interval and ST segment of the fetal ECG in response to hypoxaemia has prompted the use of computerised fetal ECG analysis in combination with conventional CTG to monitor the fetus in labour.

A Cochrane review¹² and a recent meta-analysis¹³ compared the effectiveness of EFM with additional ST analysis in vertex term singleton pregnancies with conventional EFM. The combined use of ST analysis (STAN™) and CTG monitoring was associated with a reduction in the number of fetal blood samplings and fewer operative vaginal deliveries. However, there was no difference in the number of babies born with significant metabolic acidosis at birth (defined by pH <7.05 or base deficit >12 mmol/L) or neonatal encephalopathy. There was no difference in the numbers of births by CS or Apgar score <7 at 5 minutes. Monitoring with PR interval analysis did not appear to confer clinical benefit.

There are few data currently regarding the long-term development of infants who participated in these studies.

ST analysis in labour shows promise but there are a number of disadvantages. The technique requires additional equipment and training in interpretation for all caregivers. The use of a spiral fetal scalp electrode is necessary and, if ST analysis is to be commenced where FHR abnormalities are present, it may be necessary to obtain the results of a fetal blood sample before commencing such monitoring.

Non-invasive fECG acquisition using abdominally sited electrodes is now technically possible¹⁴ and in the future may become feasible in clinical practice. This technique avoids the use of a scalp electrode and also allows earlier fECG monitoring in labour.

Computerised CTG analysis

It is well known that there is significant intra-observer and inter-observer variation in the assessment of FHR recordings.

Although the CTG has been the mainstay of monitoring high-risk pregnancies and has remained largely unchanged for more than 40 years, the poor reproducibility and reliability of clinicians to predict fetal compromise using this tool remains a problem and challenge in modern obstetric practice.

Computerised analysis of intrapartum fetal signals has recently been developed but there is no published evidence yet that this technology results in improved perinatal outcomes. Results from prospective randomised trials, comparing intrapartum conventional CTG and computerised analysis of fetal monitoring signals with real-time alerts, are eagerly awaited.

Fetal pulse oximetry

There is no evidence that fetal pulse oximetry is of benefit in labour. The largest RCT to date failed to show any benefit in terms of CS rate or neonatal condition.¹⁵ Fetal pulse oximetry is not in use in the UK and it has not received the support of the ACOG in the USA.

THE MANAGEMENT OF SUSPECTED FETAL COMPROMISE

Improve placental blood supply.

- 1 Correct maternal hypovolaemia and/or hypotension.
 - Maternal positioning to avoid aorto-caval compression.
 - Intravenous fluids when appropriate.
 - Vasoconstrictors such as ephedrine for lower limb vasodilatation secondary to epidural analgesia.
- 2 Diminish uterine activity, particularly if excessive.
 - Decrease or stop any oxytocin infusion.
 - Remove vaginal prostaglandins if given recently. This may require vaginal lavage if gels have been used.
 - Use bolus tocolytics (e.g. terbutaline 0.25 mg)

Improve maternal oxygenation.

Maternal oxygen therapy should not be used for more than a short period of time unless there is documented low maternal oxygen saturation. There is no evidence of benefit and a suggestion of possible detrimental effect when applied for more than a few minutes [Ia].

Improve umbilical blood flow.

Increase amniotic fluid volume. Transcervical amnio-infusion may reduce cord compression and frequently leads to an improvement in the FHR. One randomised trial showed a significant reduction in operative intervention and an

improvement in cord pH at delivery.¹⁶ Common protocols include infusing 500 mL of Hartmann's solution over 20–30 minutes followed by up to 250 mL/hour. To minimise the risk of amniotic fluid embolus and over-distension, the infusion should be gravity fed.

Decide if delivery is indicated, based upon:

- 1 the CTG and secondary tests of fetal wellbeing including fetal blood sampling;
- 2 the whole picture – including obstetric risk factors and progress in labour;
- 3 other complications, such as abruption, cord prolapse, chorioamnionitis, suspected scar dehiscence.

A CLINICAL APPROACH TO REVIEWING INTRAPARTUM CTGS IN THE FIRST STAGE OF LABOUR

Does the abnormality require immediate delivery if it continues?

Yes (Think little, do lots):

- 1 Is there a possible precipitant?
 - Cord prolapse/recent epidural/excessive uterine activity/bleeding/scar dehiscence etc.
 - If possible, rapidly take steps to correct any precipitants identified.
 - If no corrective steps are possible or there is no response, deliver by caesarean section.

No (Do little, think lots):

- 1 For comparison, has there been a 'normal' CTG:
 - earlier in labour?
 - within a few weeks of admission?
- 2 On the current CTG, what normal features are present?
 - Stable baseline with normal rate;
 - Good variability;
 - Accelerations.
- 3 On the current CTG, what abnormal features are present? **Compare 1 and 2 with 3 to decide on the severity of any CTG abnormality and classify as normal, suspicious or pathological. (See Table 51.1)**
- 4 Is there a possible precipitant?
 - Cord prolapse/cord compression/recent epidural/excessive uterine activity/bleeding/scar dehiscence etc.
 - If possible, take steps to correct any precipitants identified in 4.**
- 5 What risk factors were present in the antenatal period?
- 6 Were there any recent changes immediately prior to labour?
 - Maternal illness/reduced fetal activity etc.

- 7 Have any risk factors developed during labour?
 - Meconium/bleeding/poor progress/fever etc.
 - **Then use 5, 6 and 7 to decide:**
 - if and for how long this abnormality can be tolerated before delivering or employing secondary tests of fetal wellbeing (eg. FBS), *and*
 - when to next review the CTG – a deliberate plan is the best approach.

Always try to answer 'What is causing this CTG abnormality?'

Do not forget 'benign' causes, such as recent narcotic analgesia or a rapidly progressing labour.

KEY POINTS

- Intrapartum events rarely lead to perinatal mortality or neurodevelopmental disability after uncomplicated term pregnancies.
- Electronic fetal monitoring is a crude screening test with a poor predictive value for acidosis.
- Always review EFM in the context of the whole pregnancy and labour.
- Secondary tests of fetal wellbeing after non-reassuring CTGs are necessary to avoid over-intervention.
- Intrauterine therapy can improve non-reassuring CTGs and reduce operative delivery.

Chapter 52 Obstetric anaesthesia and analgesia

David M Levy and Duncan S Cochran

MRCOG standards

Candidates are expected to:

- understand and be able to counsel women about the options for pain relief in labour, and their respective risks;
- understand the influence of various complications of pregnancy and labour (e.g. pre-eclampsia, coagulopathy and major haemorrhage) on the choice of anaesthetic.

INTRODUCTION

Obstetric *analgesia* is pain relief in labour; *anaesthesia* is the abolition of sufficient sensation to allow operative delivery.

Provision of analgesia is a key element of the modern management of labour. Women receive education antenatally about the options for analgesia in labour and often have very high expectations on admission to the delivery suite.

Regional (spinal, epidural or combined spinal–epidural) anaesthesia is now used for the vast majority of caesarean sections.

ANALGESIA FOR LABOUR

Modes of analgesia include:

- relaxation therapy;
- immersion in warm water;
- aromatherapy;
- transcutaneous electrical nerve stimulation (TENS);
- inhalation of nitrous oxide – and other inhalational anaesthetics – in oxygen;
- parenteral opioids;
- regional analgesia.

The requirement for pharmacological pain relief in labour is reduced when a known practitioner provides continuous support throughout labour [A].¹ Immersion in water during the first stage of labour reduces analgesic requirements.² The

evidence underpinning nonpharmacological methods of pain relief in labour (including continuous support, bathing, upright position and massage) has been systematically reviewed.³

Transcutaneous electrical nerve stimulation

Electrical impulses are applied to the skin via flexible carbon electrodes from a battery-powered stimulator. Stimulation of A-fibre transmission and local release of β -endorphins modulate pain, closing a postulated ‘gate’ in the dorsal horn of the spinal cord. The effect is similar to massage of the lower back by a birthing partner.

- Electrodes are placed over the T10–L1 dermatomes on either side of the spinous processes to provide analgesia for the first stage of labour. A second set of electrodes is placed over the S2–S4 dermatomes for second-stage pain relief. Women can control the level of current delivered.
- There is no evidence that TENS provides better analgesia than placebo (‘sham’ TENS). However, TENS can diminish the need for other analgesic interventions, and is completely free from adverse effects.⁴ TENS ‘analgesia’ seems to be rated more highly in retrospect than contemporaneously.

Opioid analgesia

The analgesic efficacy of opioids in labour is limited, although sedation is almost invariable.⁵

- All opioids can cause decreased Apgar and neurobehavioural scores and neonatal respiratory depression, even when administered many hours before birth.
- Neonatal respiratory depression is readily reversible with naloxone, a specific opioid antagonist. The neonatal dose is 10 mcg/kg IM, repeated if necessary.
- Maternal gastric emptying is inhibited and the incidence of nausea and vomiting increased. An anti-emetic (e.g. cyclizine 50 mg or prochlorperazine 12.5 mg) should be given IM with the chosen opioid.

- Midwives can prescribe and administer controlled drugs in accordance with Nursing and Midwifery Council (Midwives) Rules and locally agreed policies and procedures. In the UK, pethidine is the most widely used IM opioid, although the use of diamorphine is increasing in the UK without evidence of greater efficacy.⁶ Comparisons of pethidine 100 mg with diamorphine 5 mg, meptazinol 100 mg and tramadol 100 mg have failed to demonstrate superior analgesic efficacy or a more favourable side-effect profile associated with any one agent.
- Because of the additive risk of maternal respiratory depression, IM opioids should never be given in the event of inadequate regional analgesia without prior reassessment of the woman by an anaesthetist.
- A reduction in baseline CTG variability can make interpretation difficult.
- Hyperventilation with N₂O/O₂ can be followed by a short period of apnoea; therefore, the woman should always hold the mouthpiece or mask herself. If she loses consciousness, she will let go. A few breaths of air eliminate the N₂O and consciousness is invariably soon regained.
- A number of studies have questioned the analgesic effect of N₂O/O₂. Pain is often still perceived under the influence of the drug – it is merely rendered more bearable by the intoxicated state. Thirty to 40 per cent of women in labour derive no benefit.
- The risk of cross-contamination between patients sharing breathing systems dictates that mouthpieces and masks should be disposable, or sterilised between patients. Either a new disposable breathing system should be used for each patient, or a disposable breathing system filter interposed between the tubing and mouthpiece/mask.

Patient-controlled analgesia

Intravenous opioid by PCA system is useful in women with thrombocytopenia or other haematological reasons for avoiding regional analgesia or IM injections. The potency and rapidity of action of remifentanyl can predispose to sudden respiratory depression – as labour pain is episodic as opposed to continuous, the therapeutic window is particularly narrow. There appears to be wide variation in the dose required for effective labour analgesia.

Despite a slower onset of action and less rapid clearance, fentanyl is perhaps the drug of choice, by 20–30 mcg bolus and 5-minute lockout period [E].

Analgesia by inhalation

Sixty to 70 per cent of labouring women in the UK seek analgesia by inhalation of a 50:50 mixture of nitrous oxide and oxygen (N₂O/O₂). Marketed as Entonox[®] and Equanox[®], the gas mixture is supplied in cylinders with a blue body and blue/white shoulders and is piped to labour rooms in many hospitals. The future availability of nitrous oxide is not assured. Protracted inhalation of N₂O can inactivate vitamin B₁₂ and inhibit DNA synthesis. Isoflurane and sevoflurane, two fluorinated, potent inhalational anaesthetics, have been studied in labour at low doses, but not yet widely adopted.⁵

- N₂O/O₂ is self-administered by inspiration through a facemask or mouthpiece, which opens a demand valve. Diffusion from alveoli to pulmonary capillaries and delivery to the brain by the cardiac output are not instantaneous. Inhalation should therefore start as soon as a contraction begins, to allow maximum drug effect at the peak.
- The drug is non-cumulative and does not affect the fetus. N₂O/O₂ causes highly variable maternal sedation. Some women appear to be dreaming or drunk; others become somnolent or even briefly unrousable.

Regional analgesia for labour

Regional analgesia is the provision of pain relief by blockade of sensory nerves as they enter the spinal cord. Local anaesthetic and/or opioid can be introduced into epidural and/or subarachnoid (intrathecal) spaces.

Comparisons of regional analgesia regimens require careful scrutiny of which drugs have been introduced into which space(s) and their mode of administration (bolus or infusion).

Compared with other analgesic modalities, pain relief from regional blockade is undoubtedly superior.⁷ Ninety per cent of consultant obstetric units in the UK provide a 24-hour regional analgesia service. The UK Obstetric Anaesthetists' Association (OAA) captured data in 2011 from 558,256 mothers in 148 units. The regional analgesia rate was 22.7 per cent. In the USA, the rate is 60 per cent.

Contraindications to regional blockade are outlined in Table 52.1. Subcutaneous LMWH within the previous 10–12 hours is a relative contraindication. Scar tissue from previous spinal surgery can make identification of the epidural space difficult, and impede spread of local anaesthetic solution. However, catheterisation of the subarachnoid space might nevertheless be feasible – early referral (ideally with the post-operative radiographs) should be made to an obstetric anaesthetist. Untreated pyrexia in labour raises the possibility of bacteraemia and seeding a vertebral canal abscess in the event of bleeding from an epidural vein. However, the likelihood of such a complication has to be weighed against the probably greater risks of general anaesthesia (e.g. anaphylaxis to succinylcholine) that might otherwise be avoided. Regional analgesia has been shown to cause pyrexia in labour in around 15 per cent of women. Suggested mechanisms include abolition of hyperventilation and sweating (from the lower half of the body) and promotion of shivering. The potential importance is that maternal fever, particularly in association with fetal acidosis, greatly increases the risk of neonatal encephalopathy. Acetaminophen (paracetamol) and active

Table 52.1 Contraindications to regional analgesia, with associated risks

Contraindication	Risk
Uncorrected anticoagulation or coagulopathy	Vertebral canal haematoma
Local or systemic sepsis (pyrexia >38°C not treated with antibiotics)	Vertebral canal abscess
Hypovolaemia or active haemorrhage	Cardiovascular collapse secondary to sympathetic blockade
Patient refusal	Legal action
Lack of sufficient trained midwives for continuous care and monitoring of mother and fetus for the duration of epidural blockade	Delayed recognition and treatment of maternal collapse/convulsion/respiratory arrest or fetal compromise

cooling are indicated. The link between epidural analgesia and backache has been thoroughly investigated and no evidence of causation found.⁷ The risk of permanent neurological injury is probably less than 1:100,000. Obstetric palsies (e.g. compression of the lumbosacral trunk) are far more common.

Regional analgesia does not impair the initiation of breast feeding.

Epidurals and spinals

The epidural space is identified by the loss of resistance to depression of a syringe plunger as a Tuohy needle is advanced (Fig. 52.1) through the ligamentum flavum. A catheter is then threaded through the Tuohy needle (Fig. 52.2) to facilitate bolus top-ups or a continuous infusion. The subarachnoid space, which contains CSF, is a few millimetres deeper, inside the meninges. Needles used for deliberate spinal injection are much finer than Tuohy needles (Fig. 52.3). Unlike local anaesthetics, which prevent the conduction of nerve impulses, opioids act on specific receptors in the spinal cord. Synergistic mixtures of local anaesthetic and opioids (usually fentanyl) have permitted significant reductions in the amount of local anaesthetic used. Side effects specific to opioids are respiratory depression (in the most unlikely event of cephalad spread of opioid to the brainstem) and pruritus.

Dural tap

Accidental meningeal puncture with a Tuohy needle is called a 'dural tap'. Eighty-five per cent of women who have a dural tap will develop a severe, characteristically postural headache, caused by leakage of CSF. Only the presence of headache during labour is an indication for elective forceps or vacuum extraction at full dilatation. The definitive treatment is epidural injection of autologous blood (up to 20 mL) – a 'blood patch', best undertaken at 24–48 hours post-delivery. Occasionally, the patch has to be repeated. Women with persistent headache must be followed up until symptom-free. Intracranial

**Fig. 52.1** Tuohy needle with loss-of-resistance syringe**Fig. 52.2** Tuohy needle advanced through the ligamentum flavum, with the catheter in the epidural space**Fig. 52.3** Epidural Tuohy (above) and spinal needles

hypotension (low CSF pressure) can be complicated (albeit very rarely) by cranial subdural haematoma secondary to tearing of a dural bridging vein.

Total spinal

Five to ten times the dose of local anaesthetic is required for an equivalent effect after epidural as opposed to subarachnoid injection. Any communication between epidural and subarachnoid spaces introduces the risk of a large dose of local anaesthetic, intended for the epidural space, reaching the subarachnoid space. A block high enough to impair diaphragmatic innervation and cause respiratory arrest is known as a 'total spinal'. A total spinal should be a survivable event for mother and fetus. The mother will require emergency tracheal intubation and treatment of hypotension. The urgency of CS will be dictated by the FHR pattern. Tracheal extubation should be feasible within 2–3 hours, once the high block has regressed.

Local anaesthetic toxicity

If local anaesthetic is injected inadvertently into an epidural vein, symptoms and signs of local anaesthetic toxicity (Table 52.2) can arise from the effect of high concentrations of local anaesthetic in the CNS. Initial treatment follows the 'ABC' principle: airway, breathing and circulation (with relief of aorto-caval compression). A new, specific and effective treatment has been introduced for local anaesthetic-induced cardiac arrest: intravenous Intralipid™ 20 per cent. The dose for a 70 kg adult is 100 mL. All delivery suites should have a readily available emergency LipidRescue™ box, containing a 500 mL bag of Intralipid 20 per cent, 50 mL syringes and giving set. Details of evolving guidelines for this novel treatment are available at www.lipidrescue.org. One of the deaths in the most recent Report on Confidential Enquiries into Maternal Deaths⁸ (accidental IV administration of bupivacaine from an infusion bag intended for epidural use) might have been averted had this therapy been available.

Combined spinal–epidural analgesia

Combined spinal–epidural (CSE) analgesia entails an initial subarachnoid injection of fentanyl (in the UK) mixed with a small amount of local anaesthetic. The spinal injection makes the onset of analgesia considerably faster (5 minutes, as opposed to at least 20 minutes with an epidural). The resulting motor block is sufficiently minimal for women to retain sufficient muscle power to walk in labour. However, depending

Table 52.2 Symptoms and signs of local anaesthetic toxicity

Symptoms	Signs
Numbness of tongue or lips	Slurring of speech
Tinnitus	Drowsiness
Light-headedness	Convulsions
Anxiety	Cardiorespiratory arrest

on the drug regimen, proprioception (information from joint receptors to maintain balance) might be impaired. The Comparative Obstetric Mobile Epidural Trial (COMET)⁹ found that both low-dose infusion epidurals and CSE analgesia resulted in a lower incidence of instrumental vaginal deliveries compared to traditional intermittent (midwife-administered) bolus epidurals (Table 52.3) [B]. It is presumed that this is attributable to the preservation of motor tone and the bearing-down reflex, as mode of delivery was not influenced by whether or not women walked during the first stage of labour. The effect of mobility after full cervical dilatation remains equivocal.¹⁰ A Cochrane review failed to find a difference in overall maternal satisfaction with CSE compared to epidural analgesia, despite the faster onset. CSEs were associated with more pruritus.¹¹

Patient-controlled epidural analgesia

Increasing numbers of units (25 per cent in 2011) favour self-administration of epidural opioid and local anaesthetic: patient-controlled epidural analgesia (PCEA).¹² Compared with continuous infusion techniques, PCEA reduces the total administered dose of local anaesthetic, the degree of motor block and the number of anaesthetists' interventions. Some studies suggest that analgesia is improved by a continuous background infusion.

Regional analgesia and progress of labour

Regional analgesia can improve uteroplacental blood flow in labour. However, a fall in blood pressure after a bolus dose of local anaesthetic can precipitate a fetal bradycardia. Adoption of full left-lateral position and treatment of hypotension by i.v. fluid bolus and/or vasopressor should resolve the FHR abnormality.

Despite better pain relief than other methods of analgesia, regional analgesia has been associated with longer first and second stages of labour, an increased incidence of fetal malposition, greater use of syntocinon®, and an increased risk of instrumental vaginal birth. No direct effect on the CS rate has been demonstrated.⁷

A recent large RCT compared neuraxial (subarachnoid) fentanyl (at the initiation of CSE) with parenteral opioid

Table 52.3 COMET: analgesic regimen and mode of delivery

Delivery	'Traditional' epidural (n = 353)	Combined spinal epidural (n = 351)	Low-dose infusion epidural
Normal vaginal	124 (35%)	150 (43%)	150 (43%)
Instrumental vaginal	131(37%)	102 (29%)	98 (28%)
Caesarean section	98 (28%)	99 (28%)	102 (29%)

- $p = 0.04$, 1 DF (degree of freedom) for normal versus other deliveries

(hydromorphone) at the first request for pain relief in labour, with deferral of regional analgesia.¹³ Women who received early CSE experienced superior analgesia and a shorter duration of labour. The rates of CS and instrumental delivery were similar (the study had 90 per cent power to detect a 50 per cent difference in CS rate [B]).

There is no high-level evidence upon which to withhold modern regional analgesia because an arbitrary degree of cervical dilatation has not yet been achieved.

Instrumental delivery

When epidural analgesia is topped up for instrumental delivery, the block height and density should be adequate for CS, in case the need arises to proceed swiftly to operative delivery if the instrument application fails.

ANAESTHESIA FOR CAESAREAN SECTION

The OAA 2011 data collection identified a CS rate of 24.8 per cent. Fifty-nine per cent were performed under single-shot spinal anaesthesia. Epidural anaesthesia was used in 19.8 per cent of cases (most were topped-up labour epidurals and CSEs). The GA rate was 8.2 per cent (Fig. 52.4). The NICE caesarean section guideline (www.nice.org.uk/Guidance/CG132) includes anaesthesia recommendations.

Categorisation of urgency

Good communication among obstetric, anaesthetic, midwifery and theatre staff is vital for a well-organised caesarean section. A four-point classification (1–4) of urgency of CS

Fig. 52.4 UK caesarean sections, 2011 (NOAD)²¹

(Table 52.4), similar to that used by the National Confidential Enquiry into Patient Outcome and Death (NCEPOD), has been validated by close agreement between anaesthetists' and obstetricians' gradings of more than 400 cases, and recently reassessed.¹⁴ It has replaced the more traditional 'emergency', 'urgent', 'elective' terminology. A decision-to-delivery interval of 30 minutes has become widely adopted as an audit standard, despite lack of any evidence that 30 minutes is a critical threshold in the development of intrapartum hypoxia. Spinal anaesthesia is often appropriate for urgent (Table 52.4) CS, although a CESDI deemed repeated attempts at regional anaesthesia to be inadvisable in the absence of significant risk factors for general anaesthesia.¹⁵ Auditable standards published by the Royal College of Anaesthetists (www.rcoa.ac.uk/docs/ARB-section8.pdf) are listed in Table 52.5.

In-utero fetal resuscitation

Anaesthetists are increasingly attuned to contributing to the multidisciplinary management of in-utero fetal compromise. The Bristol 'SPOILT' acronym is a useful aide memoire:

- Syntocinon® off;
- Position: full left lateral;
- Oxygen;
- Intravenous infusion of crystalloid;
- Low blood pressure: IV vasopressor;
- Tocolysis: SC terbutaline 250 mcg.

Mortality

Maternal mortality attributed to anaesthesia has fallen considerably over the last 50 years (Fig. 52.5). Capnography is arguably the most valuable component of physiological monitoring. Tracheal or oesophageal intubation can be confirmed immediately, with complete accuracy.

Antacid prophylaxis

Fasting intervals of 6 hours for food and 2 hours for fluids (tea/coffee with semi-skimmed milk, or fruit squash) are appropriate for women scheduled for elective caesarean section. Ranitidine diminishes gastric acid secretion; sodium citrate neutralises acid already in the stomach. Ranitidine

Table 52.4 Classification of urgency for caesarean section

Category	Definition
1	Immediate threat to life of woman or fetus
2	Maternal or fetal compromise that is not immediately life threatening
3	Needing early delivery but no maternal or fetal compromise
4	At a time to suit the woman and maternity team

Table 52.5 Audit recommendations: Royal College of Anaesthetists

Proposed standard or target for best practice	>95% RA for category 4 CS
	>85% RA for categories 1 to 3 CS
	<1% RA to GA conversion rate in category 4 CS
	<3% RA to GA conversion rate in categories 1 to 3 CS (this figure of 3% includes regional anaesthetics for labour converted to GA for CS)
Suggested data to be collected	Number of CS, category of CS, type of anaesthetic and reason for its use
	Name and grade of anaesthetist and surgeon
	Conversion rate to GA and reason (e.g. technical difficulty, poor block, maternal request, fetal or surgical reasons)
	In particular, data collected should allow units to identify reasons for a low RA rate (or high)

- CS, caesarean section; GA, general anaesthesia; RA, regional anaesthesia.

**Fig. 52.5** Maternal mortality (number of deaths) from anaesthesia 1952–2005

150 mg should be prescribed for 2 hours before an elective operation and administered 8-hourly to all women in labour with risk factors for CS. Administration of a measure (30 mL) of sodium citrate 0.3M immediately before caesarean section under general anaesthetic should be done. The risk of aspiration of gastric contents is not confined to general anaesthesia: protective laryngeal reflexes may be obtunded in the event of an excessively high regional block, though sodium citrate is not usually given prior to regional anaesthesia.

Regional anaesthesia

Single-shot spinal anaesthesia

Single-shot spinal anaesthesia has become the most popular anaesthetic technique for caesarean section (Fig. 52.4), largely as a consequence of the widespread adoption of pencil-point tip needles (Fig. 52.6). Compared to standard cutting bevel (or Quincke) needle tips, there is less leakage of CSF and a lower incidence of headache requiring epidural blood patch.

Preload – or coload?

A crystalloid fluid preload has become recognised as an ineffective means of preventing hypotension after spinal injection. Its short intravascular half-life prevents a sustained increase in cardiac output before sympathetic blockade develops. Rather than infuse crystalloid before spinal blockade, fluid is best given (from pressurised infusion bag) as the block develops – hence ‘coload’. Colloids, such as hydroxyethyl starch, are no longer recommended.

Hypotension is best managed by:

- strict avoidance of aorto-caval compression;
- rapid infusion of crystalloid immediately after intrathecal injection;
- prompt boluses or infusion of vasopressor.

Level of injection

MRI has shown that the conus medullaris of the spinal cord extends below the level of the body of L1 in 20 per cent of patients. Moreover, anaesthetists commonly underestimate the height of their approach. A series of case reports describing

Fig. 52.6 Pencil-point (top) and cutting bevel-tip spinal needles

damage to the conus medullaris has led to an authoritative recommendation that spinal needles should not be inserted higher than the L3/4 interspinous space – practically, the space at or immediately above a line joining the highest points of the iliac crests. Anaesthetists are increasingly using ultrasound probes to identify the space to be used.

Dose of local anaesthetic

Most UK obstetric anaesthetists use hyperbaric bupivacaine 0.5 per cent. Gestation is important when deciding upon the dose for a single-shot spinal. In one study, loss of cold sensation to T4 was achieved with 2.25 mL in all of a group of women at term, but only 16 per cent of women at 28–35 weeks' gestation. The progressively gravid uterus causes increasing vena caval compression, epidural venous engorgement and consequent displacement of the dura and reduced subarachnoid space volume. Postural manoeuvres after intrathecal injection, such as moving from right to left lateral or flexing the knees and thighs, promote cephalad spread of the injectate by influencing vertebral canal blood volume.

Loss of light touch sensation to T5 is a better predictor of pain-free CS under (opioid-free) spinal anaesthesia than loss of cold sensation. Light touch sensation is ascertained by asking if the woman has any appreciation of ethyl chloride dripped on to skin. The extent of the block and modality of testing should be recorded in case a subsequent claim of intra-operative pain has to be defended. The obstetrician must clarify with the anaesthetist that it is appropriate to start surgery.

Spinal anaesthesia can cause, within 5 minutes, a high block with precipitous fall in blood pressure – even despite IV coload and vasopressor. Relief of aortocaval compression by swift delivery of the baby will be required urgently. Obstetricians should not, therefore, leave the theatre suite during induction of spinal anaesthesia.

Opioids

The addition of intrathecal fentanyl, diamorphine or morphine can reduce the incidence of intra-operative visceral pain, although fentanyl does not contribute significantly to postoperative analgesia. Reports of respiratory depression

after intrathecal doses of opioids in obstetric practice are conspicuous by their absence. NICE recommends the use of 0.3 mg diamorphine for category 4 CS. Intra-operative pain should be treated promptly by IV alfentanil (0.5 mg increments) or inhaled isoflurane or sevoflurane in an N₂O/O₂ 50:50 mixture, IV ketamine (20 mg increments) or conversion to general anaesthesia.

Vasopressors

Ephedrine (alpha and beta sympathomimetic) was regarded as the vasopressor of choice in obstetrics for decades. Persisting reservations about the effects of alpha-agonists on uteroplacental blood flow were founded on studies of Columbian ewes, which did not undergo regional anaesthesia. Randomised comparisons of IV boluses of ephedrine and phenylephrine in women undergoing CS found similar changes in maternal systolic pressure and cardiac output, but significantly lower UA pH in neonates whose mothers had received ephedrine. Increased fetal metabolic rate secondary to ephedrine-induced beta-adrenergic stimulation may be the explanation. Infusions of phenylephrine, compared with ephedrine, are associated with improved maternal haemodynamic control and less nausea and vomiting [B].¹⁶ Phenylephrine is now widely regarded as the vasopressor of choice at CS and should mitigate the slight fetal acidosis that was observed in a meta-analysis of spinals compared with epidurals or general anaesthetics.

Spinal anaesthesia and pre-eclampsia

Over the last few years, it has become accepted by many that pre-eclampsia is not necessarily a contraindication to single-shot spinal anaesthesia; if the abnormal systemic vasoconstriction is of humoral rather than neural aetiology, sympathetic blockade should not, logically, cause precipitous hypotension. Prior vasodilatation by effective antihypertensive treatment (e.g. oral methyldopa or IV hydralazine) with limited intravascular volume expansion seems to avert problematic hypotension. Judicious fluid boluses and small increments of phenylephrine will correct hypotension.

Postoperative analgesia

Supplementation of intrathecal diamorphine or morphine by regular oral, rectal or IV paracetamol (1 g 6-hourly) and diclofenac (50 mg 8-hourly, 12 hours after an initial 100 mg postoperative dose), makes patient-controlled IV morphine unnecessary for most women. NSAIDs are contraindicated in the initial postoperative period if CS has been complicated by excessive bleeding or there is concern about the adequacy of haemostasis (e.g. uterine atony). In pre-eclampsia, prescription of NSAIDs should be deferred until 24 hours postpartum and confirmation of normal renal function. In 2013, the Medicines and Healthcare products Regulatory Agency (MHRA) contraindicated the use of codeine in mothers who are breastfeeding, due to fears of a small risk of respiratory depression in infants in mothers who are 'fast acetylators'.²²

Transversus abdominis plane (TAP) blocks (Fig. 52.7) have emerged as highly effective adjuncts to other analgesic modalities after general anaesthesia, though have limited use after regional anaesthesia if a long-acting intrathecal opioid has been administered.¹⁷

Epidural anaesthesia

Few elective caesarean sections are now performed under epidural anaesthesia, because the quality of anaesthesia is generally poorer than that afforded by subarachnoid block. The rate of conversion to general anaesthesia for epidurals is consistently greater than that for spinals. *De novo* epidural anaesthesia is still favoured by some when gradual establishment of block is desired to minimise hypotension e.g. in patients with cardiac disease. In severe pre-eclampsia, postoperative infusion of epidural bupivacaine/fentanyl in a high-dependency area will confer optimal analgesia and contribute to blood pressure control. A South African study demonstrated that women who were fully conscious and cooperative after an eclamptic seizure could safely undergo caesarean section under epidural anaesthesia. All women had platelet counts $>100 \times 10^9/L$ and had been treated with magnesium sulphate.¹⁸

Conversion of labour analgesia

In women in labour deemed high risk for CS – and those with potentially difficult airways – consideration should be given to instituting epidural analgesia early. It should be established that the block is working well, without missed segments. If analgesia in labour has been poor, it is unlikely that anaesthesia for CS will be satisfactory. Conversion of analgesia for labour to surgical anaesthesia for CS takes around 20 minutes. In contrast to single-shot spinal anaesthesia, abrupt changes in blood pressure are unusual. Good communication among midwives, obstetricians and anaesthetists should make general anaesthesia for the woman with a working epidural a rarity.

Even in the event of cord prolapse, traditionally managed without question by general anaesthesia, there might be time for an epidural top-up, provided upward displacement of the presenting part is effective in avoiding cord compression.

Combined spinal–epidural anaesthesia

Some units have adopted CSE anaesthesia as their standard technique for CS, despite lack of evidence of overall superiority compared with single-shot spinals. CSE anaesthesia is useful when there is a possibility that surgery might outlast a single-shot spinal block – a standard intrathecal dose of local anaesthetic lasts typically around 90 minutes. In the event of protracted surgery (e.g. caesarean hysterectomy in a woman with placenta praevia), an epidural catheter will allow extension of the block. However, the initial spinal anaesthetic block precludes ascertainment of correct positioning of the epidural catheter.

Continuous spinal anaesthesia

Threading a fine gauge catheter into the subarachnoid space can permit repeated fractionated bolus doses directly into the CSF compartment, allowing high-quality anaesthesia which can be extended if surgery is protracted. The technique has been reserved for women with cardiovascular risk factors (e.g. complex cardiac disease) for whom abrupt sympathetic blockade might be deleterious.

The US FDA banned microspinal catheters (27 g or smaller) in 1992, in response to a cluster of cases of cauda equina syndrome. The cause was, in all likelihood, pooling of hyperbaric 5 per cent lidocaine (not available in the UK) in the sacral area, as opposed to morbidity associated with the catheter *per se*. A multicentre comparison of continuous intrathecal labour analgesia versus continuous epidural labour analgesia was published in 2008, powered to detect a >1 per cent incidence of neurological complications related to use of the intrathecal

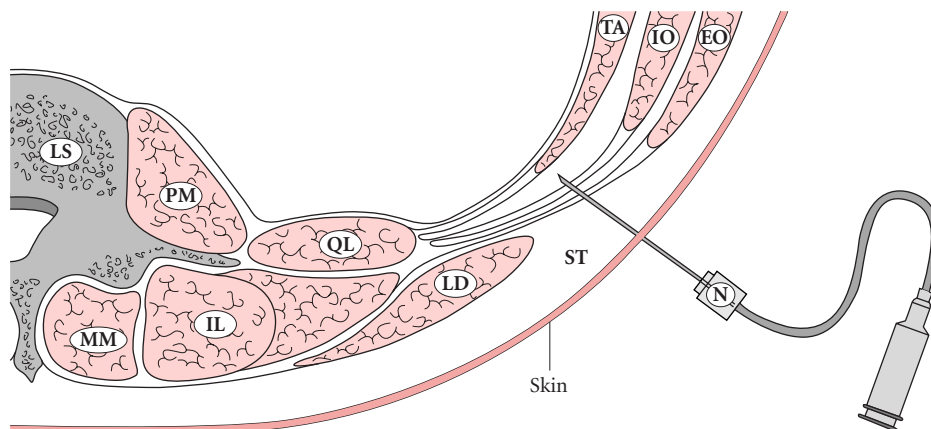

Fig. 52.7 Transversus abdominis plane block. Line drawing of a transverse section through the abdominal wall at the level of the lumbar triangle of Petit (TOP). The floor of the triangle is composed, from superficial to deep, of the fascial extensions of external oblique, internal oblique, and transversus abdominis, respectively, and the peritoneum. The needle is inserted through the triangle, using the loss-of-resistance technique. The needle is shown in the transversus abdominis plane, and the fascial layers have separated as a result of the injection of local anaesthetic.

LS, lumbar spine; LD, latissimus dorsi; PM, psoas major; QL, quadratus lumborum; MM, multifidus; IL, iliocostalis; TA, transversus abdominis; IO, internal oblique; EO, external oblique; N, 50 mm blunt-tipped needle; ST, subcutaneous tissue.

catheter [B].¹⁹ There were no permanent neurological deficits in either group.

Placenta praevia and APH

Regional anaesthesia has been associated with reduced estimated blood loss and transfusion requirements at CS with placenta praevia. Although the evidence is not high level, the commonly held obstetric view that placenta praevia mandates general anaesthesia is not supported. Individual risk factors must be considered in every case. Anterior placenta praevia in a woman over 35 who has undergone previous CS suggests a particularly high risk of placenta accreta and massive haemorrhage. General anaesthesia with intra-operative red cell salvage and provision for postoperative ICU admission might be considered prudent.

An important distinction must be made between women with the potential for major intra-operative haemorrhage (as in placenta praevia) but who are normovolaemic (i.e. have not bled), and those who present with antepartum haemorrhage. Pregnant women can compensate for significant blood loss by vasoconstriction, which will be abolished by regional anaesthesia. *Any woman who has bled and is pale and tachycardic is not suitable for regional anaesthesia, regardless of the blood pressure.*

Regional anaesthesia might be ideal for advanced placement of uterine artery balloons immediately before caesarean section, but totally inappropriate for interventional radiological management of haemorrhage.

General anaesthesia

General anaesthesia may be indicated for 'emergency' caesarean sections (Table 52.4) and for other cases for which a regional block is absolutely contraindicated (e.g. uncorrected coagulopathy) or has failed.

Good communication between the anaesthetist and obstetrician is vital in these cases, and the safety of the mother must always remain of paramount importance.

If the history or evaluation of the airway suggests that tracheal intubation might be difficult, awake fibre-optic intubation should be considered. The principal risks of general anaesthesia are:

- airway problems (e.g. failed tracheal intubation);
- aspiration of gastric contents;
- anaphylaxis (principally to succinylcholine).

In the event of anaphylaxis, adrenaline (epinephrine) is likely to improve rather than reduce uteroplacental blood flow. Rapid operative delivery while the anaesthetist administers pharmacological treatment will aid maternal resuscitation.

Depth of anaesthesia

The regimen of thiopental, succinylcholine and intubation has remained standard and largely unchanged since it superseded ether by facemask 50 years ago, and has permitted a lighter plane of inhalational general anaesthesia. General anaesthesia

is 'innocuous and reversible' for the baby, provided maternal oxygenation and normocarbida are maintained, aorto-caval compression is avoided and a paediatrician is present to support neonatal ventilation. If uterine hyperstimulation has been contributory to fetal compromise, uterine relaxation conferred by a volatile agent might be therapeutic. In contrast, a maternal stress response to excessively light general anaesthesia will be to the detriment of uteroplacental blood flow. With inhalational agent monitoring now universally available, the risk of awareness in obstetric anaesthesia should have been consigned to history. Cases of explicit awareness are attributable to failures of basic anaesthetic practice (e.g. inadequate anaesthesia during neuromuscular blockade).²⁰

The introduction of sugammadex, a specific antagonist for rocuronium, has offered the possibility of discontinuing the use of succinylcholine (the muscle relaxant with worst side-effect profile), 50 years after its introduction.

Special considerations in pre-eclampsia

Any dubious notion of light general anaesthesia for the baby's benefit should be overridden by efforts to protect the mother's cerebral circulation. A death in the 2005–2009 Confidential Enquiries was attributable to intracerebral haemorrhage sustained in the course of a predictable pressor response to difficult tracheal intubation. A generous bolus dose of opioid or magnesium should be given to supplement the IV induction. Prior communication with a paediatrician is essential in order for preparation to be made for antagonism of opioid and provision of ventilatory support for the neonate.

The onset and duration of succinylcholine are unaffected by therapeutic serum magnesium concentrations. However, the durations of action of all non-depolarising drugs are potentiated, and the use of a peripheral nerve stimulator is essential to ensure adequate reversal at the end of surgery. There should be a low threshold for blood pressure monitoring by radial arterial line, both in theatre and post-operatively in the high-dependency unit.

Any patient whose larynx was noted to be swollen at laryngoscopy, or in whom intubation was traumatic, is at particular risk of laryngeal oedema. Post-operative care must be undertaken in an ICU or high-dependency area with an anaesthetist immediately available. The ominous significance of stridor (impending airway obstruction) must be understood, and vigilance maintained. Should stridor develop, an anaesthetist must be called immediately.

Special considerations for maternal cardiac disease

In labour, the sympathetic blockade consequent upon high-dose, intermittent bolus doses of epidural local anaesthetic must be avoided. Low-dose regimens can be embraced and topped up slowly and carefully if required for operative delivery [E].

Compared to regional anaesthesia, opioid-based general anaesthesia affords greater preservation of systemic vascular resistance. Regional anaesthesia avoids myocardial depression but can lead to unpredictable decreases in preload and/or afterload. General anaesthesia might therefore be preferable for CS in women with fixed cardiac output states. If

acute peri-operative deterioration is potentially amenable to surgical remedy (e.g. emergency valve replacement), caesarean section might best be undertaken in a cardiac theatre, with extracorporeal circulatory support immediately available.

Pre-assessment and the role of the anaesthetist

All units should have a referral system between obstetricians and obstetric anaesthetists. Trainees and non-consultant anaesthetists providing out-of-hours cover should never be presented with complex cases 'out of the blue'. Obstetric referrals to a specialist physician's clinic (e.g. cardiology) should be brought to the attention of a consultant obstetric anaesthetist.

Anaesthetists' principal concerns are:

- the feasibility of regional block – which depends on flexion of the lumbar spine and normal coagulation;
- whether tracheal intubation at emergency caesarean section might be hazardous, e.g. because of limited neck flexion/mouth opening;
- the influence of medical conditions and their treatment on the safe conduct of regional or general anaesthesia.

The presence of morbidly obese women admitted in labour or to the antenatal ward should be brought to the attention of the duty obstetric anaesthetist. Morbid obesity should ring as many alarm bells as does severe pre-eclampsia. Regional blockade will almost certainly be a challenge, and general anaesthesia hazardous. A summary care plan with '6 Rs' mnemonic has been introduced at the Royal Berkshire NHS Foundation Trust:

- 1 Early review by anaesthetist on arrival on labour ward or once established labour has started;
- 2 Ranitidine throughout labour;
- 3 Early venous cannulation;
- 4 Regional block – consider early;
- 5 Heparin thromboprophylaxis – strongly consider for all but straightforward vaginal births;
- 6 Senior help will be needed for GA.

Criteria for referral are listed in Box 52.1.

EBM

- The need for analgesia in labour is reduced by the continuous support of a known practitioner.
- Regional blockade is superior to other modalities of analgesia.
- Regional analgesia entails an extremely low risk of neurological complication, and does not increase the incidence of postnatal backache.
- Regional analgesia has been associated with an increased requirement for instrumental vaginal delivery, but not caesarean section.
- Continuous low-dose epidural infusions and CSEs are associated with a lower risk of instrumental vaginal delivery than conventional bolus epidural analgesia.

Box 52.1 Criteria for antenatal anaesthetic referral

Cardiovascular problems

- Congenital heart disease
- Valvular heart disease
- Arrhythmias
- Cardiomyopathy
- Poorly controlled hypertension

Respiratory problems

- Severe asthma (requiring steroids or hospital admission)
- Breathlessness which limits daily activity
- Cystic fibrosis, or any other chronic pulmonary disease

Neurological/musculoskeletal problems

- Any spinal surgery e.g. laminectomy, scoliosis correction
- Congenital conditions e.g. spina bifida
- Muscular dystrophy, myotonia
- Myasthenia gravis
- Demyelinating disease (multiple sclerosis)
- Spinal cord injury
- Rheumatoid arthritis or any condition affecting neck/jaw
- Cerebrovascular disease e.g. aneurysm, arteriovenous malformation

Haematological problems

- Anticoagulation
- Coagulation/platelet disorders, hepatic disease
- Patients who have been treated for malignancy e.g. lymphoma, leukaemia (cardiorespiratory legacy of radiotherapy/chemotherapy)

Airway problems

- Previous difficult tracheal intubation
- Inability to open mouth or move jaw or head normally

Drug-related problems

- Cholinesterase abnormalities – succinylcholine (Scoline) apnoea
- Allergy or adverse reaction to anaesthetic drugs
- Malignant hyperthermia
- Drug misusers – with no peripheral venous access

Other

- Morbid obesity – BMI >40 kg/m²
- Needle phobia
- Panic attacks
- Any obscure eponymous syndrome that no one seems to have heard of ... which may pose problems if emergency anaesthesia is needed
- Any women with concerns regarding analgesia or anaesthesia e.g. previous problems with inadequate epidural for labour, or pain/awareness during caesarean section
- Jehovah's Witnesses

KEY POINTS

- Opioids confer more sedation than analgesia; no one agent is superior.
- Compared to intermittent bolus epidurals, low-dose epidural infusions and combined spinal-epidural analgesia result in a lower incidence of instrumental vaginal deliveries.
- Intravenous Intralipid™ can reverse local anaesthetic-induced cardiac arrest.
- Almost 90 per cent of caesarean sections in the UK are performed under regional anaesthesia.
- Single-shot spinals are the most common regional technique for caesarean section. The addition of opioid to the local anaesthetic can reduce the incidence of intra-operative pain and provide post-operative analgesia.
- Epidural anaesthesia is generally of poorer quality than spinal anaesthesia. A combined spinal-epidural technique is useful when it is anticipated that surgery might be protracted.
- General anaesthesia is indicated for the majority of caesarean sections where there is immediate threat to the life of the mother or fetus and a regional technique is absolutely contraindicated or has failed.
- The principal risks of general anaesthesia are airway problems, aspiration of gastric contents and anaphylaxis.
- Ranitidine should be prescribed for women in labour with risk factors for caesarean section.
- General anaesthesia for caesarean section in placenta praevia is usually unnecessary. Regional anaesthesia is inappropriate for women with signs of significant haemorrhage.
- All units should have a referral system between obstetricians and anaesthetists.
- Sepsis is now the leading direct cause of maternal death, and prompt use of a sepsis bundle should be undertaken if sepsis suspected.

Chapter 53 Caesarean section

Tracey A Johnston

MRCOG standards

Learning outcome:

To understand and demonstrate appropriate knowledge, skills and attitudes in relation to caesarean section.

Theoretical skills

Candidates are expected to:

- Have completed a basic surgical skills course.
- Know the abdominal and pelvic anatomy.
- Understand the indications for caesarean section, both planned and unplanned.
- Counsel a woman regarding the risks and benefits of caesarean section.
- Counsel a woman regarding the risks and benefits of vaginal birth after caesarean section.
- Read the Summary of the National Collaborating Centre for Women's and Children's Health. NICE Clinical Guideline Caesarean Section. RCOG Press, 2011.

Practical skills

Candidates are expected to:

- Be competent to perform uncomplicated caesarean section, repeat caesarean section, acute emergency caesarean section, caesarean section with sterilisation.
- Have experience in complex emergency caesarean section, caesarean section for placenta praevia, second-stage caesarean section, uncomplicated scar dehiscence/uterine rupture.
- Where possible, have seen a complex uterine rupture, classical caesarean section and caesarean hysterectomy.

INTRODUCTION

Caesarean section is a routine part of modern obstetric practice, with the aim of reducing maternal and perinatal morbidity and mortality. There is significant geographical variation in CS rates throughout the world, ranging from 0.4 per cent in Chad to 45.9 per cent in Brazil,¹ with significantly higher rates seen in developed countries. The reasons for higher CS rates in developed countries are not all clear, but include socio-demographic factors, clinical practices and, importantly, the attitudes of healthcare professionals and women towards the procedure. The 'right' CS rate is unknown, but in 1985 WHO recommended a CS rate of no higher than 15 per cent.¹ This figure is based on the increased mortality rates in countries with CS rates <10 per cent (i.e. deaths could be avoided if more CS were performed) and the fact that mortality rates are not reduced further where CS rates are >15 per cent, suggesting that many 'unnecessary' CS are performed. More recent evidence supports this figure and suggests that CS rates >15 per cent may actually result in poorer outcomes.^{2,3} The CS rate in the UK is currently around 25 per cent, and there are many drivers to try to reduce this. Figures from 2012–13⁴ show that the overall CS rate in England was 25.5 per cent, split into 10.7 per cent for elective CS and 14.8 per cent for emergency CS. Elective CS rates showed little variation across England, but there are significant differences in emergency CS rates between organisations.⁵

INDICATIONS FOR CS

Women undergoing CS fall into three main groups:

- women who have a clinical indication for CS;
- women with a previous CS (see Chapter 49), who may opt for either vaginal birth after CS (VBAC) or elective repeat CS (ERCS);
- women who are considering CS with no clinical indication (maternal request CS – MRCS).

There are many clinical indications for CS, both planned and unplanned, but the majority (>70 per cent) are performed for failure to progress in labour, presumed fetal compromise, breech presentation and ERCS.

PLANNED CS

Timing

CS before the onset of labour is associated with increased respiratory morbidity in the neonate, the risk of which decreases after 39 weeks' gestation.⁶ For this reason, planned CS should be performed after 39 weeks unless there are maternal or fetal reasons for earlier delivery [B].

Indications

Planned CS should be offered in the following circumstances:

- Breech presentation (see Chapters 41, 57). Following publication of the Term Breech Trial, women should be counselled that vaginal breech birth is associated with an increase in perinatal morbidity and mortality compared to elective CS.⁷ Women should therefore be offered elective CS if external cephalic version (ECV) is contraindicated or has failed [A].
- Twin pregnancy where the leading twin is not cephalic, and higher-order multiples (see Chapter 35). Although robust evidence of benefit does not exist, this is currently standard practice in the UK.
- Placenta praevia. Placenta praevia exists where the placenta is implanted either wholly or in part into the lower segment of the uterus. In modern obstetric practice with the routine use of ultrasound, this should always have been identified before delivery. It accounts for approximately 3 per cent of CS, and is associated with an increased risk of major haemorrhage, hysterectomy and maternal mortality. CS for placenta praevia should therefore be carried out by an experienced operator with a consultant immediately available, in a unit with on-site blood transfusion services,⁸ following appropriate counselling and consent. In uncomplicated placenta praevia, delivery should be planned between 38 and 39 weeks' gestation [D].

In cases of placenta praevia with a previous CS, the risk of morbidly adherent placenta (MAP – placenta accreta, percreta or increta) is related to the number of previous

CS⁹ – see Table 53.1. Where placenta praevia is confirmed at 32–34 weeks' gestation in cases of previous CS, colour flow Doppler should be performed to identify MAP. Magnetic resonance (MR) scanning may improve diagnostic accuracy, but the best results are obtained with gadolinium enhancement, which is not used in the UK, and although thought to be without risk, long-term safety for the fetus has not yet been established. When MR scanning is considered, careful discussion regarding the potential risks and benefits should take place and MR scanning used only if acceptable to the woman.¹⁰ Due to the diagnostic accuracy of both imaging modalities, it is best to be prepared for MAP in all cases of placenta praevia with previous CS. When planning and performing CS for potential MAP, the NPSA Intrapartum Toolkit's Placenta Praevia after Caesarean Section Care Bundle¹¹ should be used to minimise the risk of morbidity. This consists of six elements:

- Consultant obstetrician planned and directly supervising delivery;
- Consultant obstetric anaesthetist planned and directly supervising anaesthesia at delivery;
- Blood and blood products available on site;
- Multidisciplinary involvement in pre-operative planning;
- Discussion and consent includes possible interventions (such as hysterectomy, leaving placenta *in situ*, cell salvage and interventional radiology);
- Local availability of level 2 critical care bed.

In suspected MAP, in the absence of complications delivery should be planned no earlier than 36–37 weeks' gestation [D]. For both placenta praevia and suspected MAP, the use of cell salvage at the time of surgery is recommended and presently its use is being critically appraised as part of an HTA study (SALVO)[D].

- Maternal HIV infection either not on ART, where the viral load ≥ 400 copies/mL despite ART, or if HIV and hepatitis C infection are both present.¹⁰
- History of primary genital HSV infection occurring in the third trimester.¹⁰

ERCS

In a small number of cases, ERCS is recommended after the first CS e.g. if there is an upper-segment scar on the uterus (previous classical CS, previous J or T incision), but in most cases the main factor is maternal choice. When counselling a

Table 53.1 Risk of placenta praevia and morbidly adherent placenta with number of previous CS⁹

No. of previous CS	Risk of placenta praevia (%)	Risk of MAP (%)
1	0.6-1.3	11-14
2	1.1-2.3	23-40
3 or more	1.8-3.7	35-67

woman regarding the risks and benefits of ERCS vs VBAC (see Chapter 49), the following should be discussed:¹²

- The VBAC success rate is around 75 per cent [B]. Higher success rates of around 90 per cent are seen in those who have previously had a vaginal birth also.
- The risk of scar rupture during VBAC is low (approximately 1:200) [B].
- With VBAC, the risk of brain damage or death to the baby is low (approximately 1:200), but is higher than the risk if delivery is by ERCS (approximately 1:1000) [B].
- VBAC reduces the risk of respiratory problems in the baby [B].
- The risk of fetal laceration at CS is 1–2 per cent.
- VBAC carries a 1 per cent additional risk of infection and the need for blood transfusion compared to ERCS [B].
- ERCS increases the risk of damage to bowel and bladder, hysterectomy, future placenta praevia/MAP (Table 53.1) [B].

The woman's views should be taken into consideration and if after discussion she wishes ERCS, this should be performed.

MRCS

The number of requests for CS in the absence of a previous CS or an obstetric indication is increasing, with tocophobia (excessive fear of childbirth) and safety for the baby cited as the commonest reasons. In these cases, it is important to explore carefully and document the reasons for such a request, and fully counsel the woman to ensure she is fully informed of the risks and benefits for both the mother (Table 53.2) and the baby (Table 53.3). In cases of tocophobia, referral to an appropriate perinatal mental health professional who has access to the planned place of birth in the antenatal period is indicated. If after all this vaginal birth is still not an acceptable option, then CS should be offered or the woman referred to another obstetrician willing to carry out the procedure.¹⁰

Table 53.2 Effects on women's health of planned CS compared with planned vaginal birth for women with an uncomplicated pregnancy and no previous CS¹⁰

Effects around the time of birth	Planned CS	Planned vaginal birth	Relative effect (95% CI)
Reduced after planned CS			
Perineal and abdominal pain during birth	Median score 1.0	Median score 7.3	Not calculable
Perineal and abdominal pain 3 days postpartum	Median score 4.5	Median score 5.2	Not calculable
Vaginal injury	0%	0.56%	Not calculable
Early postpartum haemorrhage	1.1%	6.0%	OR 0.23 (0.06–0.94)
	3.9%	6.2%	RR 0.6 (0.4–0.9)
Obstetric shock	0.006%	0.018%	RR 0.33 (0.11–0.99)
Reduced after planned vaginal birth			
Length of stay	3.2 days	2.6 days	Not calculable

UNPLANNED CS

The commonest reasons for unplanned CS are failure to progress in labour and suspected fetal compromise. For the management of delay in the first stage of labour, see Chapter 50, and for the management of suspected fetal compromise see Chapters 51 and 54. It should be noted that the maternal risks of haemorrhage, infection, bowel injury, bladder damage, hysterectomy and death, although still very low, are higher in unplanned when compared to planned CS, but that the risks of respiratory compromise in the neonate are lower in unplanned compared to planned CS. Second-stage CS merits particular mention, as the rates of both maternal (infection, haemorrhage secondary to both uterine atony and trauma, surgical damage) and perinatal (secondary to difficulties with delivery) morbidity are higher compared to first-stage CS, and it should therefore be undertaken by an experienced operator.

CATEGORISATION OF CS

Historically, CS were classified as either elective or emergency, but this is not specific enough to allow adequate communication regarding the urgency of CS. In 2000, a new system of categorisation was introduced which has been adopted throughout the UK with the purpose of improving communication within the team and auditing process¹³ – see Table 53.4.

PRIOR TO CS

- Information: because approximately 1 in 4 women will have a CS, all women should be provided with evidence-based information about CS in the antenatal period. This should include common indications for CS (FTP in labour, suspected fetal compromise and breech presentation account for >70 per cent).
- Consent: informed consent should be obtained, including risks and benefits of the procedure for that specific

situation. The operator should be aware of any specific risk factors and include these in the counselling and consent process.

- Blood tests and investigations: a recent Hb should be available to identify those women with significant anaemia, and if there are concerns regarding the need for blood transfusion, blood should be sent for grouping and saving of serum.
- Anaesthesia: mode of anaesthesia to be employed is an anaesthetic decision, and good communication between teams is essential (see Chapter 52).
- Thromboprophylaxis: all women should have a VTE risk assessment performed and thromboprophylaxis given to reduce the increased risk of thromboembolism that is associated with CS. Hydration and early mobilisation are important in all cases, with the addition of graduated anti-embolic stockings and/or LMWH depending on the risk assessment [D].
- The bladder must be emptied prior to the start of surgery. If regional anaesthesia is employed, an indwelling catheter should be used to avoid post-operative urinary retention and re-catheterisation [A].
- Prophylactic antibiotics should be given prior to the skin incision to reduce the risk of post-operative infection, in particular endometritis, wound infection and urinary tract infection [A]. Because of the association between co-amoxiclav and necrotising enterocolitis demonstrated in preterm babies, it is advised to avoid this specific antibiotic as there are acceptable alternatives available. In cases of major haemorrhage or where the procedure lasts longer than 4 hours, a second dose of prophylactic antibiotics should be considered.
- As with any surgical procedure, the WHO surgical safety checklist should be used.

PROCEDURE

In some cases where difficulties are anticipated (e.g. placenta praevia, large fibroids, abnormal lie), ultrasound immediately before surgery can help the operator decide on the best skin incision and site of uterine incision.

Table 53.4 Categorisation of CS¹³

Category	Definition	Examples	Decision to delivery interval
1	Immediate threat to life of mother or fetus	Cord prolapse, prolonged bradycardia, pH <7.20, uterine rupture,	As soon as possible; within 30 minutes
2	Maternal or fetal compromise which is not immediately life threatening	Failure to progress in labour	As soon as possible; within 75 minutes
3	No maternal or fetal compromise but needs early delivery	Failed induction, booked category 4 CS with ruptured membranes not in labour	
4	At a time to suit the woman and her maternity service	'Elective' CS	

Skin incision

There are three different skin incisions that are used in CS:

- 1 Pfannenstiel – a low transverse, curved, suprapubic incision that uses sharp dissection to open the rectus sheath; the rectus muscles are then separated from the sheath and the peritoneum is then picked up and opened with sharp dissection.
- 2 Joel Cohen – a slightly higher straight transverse incision that employs blunt dissection to open the rectus sheath and peritoneum after a small transverse incision has been made in the rectus sheath in the midline. This approach is associated with shorter operating times, lower blood loss, less fever and less pain when compared to the Pfannenstiel incision [A].
- 3 Vertical – usually a midline sub-umbilical incision. Allows access to the abdomen as well as the pelvis and therefore is often employed if access to the upper segment of the uterus is required (some cases of placenta praevia or suspected MAP, or large fibroids) or other surgical procedures are anticipated. It is associated with increased pain and a higher incidence of wound dehiscence, and more concerns regarding the cosmetic appearance when compared to transverse incisions [B].

Uterus

Before incising the uterus, dextrorotation should be corrected, the visceral peritoneum above the bladder should be picked up to identify the upper margin of the lower segment, and the peritoneum should be incised transversely and the bladder gently pushed down to avoid injury. Following this, incision of the lower segment is the standard approach as the lower segment is thinner and less vascular than the upper segment making the procedure easier. It is also associated with fewer post-operative complications, such as ileus, peritonitis, obstruction and adhesions, as well as a significantly lower risk of scar dehiscence or rupture in a future pregnancy. The uterus is then opened using sharp dissection transversely in the midline, and extended using blunt dissection, which is associated with less blood loss, lower incidence of PPH and less need for transfusion when compared with sharp dissection [A]. In cases of second-stage CS, the upper margin of the lower segment (identified by the peritoneal reflection) is higher than usual, and it is therefore important to identify the upper margin carefully then incise the uterus higher than usual to ensure the correct part of the lower segment is opened. Opening the uterus too low will increase the risks of extension and difficulty in delivery.

The second commonest approach is the classical incision. This is a vertical incision in the midline of the upper segment, and indications include:

- preterm delivery where the lower segment is poorly formed;
- ruptured membranes with a transverse lie and the back presenting;

- placenta praevia, to minimise blood loss and/or consider conservative management in cases of MAP, by avoiding incising the placenta;
- lower-segment or cervical fibroids;
- fetal abnormality (e.g. conjoint twins, massive hydrocephaly, large sacrococcygeal teratomas).

Delivery

In a cephalic presentation, once the uterus is opened the operator's hand is inserted below the head, ensuring flexion and rotation into the occipito-transverse position. Once the head is lifted out of the pelvis into the incision, the assistant applies fundal pressure in a stepwise manner to effect delivery of the head. If the head is high, traditionally short curved forceps have been used to aid delivery, but disposable hand-held vacuum devices are also effective with perhaps a lower risk of trauma.

One of the most frightening situations for a trainee is that of the stuck head at CS. This is commoner in second-stage CS, particularly after failed instrumental delivery. It is essential not to panic and not to fight the uterine activity. Tocolysis using terbutaline, atosiban or GTN can be used to aid uterine relaxation. When the operator's hand is inserted into the uterus, very often a contraction is provoked and this may prevent the hand getting below the fetal head. It is essential to stop moving and wait for the uterus to relax before trying to advance the hand further. Constant movement of the hand will prolong or provoke a contraction. Once the uterus relaxes the hand can be advanced below the head. If another contraction happens, again stop moving and wait for it to pass. While the uterus is relaxed, the head can be flexed and lifted into the incision, and delivery completed. Occasionally, using the opposite hand is helpful. Failing this, consider delivering by the breech (a high, generous uterine incision as described above for second-stage CS facilitates this). To achieve this, the operator's hand should be run up the fetal back to the breech, flexing it down into the incision. Alternatively, gentle steady traction on one or both legs will bring the breech down into the incision. If the incision is not large enough, this should be extended. A J-shaped extension on one or both sides will generally give more room than a central inverted T-incision. In the vast majority of cases, delivery will be safely achieved with these methods. In general, however, a common response is to push the fetal head up from below, often by a member of staff with little experience in this manoeuvre. This action again provokes a contraction, thus the upward pressure being applied to the fetal head is working against the downward pressure of the contraction. This approach is associated with fracture of the fetal skull and thus should only be used as a last resort. Different devices that are inserted into the vagina to elevate the fetal head are available, but are still undergoing evaluation to prove their effectiveness.

Once delivery of the head is achieved, the shoulders should be released by lateral flexion, with delivery being completed by gentle traction. In cases of breech presentation, either the breech can be flexed and lifted into the incision in a similar manner to the head, or one or both feet/legs can be delivered first with delivery of the breech being achieved by

gentle traction. Once the breech is delivered, gentle traction will achieve delivery of the trunk, with the arms being delivered by hooking out or rotation in a similar manner to vaginal breech delivery (breech CS is an ideal opportunity to practise the mechanisms and manoeuvres of vaginal breech delivery). The head can be delivered either by flexion or by the Burns Marshall technique of extension. With a transverse lie, it is better to try to achieve a longitudinal lie before opening the uterus. If this is not possible, once the uterus is open insert a hand and bring either pole into the incision, or find a leg and apply gentle traction to bring the breech round.

Once the baby is delivered, consider delayed cord clamping and cord gases (paired cord gases/umbilical artery pH should be performed after all CS for suspected fetal compromise, to allow review of fetal wellbeing and guide ongoing care of the baby [B]).

Placenta

Following delivery of the baby, 5 IU of oxytocin should be given by slow intravenous injection to facilitate contraction of the uterus and placental separation, and this is associated with reduced blood loss [C]. The placenta should then be delivered by controlled cord traction and the uterine cavity checked to ensure it is empty.

Placenta praevia

In cases of placenta praevia, there may be large sinuses in the lower segment, which continue to bleed and may require suturing. Full-thickness figure-of-eight sutures are effective with less risk of tearing out. Inserting a balloon into the uterus is also effective in controlling bleeding from the lower segment by tamponade.

MAP

If after administration of the oxytocin the placenta fails to separate, different options exist which should have been considered and discussed with the woman before surgery. These include:

- manual/piecemeal removal of the placenta – this is associated with an increased risk of blood loss, and may not be successful in removing all the placental tissue;
- hysterectomy with the placenta *in situ* – this is associated with less blood loss and may be the option of choice if fertility preservation is not an issue;
- conservative management leaving the placenta *in situ* – this can be considered if the woman is keen to preserve her fertility, there has been no antenatal bleeding and the placenta has not been breached at the time of CS. In such cases, the cord should be drained and ligated close to the placental insertion. The membranes should be trimmed close to the placental margins, and the uterus closed in the usual manner. Postnatal follow-up is essential to observe for haemorrhage, infection and to confirm placental resorption [D].⁷

Closure

The uterus should be repaired *in situ*, as exteriorisation is associated with increased pain and no decrease in haemorrhage or infection [A]. Occasionally, however, exteriorisation will allow better visualisation if there are extensions, making repair easier. In such cases, both the anaesthetist and the woman should be warned before the uterus is exteriorised. Both angles of the uterine incision should be identified, then the incision closed in two layers using a continuous absorbable suture. Occasionally, extra haemostatic sutures are required if bleeding persists after application of pressure. Single- versus double-layer closures have been compared in the CAESAR trial¹⁴ and no differences were found in any of the short-term outcomes studied, but there are concerns regarding an increased risk of scar rupture in future pregnancies¹⁵ and it is therefore recommended that until further information is available from the CAESAR follow-up study, two-layer closure should be used [B]. Classical incisions usually require a three-layer closure because of the increased thickness and vascularity. Following closure of the uterus, the adnexae should be inspected, and any adnexal surgery e.g. sterilisation conducted at this point.

With regards to the peritoneum, neither the visceral nor the parietal peritoneum should be sutured at CS, as this reduces operating time and the need for post-operative analgesia, and improves maternal satisfaction [A], but there are no follow-up studies addressing potential long-term complications such as adhesion formation and bowel obstruction. Closure of the anterior abdominal wall depends on the type of incision. In cases of a midline skin incision, mass closure of the rectus sheath and subcutaneous tissues should be employed using a slowly absorbable continuous suture as this is associated with reduced wound pain, sinus formation, incisional hernias and wound dehiscence [B]. In transverse skin incisions, the rectus sheath is closed using a non-locking, continuous, absorbable suture. If there is more than 2 cm of subcutaneous fat this layer should be closed with an absorbable suture, as this decreases the incidence of wound infection [A]. There are different methods of skin closure, including subcuticular sutures (either absorbable which do not require removal, or of material such as prolene which does require removal), interrupted sutures (which require removal) or staples. In women with an increased risk of haematoma or infection, an interrupted method has the advantage of removal of one or two to allow drainage if required. Staples, although quicker to insert, are associated with more pain [A]. Subcuticular absorbable sutures have the benefit of less pain, a good cosmetic effect and no need for removal.

Drains

There is no evidence to support the routine use of drains at CS. Intraoperative drains should only be used if there are concerns regarding the risk of ongoing bleeding, and should be of the wide-bore, non-suction variety. The CAESAR study¹⁴ showed no benefit to the routine use of subrectus drains, and

these should only be used if clinically indicated, in which case the abdominal peritoneum must be closed. Superficial wound drains do not reduce the incidence of infection or haematoma, and should therefore not be used [A].

Dressings

Following CS, an interactive dressing should be applied and remain in place for 48 hours.¹⁶ As the abdominal cavity is a large potential space it is not possible to apply effective pressure, rendering pressure dressings ineffective at stopping or preventing bleeding, but effective at hiding it. Any wound bleeding should be dealt with by applying effective pressure by pinching the area between the fingers, diathermy, or inserting another suture. The interactive dressing allows the wound to be observed for further bleeding. In other surgical specialities, vacuum dressings are being used in some cases at high risk of infection e.g. morbid obesity, and their use is beginning to be introduced into obstetrics.

POST-OPERATIVE MANAGEMENT

Following CS, women should be cared for on a one-to-one basis by an appropriately trained individual in an appropriate environment until they have regained airway control, are cardiovascularly stable and are able to communicate. Skin-to-skin contact and early breastfeeding should be facilitated as soon as possible. Maternal observations including heart rate, blood pressure, respiratory rate and pulse oximetry should be performed every 5 minutes for the first 30 minutes, then every 30 minutes for the first 2 hours. Thereafter, if stable, the frequency of observations can be reduced dependent on the maternal condition. Women should be encouraged to eat and drink as soon as they feel hungry/thirsty. The catheter is usually removed after 12–24 hours in cases of regional anaesthesia, and early mobilisation is encouraged. In all cases, a discussion regarding the reason for CS and the implications for future pregnancies should take place prior to discharge, including any recommendations regarding mode of birth in the future.

COMPLICATIONS

As with any surgical procedure, there are associated complications of CS. Intra-operative complications include:

- difficulty in gaining access to the uterus, usually secondary to previous surgery;
- difficulty in delivering the baby;
- difficulty in delivering the placenta;
- uterine extensions including into the vagina and broad ligament;
- haemorrhage;
- damage to bowel/bladder/ureter;
- fetal laceration (1–2 per cent).

Anticipation can lead to avoidance, and also allows appropriate help to be summoned in advance. Where such complications arise unexpectedly, appropriate help should be called for e.g. senior obstetric help, urologist, general surgeon. In cases of obstetric haemorrhage at CS, the majority are still secondary to atony, and this should be managed as usual with the use of uterotonic drugs in a stepwise manner, followed by mechanical methods (see Chapter 64). For bleeding secondary to trauma, lacerations should be repaired promptly.

Peripartum hysterectomy

If hysterectomy is being considered, senior help is essential to assist in making the decision as well as performing the surgery. It is wise to remember not to leave the decision too late, as this is associated with increased morbidity. In the UKOSS study of peripartum hysterectomy¹⁷ the vast majority were performed for haemorrhage, with most being for atony and/or MAP, although in many there was more than one cause. Subtotal hysterectomy is a reasonable option in cases of uterine atony, and may be associated with less morbidity, but in cases of MAP, total hysterectomy is more common to ensure the lower pole of the uterus, which is mainly where the haemorrhage is arising from, is removed. When comparing total with subtotal hysterectomy, there were no statistical differences in the rate of bladder or ureteric damage, ovary removal, further surgery and blood transfusion, although it is acknowledged that the numbers were small.¹⁷ In women undergoing peripartum hysterectomy it must be remembered that around 20 per cent will need to go back to theatre, often to control further bleeding, 20 per cent will sustain damage to other organs, and around 20 per cent will suffer from other severe morbidity [B].

Post-operative complications

The major post-operative complications include infection (see Chapter 65) and thromboembolic disease (Chapter 12). CS is associated with a significantly increased risk of both postnatal infection [D] and thromboembolic disease (TED), and the role of prophylactic antibiotics and thromboprophylaxis has been discussed above. There has been a significant reduction in the incidence of TED following the introduction and implementation of the RCOG Green-top Guidelines for both antenatal and postnatal thromboprophylaxis.

FUTURE PREGNANCIES

Prior to discharge, all women should be debriefed regarding the indication for their CS and any complications at the time of surgery. They should be informed whether VBAC is appropriate in the future or whether subsequent deliveries should be by ERCS. In cases of previous CS for a non-recurrent cause, maternal choice should be taken into account in planning future mode of birth.

CONCLUSION

Caesarean section is an integral part of obstetric practice, with around a quarter of babies in the UK being born by this method. There are many drivers to reduce the number of 'unnecessary' caesarean sections. In some cases of planned CS, maternal choice should be considered in the decision-making process, including cases with no previous CS and no medical indication. The implications of CS for future pregnancies, including increased risk of stillbirth, placenta praevia and MAP, must be considered when making the decision to perform a CS. National evidence-based guidance exists for CS.

KEY POINTS

- There are significant geographical variations in CS rates, and the 'correct' CS rate is unknown.
- Maternal choice should be taken into consideration in some cases of elective CS.
- Thromboprophylaxis and prophylactic antibiotics significantly reduce the incidence of post-operative complications.
- Preparation and anticipation are essential to minimise the risks of intra-operative difficulty.
- Two of the most difficult situations are CS at full dilatation, especially following failed instrumental delivery, and placenta praevia in the presence of a previous CS, and in both situations the operator must have strategies in place to minimise the risk of complications.

SECTION SIX

Second Stage of Labour

This page intentionally left blank

Chapter 54 Fetal compromise in the second stage of labour

Myles Taylor

MRCOG standards

Candidates are expected to have:

- the ability to recognise, classify and respond appropriately to CTG patterns;
- the ability to perform fetal blood sampling and to be able to interpret the results.

In addition, we would suggest the following.

Theoretical skills

- Review theoretical knowledge for fetal compromise in the first stage of labour.
- Know the additional physiological stresses placed on the fetus during the second stage of labour.
- Appreciate the physiological (as opposed to pathological) changes seen in a second-stage CTG.

Practical skills

- Be able to recognise a potentially difficult assisted delivery, in order to:
 - decide when to use secondary tests of fetal wellbeing;
 - avoid a traumatic birth in the presence of pre-existing compromise.

INTRODUCTION

The management of suspected fetal compromise in the second stage of labour demands considerable skill, in terms of both decision making and practical ability. Uterine contractions have peaked in terms of strength and frequency, and the resulting intrauterine and uterine wall pressures are further increased by maternal pushing. These pressures will frequently be greater than maternal arterial blood pressure, temporarily abolishing placental perfusion. Compression of the fetal head and umbilical cord is at its greatest, as the amniotic fluid volume has reached a nadir and passage through

the rigid bony pelvis has begun. After many hours of stressful labour, fetal reserves may also be reduced or depleted. All these factors combine to make fetal heart rate abnormalities particularly common, although many of these abnormalities will be entirely benign. Having reached full dilatation, there is also an expectation that vaginal birth will be achieved.

Despite the factors detailed above, clinicians must remain wary of undertaking difficult assisted vaginal deliveries in the presence of fetal compromise. For this reason, secondary tests of fetal wellbeing still have a place in the second stage of labour. Such tests can give reassurance that further time for head descent and/or rotation can be allowed, converting a difficult delivery into an easier one or even a spontaneous birth.

DEFINITIONS

See Chapter 51.

WHAT TYPE OF FETAL MONITORING IS BEST IN THE SECOND STAGE?

The debate over the advantages and disadvantages of intermittent auscultation versus continuous electronic monitoring in the first stage of labour also arises when considering fetal monitoring in the second stage. Unfortunately, there is little evidence to inform this discussion. However, an obvious practical disadvantage of intermittent monitoring in the second stage is that it is difficult for an obstetrician called to undertake an assisted delivery to confirm fetal wellbeing. Instead, any concern regarding a difficult delivery should be met with either a short period of EFM or fetal scalp blood sampling.

Intermittent auscultation

In the low-risk situation, intermittent auscultation, either by Pinard stethoscope or by handheld Doppler, remains popular. Conventional guidelines, such as those issued by

RCOG (2007), suggest auscultating the FHR for at least 1 minute at least every 5 minutes in the second stage and the maternal pulse should also be recorded.

WHAT IS A NORMAL SECOND-STAGE CTG?

In an early large study of 1755 second-stage heart rate traces, 75 per cent maintained a normal baseline rate, with about 5 per cent becoming tachycardic.¹ The remaining 20 per cent of traces developed a baseline bradycardia that was transient in one third, persistent in one third and progressive in the remaining third.

Overall, a normal baseline in combination with an absence of decelerations was seen in only one quarter of second-stage heart rate tracings. However, 60 per cent of these 'normal' traces either exhibited no accelerations or poor variability, resulting in 90 per cent of all second-stage CTGs showing some degree of abnormality.

Therefore, the definition of a normal second-stage CTG is difficult. Using standards applied for antenatal or even first-stage CTGs, a normal CTG would appear to be rare in the second stage of labour.

Early studies of second-stage CTG abnormalities related neonatal outcome to Apgar scores rather than cord pH. Provided the baseline heart rate remained normal, only 2 per cent of neonates ended up with a 5-minute Apgar score <7.¹ Later studies found a similar risk of metabolic acidosis in this situation.²⁻⁵

WHAT IS AN ABNORMAL SECOND-STAGE CTG?

Baseline. Apart from late decelerations, the only FHR pattern that is strongly suggestive of fetal hypoxaemia is a continuous or progressive bradycardia.

Approximately 10 per cent of persistent or progressive bradycardias in the second stage will lead to 5-minute Apgar scores <7.¹ Neither superimposed early nor variable decelerations influence these figures. In later studies, fetal bradycardia was linked with neonatal acidosis.³⁻⁵ Both Piquard *et al.*⁶ and Cordoso *et al.*⁵ found the mean umbilical artery pH to be lower in the presence of a fetal bradycardia. The severity of the bradycardia also correlates with perinatal risk. Acidosis was found in 30–40 per cent of moderately to severely bradycardic fetuses;^{3,4} in more than half of the cases there was a metabolic acidosis. One study found that an FHR of <70 bpm increased the risk of acidosis 26-fold and the risk of metabolic acidosis 5-fold.²

A baseline tachycardia is reportedly associated with low 5-minute Apgar scores in 6 per cent of cases¹ and with

neonatal acidemia in up to 20 per cent.^{3,4} However, it is rarely linked with a base excess >12 mmol/l.⁴

Variability. The work of Gilstrap *et al.*³ suggested that absent variability dramatically increased the risk of neonatal acidosis, even in the presence of an otherwise normal CTG. A cord pH <7.20 was seen in 24 per cent of cases with isolated absent variability, compared to 3 per cent of completely normal second-stage traces. Gull *et al.*⁷ investigated the inter-relationship between baseline bradycardias and variability. In the presence of a baseline heart rate <100 bpm, the risk of neonatal metabolic acidemia increased as the interval before loss of variability shortened and as the duration of loss of variability increased. This suggests that loss of variability corresponds to fetal decompensation.

Accelerations. These are not commonly present in the second stage.

Decelerations. Decelerations are remarkably common, and are seen in more than 70 per cent of second-stage heart rate traces.

- *Early decelerations* occur in 14 per cent of second-stage traces. They do not appear to increase the risk of a low 5-minute Apgar score,¹ and should be viewed as benign – regardless of baseline rate.
- *Variable decelerations* are much commoner, being seen in approximately half of second-stage CTGs. After taking into account the baseline heart rate, mild variable decelerations have little influence on the incidence of low Apgar scores.¹ However, deep variable decelerations, with a drop in FHR of <70 bpm, are associated with a 10-fold increase in the risk of metabolic acidosis.²
- *Late decelerations* are relatively uncommon in the second stage, being seen in only 5 per cent of traces. However, their presence dramatically increases the chances of a low 5-minute Apgar score, regardless of baseline rate.¹ If the baseline rate is normal, a 5-minute Apgar score <7 is seen in 10 per cent of cases. This increases to 20–25 per cent when superimposed on a persistent or progressive baseline bradycardia. The combination of a baseline tachycardia and late decelerations is associated with a 14 per cent risk of low Apgar scores. The presence of late decelerations increases the risk of metabolic acidosis 17-fold.²

ACTIVE VERSUS PASSIVE SECOND STAGE

Many clinicians now divide the second stage of labour into a passive and an active phase. During the former, continued descent of the fetal head occurs with neither maternal effort nor urge to push. The risks of acidosis in this passive phase are probably similar to those of the active first stage. Certainly, Nordstrom *et al.* showed fetal scalp lactate to increase in parallel with the length of *active* pushing in the second stage.⁸

SECONDARY TESTS OF FETAL WELLBEING

Fetal blood sampling

Fetal scalp pH studies remain the principal secondary test of fetal wellbeing in the second stage of labour. There is no evidence that their accuracy falls, and they are usually technically very easy.

Other secondary tests

There has been little investigation into the prognostic ability of other secondary tests of fetal wellbeing, such as vibro-acoustic stimulation, scalp stimulation, fetal ECG or pulse oximetry in the second stage of labour. Combining ST analysis (STAN™) with CTG monitoring has the advantage of reducing operative vaginal delivery rates by 10 per cent.⁹ However, guidelines on the use of STAN have emphasised that ST monitoring should not be commenced in the second stage as this risks missing ST changes which have already occurred in cases of pre-existing fetal hypoxia.¹⁰

THE MANAGEMENT OF SUSPECTED FETAL COMPROMISE IN THE SECOND STAGE OF LABOUR

- **Improve placental blood supply.**
 - Maternal positioning to avoid aorto-caval compression.
 - Intravenous fluids when appropriate.
 - Vasoconstrictors such as ephedrine for lower limb vasodilatation secondary to epidural analgesia.
- **Improve maternal oxygenation.**
 - Maternal oxygen therapy may be helpful if used for a short period while other measures are instituted. However, the routine use of oxygen therapy in the second stage was found to lead to an increase in newborn acidosis.¹¹
- **Diminish uterine activity if excessive.**
 - Decrease or stop any oxytocin infusion. In the second stage, bolus intravenous tocolytics have been associated with an increase in instrumental delivery but no improvement in fetal outcome.¹² Their use in this situation should be restricted to cases where a short delay is expected before operative delivery can be undertaken.
- **Decide if delivery is indicated, based upon:**
 - the severity of the CTG abnormality and results of any secondary tests of fetal wellbeing;
 - response to the above interventions to improve the situation;
 - the whole clinical picture, including obstetric risk factors, progress in labour and potential assisted delivery;

- untreatable fetal complications such as abruption, cord prolapse and chorioamnionitis, and scar dehiscence.

There is little evidence to support the use of amnioinfusion in the second stage of labour to reduce cord compression and improve umbilical blood flow.

A CLINICAL APPROACH TO REVIEWING ABNORMAL SECOND-STAGE CTGS

Always ask yourself:

What factors are present that increase the neonatal risk of instrumental delivery?

For example, meconium/macrosomia/malposition/mid-cavity arrest/diabetes/previous shoulder dystocia.

Does the abnormality require immediate delivery?

Yes

Is an assisted delivery likely to be easy?

- Yes – occiput anterior (OA)/low station/little caput or moulding.
 - Deliver in room.
- No – malposition/mid-cavity arrest/major moulding or caput.
 - Undertake delivery in theatre either as trial or directly by caesarean section.
 - Strongly consider FBS before trial of instrumental delivery.

No

Is an assisted delivery likely to be easy?

- Yes – OA/low station/little caput or moulding.
- Has progress been steady in active second stage?
- Yes: offer mother choice of continued pushing for set time before recommending assisted delivery.
- No: consider oxytocin (consider FBS beforehand) if mother wishes to avoid assisted delivery.
 - If no intervention possible to improve situation, recommend assisted delivery in room.
- No – malposition/mid-cavity arrest/major moulding or caput).
 - Has progress been steady in active second stage?
 - Yes: consider FBS to allow more time and convert to an easier delivery.
 - No: consider FBS and then oxytocin.
 - If inappropriate to intervene to improve progress, recommend delivery.
 - In theatre either as a trial or directly by CS, strongly consider FBS before trial of instrumental delivery.

Published Guidelines

NICE: *Intrapartum care – care of healthy women and their babies during childbirth*. September 2007.

KEY POINTS

- CTG abnormalities are very common in the second stage but many are benign.
- Particular attention should be paid to marked bradycardias, any bradycardia with reduced variability and late or severe variable decelerations.
- Use fetal scalp sampling to avoid potentially difficult instrumental deliveries in the presence of pre-existing fetal compromise.

Chapter 55 Shoulder dystocia

Jenny Blackman and Myles Taylor

MRCOG standards

All candidates are expected to attend hands-on training sessions in the management of shoulder dystocia.

Theoretical skills

- Revise knowledge of female bony pelvic anatomy and mechanics of parturition.
- Know the individual risk factors for shoulder dystocia and their relative importance.
- Be able to advise a woman antenatally about the risk of shoulder dystocia in her current pregnancy.
- Recognise a labour at risk of shoulder dystocia

Practical skills

- Be able to assess the severity of a reported shoulder dystocia in a previous delivery.
- Be able rapidly to recognise shoulder dystocia.
- Have a clear plan for the management of shoulder dystocia, including:
 - organisation of staff;
 - sequentially applied procedures;
 - later maternal debriefing after the event;
 - use of a *pro forma* and correct documentation.

INTRODUCTION

Shoulder dystocia is an acute obstetric emergency requiring rapid intervention to prevent neonatal morbidity and mortality. The relative infrequency of shoulder dystocia means that few obstetricians are truly experienced in its management. However, the high perinatal mortality and morbidity

associated with this condition means that all labour ward practitioners must possess a detailed knowledge of the condition and how to overcome it.

DEFINITION

Classically, shoulder dystocia is recognised when the fetal chin retracts firmly back onto the perineum immediately after delivery of the head, the so-called ‘turtle-neck’ sign. A widely used but not universally accepted definition of shoulder dystocia is a delivery that requires additional obstetric manoeuvres to release the shoulders after gentle downward traction has failed.¹

A logical approach to the assessment of severity of an earlier shoulder dystocia is essential. Events surrounding the delivery should be considered under three headings.

- 1 Additional manoeuvres.
 - What steps were required to effect delivery? See ‘first-line’, ‘second-line’ and ‘third-line’ under ‘management’ below.
- 2 Fetal complications:
 - Apgar scores and degree of resuscitation required;
 - neonatal unit admission;
 - direct fetal trauma (brachial plexus injury, fractures);
 - long-term disability (neurodevelopmental, palsy).
- 3 Maternal complications:
 - perineal trauma (extended episiotomy or tear, third-degree tear);
 - postpartum haemorrhage;
 - psychological trauma.

INCIDENCE

The lack of a universally agreed definition for shoulder dystocia hampers any estimate of incidence. As a rough guide less than 1 per cent of deliveries are complicated by shoulder dystocia.

COMPLICATIONS

Fetal

Short-term complications such as fractures of the humerus or clavicle are not uncommon. However, these heal well and have an excellent prognosis. Transient brachial plexus injury, such as Erb's palsy, is also relatively common. Fortunately, with early recognition, prompt physiotherapy and even neurosurgical treatment, most improve over time, leaving only 1–2 per cent of shoulder dystocia cases with long-term dysfunction. Hypoxic–ischaemic encephalopathy may develop after severe cases and carries a risk of later neurodevelopmental disability. Perinatal mortality secondary to shoulder dystocia was reported in 56 cases in the UK in 1994–95, an incidence of approximately 1 in 25,000 births.²

Maternal

Possible complications include excessive blood loss from extensive perineal, vaginal and cervical lacerations and extension of perineal trauma into third- or fourth-degree tears.

AETIOLOGY

The mechanics underlying shoulder dystocia have been reviewed by Johnstone and Myerscough.³ Although the bisacromial diameter is larger than the biparietal diameter, the shoulders have the advantage of inherent mobility. As the fetal head passes through the pelvic outlet, the shoulders simultaneously enter the pelvic inlet. Ideally, the shoulders should enter the pelvis transversely, although they are usually oblique, with the posterior shoulder moving towards the sacrosacral notch. As restitution of the fetal head occurs, the shoulders rotate through the pelvis and the anterior shoulder presents under the symphysis pubis.

In cases of true shoulder dystocia, either the anterior shoulder or, in severe forms, both the anterior and posterior shoulders are arrested at the pelvic inlet. It is a common misconception that the pelvic outlet and perineum contribute to shoulder dystocia.

PREDISPOSING FACTORS

There are well-recognised antenatal factors associated with shoulder dystocia such as a history of previous shoulder dystocia, macrosomia >4.5 kg, maternal diabetes, maternal obesity and induction of labour.

Excessive fetal size

The incidence of shoulder dystocia is known to increase in line with birthweight. Below 3.5 kg, the reported incidence is 0.2–0.8 per cent, rising to 5–23 per cent with birthweights above 4.5 kg.^{4,5}

Despite this relationship, half of all shoulder dystocia cases occur with babies of normal birthweight. This may be because some babies that fail to meet an absolute criterion for macrosomia (such as a birthweight >4.0 kg) are actually relatively 'large for gestation' for that particular woman. Unfortunately, it is difficult to know in advance the 'intended' birthweight for any individual woman's offspring. However, customised fetal growth charts are increasingly available; these use maternal ethnic origin, build and parity to individualise predicted fetal weight at any gestation.

Clinicians must remain wary of any clinical situation or condition that is likely to increase fetal weight abnormally. Maternal diabetes, long known to be associated with a risk of excessive fetal growth, is a major risk factor [B].⁶ Other causes of fetal macrosomia, either relative or absolute, include maternal obesity, multiparity and post-dates pregnancies.

Diabetes

Babies born to diabetic mothers have a 2- to 4-fold increase in the incidence of shoulder dystocia compared with babies of non-diabetic mothers of the same birthweight.

Previous history of shoulder dystocia

Overall recurrence risks for shoulder dystocia are approximately 10–15 per cent.^{7,8} These may underestimate the risks, since CS may have been advised for those pregnancies in which a poor outcome occurred after shoulder dystocia.

Intrapartum events

Relative disproportion is often suggested by poor progress in labour, but this is a poor predictor of subsequent shoulder dystocia.^{6,9} Shoulder dystocia has been associated with secondary arrest and mid-cavity instrumental deliveries,⁹ but since this reflects a significant failure of descent, it is again highlighting poor progress in labour.

Parturition has long been linked with the three Ps – the passages, the passenger and the powers. It may be that inefficient uterine contractile activity underlies some cases of shoulder dystocia. It has been suggested that the endogenous powers pushing the shoulders through the birth canal in cases of shoulder dystocia are actually more important than the traction forces generated by the obstetrician.¹⁰ An aetiological role for the 'powers' is also suggested by the increased incidence of shoulder dystocia found in induced labours, associated with an increased risk of dysfunctional labour and operative delivery.^{5,9,11}

PREDICTION OF SHOULDER DYSTOCIA

Despite evidence for antenatal and intrapartum factors associated with shoulder dystocia, models for prediction of this emergent obstetric event are highly unreliable even when a combination of predisposing factors are present.

Review of previous delivery

A careful review of the events surrounding an earlier delivery is essential, using the system outlined under 'Incidence'. This must include a review of the previous maternity notes, which may necessitate correspondence with other units.

Screening for gestation diabetes

If there is any suspicion of excessive fetal growth in a previous pregnancy (regardless of birthweight), a glucose tolerance test should be arranged for 28 weeks' gestation. If impaired glucose tolerance is found, measures should be implemented to minimise any fetal effects [C].

Pelvimetry

There is no evidence to support the routine use of pelvimetry in this situation. Its use should be highly selective. Examples of situations in which it might be considered include marked shoulder dystocia with a small baby or a predisposing factor for pelvic contraction, such as a previous significant fracture.

Identification of fetal macrosomia

The prediction of fetal weight, either clinically or by ultrasound, is inaccurate in the third trimester where the margin of error in predicting birthweight exceeds 10 per cent. Thus information gained from prenatal assessment of size can only be used as one risk factor in the overall clinical picture. It facilitates advance planning and preparation but, in isolation, should not dictate any particular management. The recognition of significant macrosomia in association with other risk factors, particularly diabetes or a previous birth with shoulder dystocia, requires careful assessment.

SHOULDER DYSTOCIA PREVENTION

Early induction

Evidence from observational and randomised trials does not support the use of induction to prevent shoulder dystocia in suspected fetal macrosomia in a non-diabetic woman.^{11,12,13}

As mentioned previously, induced labours are reported to have a higher incidence of shoulder dystocia. However, there is evidence that in the presence of maternal diabetes, the incidence of shoulder dystocia is reduced with early IOL. The current NICE recommendation for diabetic women, irrespective of macrosomia, is to offer elective delivery from 38 weeks' gestation.

A meta-analysis of 5 RCTs of specific treatment for gestational diabetes including offering early IOL compared with usual care concluded that the incidence of shoulder dystocia was significantly reduced in those specifically treated.¹⁴

Elective caesarean section

The ACOG Practice Bulletin 22 Guideline recommends considering elective caesarean section when the birthweight is predicted to be greater than 5 kg in non-diabetics or 4.5 kg in diabetics [D].¹⁵ Despite this, it acknowledges that such a policy would result in 443 caesarean sections in diabetic women to prevent a single permanent newborn injury.

Extremely macrosomic babies (>5 kg) may have a 26-fold increase in shoulder dystocia and, in this group, a much higher incidence of brachial plexus injury. However, the difficulty in accurately predicting birthweight means that choosing the appropriate timing and mode of delivery it is not straightforward.¹⁶

At present, there are few grounds on which to recommend elective caesarean section on the basis of fetal size alone. Decisions should be individualised, based on an appreciation of all risk factors present.

Diabetic control

It is logical to suppose that tight diabetic control may reduce the incidence of fetal macrosomia. At present, there is a small body of evidence to support this assumption [C].

Intrapartum management

Advance planning

Antenatal risk factors for shoulder dystocia should be noted.

- Reassessment of risk should be carried out if there is poor progress in labour. In women believed to be at significant risk, advance preparation is essential.
- Midwifery and medical staff should establish a contingency plan involving:
 - who needs to be aware of the potential problem;
 - who will be present at the delivery;
 - what steps will be taken should difficulties arise.

In mothers who have failure of descent in the second stage, the presence of other risk factors for shoulder dystocia will influence not only if but also where and by whom an instrumental delivery is attempted. Although a trial of instrumental delivery in theatre does not reduce the risk of shoulder dystocia, it ensures the presence of adequate staffing to deal with it efficiently.

An epidural should always be considered in situations in which there is judged to be a considerable risk of shoulder dystocia, particularly if it is felt that maternal distress may interfere with cooperation.

Prophylactic use of the McRoberts manoeuvre is not recommended prior to delivery of the head in view of the absence of evidence for its benefit.

Early diagnosis allows prompt intervention. If there is difficulty delivering the face and chin or the head remains tightly applied to the vulva, retracts or there is failure of restitution

then shoulder dystocia may be anticipated. Examination to define the location of the anterior shoulder (above or below the symphysis) can be helpful.

SHOULDER DYSTOCIA MANAGEMENT

There are no randomised trials to provide guidance for the management of this obstetric emergency.

Manoeuvres to overcome shoulder dystocia cannot solely be learnt from a book. Practical training in obstetric emergencies is strongly recommended, as offered on an ALSO© Course, PROMPT course or similar.

High-fidelity simulations should be used.¹⁷

Recent evidence has shown that sustained practical staff training improved the management of shoulder dystocia with extremely low morbidity and no cases of permanent obstetric brachial plexus injury in over 17,000 vaginal births.¹⁸

Help should always be summoned as soon as a problem is recognised. Clearly stating the nature of the emergency “Shoulder dystocia!” to the arriving team has been shown to prompt a coordinated response.¹⁹

As well as additional midwives, neonatology and anaesthetic staff should be called.

Identify a ‘scribe’ to note times of staff attendance and manoeuvres performed using a designated *pro forma*.

Fundal pressure is not recommended as this can cause uterine rupture. Maternal pushing should be discouraged as this may lead to further impaction of the shoulders.

An episiotomy should be considered but it is not mandatory. An episiotomy or extension of an episiotomy serves to create increased vaginal access to perform internal manoeuvres but may cause considerable maternal trauma.

The steps for approach to management of shoulder dystocia are described in the RCOG guideline on shoulder dystocia.

Manoeuvres for shoulder dystocia are aimed at addressing one or a combination of the following:

- increasing the size of the pelvis (McRoberts and all-fours position);
- decreasing the bisacromial diameter of the fetal shoulders (externally by suprapubic pressure or internally by delivery of the posterior arm);
- changing the relationship of the bisacromial diameter in the mother’s bony pelvis (internal rotational manoeuvres).

SIMPLE FIRST-LINE MEASURES

The first step should always be the McRoberts manoeuvre which is successful in up to 90 per cent of cases. Remember to maintain the head in a neutral position (axial and in line with the fetal spine), avoiding excessive lateral traction.

- The McRoberts manoeuvre involves hyperflexion of the maternal thighs onto the maternal abdomen, either by the mother herself or by a pair of assistants. It has been shown radiographically to flatten the lumbosacral curve and lessen any obstruction from the sacral promontory.

- Suprapubic pressure is often used simultaneously. Using a stance similar to that of CPR, pressure is exerted obliquely on the posterior aspect of the anterior shoulder. The aim is to move the shoulders into the wider oblique diameter of the pelvis and force the anterior shoulder under the symphysis pubis.

SECOND-LINE MEASURES: INTERNAL MANIPULATIONS

Failing correction of the problem with simple measures further manipulations will be required either by internal rotational manoeuvres or by delivery of the posterior arm. These may involve considerable discomfort to the mother (and distress to her partner) and warning should be given.

The aim of these manoeuvres is to rotate the fetal trunk into an oblique position to allow delivery of the shoulders.

The most spacious part for access is the sacral hollow and the hand should be introduced into the posterior vagina. A generous episiotomy may be required.

Internal rotational manoeuvres

- *Rubin’s manoeuvre*. By approaching the anterior shoulder from behind attempts should be made to rotate the shoulders into the oblique diameter of the pelvis, using a finger hooked into one axilla. Ideally, one should attempt to move the fetus in a direction that allows the shoulder to move inwards towards the chest, which will decrease the dimensions of the shoulders. Once disimpacted, traction can again be tried.
- *Wood’s screw manoeuvre*. If simple rotation fails and the posterior shoulder is below the sacral promontory, Wood’s screw manoeuvre should be attempted. Approach the posterior fetal shoulder from the front and rotate the posterior shoulder through 180° so that it becomes the anterior shoulder. By simultaneously combining this with a degree of downward traction, the rotated shoulder remains within the pelvis and appears under the symphysis.
- *Reverse Woods screw manoeuvre*. Approach the posterior shoulder from behind and rotate the fetus in the opposite direction from Rubin or Woods screw manoeuvres – this may be successful when previous manoeuvres have failed.

Delivery of the posterior arm

By advancing a hand into the uterus posteriorly and finding the fetal hand, delivery of the posterior fetal arm can be achieved by sweeping it across the fetal chest.

The ‘All-fours’ technique

The decision to move the mother into this position will depend on the setting, feasibility and accoucheur. It may be

tried (and is reported with high success²⁰) if simple measures fail either before or after attempting internal manoeuvres.

If delivery still has not been achieved then repeating the above stepwise approach of manoeuvres is recommended.

THIRD-LINE MEASURES

If all the above measures have been tried and retried and the baby is still alive, third-line measures could be considered. However, the likelihood of any individual obstetrician gaining experience of these techniques within the UK is remote. Furthermore, publication bias means that clinicians often only report their successes. It is likely that heroic measures have, on many occasions, been followed by stillbirth, neonatal death or profound disability, at a cost of considerable maternal morbidity.

- *Cleidotomy* or deliberately fracturing the fetal clavicle(s) can be used to shorten the biacromial diameter. However, this can be difficult to perform and can lead to injury of underlying vascular and pulmonary structures.
- *Zavenelli manoeuvre*. The fetal head is replaced into the uterus by reversing the steps of parturition. This may require additional uterine relaxation, using either bolus tocolytics or general anaesthesia. Abdominal rescue describes intrauterine manipulation through a transabdominal hysterotomy to facilitate vaginal delivery.
- *Symphiotomy* can lead to a 2–3 cm increase in the bony pelvic diameters. However, there is a significant risk of long-term maternal morbidity. Special skills and equipment are required, including a solid-bladed scalpel. The urethra must be catheterised and displaced laterally. In the absence of an epidural, local anaesthesia is needed. It is likely that the fetus will have been severely compromised by the time a symphiotomy could be safely performed on most UK labour wards.

AFTER DELIVERY

- Postpartum haemorrhage and significant maternal trauma are associated with shoulder dystocia.
- The baby should always be carefully examined by the neonatologist.
- Explanation of events is essential for the mother and her partner. Mothers must understand what went wrong, both to minimise inappropriate blame of themselves or others and so that they may alert their caregivers in the next pregnancy.

DOCUMENTATION

After a delivery complicated by shoulder dystocia, it is important that the details surrounding the delivery are accurately recorded. A designated *pro forma* is ideal for this purpose. (see <http://www.rcog.org.uk/files/rcog-corp/>

GTG42_25112013.pdf). This is important for medico-legal reasons. For example, brachial plexus injury is the most common reason for litigation and where Erb's palsy is present, it is important to determine whether the affected shoulder was anterior or posterior, since trauma to the posterior shoulder plexus is unlikely to be due to action by the accoucheur (RCOG Guideline No.42).

Not only should the individual document their part in the management of the shoulder dystocia with care and detail, but the medical records should be reviewed contemporaneously, checking for completeness and consistency between health-care professionals.

Good documentation is also useful for helping form a plan in any subsequent pregnancy.

It is important to record the following:

- time of the delivery of the head;
- the direction the head is facing after restitution;
- the manoeuvres performed, their timings and order;
- time of the delivery of the body;
- the staff in attendance;
- the condition of the baby, Apgar scores, and cord pH blood levels;
- estimated maternal blood loss.

KEY POINTS

- Neither fetal macrosomia nor shoulder dystocia can be reliably predicted.
- The presence of known risk factors, particularly two or more, should trigger advance preparations to deal with or avoid the situation, before it actually arises.
- Since shoulder dystocia will often occur without warning, obstetricians must have well-rehearsed strategies to overcome it.

Chapter 56 Instrumental vaginal delivery

Tracey A Johnston

MRCOG standards

Learning outcome:

To understand and demonstrate appropriate knowledge, skills and attitudes in relation to instrumental vaginal birth.

- Theoretical skills - candidates are expected to:
 - have completed a basic surgical skills course;
 - know the anatomy of the pelvis and the fetal head;
 - understand the mechanisms of birth;
 - understand the indications for instrumental vaginal delivery;
 - understand the risks and benefits of forceps vs ventouse;
 - understand when rotational delivery is appropriate.
- Practical skills - candidates are expected to:
 - be competent to perform non-rotational forceps and vacuum delivery;
 - have experience in manual rotation and rotational vacuum delivery;
 - where possible, have seen a rotational forceps delivery.

INTRODUCTION

Instrumental vaginal delivery (IVD) is an essential part of the obstetrician's armamentarium, and s/he must be competent and confident in both forceps and vacuum for non-rotational delivery, and at least one technique for rotational delivery. Second-stage caesarean section (see Chapter 53) is associated with increased maternal and neonatal morbidity,¹ and therefore should be avoided if safely possible. The risks are higher for CS following failed instrumental delivery, and neonatal morbidity is increased with sequential use of instruments.² Thorough assessment and selection of the most appropriate mode of birth are therefore essential to minimise morbidity, as is skill in performing the procedure. National guidance

exists³ which addresses the indications and contraindications for intervention, the relative merits of forceps and vacuum, classification of operative delivery and prerequisites for operative delivery, as well as place of delivery and aftercare. As with CS there are geographical variations in the incidence of IVD, but the rate has remained relatively constant in the UK for the past few years, with the most recent figures for England showing a rate of 12.8 per cent, with 6.8 per cent being forceps and 6 per cent being vacuum.⁴ This is despite an increase in the CS rate, which has not been associated with a concomitant reduction in operative vaginal birth.

REDUCING THE NEED FOR IVD

There are several evidence-based strategies that should be routine practice on the labour ward to reduce the need for operative intervention. It has been established for some time that one-to-one care in labour reduces intervention and improves maternal satisfaction, especially when the continuous carer is not a member of staff [A].⁵ This raises the question regarding the use of doulas as a cost-effective mechanism for increasing the normal birth rate. The mother being supine or in lithotomy in second stage increases the rate of IVD [A].⁶ Epidural analgesia is associated with an increased operative vaginal delivery rate,⁷ but the COMET trial demonstrated that more modern methods of regional analgesia such as combined spinal epidural and 'mobile' epidurals improved the normal delivery rate mainly by reducing the IVD rate [B].⁸ In nulliparous women with an epidural, delayed pushing by extending the passive second stage of labour is associated with a reduction in IVD [B],⁹ as is the judicious use of oxytocin in the second stage [B].¹⁰ The BUMPES trial has recently finished recruitment and seeks to determine whether maternal position in second stage with an epidural influences mode of birth.¹¹

CLASSIFICATION

Standardised terminology should be used when defining and classifying IVD. Table 56.1 sets out the preferred classification, adapted from ACOG.¹²

Table 56.1 Classification for instrumental vaginal birth (adapted from ACOG, 2000)

Outlet Vertex visible
Fetal skull has reached pelvic floor
Sagittal suture is in the anterior–posterior position with no more than 45° of rotation
Fetal head at or on the perineum
Low cavity Vertex 2 cm or more below the ischial spines but not on the pelvic floor
* Rotation of 45 degrees or less from the occipito-anterior position
* Rotation of more than 45 degrees including the occipito-posterior position
* Rotation of more than 45 degrees including the occipito-posterior position
Mid cavity Head no more than 1/5 palpable abdominally
Vertex between ischial spines and spines +2 cm
* Rotation of 45 degrees or less from the occipito-anterior position
* Rotation of more than 45 degrees including the occipito-posterior position
High cavity Head >2/5 palpable abdominally
Presenting part above ischial spines
Instrumental birth is not recommended in this situation

INDICATIONS

IVD is used to expedite delivery by shortening the second stage of labour. There are both maternal and fetal indications for IVD (Table 56.2) but it must be remembered that no indication is absolute, and each case must be assessed individually and the risks and benefits of continued pushing balanced against those of intervention. The commonest indications for IVD are confirmed fetal acidaemia (following FBS) or suspected fetal compromise (abnormal CTG), and delay in second stage. Chapter 54 covers fetal compromise in the second stage and will therefore not be discussed further here.

Table 56.2 Indications for instrumental vaginal birth

Maternal	Prolonged second stage
	Maternal fatigue
	Poor maternal effort (e.g. dense epidural block)
	Certain maternal medical disorders
Fetal	Confirmed fetal acidaemia
	Presumed fetal compromise

Delay in second stage

The NICE guideline for Intrapartum Care⁹ sets out a definition and recommended limits for the length of the second stage

of labour for nulliparous and multiparous women. These recommended limits are based on the increased risks of mainly maternal compromise, such as chorioamnionitis, operative birth, PPH and perineal trauma. With appropriate fetal monitoring and intervention if indicated, prolonged second stage does not appear to be associated with significantly increased neonatal morbidity.⁹ Passive second stage of labour is defined as the finding of full dilatation of the cervix before or in the absence of involuntary expulsive contractions. The onset of the active second stage of labour is defined by the baby being visible, expulsive contractions with a finding of full dilatation of the cervix or other signs of full dilatation of the cervix, or active maternal effort following confirmation of full dilatation of the cervix in the absence of expulsive contractions. With regard to the normal length of the active second stage, it varies depending on parity and whether the woman has an epidural. The range and upper limit of normal for the active second stage in women giving birth to their first baby is about 0.5–2.5 hours without an epidural, and 1–3 hours with an epidural, and for women giving birth to second or subsequent babies, up to about 1 hour without an epidural, and 2 hours with an epidural. Delay should be diagnosed in nulliparous women when the active second stage has lasted 2 hours and birth is not imminent, and when the active second stage has lasted 1 hour and birth is not imminent in multiparous women.⁹ When an epidural is *in situ*, birth should be achieved within 4 hours of the diagnosis of second stage, irrespective of parity,⁹ and this must be borne in mind when implementing delayed pushing (i.e. prolonging the passive second stage), which is associated with a significant reduction in the incidence of mid-cavity and rotational IVD.¹³ When delay in second stage is diagnosed, operative intervention should be considered to achieve birth. In most cases this will be by IVD, but in some cases second-stage CS is appropriate (Chapter 54).

Other maternal indications

With respect to maternal fatigue and poor maternal effort, supportive measures should be employed including appropriate analgesia, but if these measures are not successful, operative intervention can be offered.

Maternal medical disorders which merit shortening of the active second stage should usually be identified in the antenatal period and appropriate discussion and planning put in place. Such conditions include New York Heart Association class III and IV maternal cardiac disease, severe hypertension (crisis), proliferative retinopathy and myasthenia gravis. Accidental dural puncture is not an indication for IVD [C].

CONTRAINDICATIONS

There are few absolute contraindications to IVD, the main one being lack of appropriate skill in performing the procedure.

Vacuum should not be used below 34 weeks' gestation because of the increased susceptibility of the preterm infant to cephalohaematoma, intracranial haemorrhage, subgaleal haemorrhage and neonatal jaundice [D]. The safety of vacuum is not clear between 34 and 36 weeks' gestation [D]. Vacuum is also contraindicated in face presentation, although forceps can be used if mento-anterior. Fetal bleeding disorders (e.g. thrombocytopenia, haemophilia) and bone disorders associated with fractures (e.g. osteogenesis imperfecta) are relative contraindications, but a non-rotational low cavity IVD is associated with less trauma than CS if the head is deep in the pelvis. Careful assessment and a skilled operator are required in these cases, as is appropriate instrument selection taking into account that forceps reduce the haemorrhagic risk compared to vacuum and vacuum reduces the risk of fracture compared to forceps.

Blood-borne viral infection is not a contraindication to IVD [D] (although fetal scalp electrodes and FBS should be avoided), although difficult IVD with an increased risk of fetal laceration is probably best avoided. FBS and fetal scalp electrodes again are not contraindications to IVD, as the risk of significant scalp haemorrhage with vacuum is minimal [C].

PREREQUISITES

To minimise risk to both mother and baby, careful case and instrument selection are vital. Before embarking on an instrumental delivery, specific prerequisites must be fulfilled.

- An operator with the required skills and a willingness to abandon the procedure if indicated.
- Cephalic presentation not more than $\frac{1}{5}$ palpable per abdomen (in certain circumstances skilled operators may perform a vacuum extraction with a higher presenting part e.g. second twin). The presenting part should be the vertex, although forceps can be used in mento-anterior face presentations, and in brow presentations where the pelvis is adequate and the fetus small (e.g. late preterm). In these circumstances, the operator must have the appropriate level of expertise to conduct these more complicated instrumental vaginal deliveries.
- Cervix fully dilated with ruptured membranes (again, skilled operators may perform vacuum extraction prior to full dilatation in specific circumstances e.g. acute bradycardia in a parous woman approaching full dilatation).
- Adequate pelvis – beware significant moulding.
- Position of the presenting part *must* be known to ensure correct application of both forceps and vacuum.
- Informed consent of the mother – this is usually verbal consent, but if there is time written consent should be obtained if possible. In cases of trial of instrumental birth, written consent for the trial and possible caesarean section should be obtained.¹⁴
- Adequate analgesia – often regional analgesia although a pudendal block can be used, particularly if regional

anaesthesia is declined or there are concerns regarding fetal wellbeing.

- Bladder empty and catheter removed or balloon deflated.
- There is no prerequisite for episiotomy, as it is not clear from the evidence whether routine episiotomy protects against anal sphincter injury in either forceps or vacuum, and restrictive use using the operator's clinical judgement is reasonable [B].

PLACE OF DELIVERY

IVD can be conducted in the labour room or in theatre. In cases where a higher failure rate may be anticipated, delivery should be performed as a trial in theatre to facilitate immediate recourse to CS if IVD is unsuccessful [C]. Such cases include malposition, mid-cavity/head palpable abdominally (no more than $\frac{1}{5}$), big baby and raised maternal BMI.¹ Increased perinatal morbidity is seen where there is a delay between failed IVD and CS, whereas there is no difference in neonatal outcome when failed IVD followed by immediate CS is compared to immediate CS without an attempt at IVD.¹⁵ In cases where there is a concern over fetal wellbeing, timescales must be taken into account. On average, IVD undertaken in the delivery room takes around 15 minutes, whereas IVD following transfer to theatre takes around 30 minutes,¹⁶ thus the risks of delaying delivery by transferring to theatre must be balanced against the risks of a failed IVD in the room.

CHOICE OF INSTRUMENT

There are many different types of forceps and vacuum devices available. For forceps, the easiest way to categorise them is secondary to their physical characteristics. Forceps are either curved or straight, depending on whether they have a pelvic curve or not, and either have a long or a short shank. In the UK, the only short forceps available are short curved forceps, or Wrigley's forceps. These are generally used for 'lift-out' deliveries, when the vertex is at the introitus. The only straight forceps available are long straight forceps, or Kielland forceps, which are used for rotational deliveries (see later). The most commonly used forceps are long curved forceps of which there are around 700 varieties, with very little to choose between them (e.g. Neville-Barnes, Haig-Ferguson, Andersons and so on).

There are also different types of vacuum extractors and cups, again with different pros and cons. In current practice, the disposable hand-held vacuum device (Kiwi™ Ommicup, Clinical Innovations Europe Ltd, Abingdon UK) seems to be the most commonly available vacuum in many units, and indeed may be the only device available. Unfortunately, higher failure rates have been reported in RCTs comparing Kiwi with conventional vacuum [B]^{17,18} although the failure rate decreases in skilled hands.¹⁹

With conventional vacuum, there are a variety of cups. Metal cups come in different sizes and are generally either OA or OP cups, with OP cups having the tubing insertion point on the side to allow placement over the flexion point on a deflexed, OP position. Large, soft silastic cups gained popularity for their ease of application and lower incidence of scalp trauma, but have been shown to have a higher failure rate when compared to rigid cups [A].²⁰

With any vacuum delivery, poor cup placement is associated with an increased failure rate, which is why it is essential to determine where the flexion point is to enable correct cup placement over the flexion point. If the cup is placed correctly over the flexion point (a flexing median application), the failure rate for vacuum extraction should be in the region of 4 per cent. A flexing paramedian application increases the failure rate to around 17 per cent, a deflexing median application with the cup placed too far anteriorly is associated with a failure rate of 29 per cent and a deflexing paramedian application has a failure rate of up to 35 per cent. These figures confirm the importance of correct cup placement and firmly refute the 'suck it and see' approach which unfortunately does still exist. Unless the flexion point is clearly identified and the cup placed correctly, any attempt at vacuum delivery should not proceed.

When using vacuum, there is no evidence of benefit in a slow, incremental increase in pressure compared to a rapid increase.²¹

When selecting which instrument to use, the operator must take into account their personal skill set and the particular clinical scenario in each case, as the objective must

always be to achieve delivery safely with the first instrument of choice. For non-rotational deliveries, the options are either non-rotational forceps or vacuum, and there are pros and cons to both [A] (Table 56.3). Operators should be skilled in the use of both instruments, and fully understand the impact of different clinical situations on likely outcome. In cases of outlet deliveries, there may be little to choose between the two in terms of success rates, but overall forceps are associated with a significantly increased success rate compared to vacuum [A], and achieve delivery more quickly,⁹ which is an important feature to consider in cases where delivery needs to be achieved quickly. Factors which should warn the operator of an increased risk of failure with vacuum include: excessive caput or moulding (may be an indicator of relative cephalo-pelvic disproportion, less likely to achieve adequate seal), malposition, and poor maternal effort (particularly following epidural top-up or spinal for a trial in theatre). Most trainees become comfortable with vacuum before forceps, but when looking at the pros and cons listed in Table 56.3, with fully informed counselling it may be that, given that there is no difference in long-term outcomes, most women would be prepared to accept more pain and discomfort, and increased rates of perineal trauma, to optimise the chance of success with the first instrument of choice and ensure less trauma to and concerns about their baby.

In cases where rotation is required to achieve delivery, there are three options:

- manual rotation and either forceps or vacuum to complete delivery;

Table 56.3 Outcomes when vacuum compared to forceps

Vacuum compared to forceps	OR	95% CI
Procedure:		
More likely to fail with selected instrument	1.69	1.31–2.19
No difference in CS rates	0.56	0.31–1.02
Reduction in the use of anaesthesia	0.59	0.51–0.68
Takes longer to achieve delivery ⁹		
Maternal:		
Reduction in maternal genital tract injury	0.41	0.33–0.50
Reduced pain during birth	1.5	0.5–4.2
Reduction in severe perineal pain at 24 hours	0.54	0.31–0.93
Increase in maternal anxieties about the baby	2.17	1.19–3.94
No difference in incontinence at 5 years	1.47	0.44–4.92
Neonatal:		
Increased risk of cephalohaematoma	2.38	1.68–3.37
Increased risk of retinal haemorrhage	1.99	1.35–2.96
No difference in Apgar score <7 at 1 minute	1.13	0.76–1.68
No difference in scalp and facial injuries (excluding cephalohaematoma)	0.89	0.7–1.13
No difference in need for phototherapy	1.08	0.66–1.77
No difference in perinatal death	0.8	0.18–3.52

- rotational vacuum;
- rotational forceps.

Many such deliveries are conducted as trials in theatre with regional anaesthesia, which limits maternal effort, and clinicians must be skilled in at least one of the above techniques. Rotational vacuum is most commonly used, but the higher failure rates must be taken into account. Using a conventional vacuum device with a rigid OP cup will maximise the chances of success. Manual rotation can indeed avoid IVD, as following rotation maternal effort may be successful in achieving birth without further assistance. The fetal head is flexed and then rotated into the occipito-anterior position, and held there until either the mother pushes and the head descends, or either vacuum or forceps are applied to achieve delivery. The most effective instrument in achieving rotational delivery is Kielland forceps, but in many units the skill in using them has disappeared, mainly because of concerns over increased maternal and perinatal morbidity. There are reports in the literature regarding poor outcomes with Kielland forceps, but many of these are old and from uncontrolled observational studies and in many cases the fault lies with poor case selection and an unwillingness to abandon the procedure at the appropriate time. A recent review of almost 900 cases shows that neonatal admission rates following rotational forceps delivery are no higher when compared to normal birth and vacuum delivery, and are lower than emergency CS. In terms of maternal morbidity, rotational forceps delivery was associated with lower rates of PPH than emergency CS [B].²² This demonstrates that in skilled hands rotational forceps still have a valuable place in modern obstetrics in terms of safely achieving vaginal birth and avoiding second-stage CS.

WHEN TO ABANDON

It is essential before embarking on an instrumental delivery that the operator has the appropriate skills, and in particular knows when to abandon the procedure. Both maternal and neonatal morbidity are increased with prolonged, repeated or excessive traction in the absence of progress. If there is no descent after the first pull, the situation should be reassessed and requesting senior help should be considered, as this may be indicative of an increased risk of failure. Possible explanations to exclude are incorrect determination of position or station (OP instead of OA), incorrect cup placement (not over the flexion point), poor maternal effort (particularly with vacuum, and with spinal or dense epidural blockade), cephalo-pelvic disproportion and, rarely, equipment failure (leak in the vacuum system). If delivery is not imminent after three pulls, if the vacuum cup detaches three times, or delivery is not completed within 30 minutes of the decision to deliver, then the procedure should be abandoned [B], with recourse, in the majority of cases, to CS. As the success rate with forceps is higher than with vacuum, there is a temptation to try forceps if vacuum fails. This practice is associated with an increased

risk of perinatal trauma [B], especially intracranial haemorrhage, retinal haemorrhage and feeding difficulties,² and the risk of this must be balanced against the risks of CS following failed IVD (see Chapter 53). In cases where the head is in the low cavity or on the perineum, forceps may be the safer option, but caution must be exercised and this should be a senior decision.

POST-DELIVERY CARE

Paired cord gases should be obtained in cases where fetal compromise is suspected, and a careful examination of the neonate conducted, assessing for any signs of trauma secondary to the instrument used. Any injuries should be explained to the parents and documented, and if there are concerns the baby should be seen by an appropriately qualified practitioner. It is good practice for the operator to note any marks on the neonate to confirm where the instrument used was placed e.g. is the chignon over the flexion point? Are any forceps marks in the correct place? This gives immediate feedback regarding appropriate application and placement, and will inform skill development. Maternal aftercare should include appropriate analgesia (paracetamol and diclofenac if no contraindications), a venous thromboembolism risk assessment and thromboprophylaxis if indicated [D]²³ and good bladder care. The timing and volume of the first void should be monitored and documented [C], and assessment of post-void residual carried out if retention is suspected, to avoid over-distension injury. If regional anaesthesia has been used, an indwelling catheter should be left *in situ* for 12 hours after delivery. There is no evidence to support the use of antibiotic prophylaxis in cases of IVD [A]. The women should be given a full explanation of the indication for IVD, preferably by the operator, to ensure she has full understanding as well as the opportunity to ask questions. She should also be informed of the high chance of a successful vaginal birth in future pregnancies [B].²⁴

TRAINING

Inexperience and inadequate training are associated with adverse outcomes,²⁵ and training is a key component of patient safety initiatives.²⁶ The RCOG curriculum specifies the training requirements for IVD (Core Module 11), and trainees should have both formative and summative objective structured assessments of technical skill (OSATs) performed to ensure achievement and maintenance of competencies. Hands-on experience cannot be replaced in total by other learning modalities. More experienced operators are more likely to achieve successful IVD²⁷ and formal postgraduate training is associated with a reduction in both neonatal and maternal morbidity.²⁸ This requires appropriate supervision by clinicians who have achieved the appropriate competencies, and increased consultant presence on the labour ward will facilitate this.

KEY POINTS

- One-to-one care in labour, non-supine position in second stage, delayed pushing in the presence of epidural analgesia and the judicious use of oxytocin all reduce the need for IVD.
- The main indications for IVD are fetal compromise and delay in second stage.
- Successful delivery is more likely to be achieved with forceps, and more quickly, than with vacuum.
- Sequential use of instruments is associated with increased neonatal morbidity.
- Correct case selection, correct instrument selection and appropriate skills are all essential to optimise success rates.
- Know your limitations and ask for help!

Chapter 57 Breech presentation

Alexander M Pirie

MRCOG Standards

Module 1: Clinical skills

- Communicate effectively.
- Take notes concisely and accurately.

Module 3: Information technology, clinical governance and research

- Understand how to perform, interpret and use clinical audit cycles.
- Understand the production and application of clinical standards, guidelines and care pathways and protocols.
- Understand the skill necessary to critically appraise scientific trials and literature.
- Understand the principles and legal issues surrounding informed consent.

Module 5: Core surgical skills

- Demonstrate an understanding of the issues surrounding informed consent, including knowledge of complication rates, risks and likely success rates of different operations.

Module 8: Antenatal care

- Demonstrate skill in listening and conveying complex information (e.g. concerning risk).
- External cephalic version.

Modules 10 and 11: Management of labour and management of delivery

- The exam may test certain aspects of practical skill relating to normal and abnormal delivery.
- Vaginal breech delivery including second twin.

their breech so smoothly and naturally, that we worry wakefully that our modern tilt towards caesarean section may be costly and invasive, introducing morbid and mortal risk whilst taxing young mothers with prolonged recovery times.

As we lean towards CS (based on better short-term neonatal outcomes), we fear a future where the rising CS rate multiplies the risks of haemorrhage, transfusion, sepsis, visceral injury and ‘returns to theatre’ as well as the psycho-social and parenting implications of longer recovery times. Caesarean for breech increases the likelihood of more complex caesarean in subsequent pregnancies, with an escalation in the challenging realities of placenta accreta with catastrophic haemorrhage, obstetric hysterectomy, uterine scar rupture, cerebral palsy and maternal death. Caesarean sections carry resource implications for facilities and finance as well as the learning of new skills for complex repeat obstetric surgery, as well as the loss of obstetric skills in vaginal breech birth. And we need to consider both resource-rich and resource-poor settings, as well as the increasing plight of women who may move from rich country to poor (e.g. after failed asylum application) with dire consequences for their next pregnancy if they have a scarred uterus.

Research to help us guide a mother’s choice between caesarean and vaginal birth has evolved from the primordial soup of expert opinion, up through the jungles of retrospective and prospective cohort studies, to the shining Grade A quality of randomised trials, meta-analysis and systematic review. The dawn of a regularly revised RCOG guideline systematically produced by a multidisciplinary expert group is a shining beacon for modern practice, yet still we are left with shadowy uncertainties. The spectres of controversy and critique still haunt labour suites and courtrooms as we weigh the risks in the longer term. The hired guns of obstetric litigation duel their heavy arguments for cause and effect before the civil courts. It has been said that some expert obstetricians may be more comfortable discoursing in a lawyer’s chambers than using head, hand and heart in a busy labour suite. Unlike the high scientific standard of proof which all doctors assume for research trials (95% probability; $p < 0.05$), or the high standard of proof (‘beyond reasonable doubt’) in criminal trials, a civil court trial for medical negligence applies the lowest standard of proof (‘balance of probabilities’) which means the judge awards success to the side whose argument appears to be more probable than not (in other words, at least 51%

INTRODUCTION

Seasoned obstetricians are vexed long in our wakeful nights by the memories of a sick child born by vaginal breech birth. Tragic outcomes for breech are well recognised, yet they happen even after caesarean sections as well as technically flawless vaginal breech births. The cause of an unhappy outcome is often not the mode of birth. Every experienced midwife and obstetrician recalls happy memories of mothers who birth

probability of being true). Yet the history of science is punctuated by seemingly probable arguments that turn out to be wrong. The Earth can look fairly flat, despite being round.

Critical appraisal of both research and litigation, and qualitative research on which outcomes are important to women, must blend in the crucible of our understanding if we are to transform care into a gold standard for breech babies and supporting their mothers' informed choices.

Eight questions faced by hands-on obstetricians are worth meditation by the MRCOG candidate:

- 1 How would you counsel a woman in antenatal clinic at 37 weeks' gestation whose baby is found to be a breech presentation, and ensure she had 'informed choice'?
- 2 What if a woman were first found to be breech at 7 cm dilatation in labour at term?
- 3 What if the gestation were 24 weeks, 28 weeks or 32 weeks in a labouring woman?
- 4 What about twins where either the first or second twin is breech?
- 5 What would you do if she politely refused your recommendations?
- 6 Could you write a guideline and set audit standards for performing ECV?
- 7 Can you overview and critically appraise the evidence for the options of vaginal breech versus caesarean birth?
- 8 Can you demonstrate using a model the recognised manoeuvres for assisted vaginal breech birth and its complications, and discuss the minimisation of the common neonatal injuries?

This chapter aims to inspire you, the reader, to answer these questions, to breed excellence in your future clinical practice, to strengthen your ability to contribute to service, research and quality improvement, and for you to flourish in the MRCOG examination.

PREVALENCE

The frequency of breech presentation at term is around 3 per cent of pregnancies at 37 weeks.¹⁻⁴ This figure has been very constant over the last century. It is much commoner with preterm babies, perhaps due to the mobile, smaller baby and immature brain, such that the prevalence at 28 weeks' gestation is around 20–30 per cent.

TYPES OF BREECH

Extended breech is commonest (70 per cent) and easiest of all breeches to deliver vaginally with the buttocks fitting roundly into the cervix. The legs are extended at the knees and flexed at the hips, with the feet up near the face. It is sometimes confusingly called 'frank' breech.

Flexed breech has the knees flexed and the feet at or below the breech. This is sometimes called a 'complete' breech.

Footling breech has one or both legs extended at the hip and knee, so the foot may prolapse down the birth canal with a high risk of cord prolapse.^{5,6}

CAUSES

Ultrasound has become an essential tool for discerning any underlying cause, where management of the underlying condition is an important facet of management of breech. Many breeches are idiopathic, and an old hypothesis was that neural immaturity prevents flexion of the legs, leaving them in extension which then splints the trunk, preventing the flexion necessary for the natural forward roll to cephalic presentation.¹⁻⁶

There are fetal, placental and maternal factors that increase the prevalence of breech:

- polyhydramnios (e.g. maternal diabetes, fetal anomaly such as oesophageal or duodenal atresia);
- oligohydramnios (associated with fetal growth restriction, amniorrhexis, renal tract dysgenesis);
- fetal anomaly (e.g. hydrocephalus, myelomeningocele, aneuploidy);
- placenta praevia;
- uterine anomaly (e.g. bicornuate uterus);
- pelvic mass (e.g. uterine fibroids, ovarian cyst);
- prematurity;
- multiple pregnancy;
- multiparity.

DIAGNOSIS

A woman with a breech presentation may complain of a hard lump or discomfort under her ribs. The firm round 'cricket ball' feeling of the baby's head may be felt in the upper abdomen, and the presenting part will be soft without the usual hard 'ballotable' head. For those with experience of auscultation of the fetal heart, it will be loudest above the maternal umbilicus rather than below.

On vaginal examination the presenting part is soft, although a tightly moulding breech deep in the pelvis can occasionally be mistaken for a head with the natal cleft and anus simulating the sagittal fissure and fontanelle, and so a high degree of vigilance should be maintained. It used to be said to beware the deeply engaged head for the head may not be there at all, if it were actually a breech. Palpation of the hard ischial tuberosities and sacrum helps differentiate the breech from a face presentation where the malar bones, hard chin and mouth can be felt.^{5,6}

Screening for breech is an important function of the late antenatal check, and this satisfies Wilson's WHO Criteria for a screening test.⁷ Clinical suspicion of breech after 36 weeks should be confirmed by ultrasound. Even in experienced hands, palpation in the absence of ultrasound still misses the diagnosis of breech, particularly in women with high BMI.^{1,5,6}

Detection of breech with 100 per cent sensitivity is an argument for routine ultrasound late in antenatal care.

The first recognition of breech presentation is sometimes at vaginal examination in labour, which is less than ideal for enabling informed choice and planned CS. Women in threatened preterm labour are at higher risk of breech presentation and so need particular suspicion for breech with a documented discussion of the risks and benefits of the options for birth.

COMPLICATIONS

The risks of vaginal breech birth are well known but must be balanced against the significant risks of CS for this and future pregnancies. The harms of vaginal breech are:¹⁻⁶

- cord prolapse, particularly with footling or flexed breech, where the presenting part does not seal the birth canal at membrane rupture;
- visceral injury, particularly perinephric haematoma: where the fetal abdomen has been grasped during delivery instead of the buttocks;
- fractures of femur and humerus: where limbs are manipulated particularly with the nuchal arm, or much rarer bilateral nuchal arms;
- brachial plexus injury with subsequent Erb's or Klumpke's palsy;
- dislocation of hips: common with the shallow acetabulum characteristic of breech, but more so if legs released using non-standard manoeuvres;
- cord compression: once the head has entered the pelvis, the cord can undergo compression released only by delivery, especially if the cord is round the neck. This can cause relative hypovolaemia and asphyxia and is often blamed for hypoxic brain injury in vaginal breech;
- arrest of the after-coming head: the obstetrician's nightmare where the head gets stuck but the cord and body have delivered;
- tentorial tear and intracranial haemorrhage: thought to result from the unmoulded breech head being delivered too rapidly, and the base of the skull is pulled apart from the bones of the cranial vault exerting force on the tentorium and veins of Galen.

MANAGEMENT

Decision models and the 'Inner Consultation'

The main management decision is between the three options of external cephalic version, vaginal breech birth or caesarean section, and the specifics will vary with antenatal or intrapartum diagnosis, term or preterm, causes, parity and choice. I would like to reflect on how we enable informed choice and support women in their decision making. This is highly

relevant to performing well in the structured clinical examination in the MRCOG, as well as becoming the best doctors that we can be.

In the past, obstetricians in the UK have used a highly directive model of counselling, often described as 'paternalistic'. This is where the 'expert' paternal figure issues 'doctor's orders' as to what the patient should do, and the paternal figure is framed as protecting the patient from risk. This is still the expected model in some subcultures where the doctor is not expected to give the patient a choice, and the idea of supporting the patient's legal right to bear their own personal risks of harm seems cavalier. It is vital that the doctor recognises the potential for such 'framing error' in communication within sub-cultures, as the offering of choice can be perceived as the options being equally devoid of risk. Such patients say afterwards that they were offered a choice therefore assumed the risks were negligible, otherwise they believe the protective paternal figure would have forbidden choice. I know of legal cases for damaged babies where women have come from cultures where doctors were expected to give orders rather than choices, and the women have refused medical advice to have intervention because it was presented as a choice.

Nowadays, the shared-decision model of care involves partnership with patients and enables informed choice.^{8,9} The post-modern western society is suspicious and critical of expert authority, and women place high value on personal autonomy and the right to choose and bear calculated personal risk. Adults make risk decisions every day when they smoke, drink and drive cars and so we value making our own decisions about our own medical care. Where women's autonomy and choice are not respected, women can exert their legal right to have a home birth, and this probably carries higher risks for a vaginal breech than labour in hospital. The NHS Constitution⁹ and the NICE guideline for Intrapartum Care¹⁰ specifically instruct that 'patients should have the opportunity to make informed decisions about their care and treatment, in partnership with their healthcare professionals'. Patients are, after all, experts in their own lives.

A skilled consultation requires good counselling and listening skills. The following 'three-domain decision model' imposes useful structure on the consultation and allows rapid shared analysis of the issues for each woman.

- 1 The first domain is the woman's perception of the risks associated with each option. There is good evidence that risk is notoriously over- or under-perceived by doctors and patients, and creating perspective to show the true size of each risk is crucial. Also, care has to be taken in applying population risks to individuals. The population risk for an adverse event may be e.g. 1 per cent, but the adverse event will either happen (100% risk) or not happen (0% risk) to that individual, irrespective of the population risk.
- 2 The next domain is the woman's values. Some women place very high value on vaginal birth; they may view labour as a transformative 'rite of passage' and feel deeply traumatised if they are persuaded to have a CS. Other

women place high value on the perceived convenience and control of planned CS. It needs to be established what is important to each woman, rather than the doctor make paternalistic value judgements as to what they imagine should be important.

- 3 The final domain is intuition or gut instinct. Sometimes we are confused by too much information and overthinking, creating cognitive dissonance with our subliminal intuitive intelligence. There is a significant literature on intuitive knowledge, and it is probably unwise to go against a woman's gut feeling about how she should have her baby, after a full discussion of the other domains.

The concept of the 'inner consultation' is useful in providing non-directive counselling, because doctors bring their own conscious and unconscious bias to polarise their counselling. Inner consultation involves the doctor reflecting deeply upon their own feelings after the 'outer consultation' with the patient, and being open to the idea that unconscious processes drive our actions, which are often irrational and not always helpful to our patients. Such reflection brings the unconscious bias to light, and allows us to serve our patients more skilfully. In the Inner Consultation, there are no irritating patients, only irritable doctors!¹⁰

For example, we may see ourselves as risk averse for compassionate reasons, protecting our patients from harm. The unconscious driver may be our narcissistic urge not to look bad if things go wrong, or to be the powerful 'saviour' who fixes people. In becoming conscious of this, we can move from 'narcissistic conscientiousness' to 'compassionate conscientiousness' and better support our patients in their decisions by removing our own selfish drivers from the consultation.

Sometimes we are driven by a memory or fear of a single tragic outcome from the past, which is as irrational as generalising outcomes from an 'n=1' research trial. Or we are driven by the internalisation of a role model such as a persuasive teacher, who themselves were driven by irrational processes or outdated evidence. We could then harm large numbers of patients in trying to prevent a single unlikely complication on the basis of our single bad experience. GPs are now selected for their ability to 'bear uncertainty' so as to protect their patients from over-investigation and overly interventional approaches, where harms can exceed benefits. The price of bearing this uncertainty is sometimes being wrong, but that is seen as worthwhile in the face of the benefit of protecting the majority from harm.

And sometimes we have delusions of power over circumstances. For example, we may be rationally aware of an association of a bad outcome with a certain condition (e.g. fetal growth restriction and stillbirth, breech babies and neonatal morbidity) but be in denial that our interventions are ineffective, or come at high cost in terms of service provision or introducing new risks. We are then treating ourselves rather than our patients.

If the obstetrician recognises their own psychological tendencies in relation to clinical risk and their understanding of

probabilities, we become less directive in our counselling and skilful enablers of truly informed choice, in line with each woman's legal right.⁹

UNDERSTANDING THE CONTROVERSY BETWEEN CAESAREAN SECTION AND VAGINAL BREECH

Most people interpret their world by seeing patterns, forming hypotheses around those patterns, and then continuing to see the world through this frame or hypothesis even though new facts may refute their hypothesis. If we see our beliefs as hypotheses, we are perhaps more able to let them go in the face of contesting evidence. But if we see our hypotheses as truth, or part of our identity, we can become emotional rather than rational, and we project our shadows onto our challengers unconsciously minimising our psychological distress. The history of the debate between vaginal breech and CS is often clouded by such 'believers' or 'enthusiasts' on each side clinging to their prior viewpoints, and each interpreting new findings in ways that support their prior belief. Much emotion is attached to obstetricians' beliefs about caesarean versus vaginal birth for myriad reasons. A single tragic experience of vaginal breech, or a single tragic experience of a CS, can bias in either direction and the various unconscious drivers listed under the 'inner consultation' conspire to leave us with beliefs which are less rational than we would often like to believe. Expert opinion may fly in the face of contrary factual evidence, because experts are tainted by the cognitive bias which comes from their own status as expert.

Obstetric policies around issues like CS have huge impact on society, financially, physically, socially and psychologically. We need vocal, thinking obstetricians engaging in dialectical discourse where opposing views are comfortably argued, and dangerous 'group think' avoided by accommodating a contrarian 'devil's advocate' to challenge conditioned group norms. This will help us cultivate self-awareness around our psychological tendencies if we are to discover the best way to deliver breech babies. We also need to support qualitative research to identify the vital 'patient-reported outcomes' which are the true objective of good medicine. And we should remain conscious that what seems obvious at first often turns out to be wrong.

So let us try to understand the obstetric dialectic around published evidence and the RCOG guidelines on breech.¹

The Term Breech Trial

This extraordinary trial was published in 2000 and involved 121 centres in 26 countries, including the UK, to recruit 2088 women.¹¹ Their babies were extended or flexed breech, and they were randomised to either CS or vaginal breech birth. The analysis was performed on an 'intention to treat' basis which is important, because the trial was designed to inform us how to advise (or 'treat') women in antenatal clinic with

breech presentation, rather than analyse the results on how the baby ended up being born. Almost 10 per cent of the women randomised to CS actually had a vaginal breech birth, and only 57 per cent of those randomised to vaginal birth actually had a vaginal birth. This tells us that the conversion to CS rate in women assigned to vaginal birth is around 43 per cent. It is important for you to make women aware of that when choosing vaginal birth when counselling for informed choice.

The trial was stopped early when the data monitoring committee noted the event rate (mortality and morbidity) was higher than expected, so the trial never reached its full statistical power. However, perinatal mortality, neonatal mortality or serious neonatal morbidity was significantly lower for the women randomised to planned CS by two thirds (RR 0.33, 95% CI 0.19–0.56). There were 17 morbid or mortal 'events' in the 1041 women in the planned CS group compared with 52 'events' out of the 1039 women in the planned vaginal birth group. There were no significant differences in terms of maternal mortality or serious maternal morbidity.

The authors concluded that 'planned caesarean section is better than planned vaginal birth for the term fetus in the breech presentation; serious maternal complications are similar between the groups'. When the trial was published, there was a massive change in worldwide obstetric practice towards CS for breech. However, the controversy, criticisms and follow-up studies which ensued are a fascinating social study in themselves. The controversy created a vital dialectic in the search for the truth of how we should organise obstetric services.

Cochrane systematic reviews 2003 and 2011

The Cochrane trial register contains three randomised trials in this area. The meta-analysis¹² contains 2396 patients and given that most of the data were from the Term Breech Trial, the results showed the same two-thirds reduction in perinatal and neonatal mortality and serious morbidity in the planned CS group. Interestingly, the highest reduction in mortality was in countries with already low mortalities, such as the UK.

However, the meta-analysis did show that planned CS was associated with increased short-term maternal morbidity (RR 1.29, 95% CI 1.03–1.61) although three months after delivery, the women allocated to CS reported less urinary incontinence (RR 0.62, 95% CI 0.41–0.93) and less perineal pain although more abdominal pain.

Vitality, at two years there were no differences in the combined outcome 'death or neurodevelopmental delay' and maternal outcomes at two years were also similar.¹³ This important fact is discussed later under 'Controversy'.

In subgroup analysis, the perinatal mortality, neonatal mortality/serious neonatal morbidity was still halved (RR 0.49, 95% CI 0.26–0.91) even after the exclusion of women with prolonged labours, inductions or augmentations, footlings or the protocol violation of no experienced obstetrician being present.¹² Another subgroup analysis based on actual mode of delivery found that adverse perinatal outcomes were least with

CS before labour, then increased progressively with CS in early labour, later labour and vaginal birth.¹⁴ Subgroup analysis has well-known methodological limitations (as trials are not designed to answer the questions fished out in later retrospective analyses) and care should be taken in drawing confident conclusions from this type of secondary analysis.¹⁵

Cost effectiveness

A policy of planned CS was associated with lower healthcare costs in countries with low perinatal mortalities (mean difference of \$877 Canadian). Vitality, however, this did not include the future costs which may be associated with a scarred uterus e.g. likelihood of repeat CS, risk of uterine rupture and its consequences, which limits the value of the cost analysis.¹²

This has been presented as a powerful set of arguments to support a policy of recommending planned CS for a woman found to be breech in the antenatal setting. It is harder to know how this can be extrapolated to other settings, such as initial diagnosis of breech in labour, preterm breech and twins.

The controversy: obstetric dialectics

Enormous controversy followed these publications in the obstetric world. The two-year follow-up showing no difference in the combined outcome 'death or neurodevelopmental delay' was entirely unexpected, and suggested there was no real long-term benefit of CS over vaginal birth.^{3,13} The higher number of deaths in the vaginal birth group was balanced by the higher number of delayed infants in the CS group. Those neurologically delayed infants in the CS group had appeared healthy in the perinatal morbidity figures. This confirms the long-known fact that early neonatal morbidity is not a good predictor of long-term disability.

Also, although the combined outcome was a primary outcome determined prior to starting the trial, one must be careful of making a value judgement and equating a developmentally delayed infant with a baby which has died.

Likewise the apparent cost effectiveness of planned CS did not include the forward costs of the scarred uterus (e.g. increased likelihood of repeat CS, placenta accreta, uterine rupture, etc.), leading RCOG to advise the uncertainty to be communicated to women when supporting them in making their birth choices by the time the 2006 guideline was published.^{1,12}

The trial was heavily criticised for its protocol violations (e.g. experienced obstetricians were not always in attendance, some breeches were footling which should have been excluded, many women were recruited in active labour and there was large institutional variation in the standards of care), although the subgroup analyses (which have methodological limitations) refuted this to some extent.^{3,16-18}

The trial was also criticised for not requiring ultrasound assessment of the baby, to exclude fetal growth restriction and macrosomia, to assess the attitude for exclusion of stargazers (see below) or to confirm breech type. Three per cent of

the babies in the trial were actually cephalic. Seven out of 16 perinatal deaths were due to undiagnosed fetal growth restriction. Continuous EFM was not required by the trial protocol and only one third of the babies had it. Of the 18 babies with serious early neonatal morbidity that were followed up, 17 of them were neurologically normal at 2 years and one died of congenital subglottic stenosis, a complication not obviously related to the mode of delivery.

In fact, at 2 years of age, the only significant difference in infant outcome was fewer 'medical problems in the past several months' in the vaginal birth group (15% vs 21%, $p = 0.02$). The neonatal immune system is stimulated by labour, and there may be causal relations between absence of labour and later allergic and auto-immune disease.^{19,20} In the trial, women had a 97 per cent chance of having a neurologically normal 2-year-old, regardless of planned mode of birth. Those randomised to a trial of labour had a 6 per cent absolute lower chance (or 30 per cent relative risk reduction) of having a 2-year-old child with fewer 'medical problems in the last few months', consistent with the idea that labour confers benefits on the child's immune system.

There were calls for the authors to publish formal withdrawal of their conclusions, on the basis of the methodological critique. Others criticised the fact that the *Lancet* had fast-tracked the paper through its peer review process, thus invalidating the 'sanctity' of the peer-review process.¹⁷ The fast track was justified by the *Lancet* on the basis of the mortal significance of the authors' conclusions, but they were accused of doing so against the advice of some of their own peer reviewers.

By 2012, some Australian obstetricians were calling for the early criticisms of the trial to be revisited as the first maternal deaths were now being reported from the complications of the original CS for the subsequent pregnancies.¹⁸

There is a strong argument that in units where vaginal breech is common practice, and where strict criteria are rigorously applied antenatally and during labour, vaginal breech birth is a safe option. A prospective cohort study tested this, recruiting 2526 women with planned vaginal deliveries where 71 per cent successfully had a vaginal birth and the neonatal morbidity and mortality was only 1.60 per cent (95% CI 1.14–2.17), much lower than the 5 per cent in the Term Breech Trial and not significantly different to the planned section group.²¹

THE SHORT- AND LONG-TERM RISKS OF CAESAREAN SECTION

In popular belief (as well as doctors who are not obstetricians) CS is a safe, simple operation, almost like going to the hairdressers. However, women must be made aware of the risks of haemorrhage, transfusion, sepsis, visceral injury and 'returns to theatre' in the short term as well as the psychosocial and parenting implications of longer recovery times. CS for breech increases the likelihood of having another CS in subsequent pregnancies, and repeat sections are surgically more complex with risks of placenta accreta with catastrophic haemorrhage,

obstetric hysterectomy, uterine scar rupture, cerebral palsy and maternal death.^{22–26}

THE WOMAN ALREADY IN LABOUR

EBM

The RCOG guideline conclusions:

- Women should be informed that planned CS carries a reduced perinatal mortality and early neonatal morbidity for babies with a breech presentation at term compared with planned vaginal birth.
- Women should be informed that there is no evidence that the long-term health of babies with breech presentation at term is influenced by how they are born.
- Women should be advised that planned CS for breech carries a small increase in serious immediate complications for them compared with planned vaginal birth.
- Women should be advised that the long-term effects of planned CS for term breech on future pregnancy outcomes for them and their babies are uncertain.

Enabling informed choice is more challenging where a woman is diagnosed with breech for the first time whilst she is in labour. Pain, analgesia and the labour process itself produce cognitive distraction such that choices may not be made that would have been made in the cold seat of an antenatal clinic. Advice as to mode of delivery will be based on an assessment of her wishes (using the three-domain decision model described above where possible), her gestation, parity, previous labour performance, fetal wellbeing and any underlying cause for breech. The rate of progress of labour will also be a factor.

Care needs to be taken in extrapolating the recommendations to a woman with a breech in antenatal clinic, to a woman with a breech already progressing in labour. The risks of CS in labour are higher than the risks of a planned CS. Subgroup analysis from the Term Breech Trial based on actual mode of delivery found that adverse perinatal outcomes were least with CS before labour, then increased progressively with CS in early labour, later labour and vaginal birth.¹⁴ Furthermore, the risks of a CS at or near full dilatation (second-stage CS) are particularly higher than at other times, and this needs to be weighed against the risk of vaginal breech birth and the skills available.^{23–25}

THE PRETERM BREECH

The current research evidence on the term breech baby does not readily extrapolate to the preterm breech, where the baby is smaller, the risks are different and caesarean may need to be by the more complex classical method rather than lower segment (especially before 28 weeks). With a higher mortality for

preterm babies, CS may also needlessly compromise a woman's future pregnancies.

The current RCOG guidelines advise that the mode of delivery for preterm labour should be discussed with the woman and her partner but that routine CS is not advised unless there are other factors.¹ While there are retrospective cohort study data showing better outcomes after CS, even the authors themselves are reluctant to attribute this to the mode of delivery as there are other sources of bias in this type of study. Poor neonatal outcomes relate more to the complications of prematurity than to vaginal birth.

On current evidence, the proven benefits to the preterm baby are with use of antenatal steroids, consideration of maternal magnesium sulphate infusion for fetal neuroprotection and delayed cord clamping, rather than mode of delivery.

On the other hand, if the woman is not in labour but there is a strong indication for delivery of the preterm baby, CS would then become appropriate.

Head entrapment is uncommon, but is a significant fear for the obstetrician assisting a woman with preterm vaginal breech birth. The smaller baby can deliver while the cervix is not completely dilated and the head can get stuck above the cervix. Gentle insertion of a finger into the cervix can frequently flex the head to bring a smaller diameter through the cervix. Alternatively, Durer's incisions on the cervix can be performed to release the head. With appropriate analgesia, the fingers of the left hand can gently grasp the cervix whilst the right hand inserts scissors to make cuts at the 4 and 8 o'clock positions, and these can be sutured postpartum if they continue to bleed.

Management points for preterm breech in labour

- What has caused labour? (e.g. abruption, amniorrhesis, sepsis, cervical weakness, polyhydramnios);
- Documentation and discussion of options;
- Neonatal counselling in anticipation of outcomes;
- Tocolysis to allow maternal steroid benefits;
- Antenatal steroids;
- Magnesium sulphate for fetal neuroprotection;
- Analgesia (e.g. epidural may allow obstetric manoeuvres such as Durer incisions, and the softened pelvic floor may be protective to the immature skull as well as preventing maternal pushing before full dilatation);
- Gentle handling during delivery to minimise bruising, visceral and intracranial injury;
- There may be a benefit to the baby of being delivered within the membranes (*en caulle*);
- If CS is required, for smaller babies before 28 weeks, the lower segment may be empty or unformed, and consideration should be given to the low classical section, or J- or T-shaped uterine incisions. This minimises the traction and trauma to the fragile preterm baby. The abdominal incision (as opposed to the uterine incision) however is usually still low transverse;

- Cord clamping should be delayed by a timed 30 seconds, with the baby held dependent in a birth bag to prevent evaporation and heat loss;
- Senior paediatrician present at delivery.

FIRST TWIN IS BREECH

In assisting the woman to make an informed choice, it seems reasonable to extrapolate the research findings from singleton breech to twins where the first twin is breech.¹ This would be to advise the woman of the reduced perinatal complications for the first baby, but the increase in short-term complications for her, and less certain longer-term issues for future pregnancy.

There is a traditional anxiety about breech/cephalic twin pairs 'interlocking' where the after-coming head gets stuck above the second twin's head. This is rare (around 1 in 817 where twin I is breech) and is signalled by slow descent of the trunk. It is treated either by external displacement of twin II head upwards, or by immediate CS. It is an argument for performing breech/cephalic twin deliveries in an operating theatre rather than a labour suite.

SECOND TWIN IS BREECH

For the 40 per cent of twins where the first twin is a cephalic presentation but the second twin is non-vertex, current guidelines do not support routine CS.¹ Various cohort studies and small randomised trials have shown no benefit to CS, although these are statistically under-powered to show small but significant differences.

Where the second twin begins as non-vertex, once the first baby has delivered, the second twin often turns to cephalic spontaneously. Alternatively, the obstetrician can perform ECV in uterine diastole, followed by amniotomy at the height of a contraction. Many practitioners prefer to perform internal podalic version, by grasping the feet through the membranes then performing amniotomy at the height of contraction (to minimise the risk of cord prolapse) followed by breech extraction. This is probably the only agreed indication for active breech extraction in UK practice.

PRACTICAL SKILLS

External cephalic version

The RCOG guidelines advise that women with a breech baby should be offered ECV as it lowers their chances of having a CS.²⁷ For every six women attempting ECV, it will prevent one of them having a CS. About 50 per cent of ECV attempts are successful in turning the baby, but the baby can turn back again. Also women following successful ECV have a higher rate of obstetric intervention than women who have not had ECV.

ECV should be offered from 36 weeks' gestation in nulliparous women and from 37 weeks in multiparous women.

Conduct of external cephalic version

- Informed consent to include discussion of 50 per cent likelihood of success and small risk of placental abruption or cord entanglement (of the order of 0.5 per cent). They should also be advised that it can be uncomfortable but that they can stop any time they wish. Ideally, this information would be provided in a written form.
- Ultrasound to confirm breech, type of breech and position of spine as well as to exclude placenta praevia, fibroids or fetal anomaly.
- It is common practice to obtain 30 minutes of CTG to assess fetal wellbeing.
- Lay patient with head slightly below feet to allow breech to disengage. Left lateral tilt or a wedge can be used to prevent aorto-caval compression.
- Terbutaline can be given to aid uterine relaxation as this improves the chances of success. The woman should be warned that it can cause tachycardia and feelings of anxiety.
- A mixture of nitrous oxide and air can be used to aid relaxation.
- The obstetrician should elevate the breech from the pelvis and attempt to flex the baby by gently pushing the head forwards towards the breech.
- Then a forward roll should be attempted. Sometimes the baby just has to be flexed and held for a kick to cause it to turn itself.
- If this fails, a backward flip can be attempted.
- If this fails, the fetal heart should be checked followed by a 30-minute CTG. The mother should be advised to attend if there is bleeding or amniorrhesis.
- A discussion needs to follow as to the alternatives of vaginal breech birth or CS, and full documentation is essential.
- Anti-D prophylaxis if appropriate.

Absolute contraindications to ECV

- Where caesarean is necessary for other reasons;
- Antepartum haemorrhage within 7 days;
- Abnormal CTG;
- Major uterine anomaly;
- Ruptured membranes;
- Multiple pregnancy (except after delivery of first twin).

Conditions such as fetal growth restriction, pre-eclampsia and previous CS are not absolute contraindications, but many obstetricians would not perform ECV in these situations.

Conduct of assisted vaginal breech birth

Breech extraction vs assisted vaginal breech

Firstly, don't make the common error of confusing *assisted vaginal breech delivery* with *vaginal breech extraction*,^{5,6} as these are very different techniques.

Vaginal breech extraction is when you apply traction on the baby to pull it down, either by fingers in the flexed groin, or pulling on a foot or feet. In the UK this is not recommended for a vaginal breech except for a second twin, usually after podalic version. The worry is that traction can cause the trunk and neck to de-flex (by the Moro reflex), making the baby look upwards ('stargazing') which would draw the highest cephalic diameter (mento-vertical) down and make delivery difficult.

Assisted vaginal breech delivery is when the natural process of labour including maternal effort causes flexion and descent of the baby, and the obstetric manoeuvres are only used to free the head and limbs. Traction is avoided almost completely, at least until after birth of the umbilicus.

Assessment criteria for assisted vaginal breech

Prior to assisting a vaginal breech birth, it is vital to consider the following criteria:¹

- Woman's choice based on accurate understanding of risks and benefits to herself and baby.
- Factors excluded which are likely to exacerbate mechanical difficulties e.g. placenta praevia, fibroids, hydrocephalus or myelomeningocele, pelvic disruption (e.g. childhood rickets).
- Fetal growth restriction is often associated with breech presentation. The associated placental insufficiency means the baby will be less likely to tolerate the cord compression associated with the later stages of breech delivery.
- Large babies may be more likely to benefit from CS e.g. estimated weight above 3800 g; diabetic macrosomia may also be associated with higher susceptibility to hypoxia.
- Extended ('frank') breech is easiest to deliver vaginally, followed by flexed ('complete') breech. Footling breech at term where hip and knee are both extended is probably best delivered by CS.
- Clinical pelvimetry should confirm adequacy of pelvis and help exclude fetopelvic disproportion.
- Previous obstetric history such as previous CS would usually preclude vaginal breech birth (although there are small cohort studies with largely successful outcomes).

Ultrasound prior to vaginal breech

The obstetrician assisting a vaginal breech birth should be appropriately trained in the use of ultrasound¹ for the following:

- Exclude placenta praevia and fibroids;
- Exclude macrosomia and fetal growth restriction;
- Identify type of breech;
- 'Stargazers' with hyperextended necks may have poorer outcomes (thought to be due either to nuchal cord, uterine anomalies or congenital iniencephaly);
- Estimated fetal weight can be calculated. Although there is no good evidence to support its use, and there is at least 15 per cent error in the estimate, many practitioners recommend CS if the estimate is above 3800 g, as per the RCOG guidelines.

Clinical pelvimetry

Many practitioners recommend clinical pelvimetry prior to vaginal breech to help exclude fetopelvic disproportion, but the evidence base is weak and the assessments are highly subjective.¹⁻⁴ X-ray and MRI pelvimetry have been extensively used in the past but studies have failed to show their usefulness in predicting vaginal birth or improving neonatal outcomes. A method of clinical pelvimetry is as follows.

- Ensure the woman understands the purpose, process and discomfort of pelvic assessment and freely gives consent.
- Remember to document the name and presence of the chaperone.
- Gently insert a finger in the vagina and palpate posteriorly up to the sacral promontory. The distance from the promontory to the lower surface of the pubic symphysis is the 'obstetric conjugate diameter'. It serves as a clinical approximation of the pelvic inlet (which cannot be directly measured clinically as it's the distance from the promontory to the upper surface of the pubic symphysis).
- It is held that the obstetric conjugate diameter should be more than 11.5 cm for successful vaginal breech. The obstetrician should know the length of his/her own forefinger to each knuckle and to the pollex–metacarpal angle. My own is 17.5 cm with 11.5 cm forefinger length, so if I can't reach the promontory, that is a good sign.
- From the promontory, the finger should turn towards the sacrum, and then palpate the depth of the sacral curve. Ideally the curve is deep and capacious rather than flat. (Take greater care if the rectum is full.)
- Turn the fingers towards the front and gently open them to palpate the ischial spines in the mid-pelvis, which should not be too prominent. If analgesia is appropriate (e.g. epidural), the intertuberous distance should accommodate a closed fist.
- Fingers facing the front, gently palpate the angle under the pubic symphysis. The ideal sub-pubic arch allows space for two fingers to be side by side unlike the android pelvis where the fingers are crushed into overlap.

Continuous EFM

The commonest avoidable cause of perinatal morbidity and mortality in breech has been identified as sub-optimal care in labour.^{1,3} For this reason, continuous EFM is recommended. Although FBS can be performed from fetal buttocks, the higher background risk for breech babies means that CS may be the better response to CTG abnormalities in breech labour.

Induction or augmentation of labour

Although there is no high-quality evidence to inform practice in the area of induction or augmentation, many experienced obstetricians worry that slow progress in labour may represent fetopelvic disproportion and the RCOG guideline advises against augmentation. IOL is supported by the RCOG guidelines 'where individual circumstances are favourable'. ACOG currently do not support the use of oxytocin either for

induction or augmentation, whereas the Canadian College supports oxytocin only for augmentation where there is uterine inertia.¹⁻⁴

Analgesia

There were arguments in the past in favour of epidural analgesia because it allowed obstetric manoeuvres to be performed with ease, such as Durer's incisions, forceps to the after-coming head, etc. It was also argued that the softer pelvic floor with the dense motor block common with older-style epidurals (which used more local anaesthetic than opioid) offered protection to the vulnerable fetal skull, particularly with preterm breech. Epidural may also prevent maternal pushing before full dilatation. In the absence of strong evidence to the contrary, the current RCOG guidelines recommend individualised discussion with each woman, offering the full range of analgesic options including spinal, epidural or pudendal block.

Timing of first and second stages of breech labour

Active labour is diagnosed when there are strong regular uterine contractions and the cervix is 4 cm or more dilated. Uterine contractions before this dilatation are part of the latent phase of the first stage of labour. The Term Breech Trial protocol allowed for normal progress to be anything more than 0.5 cm per hour. However, there are more recent data suggesting that progress from 5 cm to 10 cm should not be more than 7 hours.^{3,10,11}

Full dilatation is more difficult to diagnose with a breech presentation than cephalic, because the softer presenting part starts to descend through the cervix before full dilatation, and so an experienced practitioner should confirm full dilatation, trying to assess around the sides of the presenting part and above in case a rim of cervix is hiding there. Correct diagnosis is essential because timing the length of the second stage is an important criterion for good outcome. The Term Breech Trial allowed for a second stage of 3.5 hours. Based on this and later data, it seems reasonable to allow 90 minutes of passive second stage for the breech to descend and up to 60 minutes of active second stage, giving a maximum full second stage of 2.5 hours.^{3,10,11} If strict safety criteria are being applied, it would seem prudent to recommend CS if the baby has not delivered by this time, even if the breech is on the perineum (assuming accurate diagnosis of the onset of full dilatation).

Neonatology

Because breech babies frequently have low Apgar scores, a neonatologist of sufficient experience should be present at the birth.

Technique of assisted vaginal breech^{1,3,5,6,27}

- 1 Ensure again that the woman has made an informed choice which has been documented.
- 2 Perform ultrasound and clinical pelvimetry as above and discuss analgesia, continuous fetal monitoring and the indications for changing to CS (slow progress or CTG

abnormality). Discuss birth positions (most experience is with the lithotomy position) and what will happen at delivery in terms of waiting, pushing and assisting, and who will be present (anaesthetist, neonatologist, midwife, etc.).

- 3 The active first stage of labour should progress at 0.5–1 cm per hour with supportive coaching. Slow progress or CTG abnormalities should give strong consideration to CS given the higher background risk for breech babies.
- 4 At full dilatation, the traditional advice is patience and ‘Keep your hands off the breech until it’s climbing the perineum.’ Significant delay in descent in the second stage or significant CTG abnormalities should give strong consideration for CS as feto-pelvic disproportion and cord compression are risks. Otherwise, the appearance of the fetal anus at the perineum should be patiently awaited with uterine contractions and maternal effort alone.
- 5 Once the fetal breech is at the perineum, with her agreement, the woman is placed in the lithotomy position with some lateral tilt or a wedge to minimise aorto-caval compression. If there is no epidural, a pudendal block or perineal block can be inserted as appropriate.
- 6 If the perineum is being distended, an episiotomy can be performed with consent around now, taking care to avoid the fetal genitalia. There is an old argument to avoid episiotomy as the firm perineum encourages flexion of the baby, but selective episiotomy is supported by the RCOG guideline if thought to be appropriate.
- 7 The breech usually enters the pelvis with the inter-trochanteric diameter in the pelvic transverse (sacro-posterior) then rotates through 90° so the breech appears at the perineum in the sacro-lateral position. As descent occurs by uterine contraction and maternal effort, the breech usually rotates to the sacro-posterior position again as the shoulders enter the pelvis with the bisacromial diameter in the pelvic transverse. Although advice at this stage is ‘Keep your hands off the breech’, and no traction should be applied, it is acceptable to perform small rotational movements to help ‘get the back up’ to sacro-posterior.
- 8 Visceral injury is a real risk to breech babies, as are deep haematomas in thighs, calves and arms. Gentleness in handling the baby is essential, and the rotational movement should be applied by grasping the buttocks with the thumbs against the bony sacrum. With larger hands it is tempting to grasp round the abdomen and kidneys but this can cause perinephric haematomas and adrenal trauma (Fig. 57.1).
- 9 Spontaneous delivery of the buttocks and trunk should continue to the level of the umbilicus when many practitioners advise gently pulling down a loop of cord to protect against compressive cord injury. Others advise against handling cord as it may cause vasospasm. Each situation must be judged on its own merits.
- 10 For the extended breech climbing the perineum (once the umbilicus has delivered), two fingers can be slid along

Fig. 57.1 Fingers grasp sacrum not kidneys (with the assistance of Ruth Cavey-Wilcox and Sami Saba)

the posterior surface of the fetal thigh towards the popliteal fossa. Gentle pressure along the thigh causes slight abduction of the hips along with gentle pressure on each popliteal fossa to allow flexion of the knee in its natural plane of movement which brings the foot down, expediting delivery (Pinard’s manoeuvre). Gentleness and natural planes of movement will help avoid femoral fracture and hip dislocation.

- 11 Now the legs and trunk have delivered, the breech is allowed to hang on the perineum until the lower border of the fetal scapula is seen under the pubic arch.
- 12 This is a critical stage because the cord is now delivered and at risk of compression as the head enters the pelvis. Ideally, delivery from now should occur within 3 minutes. This is more time than it may seem, and sufficient for allowing calm progression through the appropriate delivery manoeuvres. The obstetrician should be aware of the risk of panic at this stage, because traction and firm grasping of the abdomen or limbs should be avoided. Traction can cause the head to de-flex or the arms to extend, making the delivery all the more fraught. Remind yourself that the baby will deliver, once all the practised moves are made, and it’s important to portray calm to the patient and delivery team so that everyone cooperates and the mother feels safe and does not tense up and lose control.
- 13 When the scapula is seen and the baby’s back is up, slide two fingers up the baby’s spine, then laterally over the fetal shoulder and down the arm to splint the humerus and gently push the fetal arm over the chest and down in a ‘windscreen wiper’ movement for delivery of the hands. Gentleness and natural planes of joint movement will minimise the risk of humeral fracture and shoulder dislocation. The baby can be rotated 90° to either side to make this easier, but the abdomen should not be grasped, only the buttocks with thumbs pressing on the hard sacrum. If the baby is slippery and hard to rotate, a drape can be used to wrap the baby which also helps keep it warm (Fig. 57.2).

- 14 The main issues around delivery of the fetal head are promoting and maintaining flexion to minimise arrest of the after-coming head and gentle, slow delivery to minimise the risk of reverberation injury from sudden compression–decompression of an unmoulded head. With the head in flexion, the smallest diameter of the fetal head is brought down (the sub-occipito-bregmatic diameter, same as in occipito-anterior vertex births). De-flexion will increase the diameter to the sub-fronto-occipital diameter (same as in occipito-posterior cephalic births) and extension will bring the widest diameter into play, the mento-vertical.
- 15 The trunk, arms and legs have been delivered and can be supported by the obstetrician while the trunk is allowed to hang on the perineum, allowing flexion of the head. When the nape of the neck (hairline) is seen under the pubic arch, the head can be delivered by one of three methods, all of which should be gentle and slow. The RCOG guideline states there is no evidence to favour one over another although concerns have been expressed about the Burns-Marshall method where hyperextension of the neck can be dangerous. The three methods are:
- *Mauriceau-Smellie-Veit (MSV) manoeuvre*: the baby's trunk is supported along the forearm of the obstetrician who pushes the fingers of the supporting arm against the fetal malar bones to pull the head into flexion. The other hand can be applied to the nape of the neck to increase the flexion. Traditionally, a finger was placed in the fetal mouth to cause flexion, but this can result in jaw dislocation unless it is done very gently. This two-handed flexion manoeuvre splints and protects the cervical spine, and the head is moved towards the mother's back rather than her feet to allow a controlled delivery of the head (Fig. 57.3).
 - *Forceps to the after-coming head*: some obstetricians favour this method because they believe the cradling effect of the forceps protects the head against compression–decompression injury as well as allowing flexion and controlled descent. A scrubbed assistant is

Fig. 57.3 Flexing the head in MSV manoeuvre (with the assistance of Ruth Cavey-Wilcox and Sami Saba)

required to hold the baby's trunk and legs just above the horizontal plane, taking care not to over-extend the neck. The forceps are applied by wandering them over the head in the 4 and 8 o'clock positions with the other hand guiding the tips and protecting the maternal tissues. Any long-handled forceps can be used (including Kiellands), although Piper's forceps were specifically developed for this purpose if they are available (I have never seen them in the UK). Gentle traction is applied during a contraction with maternal effort. The direction of traction is towards the floor until the chin and mouth are seen, then the forceps and trunk are raised upwards for the head to be delivered.

- *The Burns-Marshall method*: a scrubbed assistant wraps a drape round the baby's trunk and legs to improve grip and keep baby warm. The legs and trunk are gently swept upwards, extending the neck. Great care is required not to hyperextend the neck as such concerns have been voiced about this method. This allows the head to flex within the pelvis and effect delivery. I personally have very little experience of the method.

Managing the complications of assisted vaginal breech

The following manoeuvres should be practised on models until deeply internalised for their instinctive use in emergency.

- 1 *Delay in head entering the pelvis*: if the trunk and legs have delivered but the head does not engage, the RCOG guideline recommends suprapubic pressure by an assistant to assist flexion of the head (Bracht's manoeuvre) (Fig. 57.4). The buttocks can be grasped and used to

Fig. 57.4 Suprapubic pressure in Bracht manoeuvre (by courtesy of Dr Nargis Pirie)

Fig. 57.5 Flexion and descent with MSV manoeuvre (with the assistance of Ruth Cavey-Wilcox and Sami Saba)

rotate the baby sideways at the same time, to allow the long axis of the head to enter the pelvis in the transverse or oblique diameter. Failing this the MSV manoeuvre can be used as described above, but this time with the hand inside the birth canal (Fig. 57.5).

- 2 *Arrest of the after-coming head:* if the trunk, legs and arms have delivered but the head has arrested despite the manoeuvres already described, the RCOG guideline recommends consideration of Durer's cervical incisions if the cervix is not completely dilated, or consideration of symphysiotomy or even replacing the trunk and performing CS, all of which have been successfully described.
- 3 *Nuchal arm or arms:* if the arms are not in their usual position of being flexed across the fetal chest or face, they may be trapped behind the neck. It is rare for this to be both arms. The buttocks should be grasped (a drape helps with this) and the baby rotated in the direction of the trapped hand. This 'unwinds' the arm from the neck and allows delivery as above. The manoeuvre can be reversed to 'unwind' the other arm.
- 4 *Extended arms:* Lovset's manoeuvre²⁸ involves grasping the buttocks, exerting gentle downwards traction and rotation with the back in the anterior oblique position, then flexing the baby laterally by lifting the trunk upwards to bring the posterior shoulder into the pelvis. The baby is then gently rotated to bring that posterior shoulder anteriorly under the symphysis where the arm can then be delivered. This is then reversed to deliver the other arm.
- 5 *Posterior rotation of the trunk:* occasionally, the baby has not been kept with the back upwards, perhaps because of rapid delivery. The head is then in an occipito-posterior position. It can sometimes be rotated to occipito-anterior (taking great care not to place rotational strain on the cervical spine) where delivery can be completed as normal. If it cannot be rotated, a reverse Prague

manoeuvre can be used where the right hand lifts the baby's feet upwards and forwards to flex the baby, and the left hand cradles beneath the shoulders pulling gently downwards to flex the head and effect delivery.
