WILEY-BLACKWELL

Schiff's Diseases of the Liver

Companion website

Purchasing this book entitles you to access to the companion website:

www.schiffsdiseasesoftheliver.com

The website includes:

- Eighty multiple choice questions of the standard used in ABIM board exams in gastroenterology, to allow the user to self-assess their clinical knowledge
- All 450+ figures from the book in a high-quality, fully transportable and downloadable electronic format
- High-quality video clips of a variety of surgical procedures
- 35 case studies featuring real-life clinical scenarios.

How to access the website:

1. Carefully scratch away the top coating on the label on the inside front cover of the book to reveal PIN code.
2. Go to www.schiffsdiseasesoftheliver.com to register your PIN and access the site.

We dedicate this eleventh edition of *Diseases of the Liver* to Dr Harvey Alter, who has been an outstanding leader in the development of knowledge regarding viral hepatitis. Dr Alter is a gifted scientist, physician, teacher, and mentor. His abilities to create and transmit information with clarity and enthusiasm have inspired and enriched us all.

In addition, we wish to recognize the tremendous contributions to the field of hepatology by the late Dr Baruch Blumberg.

We further dedicate this edition to our wives Dana, Shirley, and Ann for their continuing support of our endeavors.

It has been an honor and a privilege for us to participate in the creation and editing of *Diseases of the Liver*.

Contents

List of Contributors, viii

Foreword, xii

Preface, xiii

Part I Overview: Clinical Fundamentals of Hepatology

1 History Taking and Physical Examination for the Patient with Liver Disease, 3
Norton J. Greenberger

2 Laboratory Tests, 17
H. Franklin Herlong and Mack C. Mitchell Jr

3 Liver Biopsy and Laparoscopy, 44
Alyson N. Fox, Lennox J. Jeffers, and K. Rajender Reddy

4 Noninvasive and Invasive Imaging of the Liver and Biliary Tract, 58
Kunal Jajoo, Kevin Mennitt, and Ira Jacobson

Part II General Considerations

5 Physioanatomic Considerations, 89
Ian R. Wanless

6 Bilirubin Metabolism and Jaundice, 120
Allan W. Wolkoff and Paul D. Berk

7 Hepatic Histopathology, 152
Zachary D. Goodman

8 Mechanisms of Liver Injury, 216
Harmeet Malhi and Gregory J. Gores

9 Hepatic Manifestations of Systemic Disorders, 232
Stuart C. Gordon and Hemal K. Patel

10 Hepatobiliary Complications of Hematopoietic Cell Transplantation, 255
Josh Levitsky and Natasha Walzer

11 The Liver in Pregnancy, 271
Yannick Bacq

Part III Consequences of Liver Disease

12 Hepatic Fibrosis, 297
Scott L. Friedman

13 Preoperative Evaluation of the Patient with Liver Disease, 316
Lawrence S. Friedman

14 Portal Hypertension: Nonsurgical and Surgical Management, 326
Hitoshi Maruyama and Arun J. Sanyal

15 Renal Complications of Liver Disease and the Hepatorenal Syndrome, 362
Florence Wong

16 Pulmonary Manifestations of Liver Disease, 381
Rajan Kochar and Michael B. Fallon

17 Ascites and Spontaneous Bacterial Peritonitis, 393
Bruce A. Runyon

18 Hepatic Encephalopathy, 421
Ravi K. Prakash and Kevin D. Mullen

19 Acute Liver Failure, 445
Anne M. Larson

Part IV Cholestatic Disorders

20 Primary Sclerosing Cholangitis, 477
Douglas L. Nguyen, Nicholas F. LaRusso, and Konstantinos N. Lazaridis

21 Primary Biliary Cirrhosis, 490
Stephen P. James

22 Autoimmune Hepatitis, 508
Edward L. Krawitt

Part V Viral Hepatitis

Overview, 519
Eugene R. Schiff

23 Hepatitis A and E, 521
Joshua Watson and Maria H. Sjogren

24 Hepatitis B and D, 537
Anna S.F. Lok and Francesco Negro

25 Hepatitis C, 582
Jama M. Darling, Stanley M. Lemon, and Michael W. Fried

Part VI Alcohol and Drug-induced Liver Disease

Overview, 653
Willis C. Maddrey

26 Alcoholic Liver Disease, 657
Srinivasan Dasarathy and Arthur J. McCullough

27 Drug-induced Liver Disease, 703
Shivakumar Chitturi and Geoffrey C. Farrell

28 Mechanisms of Drug-induced Liver Injury, 784
Paul B. Watkins

Part VII Genetic and Metabolic Disease

29 Wilson Disease, 805
Michael L. Schilsky and Anthony S. Tavill

30 Hemochromatosis and Iron Storage Disorders, 825
Bruce R. Bacon and Robert S. Britton

31 Alpha-1 Antitrypsin Deficiency, 845
David H. Perlmutter

32 Nonalcoholic Fatty Liver Disease, 868
Stephen H. Caldwell, Curtis K. Argo, and Abdullah M.S. Al-Osaimi

Part VIII Vascular Diseases of the Liver

33 Vascular Diseases of the Liver, 911
Ranjeeta Bahirwani, Mark A. Rosen, and Thomas W. Faust

34 The Liver in Circulatory Failure, 924
Santiago J. Munoz, Jonathan M. Fenkel, and Kiley Kolb

Part IX Benign and Malignant Tumors; Cystic Disorders

35 Benign Tumors, Nodules, and Cystic Diseases of the Liver, 937
Adrian M. Di Bisceglie and Alex S. Befeler

36 Hepatocellular Carcinoma, 978
Alejandro Forner, Carmen Ayuso, and Jordi Bruix

37 Surgical Options in Liver Cancers, 990
B. Daniel Campos and Jean F. Botha

Part X Infectious and Granulomatous Disease

38 Amoebic and Pyogenic Liver Abscesses, 1009
Marco A. Olivera-Martínez, and David Kershenobich

39 Parasitic Diseases, 1017
Michael A. Dunn

40 Granulomas of the Liver, 1034
James H. Lewis

41 Hepatobiliary Manifestations of Human Immunodeficiency Virus, 1060
Marie-Louise Vachon, Ponni Perumalswami, and Douglas T. Dieterich

Part XI Elements of Liver Transplantation

Overview, 1083
Michael F. Sorrell

42 Selection and Timing of Liver Transplantation, 1085
Richard B. Freeman Jr.

43 Immunosuppression: The Global Picture, 1096
Russell H. Wiesner

44 The First Six Months Following Liver Transplantation, 1110
Rajender Reddy and Manuel Mendizabal

45 Long-term Management of the Liver Transplant Patient, 1124
Timothy M. McCashland

46 The Liver Transplant Procedure, 1137
Bijan Eghtesad and John J. Fung

47 Recurrent Disease Following Liver Transplantation, 1152
Kymberly D.S. Watt and Marie A. Laryea

48 The Role of Retransplantation, 1172
Peter L. Abt and Kim M. Olthoff

49 Controversies in Liver Transplantation, 1183
James F. Trotter

Appendix Multiple Choice Answers, 1199

Index, 1209

Companion website

Purchasing this book entitles you to access to the companion website:

www.schiffsdiseasesoftheliver.com

The website includes:

- Eighty multiple choice questions of the standard used in ABIM board exams in gastroenterology, to allow the user to self-assess their clinical knowledge
- All 450+ figures from the book in a high-quality, fully transportable and downloadable electronic format
- High-quality video clips of a variety of surgical procedures
- 35 case studies featuring real-life clinical scenarios.

How to access the website:

1. Carefully scratch away the top coating on the label on the inside front cover of the book to reveal PIN code.
2. Go to www.schiffsdiseasesoftheliver.com to register your PIN and access the site.

Foreword

At the start of my clinical training three decades ago, the study of hepatology was dominated by two academic phenotypes, including investigators devoted to metabolic biochemistry and bilirubin, and astute diagnosticians capable of artful and accurate prognostication but who possessed few tools to alter clinical outcomes. Fear of bile acid metabolism almost kept many of us out of the laboratory, but the promise of better tools to come was alluring. The progress has been remarkable on both fronts. Transplantation, molecular diagnostics, effective antiviral therapies, and sophisticated supportive treatments have altered the landscape dramatically. Further, advances in understanding the human genetic factors responsible for the substantial person-to-person differences in pharmacokinetics, response to interferon, and susceptibility to liver diseases foreshadows the coming era of personalized hepatology based on a prospective assessment of risk.

Against the scope and pace of these changes, it has been argued that the traditional role of the textbook is challenged by electronic media. An authoritative textbook, however, has a different function. Under the best of circumstances, a textbook provides history, context, and the leavening ability to integrate advances and put them in their proper perspective. This perspective is essential to understanding the implications of science for both physiology and clinical care. It also allows for appropriate humility, since the scientific news of the day fails to withstand scrutiny more often than we would like to admit.

Given these considerations, the timeliness and authority of this new edition of *Schiff's Diseases of the Liver* is remarkable. This is a classic text based solidly in the biochemical origins of our discipline. It also succeeds masterfully in providing the depth and perspective that is essential to students at any stage of their careers. This results in large part from the careful selection of chapters with broad thematic relevance, and to the equally critical selection of authors who are the best in the field. The result is an authoritative statement of where we are today. Beyond the appeal to trainees, this text is one that targets important issues in clinical care. Accordingly, clinicians can use this textbook with confidence to inform and support decisions in patient care. Beyond that, the scientific basis for the presentations assures that investigators also can rely on *Schiff's* for keeping pace with the broader advances in hepatology based on appropriate cell and molecular biology.

The chapters are organized and comprehensive. Opening sections on Clinical Fundamentals, General Considerations, and Consequences of Liver Disease provide a foundation for clinical assessment, pathologic diagnosis, and imaging. The chapter on mechanisms of liver injury has broad implications for the authoritative chapters on the major complications of liver injury that follow, including portal hypertension, hepatorenal syndrome, peritonitis, and encephalopathy. In each case the emphasis on the physiologic basis for management is emphasized. The subsequent sections are organized around more specific groups of disorders, including Cholestasic Disorders, Viral Hepatitis, and Alcohol and Drug-induced Liver Disease. The section on Genetic and Metabolic Disease has benefited from considerable changes as required by the scientific and clinical advances in that area. Finally, emphasis is placed on the emerging challenges in the care of patients with liver tumors and liver transplantation. Collectively, the authors include both future and established leaders of hepatology, and they are to be congratulated for a comprehensive yet disciplined assessment of the state of our field.

The challenges in hepatology are still substantial. Clinical manifestations range from isolated and clinically silent laboratory abnormalities to dramatic and life-threatening complications of liver failure. The incidence of cirrhosis is increasing, but the best estimates suggest that up to 40% of those so affected are without symptoms, resulting in long delays in diagnosis and treatment. The result is unusually high human and economic costs. This new edition of *Schiff's Diseases of the Liver* is solidly grounded in the tradition of the investigators and diagnosticians who have advanced our discipline so far, and provides a timely and comprehensive statement of the current art to prepare a new generation to make advances in the future.

J. Gregory Fitz, MD
Provost and Dean
UT Southwestern Medical School, Dallas, TX

Preface

This eleventh edition of *Schiff's Diseases of the Liver* and a retrospective review of the previous editions attests to the remarkable advances in our understanding of the pathogenesis and treatment of liver diseases. New treatments, particularly of chronic viral hepatitis, are interrupting the progression towards cirrhosis and reducing the risk for hepatocellular carcinoma. An accurate history, physical examination, and standard laboratory chemistries will still make the diagnosis in the majority of patients with hepatobiliary disorders. Worldwide, liver biopsy is gradually being replaced by noninvasive diagnostic modalities. However, histopathologic examination is paramount in establishing the type and degree of liver injury. Antifibrotic therapies are evolving and clinical trials have been initiated. Improvement in the management of acute liver failure and complications of cirrhosis have allowed for more patients to be salvaged with liver transplantation.

There remain a significant number of patients with idiopathic acute and chronic liver disease where the etiology has not yet been established. Autoimmune hepatitis commonly overlaps with both intrahepatic and extrahepatic biliary disease. Successful treatment of primary sclerosing cholangitis is a challenge for the future. The development and implementation of vaccinations for hepatitis A, B, and more recently E, will continue to reduce the incidence of acute viral hepatitis. Yet the spectrum of molecular variants within the sphere of hepatitis C has frustrated the successful development of a hepatitis C vaccine.

Proteonomics and genomics are becoming germane to understanding the pathogenesis of liver disease, particularly drug-induced liver disease. Comorbidities of steatohepatitis, both alcoholic and non-alcoholic, together with genetic predispositions including heterozygous states for alpha-1 antitrypsin deficiency and iron overload are often involved in the pathogenesis of liver disease. With increased life expectancy and an older aged population, cardiac disease and ischemic hepatitis are becoming more prevalent. Earlier detection of hepatocellular carcinoma coupled with more accurate radiologic examination and newer therapeutic options have salvaged many of these patients. As advances in the prevention and treatment of liver disease evolve, the last resort for those with decompensated liver disease remains liver transplantation. Improvement of tolerance for the transplanted liver is a major focus of research.

This eleventh edition of *Diseases of the Liver* is a readily accessible and valuable resource reflecting the talent and expertise of outstanding authors.

PART I

Overview: Clinical Fundamentals of Hepatology

CHAPTER 1

History Taking and Physical Examination for the Patient with Liver Disease

Norton J. Greenberger

Division of Gastroenterology, Hepatology and Endoscopy, Brigham and Women's Hospital, Boston, MA, USA

Key concepts

- In the care of patients with jaundice, a careful history, physical examination, and review of standard laboratory tests should allow a physician to make an accurate diagnosis in 85% of the cases.
- The triad of findings of splenomegaly, ascites, and an increased number of venous collateral vessels on the anterior abdominal wall indicates a diagnosis of portal hypertension.
- The presence of two physical findings (ascites and evidence of portasystemic encephalopathy (asterixis)) and two laboratory findings (hypoalbuminemia (<2.8 g/dL) and a prolonged prothrombin time (international normalized ratio >1.6)) indicates a diagnosis of cirrhosis of the liver.
- Three physical findings (parotid enlargement, gynecomastia, and Dupuytren contracture) indicate that a patient is almost certainly consuming excessive amounts of alcohol.
- In adult patients with a new onset of jaundice, ten disorders account for 98% of the ultimately established diagnoses. They include decompensated chronic liver disease, alcoholic hepatitis, gallstones, malignancy, sepsis/abnormal hemodynamics, drug-induced liver disease, hemolysis (sickle cell anemia), postoperative jaundice, viral hepatitis, and primary biliary cirrhosis and primary sclerosing cholangitis. By the time patients with metastatic liver disease have jaundice, the diagnosis should be obvious because the liver has been extensively replaced by tumor.

Jaundice is a common presentation among patients with liver and biliary tract disease. The terms *jaundice* and *icterus* are used to designate skin and eyes appearing yellow resulting from the retention and deposition of biliary pigments (biliary monoglucuronides and diglucuronides). Although bilirubin stains all tissue, jaundice is most evident in the sclerae, face, and trunk. Jaundice is most commonly caused by parenchymal liver diseases such as viral hepatitis or cirrhosis, obstruction of the extrahepatic biliary tree as in choledocholithiasis and carcinoma of the pancreas, and less commonly, disorders associated with brisk hemolysis such as sickle cell anemia. The late Franz Ingelfinger stated in 1958 that the cause of jaundice can be identified in approximately 85% of patients after a careful study of the history and the performance of a physical examination and review of standard laboratory data. The same applies today. Box 1.1 lists specific questions to ask in relation to the different causes of liver and biliary tract disease.

History taking for patients with jaundice or abnormal liver test results

Anorexia is a cardinal symptom of viral hepatitis and of neoplasms involving the liver, colon, biliary tree, or pancreas. Weight loss of more than 10 pounds (4.5 kg) should always raise the question of a neoplastic disorder.

Chills and fever along with headache and myalgia should raise the question of viral hepatitis. Chills and fever along with right upper quadrant abdominal pain suggest a diagnosis of biliary tract disease, especially choledocholithiasis and ascending cholangitis.

Arthritis can be the harbinger of viral hepatitis, autoimmune chronic hepatitis, inflammatory bowel disease with underlying liver disease, primary sclerosing cholangitis, or granulomatous disorders such as sarcoidosis.

Fleeting skin lesions are often present in patients with viral hepatitis type B. Excoriations, indicating pruritus, should raise the question of either intrahepatic or

Box 1.1 Specific questions to ask patients with jaundice or liver disease.

Questions related to viral hepatitis

- Blood transfusions (especially if before 1990)
- Intravenous drug use
- Sexual practices:
  - Anal-receptive intercourse
  - Sex with a prostitute
  - History of sexually transmitted disease
  - Multiple sexual partners (>5/year)
  - Intercourse with individuals with hepatitis B or C
- Contact with individuals with jaundice
- Changes in taste and smell
- Needlestick exposure
- Work in renal dialysis units
- Surgeons in trauma units or operating rooms exposed to users of intravenous drugs
- Shared razors or toothbrushes
- Body piercing (ears, nose)
- Tattoos
- Intranasal cocaine use

Special risk factors for hepatitis A (if not previously immunized)

- Travel to endemic areas
- Ingestion of raw shellfish (harvested from contaminated waters)
- Exposure to patients in places where clusters of hepatitis may occur (e.g., institutions, prisons, preschool nurseries)

Medication-related questions

- Review all prescription medications
- Ask specifically about all over-the-counter drugs
- Ask specifically about vitamins (especially vitamin A)
- Ask specifically about any foods, herbal preparations, and home remedies purchased in a health food store

Alcohol use questions

- Obtain detailed *quantitative* history of both recent and previous alcohol use from the patient *and* family members
- Question whether patient has experienced withdrawal symptoms or driving-under-the-influence convictions
- CAGE (cut down, annoyed, guilty, eye opener) criteria (see text)
- Check for evidence of alcohol-associated illnesses (pancreatitis, peripheral neuropathy)

Miscellaneous questions

- Pruritus (suggests cholestasis, either intrahepatic or extrahepatic)
- Evolution of jaundice (dark urine, light stools)
- Recent changes in menstrual cycle (amenorrhea suggests chronic liver disease, often cirrhosis)
- History of anemia, sickle cell disease, known hemoglobinopathy, or artificial heart valves
- Symptoms suggestive of biliary colic or chronic cholecystitis
- Family history of liver or gallbladder disease
- History of inflammatory bowel disease (should raise the question of primary sclerosing cholangitis and receipt, if any, of blood transfusions)
- Occupational history and, specifically, exposure to hepatotoxins

extrahepatic cholestasis, particularly primary biliary cirrhosis or primary sclerosing cholangitis. With regard to abdominal pain, the standard questions to ask concern the location, character, radiation, factors precipitating or relieving pain, and whether there are other systemic symptoms that accompany the pain. Patients should be asked to compare current abdominal discomfort with other causes of abdominal pain that they have experienced in the past (e.g., gastroesophageal reflux symptoms, non-ulcer-type dyspepsia).

Questions to be asked in relation to viral hepatitis include specific questions about blood transfusions, especially whether they were received before 1990. The date is important because before that time no serologic tests were available for the detection of infection with hepatitis C virus. Intravenous drug use is currently the most common cause of hepatitis C. It is important to ask specifically about sexual practices, especially high-risk sexual behavior. In this regard, anal-receptive intercourse is known to be a significant risk factor for hepatitis B. Sexual practices associated with an increased risk of hepatitis C include a history of sexual relations with a prostitute, history of a sexually transmitted disease, and multiple sexual partners per year. In addition, intercourse with patients known to be positive for hepatitis B and C (e.g., spouses) is known to be a risk factor for contracting these forms of hepatitis. Contact with jaundiced individuals may be a risk factor for hepatitis A and B. Changes in taste and smell occur fairly frequently in patients with viral hepatitis. They contribute, in a large part, to the anorexia experienced by such patients. This is in part due to a decreased sense of smell (hyposmia), perception of unpleasant smells from foods that are not ordinarily perceived as unpleasant (dysosmia), a decreased sense of taste (hypogeusia), and perception of unpleasant tastes (dysgeusia). Hypogeusia is often reflected in the fact that patients may spontaneously state that they have lost their taste for cigarettes.

Health care professionals are at risk of contracting hepatitis C. This can occur through needlestick exposure, by working in renal dialysis units, and by working in trauma units, emergency departments, or operating rooms through surgical procedures on patients harboring the hepatitis C virus in whom that diagnosis is not immediately apparent. All users of intravenous drugs should be suspected of harboring the hepatitis C virus. Special risk factors for hepatitis C include tattoos, body piercing (e.g., of the ears and nose), a history of snorting cocaine, and the use of shared razors or toothbrushes.

The incidence of hepatitis A and hepatitis B has decreased markedly due to immunization, however, there are special risk factors for hepatitis A that include travel to endemic areas such as Mexico and Latin America and the African subcontinent, ingestion of raw shellfish that

may have been harvested from contaminated waters, and exposure to patients in places where clusters of hepatitis may occur. The latter has been well documented in mental institutions, prisons, preschool nurseries, and close living quarters. Hepatitis A can be transmitted parenterally because there is brief viremia.

Medication use, including all prescription drugs and all over-the-counter drugs, should be carefully reviewed. The constellation of clinical features that include fever, arthritis or arthralgia, rash, and eosinophilia in a patient with jaundice or abnormal results of liver tests should always raise the question of medication-induced liver disease. This can be recalled by the mnemonic FARE, which stands for *f*ever, *a*rthritis, *r*ash, and *e*osinophilia. The patient should be asked specifically about intake of vitamins, especially vitamin A, and about any foods, herbal preparations, or home remedies purchased in health food stores. Several herbal preparations have been found to be hepatotoxic.

Detailed quantitative information should be obtained from both the patient and family members about recent and previous alcohol use. For reference purposes, 30 mL (1 ounce) of bourbon whiskey contains 10–11 g of alcohol, as does one 360 mL (12-ounce) container of beer or 120 mL (4 ounces) of red table wine. Each one of these can be considered as 1 unit. Ingestion of more than 3 units/day every day or more than 21 units/week is excessive, especially for women. The threshold for alcohol-induced hepatic injury appears to be 30 g/day for women and 60 g/day for men if ingested over 5–10 years. These numbers may have to be modified if additional risk factors for liver disease are present (e.g., hepatitis C). One also needs to determine whether the patient has experienced withdrawal symptoms. The CAGE criteria are reliable indicators of excessive alcohol use. The CAGE criteria relate to the following four questions:

1 Has the patient tried to *c*ut back on alcohol use?
2 Does the patient become *a*ngry when asked about his or her alcohol intake?
3 Does the patient feel *g*uilty about his or her alcohol use?
4 Does the patient need an eye opener in the morning?

In this regard, many patients with chronic alcoholism experience morning nausea and dry heaves. The examiner should check for evidence of alcohol-associated illnesses (e.g., pancreatitis and peripheral neuropathy).

A history of pruritus suggests cholestasis, either intrahepatic or extrahepatic. Box 1.2 shows the differential diagnosis of jaundice [1]. The patient should be specifically asked about the evolution of jaundice (i.e., the onset of dark urine and light stools), which may provide clues to the duration of illness. Recent changes in the menstrual cycle, particularly amenorrhea, if present, suggest chronic liver disease and often cirrhosis. A history of anemia, sickle cell disease, and hemoglobinopathy should also be ascertained for African-American patients. Right upper quadrant abdominal pain should prompt detailed questions about whether such pain is consistent with biliary colic or chronic cholecystitis. A history of inflammatory bowel disease should raise the question of

Box 1.2 Differential diagnosis of jaundice.

Most common causes
- Decompensation of chronic liver disease
- Alcoholic hepatitis
- Gallbladder disease (cholecystitis, choledocholithiasis)
- Sepsis/abnormal hemodynamics
- Malignancy (pancreatic cancer, liver metastases)

Common causes
- Viral hepatitis
- Drug- or toxin-induced liver disease (especially acetaminophen)
- Hemolysis (especially sickle cell anemia)
- Postoperative (multiple factors)
- Primary biliary cirrhosis
- Primary sclerosing cholangitis

Less common causes
- Hodgkin disease and non-Hodgkin lymphoma
- Total parenteral nutrition
- Gilbert syndrome; while unconjugated hyperbilirubinemia ≥1.2 mg/dL occurs in 2–5% of the population, serum bilirubin levels infrequently exceed 3.0 mg/dL and detectable jaundice is unusual

Causes and presumed sites of intrahepatic cholestasis
- Liver cell (hepatocellular):
  - Viral hepatitis
  - Alcoholic liver disease
  - Chronic active liver disease
  - α_1-Antitrypsin deficiency
- Hepatocanalicular:
  - Drugs (androgens, phenothiazines)
  - Sepsis
  - Postoperative state
  - Total parenteral nutrition
  - Hodgkin and non-Hodgkin lymphoma
  - Amyloidosis
  - Sickle cell anemia
  - Toxic shock syndrome
- Ductular:
  - Sarcoidosis
  - Primary biliary cirrhosis
- Bile ducts:
  - Intrahepatic biliary atresia
  - Caroli disease
  - Cholangiocarcinoma
  - Primary sclerosing cholangitis
- Recurrent cholestasis:
  - Benign recurrent intrahepatic cholestasis
  - Recurrent jaundice of pregnancy
  - Dubin–Johnson syndrome

primary sclerosing cholangitis or, if the patient has received blood transfusions in the past, hepatitis C. An occupational history should be obtained and questions about specific exposure to a known or suspected hepatotoxin should be asked of industrial workers with jaundice or liver disease.

Physical examination of the patient with jaundice or abnormal results of liver tests

The key elements in the physical examination of a patient with jaundice or abnormal results of liver tests are summarized in Box 1.3. Several important clues are evident on general inspection of the patient. It should be determined whether scleral icterus is present, and this should be done in natural daylight. Scleral icterus can usually be detected if the serum bilirubin level is elevated to values greater than 3.0 mg/dL. The presence of pallor suggests anemia. Wasting suggests advanced chronic liver disease or a neoplastic disorder. Needle tracks or evidence of skin popping suggest intravenous drug abuse. The presence of skin excoriation confirms that the patient has been experiencing pruritus, which can be particularly severe among patients with primary biliary cirrhosis and primary sclerosing cholangitis. The one area where such patients cannot scratch is the interscapular area, and this is usually free of evidence of excoriation. The presence of ecchymosis or petechiae raises the question of clotting problems, especially thrombocytopenia. Muscle tenderness and weakness are not uncommon among patients with chronic alcoholism and alcoholic myopathy. These findings are often overlooked. When associated with severe acute pancreatitis, discoloration of the abdomen is termed the *Grey Turner sign*. This finding implies increased likelihood of death. Other less common causes of ecchymosis include rhabdomyolysis, muscle infarction, mesentery thrombosis, strangulated bowel with extensive intestinal infarction, and massive intraperitoneal bleeding.

The presence of lymphadenopathy, if generalized, suggests a lymphoproliferative disorder such as Hodgkin disease or non-Hodgkin lymphoma. Supraclavicular lymphadenopathy should raise the question of underlying malignant disease of the stomach or bronchopulmonary tract. Patients with pneumonia have jaundice in approximately 3% of cases; this is more likely to be the case among patients with pneumococcal pneumonia. Accordingly, a careful examination of the lungs is in order in the evaluation of patients with jaundice. Patients with congestive heart failure quite frequently have chronic passive congestion of the liver, which can result not only in jaundice but also in signs of portasystemic encephalopathy.

Box 1.3 Physical examination of the patient with jaundice.

General inspection
- Scleral icterus
- Pallor
- Wasting
- Needle tracks
- Evidence of skin excoriations
- Ecchymosis or petechiae
- Muscle tenderness and weakness
- Lymphadenopathy
- Evidence of pneumonia
- Evidence of congestive heart failure

Peripheral stigmata of liver disease
- Spider angiomata
- Palmar erythema
- Gynecomastia[a]
- Dupuytren contracture[a]
- Parotid enlargement[a]
- Testicular atrophy
- Paucity of axillary and pubic hair
- Eye signs mimicking hyperthyroidism

Abdominal examination
- Hepatomegaly
- Splenomegaly
- Ascites
- Prominent abdominal collateral veins
- Bruits and rubs
- Abdominal masses
- Palpable gallbladder

Signs of "decompensated" hepatocellular disease
- Jaundice
- Ascites
- Oliguric hepatic failure
- Hepatic encephalopathy:
  - Fetor hepaticus
  - Asterixis
  - Behavioral alterations (confusion, disorientation, failure to complete simple mental tasks)

[a]This triad suggests chronic alcoholism.

There are several peripheral stigmata of chronic parenchymal liver disease. Spider angiomata are usually found in the distribution of the superior vena cava and most commonly on the upper anterior chest, neck, face, and upper thorax. The presence of more than a dozen spider angiomata should raise the question of portal hypertension. The triad of gynecomastia, Dupuytren contracture, and parotid enlargement should always raise the question of chronic alcoholism. Paucity of axillary and pubic hair and eye signs mimicking those of hyperthyroidism are often found among patients with advanced liver disease. Testicular atrophy, defined by a testicular diameter of less than 3 cm, is also common.

The abdominal examination is important in determining the liver size as well as the presence of an enlarged spleen. Percussion of the abdomen is important for several reasons. First, the size of solid organs such as the liver and spleen can be evaluated with percussion. One can often determine whether an increased amount of intraperitoneal fluid (ascites) is present. The upper and lower borders of liver dullness can be assessed by means of percussion along the right midclavicular line from the midchest to the midabdomen (Fig. 1.1). Liver size can be further assessed by having the patient inspire and observing the descent of the liver (Fig. 1.2). The lower border of liver dullness alerts the examiner to the site where the liver edge should be palpable. The liver span as judged by liver dullness measures 10–12 cm in men and 8–11 cm in women. A sudden decrease in liver dullness can occur in several conditions, such as viral hepatitis with the development of submassive or massive liver cell necrosis, localized dilatation of the transverse colon (as in toxic megacolon), fulminant colitis, and ileus associated with peritonitis or a perforated viscus (e.g., duodenal ulcer or diverticulitis). The spleen is normally not palpable. Percussion over the spleen reveals an area of dullness extending from the 10th rib in the posterior midaxillary aspect to the anterior aspect of the chest (Figs 1.2 and 1.3). When the patient inspires, the area of splenic dullness moves inferiorly and to the right.

The detection of splenic dullness is important for the following three reasons:

1 It may indicate splenic enlargement before the spleen can be palpated.
2 It alerts the examiner to the site where the spleen may be palpated.
3 Increasing dullness of the left flank may be a valuable clue to the diagnosis of traumatic rupture of the spleen or subcapsular hematoma.

Figure 1.1 Determination of liver size by means of percussion over the lower right anterior chest and the right upper quadrant of the abdomen.

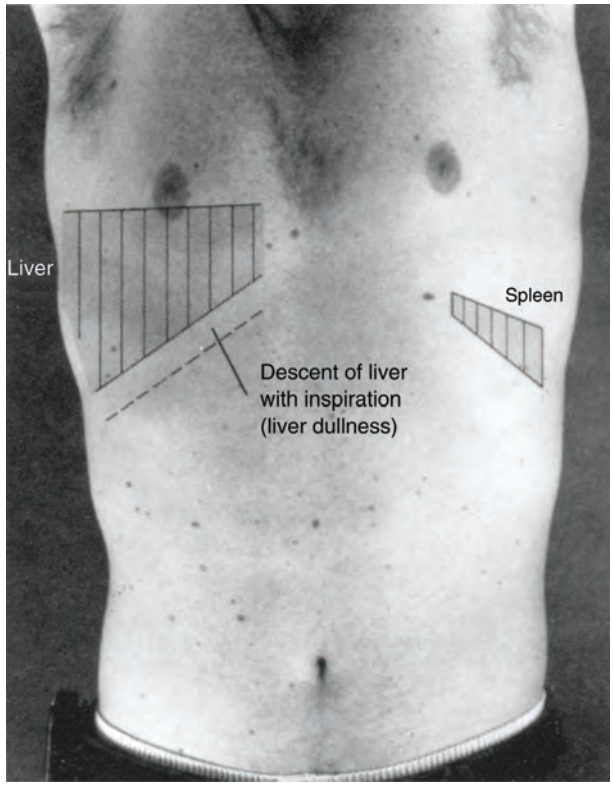

Figure 1.2 Abdomen and chest showing the location of the liver and the spleen as outlined by means of percussion. The liver descends 1–3 cm with inspiration, which is reflected by a change in liver dullness.

All quadrants of the abdomen must be palpated in an orderly manner. When palpating the abdomen, the hand should be warm and the palm and extended fingers of the right hand placed flat in a plane parallel to the surface of the abdomen (Fig. 1.4). The pads of the fingers are used together to perform light general palpation. Light palpation is used on the abdomen first, and as tense

Figure 1.3 Technique for percussion of the spleen. If splenomegaly is present, the percussion note is dull, and with inspiration the spleen moves downward and medially and the percussion note changes accordingly.

Figure 1.4 Technique for palpation of the liver.

muscles relax, deeper palpation should be tried. Quick jabbing movements should be avoided. Any area of tenderness or any increased muscular resistance should be recognized and examined in detail.

Percussion should alert the examiner to the approximate size and lower edge of the liver. Beginning at the right iliac fossa, the right hand is moved gradually upward until the edge of the liver is appreciated (Fig. 1.4). The patient can be asked to slowly take a deep breath. The descent of the diaphragm carries the liver down, which facilitates palpation of the liver edge. The edge of the liver can be felt in most healthy individuals if the patient's abdominal wall muscles are relaxed and the patient takes a slow, deep breath. In some healthy individuals, a very low lying thin segment of the liver can be palpated in the right lower quadrant. This is termed the *Riedel lobe of the liver.* An alternative approach to feeling the edge is to gently curl the fingers of the right hand below the costal margin and ask the patient to inspire slowly (Fig. 1.5). This is termed the *Middleton method.* In this manner, the liver descent is appreciated by eight fingertips. This method is important in determining minimal enlargement of the liver or a liver palpable only in the epigastrium, as can occur in advanced cirrhosis.

The examiner should determine whether the liver is soft, firm, hard, or irregular; whether the edge is rounded or sharp; whether discrete masses are present; and whether the left lobe is palpable across the midline. The presence of a palpable left lobe always denotes an abnormality, usually chronic liver disease. The size of the liver should be assessed as judged by the location of the edge below the right midclavicular line and the xiphoid. A normal liver edge is sharp, smooth, and not hard, and the left lobe is not palpable. A rounded edge suggests liver disease; a palpable left lobe suggests either chronic infiltrative or neoplastic liver disease. Modest enlargement of the liver occurs in several disorders, most notably viral hepatitis, chronic liver disease (all causes), chronic hepatitis, cirrhosis, choledocholithiasis, and extrahepatic biliary tract obstruction. Marked enlargement of the liver (edge >10 cm below the costal margin) occurs in relatively few disorders, which include: (i) primary and metastatic tumors of the liver, including lymphoma; (ii) alcoholic liver disease (fatty liver, alcoholic hepatitis, cirrhosis); (iii) severe congestive heart failure; (iv) infiltrative diseases of the liver, such as amyloidosis and myelofibrosis; and (v) chronic myelogenous leukemia. Finally, a pulsatile liver should raise the question of tricuspid regurgitation, which can occur with advanced mitral stenosis, endocarditis of the tricuspid valve, and severe pulmonary hypertension.

Percussion of the left upper quadrant may have alerted the examiner to the presence of an enlarged spleen. Palpation of the spleen should begin in the left iliac fossa and move up to the left costal margin (Fig. 1.6). If the spleen is not felt while the patient is supine, the patient should roll onto his or her right side so the examiner can again examine the left upper quadrant (Fig. 1.7). This method

Figure 1.5 Alternative technique for palpation of the liver. The best results are obtained with gentle pressure of the curled fingers on the anterior abdominal wall.

Figure 1.6 Technique for palpation of the spleen.

Figure 1.7 Palpation with the patient in the right lateral decubitus position. This should be performed on all patients with suspected splenomegaly if the spleen is not felt with the patient in the supine position.

takes advantage of the fact that when the spleen enlarges, it becomes more easily palpable inferiorly and medially. This enlargement is better appreciated when the patient is in the right lateral decubitus position. An alternative is for the examiner to stand at the patient's right side with the patient's left hand placed under the 11th rib to elevate the thorax. The examiner then curls the fingers of either one or both hands below the costal margin and asks the patient to inspire. The splenic margin may then be felt by the fingertips.

A common problem in evaluating left upper quadrant masses is differentiating the spleen and the left kidney. Palpation of a notch on the medial surface suggests that the organ being palpated is the spleen. Differentiation of the left lobe of the liver from the spleen can be difficult if massive hepatomegaly is present. One can usually discern a space or open area between the two organs. Common causes of splenomegaly include the following:

1 Portal hypertension caused by cirrhosis of the liver.
2 Infections (viral, bacterial, fungal).
3 Leukemia, lymphoma, and Hodgkin disease.
4 Connective tissue diseases (systemic lupus erythematosus and rheumatoid arthritis).
5 Infiltrative disorders (amyloidosis and sarcoidosis).
6 Hemolytic disorders.
7 Myelofibrosis.

Gallbladder

The gallbladder, when enlarged, can often be palpated in the right upper quadrant at the angle formed by the lateral border of the rectus abdominis muscle and the right costal margin. The gallbladder is palpable in approximately 25% of cases of carcinoma of the head of the pancreas (Courvoisier's law) because of painless distention of the gallbladder. The gallbladder is also palpable in approximately 30% of patients with acute cholecystitis, often because stones are impacted in the neck of the gallbladder. Often in acute cholecystitis, rather marked right upper quadrant tenderness is present, and palpation can be difficult because of intense involuntary spasms of the abdominal muscles. Percussion over the right lower anterior chest and right upper quadrant often elicits pain.

Another sign pointing to acute cholecystitis is right upper quadrant abdominal pain aggravated by inspiration (Murphy's sign). The patient is asked to inspire after the examining fingers are placed high in the right upper quadrant; inspiration causes the gallbladder to descend and come in contact with the extended fingers, causing pain and inspiratory arrest.

Bruits

Bruits are systolic sounds usually produced by the turbulence of blood flowing through diseased or compressed blood vessels. The many causes of abdominal bruits are listed in Table 1.1. The most common causes of such bruits include calcification of the aorta, celiac axis compression, and alcoholic hepatitis. An epigastric bruit can be appreciated in 20% of healthy thin young adults, especially if auscultation is performed after a meal. Such bruits are usually caused by the compression of the celiac axis artery by muscle fibers of the crus of the diaphragm. Abdominal bruits are often important clues leading to the diagnosis of hepatocellular carcinoma, renal artery stenosis, fibromuscular hyperplasia of the renal arteries, intestinal angina, aortic aneurysm, and pancreatic cancer.

Peritoneal friction rub

A friction rub heard over the liver suggests the diagnosis of liver metastasis or primary hepatocellular carcinoma. Other causes of hepatic friction rub include infarction of the liver (as in sickle cell anemia and polyarteritis nodosa) and liver abscess. A transient friction rub caused by a hematoma around the puncture site is common after liver biopsy but is usually not audible 4–6 hours after biopsy.

Ascites

Assessment of shifting dullness is often used to determine whether ascites is present. When free fluid is present in the abdomen, such fluid gravitates to the flanks, and the intestines float upward when the patient lies on his or her back. Percussion with the patient in this position discloses tympany over the anterior abdomen and dullness over the flanks. If the patient is turned to one side, the dullness shifts, and the percussion on the side that is uppermost becomes tympanic, because that area becomes occupied by gas-filled intestine.

Another physical finding pointing to the diagnosis of ascites is the fluid wave. A fluid wave is demonstrated

Table 1.1 Causes of abdominal bruit [3].

Location of bruit	Diagnostic considerations	Comment
Liver	Alcoholic hepatitis	Bruits may change day to day
	Hepatocellular carcinoma	Suspect hepatocellular carcinoma in decompensated cirrhosis with a disproportionately increased serum level of alkaline phosphatase
	Effect of surgery	
	Portosystemic shunt	
	Hepatic artery aneurysm	
	Hepatic arteriovenous fistula (trauma)	
Spleen	Splenic artery aneurysm	May see calcification in left upper quadrant on plain radiographs of the abdomen
	Splenorenal shunt	
	Splenic arteriovenous fistula	
	Calcified aorta	
Aorta	Aortic aneurysm	
	Celiac axis compression	Bruits common in thin individuals, especially after meals
	Celiac or superior mesenteric artery disease (atheroma, thrombi)	Intestinal angina characterized by the triad of: (i) bruit, (ii) weight loss, and (iii) postprandial abdominal pain
Left upper quadrant	Pancreatic cancer (body or tail)	Bruit caused by encasement of splenic artery or vein by tumor; present in 25% of cases
Umbilicus	Cruveilhier–Baumgarten syndrome	Bruit caused by increased flow through umbilical veins secondary to portal hypertensions
	Renal artery stenosis (atheroma, emboli)	
	Renal artery fibromuscular hyperplasia	Bruit may be unilateral or bilateral
	Renal artery aneurysm	

by tapping the left flank sharply with the right hand while the left hand is placed against the opposite flank (Fig. 1.8). Either the patient or a second examiner must place the ulnar surface of his or her hand along the midline of the abdomen. A positive test result is one in which an impulse on the opposite flank is percussed after the right flank is tapped. Neither the test for shifting dullness nor the test for a fluid wave uniformly reveal modest amounts of ascitic fluid (<1,000 mL). Indeed, both tests have a sensitivity of only approximately 60% compared with ultrasound examination [2]. Furthermore, the test results can be spuriously positive in examinations of obese patients.

A third sign, bulging flanks, although often present in ascites, is frequently present in obese patients as well. A fourth test of ascites is elicitation of the puddle sign. In this test, the patient lies prone for a few minutes and then moves to hands and knees. The diaphragm of the stethoscope is placed over the most dependent part of the abdomen, where puddling would be expected to occur. The examiner then repeatedly flicks the near flank of the abdomen while moving the stethoscope toward the opposite flank. A positive test result consists of a definite

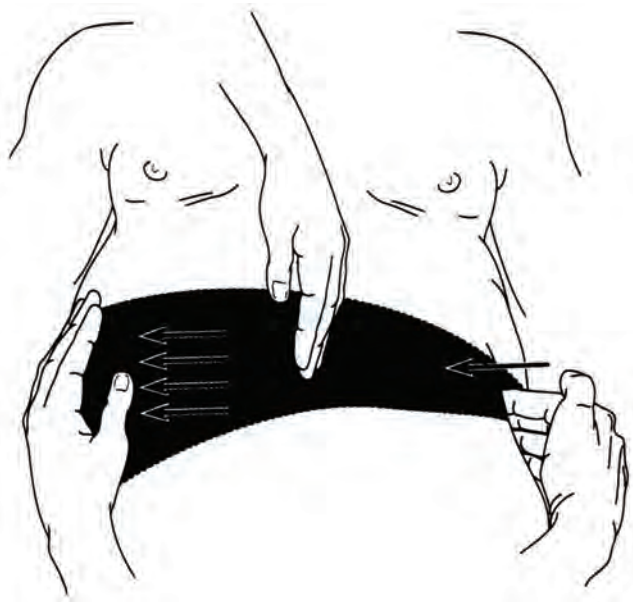

Figure 1.8 Technique for eliciting a fluid wave. The examiner's left hand is placed on the right lateral abdomen, and the right hand taps the left flank or loin while a second examiner or the patient's hand compresses the abdomen in the midline.

change in the intensity and character of the percussion note as the stethoscope is moved.

The presence or absence of ascites can be confirmed most reliably with imaging procedures such as ultrasonography and computed tomography (CT). The urinary bladder is often percussed in the hypogastrium, especially if urinary retention is present.

Abdominal masses

All nine areas of the abdomen should be palpated carefully for the presence of abdominal masses. In addition, the examiner should palpate the periumbilical area for the presence of lymph nodes. Such lymph nodes, termed Sister Mary Joseph nodes, reflect intraperitoneal tumor and are the harbinger of peritoneal carcinomatosis.

Signs and symptoms of decompensated liver disease

Signs of decompensated liver disease in patients with cirrhosis include jaundice, ascites, portal hypertension with bleeding esophageal or gastric varices, oliguric hepatic failure, and hepatic encephalopathy. These are discussed in detail in Chapters 11, 13, and 18. A bedside diagnosis of cirrhosis of the liver can be made on the basis of two physical findings and two laboratory findings. The physical findings are ascites and asterixis, and the laboratory findings are a serum albumin level of less than 2.8 g/dL and a prolongation of the prothrombin time of more than 16 seconds.

The topic of hepatic encephalopathy is discussed in detail in Chapter 18. However, this diagnosis can be made readily at physical examination when the following findings are present, especially in a jaundiced patient:

1 Hypothermia, with a temperature of less than 36°C.
2 Fetor hepaticus, which is a pungent odor in the breath caused by the excretion of sulfur-containing amino acid by-products such as dimethyl sulfide, methanethiol, and ethanethiol.
3 Asterixis, which can be elicited by two techniques (Fig. 1.9), and abnormal cognitive functioning as evidenced by an abnormal result of a Reitan trial test or A-deletion test. The latter is performed by asking the patient to delete all the As in one or two paragraphs of newsprint; the examiner tabulates how many As were not deleted.

Asterixis, although characteristic of hepatic encephalopathy, is not pathognomonic of this disorder. Asterixis is also found in patients with renal failure, pulmonary insufficiency, and congestive heart failure. Patients with hepatic encephalopathy may have difficulty with seemingly simple tasks such as drawing a square, spiral, or five-cornered star or signing their name.

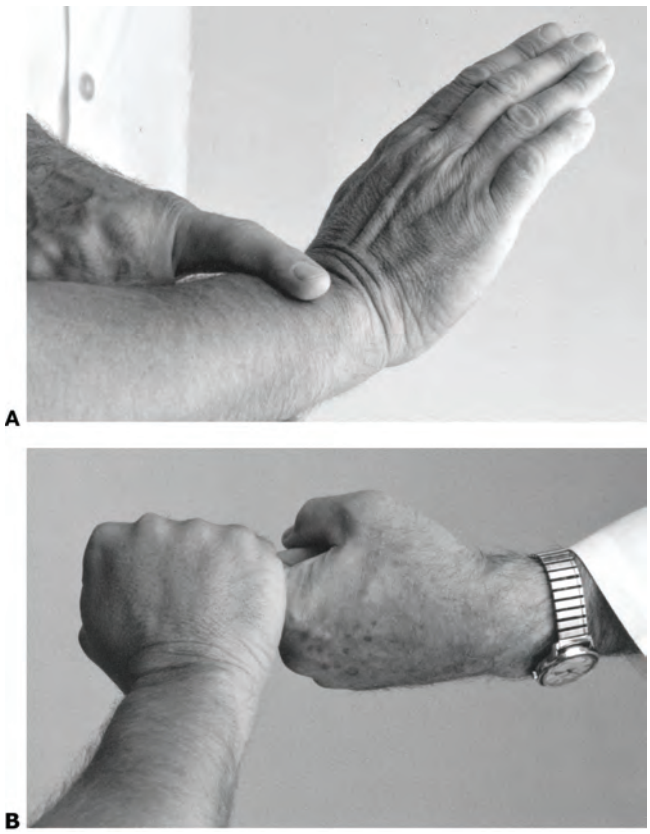

Figure 1.9 Techniques for eliciting asterixis. (A) The examiner applies his index finger over the dorsum of the patient's wrist while asking the patient to dorsiflex the wrist. Asterixis is the downward drift and abnormal recovery motion of the hand with the fingers either together or outstretched. (B) Alternative method for eliciting asterixis in patients who may not have the requisite extensor tonus. The examiner asks the patient to clench his fingers around the examiner's fingers. Asterixis is elicited with subtle movements of the examiner's wrist. In this manner, one can both feel and see the asterixis movement.

The diagnosis of chronic portosystemic encephalopathy is usually established on the basis of the following criteria:

1 Documented chronic parenchymal liver disease.
2 Evidence of portosystemic shunting, occurring either naturally (varices) or following the insertion of a transjugular intrahepatic portosystemic shunt (TIPS).
3 Behavioral alterations that can range from subtle abnormalities in cognitive functioning to frank unresponsive coma.
4 Improvement in mental status after measures directed at altering gastrointestinal ammonia metabolism, such as with dietary protein restriction or lactulose therapy.
5 An abnormal result of an electroencephalogram showing a decrease in mean cycle frequency. This is not routinely done.

Role of noninvasive imaging

Noninvasive imaging of the liver and biliary tree in the evaluation of the patient with jaundice and/or liver disease

As noted earlier, in patients with jaundice, a careful history, physical examination, and review of standard laboratory tests should allow a physician to make an accurate clinical diagnosis in 85% of cases. All too often, however, an imaging procedure is done before these basic steps have been completed and such omissions may actually delay establishing the correct diagnosis. The following are offered as guidelines to be considered for ordering imaging procedures:

1. Liver imaging procedures are not indicated in a patient with acute viral hepatitis.
2. Liver imaging procedures are not necessary in a patient with a firm clinical diagnosis of nonalcoholic fatty liver disease.
3. In a patient with jaundice and obstructive-type liver test abnormalities, that is, a disproportionately elevated serum alkaline phosphatase level and serum aminotransferases of less than 300 units, ultrasonography is the usual initial imaging procedure. Ultrasonography is reliable for differentiating medical jaundice, that is, intrahepatic cholestasis, from extrahepatic obstructive jaundice. In a patient with a serum bilirubin greater than 10 mg/dL that has been present for more than 2 weeks, ultrasound has a sensitivity of 95% and a specificity of 95% in differentiating intrahepatic versus extrahepatic causes of jaundice. Box 1.2 lists several causes of intrahepatic cholestasis. In some cases, the level and cause of bile duct obstruction can be identified.
4. If an ultrasound examination in a patient with jaundice reveals evidence of dilated intrahepatic ducts, additional imaging procedures such as CT scanning, magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasonography (EUS) with biopsies are often necessary to establish the cause of obstruction. If no dilated ducts are found and the cause of jaundice is deemed to be "medical," a liver biopsy is frequently in order.
5. In patients with suspected cholelithiasis, ultrasonography is the primary diagnostic imaging procedure. In patients with suspected choledocholithiasis MRCP is often the next step. However, if there is a question of ascending cholangitis, ERCP is the preferred diagnostic procedure as papillotomy may be indicated.
6. In a patient with new onset of ascites, Doppler ultrasonography is indicated to determine the patency of the portal and hepatic venous systems.
7. In patients with obstructive jaundice due to suspected pancreatic carcinoma, EUS is superior to CT scanning with regard to detecting a pancreatic mass but comparable with regard to tumor staging and predicting either resectability or nonresectability.
8. In patients with unexplained hepatomegaly, either ultrasound or CT scanning are appropriate initial imaging procedures.

Case vignettes: practical considerations

The following are vignettes in which the salient features of a patient's illness alert the clinician to the most likely diagnosis.

1. A 35-year-old woman is referred with the diagnosis of acute viral hepatitis. Liver tests reveal a total serum bilirubin level of 3.0 mg/dL; serum aspartate aminotransferase (AST), 900 U/L; serum alanine aminotransferase (ALT), 880 U/L; serum alkaline phosphatase, 180 U/L; serum albumin, 3.6 g/dL; serum globulins, 5.8 g/dL; and prothrombin time, 15 seconds (international normalized ratio (INR), 1.9).
   Key: The presence of marked hypergammaglobulinemia along with prolongation of the prothrombin time suggests that this patient has *chronic* rather than acute hepatitis. The most likely diagnosis for this 35-year-old woman would be autoimmune chronic hepatitis.
2. A 30-year-old man is referred for evaluation of elevated serum aminotransaminase levels. The patient weighed 230 pounds (103.5 kg) as a high school football player, 250 pounds (112.5 kg) after graduating from college, and 300 pounds (135 kg) 5 years later. Results of all liver tests are normal except for a serum AST level of 65 U/L and a serum ALT level of 80 U/L.
   Key: If a patient has no symptoms except that the transaminase values are elevated approximately twice the normal value, six considerations should come to mind. They include: (i) excessive alcohol use; (ii) obesity with a body mass index (BMI) greater than 30; (iii) hepatitis C; (iv) excessive doses of acetaminophen (>4.0 g/day); (v) use of statin-type cholesterol-lowering agents; and (vi) celiac sprue. In this patient, the most likely explanation is obesity, and he may well have nonalcoholic steatohepatitis.
3. A 30-year-old man has severe flu symptoms for 5 days. Cough, myalgia, headache, and anorexia have resulted in markedly diminished intake of food and liquid. He has been ingesting generic acetaminophen 4.0 g/day and acetaminophen plus diphenhydramine (Tylenol PM™) to facilitate sleep. He was found to have a serum AST level of 5,000 U/L and an ALT level of 5,500 U/L.

Key: Ingestion of seemingly therapeutic doses of acetaminophen by a patient who has in essence fasted for 4 or 5 days can result in drug-induced hepatotoxicity. Results of early studies indicated that concurrent ingestion of alcohol and acetaminophen was the most common cause of this presentation. However, the scenario in this case is the more common presentation now. In patients who come to medical attention with serum aminotransaminase values of approximately 5,000 U/L, the differential diagnosis is limited to viral hepatitis, effects of drugs and toxins, and ischemia with shock liver. In the United States, approximately one half of cases of fulminant hepatic failure are related to acetaminophen ingestion.

4 A 63-year-old woman with non-insulin-requiring diabetes mellitus and hypercholesterolemia has been found to have abnormal results of liver tests. Results of liver biopsy establish the diagnosis of cirrhosis, but there is no obvious cause, and the patient is considered to have cryptogenic cirrhosis.

Key: A detailed history reveals that the patient was obese through much of her adult life, weighing in excess of 300 pounds (135 kg; BMI >35). Although she weighed only 200 pounds (90 kg) when she sought medical attention, many years of obesity coupled with diabetes and hypercholesterolemia most likely caused nonalcoholic steatohepatitis, which progressed to cirrhosis. The most common cause of cryptogenic cirrhosis is antecedent nonalcoholic steatohepatitis.

5 A 28-year-old man who has had ulcerative colitis for 10 years is found through routine screening to have a serum alkaline phosphatase level of 500 U/L. Results of all other liver tests are normal.

Key: Persistent elevation of serum alkaline phosphatase level to values greater than twice the normal value in patients with inflammatory bowel disease, especially those with ulcerative colitis, should raise the question of occult primary sclerosing cholangitis. This patient needs an MRCP as the initial screening procedure.

6 A 40-year-old woman is admitted to hospital for therapy for alcohol withdrawal and impending delirium tremens. Laboratory studies reveal serum bilirubin, 2.0 mg/dL; AST, 225 U/L; serum ALT, 45 U/L; prothrombin time, 14 seconds (INR, 1.3); serum iron level, 170 μg/dL; total iron-binding capacity, 200 μg/dL; iron saturation, 85%; and serum ferritin, 700 μg/dL.

Key: The increased percentage of iron saturation and elevated serum ferritin level in this case are not indicative of a diagnosis of hemochromatosis. Serum iron levels and serum ferritin levels are frequently elevated in patients with acute liver disease and marked liver cell necrosis.

7 A 17-year-old boy is referred for evaluation of hepatosplenomegaly and thrombocytopenia. On examination, he is found to have a peculiar "wing-beating" tremor. When the patient abducts his arms and flexes his forearms, a sustained tremor develops. The patient does not have Kayser–Fleischer rings. The serum ceruloplasmin level is 30 mg/dL.

Key: The presence of a wing-beating tremor in a young man with apparent chronic liver disease is almost pathognomonic of Wilson disease. Examination of a 24-hour urine collection for copper revealed excretion of 1,100 μg of copper. Of the three standard screening tests for Wilson disease – that is, Kayser–Fleischer rings, low serum ceruloplasmin level, and increased urinary excretion of copper – results of all three are abnormal in only one third of patients. In the remaining two thirds of patients, only one test may have a positive result. The clue in this case was the unusual tremor.

8 A 25-year-old Guatemalan man who does not speak English is visiting relatives in the United States. After a large meal, he develops retching and hematemesis. Esophagogastroduodenoscopy reveals esophageal varices. The patient is admitted to hospital and found to have hepatosplenomegaly, thrombocytopenia, a normal serum albumin level, and minimal hyperbilirubinemia (serum bilirubin, 2.0 mg/dL). Through interpreters, it is learned that the patient had his first episode of hematemesis at 10 years of age. He had several subsequent episodes managed by means of banding of varices.

Key: The onset of variceal bleeding at 10 years of age with stigmata of chronic liver disease but with well-preserved liver function indicates that the most likely diagnosis is congenital hepatic fibrosis.

9 A 55-year-old man is referred for evaluation of asymptomatic hepatosplenomegaly. The patient's liver span is over 20 cm with a smooth, rounded edge felt 14 cm below the costal margin with a prominent left lobe. The spleen is palpable 4 cm below the left costal margin. Serum bilirubin, alkaline phosphatase, AST, and ALT levels are normal. The serum albumin level is 3.5 g/dL and serum globulin levels are 3.0 g/dL. The prothrombin time and partial thromboplastin time are normal. The results of a complete blood cell count and routine chemical analyses are normal. Urinalysis is unremarkable except for 2+ proteinuria. Blood glucose levels are normal, and the patient is not overweight.

Key: The finding of marked hepatomegaly with normal liver test results in the evaluation of a patient without symptoms should raise the question of infiltrative liver disease, such as amyloidosis. In addition to amyloidosis, relatively few disorders give rise

to marked hepatomegaly. These include primary and metastatic tumors of the liver, alcoholic liver disease, severe congestive heart failure, and advanced chronic myelogenous leukemia.

10 A 49-year-old man has documented end-stage chronic liver disease due to hepatitis C and alcohol ingestion. He has had previous hospital admissions for bleeding esophageal varices and ascites. Because of lack of compliance with a salt- and fluid-restricted diet, the patient has recurrent ascites despite treatment with diuretics. He is known to have diverticular disease, having had one previous episode of diverticulitis. He is admitted to the hospital with a 2-day history of severe abdominal pain, chills, fever, and anorexia. Diagnostic paracentesis reveals the following: white blood cell count, 10,000/μL with 90% polymorphonuclear leukocytes; ascitic fluid protein, 4.0 g/dL; ascitic fluid glucose, 35 mg/dL with a simultaneous serum glucose level of 120 mg/dL and peritoneal fluid of pH 7.1.

Key: This patient does not have spontaneous bacterial peritonitis. Rather, he has *primary* bacterial peritonitis. The triad of findings of a white blood cell count of 10,000/μL with a left shift, increased serum protein level, and low glucose level points to primary bacterial contamination of the peritoneal cavity, rather than spontaneous bacterial peritonitis, most likely from a perforated viscus. If a flat abdominal radiograph does not reveal evidence of free air, a CT scan should be obtained. If perforation is confirmed, the patient, despite the advanced liver disease, needs surgical exploration.

11 A 47-year-old man is referred for evaluation of ascites believed to be caused by chronic liver disease. There is no history of excessive alcohol use, risk factors for hepatitis B and C, or other gastrointestinal symptoms. There is a remote history of tuberculosis 20 years earlier managed appropriately. Previous physical examinations are said to be unremarkable except for ascites. Repeated physical examination reveals normal vital signs except for pulsus paradoxus of 20 mmHg. Inspiratory distention of the cervical neck veins is noticed. A third heart sound is heard to the left of the sternal border. The lungs are clear to auscultation. Abdominal examination reveals obvious ascites with a fluid wave. There is no peripheral edema. Ultrasound examination confirms the presence of ascites, reveals a liver that spans 15 cm, and a normal-sized spleen. The portal and hepatic veins are patent.

Key: The presence of pulsus paradoxus and a Kussmaul sign (inspiratory distention of the cervical neck veins) point to a diagnosis of constrictive pericarditis manifesting as ascites and masquerading as chronic liver disease. Results of an echocardiogram confirmed the diagnosis.

12 A 47-year-old woman is referred for evaluation of hepatosplenomegaly. The patient has no risk factors for chronic liver disease. These include absence of alcohol intake, no risk factors for hepatitis B and C, and no excessive use of vitamins or herbal teas. Urinalysis, however, reveals the presence of hematuria; a CT scan shows a lesion in the right kidney consistent with renal cell carcinoma. What is the cause of the patient's hepatosplenomegaly?

Key: Although one would be tempted to consider metastatic liver disease to be the most likely explanation for the hepatosplenomegaly, a rare syndrome termed *Stauffer syndrome* is a form of nephrogenic hepatosplenomegaly. Hypernephroma, in some ill-defined way, may elaborate hepatotropic growth factors that cause enlargement of the liver and spleen. Such patients do not usually have evidence of metastatic liver disease, and with nephrectomy the liver may actually regress in size.

13 A 57-year-old woman is referred for evaluation of ascites. She initially visited her gynecologist, who suspected that she might have ovarian carcinoma. However, a pelvic examination and pelvic and abdominal CT scans did not reveal any evidence of tumor. There is no history to explain the development of ascites except that the patient has been drinking enormous quantities of herbal tea, ingesting 18–24 cups/day for the last 2 years.

Key: An ultrasound examination with determination of portal and hepatic venous flow velocity revealed findings consistent with hepatic venous occlusion. Tumors (hepatocellular carcinoma, pancreatic carcinoma, hypernephroma, and gastric carcinoma) are infrequent causes of Budd–Chiari syndrome. The most common cause is an obvious or incipient myeloproliferative syndrome. Herbal teas may contain alkaloids that can cause both intrahepatic and extrahepatic venoocclusive disease.

14 A 62-year-old woman has been to the hospital because of pruritus and is found to have jaundice. Except for scleral icterus, the findings of the physical examination are unremarkable. The liver span measures 12 cm at percussion. Liver tests reveal the serum bilirubin level to be 8.0 mg/dL; AST, 400 U/L; ALT, 420 U/L; serum alkaline phosphatase, 500 U/L; normal serum prothrombin time; and normal serum albumin and globulin levels. Results of serum albumin, globulin, and antinuclear antibody tests are all either negative or within normal limits. An ultrasound examination shows a normal liver, gallbladder, and pancreas.

Key: A detailed history interview reveals that this woman took amoxicillin–clavulanic acid at a dosage of 2.0 g/day for 2 weeks, but this medication was discontinued 3 weeks earlier. Amoxicillin–clavulanic acid has been frequently reported to cause a cholestatic hepatitis. Jaundice and abnormal results of liver tests can develop 1–4 weeks after discontinuation of treatment. Histologic examination of the liver usually shows evidence of centrilobular (zone 3) or panlobular cholestasis, which, on rare occasions, is associated with a granulomatous hepatitis. The prognosis is excellent.

15 A 43-year-old man with a history of excessive alcohol ingestion (6 to 12 bottles of beer per day for many years) is admitted to the hospital with right upper quadrant pain, chills, fever, dark urine, and pruritus. Physical examination reveals right upper quadrant tenderness, the liver measuring 14 cm with a round, smooth, tender edge palpable 3 cm below the right costal margin. Liver tests reveal serum bilirubin, 8.0 mg/dL; AST, 220 U/L; ALT, 400 U/L; serum albumin, 3.8 g/dL; serum globulins, 3.2 g/dL; serum alkaline phosphatase, 400 U/L; mean corpuscular volume, 94 μm^3; white blood cell count, 14,000/μL with a left shift; and prothrombin time, 13 seconds (INR, 1.2).

Key: In patients with alcoholic hepatitis, the AST : ALT ratio is almost invariably 2 : 1 or greater. In this case, although the patient has consumed excessive amounts of alcohol, the disproportionately higher ALT : AST ratio suggests a cause of jaundice other than alcoholic hepatitis. An ultrasound examination showed cholelithiasis and a dilated common bile duct. This patient, although with a history of alcoholism, had biliary tract disease. A clue to the correct diagnosis was the unanticipated reversal of the AST : ALT ratio.

Multiple choice questions

1.1 **Each unit of packed red blood cells transfused to a patient contains bilirubin. Which of the following best approximates the amount infused in one unit?**

a 25 mg.
b 50 mg.
c 100 mg.
d 150 mg.
e 200 mg.

1.2 **A 20-year-old woman is transferred to your hospital because of the onset of jaundice and acute liver failure over a period of 7 days. There is no history of antecedent medication use except for acetaminophen 1.8 g/day for 2 days, no exposure to jaundiced patients, and no recreational drug use. Physical examination revealed marked jaundice, hepatomegaly, and asterixis. Laboratory studies revealed: hemoglobin 8 g/dL, hematocrit 24%, serum bilirubin 15.1 mg/dL, AST 120 U/L, ALT 150 U/L, serum albumin 1.9 g/dL, and hemoglobinuria. What is the most likely etiology of her liver failure?**

a Autoimmune hepatitis.
b Wilson disease.
c Leptospirosis.
d Acetaminophen hepatoxicity.
e Herpes simples virus.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 2
Laboratory Tests

H. Franklin Herlong & Mack C. Mitchell Jr
Department of Gastroenterology, Johns Hopkins Bayview Medical School, Baltimore, MD, USA

Key concepts

- Biochemical tests can be used to detect acute injury to the liver and chronic diseases of the liver before development of symptoms.
- Elevations in serum levels of aminotransferases (aspartate aminotransferase and alanine aminotransferase) reflect hepatocellular injury and/or permeability of the liver cell membrane, but do not correlate with the extent of fibrosis or measures of metabolic functions of the liver.
- An elevation of serum alkaline phosphatase occurs in response to intrahepatic cholestasis, extrahepatic obstruction of bile ducts, or infiltration of the liver with granulomatous inflammation, amyloidosis, or venous congestion.
- The rate-limiting step in metabolism and disposition of bilirubin is the transport of conjugated bilirubin from the hepatocyte into the bile. An elevation in the conjugated (direct-reacting) fraction of bilirubin is evidence of intrahepatic cholestasis or extrahepatic obstruction of the bile ducts.
- Serum levels of albumin may be low in patients with acute or chronic liver disease, but very often drop in response to the "acute phase response," making it difficult to evaluate hepatic metabolic function in clinical situations such as infection.
- Although single laboratory tests are generally not useful in evaluating the severity of acute or chronic liver diseases, the use of mathematical equations combining tests may be effective as surrogate markers for the extent of fibrosis, steatosis, and inflammation as well as to predict the short-term prognosis in patients with liver disease.

The use of laboratory tests is an important component of the assessment of patients with liver disease. With increasing frequency, elevations in the hepatic enzymes detected on routine screening tests provide the first evidence of liver disease in otherwise asymptomatic patients. In those patients with previously recognized hepatic dysfunction, laboratory tests can help establish the etiology of liver disease and provide valuable prognostic information. Rarely does a single test provide sufficient information to establish a diagnosis or assess severity of liver disease. A combination of tests such as serum bilirubin, albumin, aminotransferases, and alkaline phosphatase is sometimes referred to "liver function tests" or a "liver panel." These tests, in combination with the prothrombin time can provide an initial characterization of the etiology and severity of liver disease. However, one should recognize that the aminotransferases and alkaline phosphatase are tests that reflect hepatic injury not function. Traditionally liver diseases have been characterized as primarily hepatocellular or cholestatic based on the predominance of elevated aminotransferases or alkaline phosphatase. While an individual laboratory test may not provide a specific diagnosis, the pattern of abnormalities can suggest a general category of hepatic dysfunction. Although this distinction helps direct the initial evaluation there is often considerable overlap so that aggregating the diseases is less useful, as in the case of hepatotoxic drug reactions. With regard to drug-induced liver injury (DILI), those instances where the alanine aminotransferase (ALT) is greater than two times the upper limits of normal (ULN) and the ALT : alkaline phosphatase ratio is greater than 5 are considered primarily hepatocellular injuries. Those where the alkaline phosphatase is greater than two times the ULN and the ALT : alkaline phosphatase ratio is less than 2 are considered primarily cholestatic injuries. If the ALT and alkaline phosphatase are more than two times the ULN and the ratio is >2 or <5, the disorder is considered mixed hepatocellular/cholestatic. On occasion, minor elevations in the hepatic enzymes result from metabolic adaptation to drug metabolism and do not represent hepatic injury.

Laboratory tests can sometimes be helpful in assessing the severity of a liver disease, as is the case for using the prothrombin time to identify acute liver

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

failure in a patient with acute liver disease or injury. However, for chronic conditions such as alcoholic liver disease, commonly measured tests of "liver function" such as the serum albumin can be affected significantly by factors other than extent of liver disease such as malnutrition, malabsorption, or chronic inflammation. The commonly used laboratory tests also lack specificity, which may limit their effectiveness in establishing a diagnosis. For example, an elevation in the alkaline phosphatase can reflect disorders of bone or liver, while elevated aminotransferases can be seen in cardiac disease or disorders of skeletal muscle as well as liver diseases. Unfortunately the commonly measured liver enzymes do not correlate with the extent of fibrosis or measures of metabolic functions of the liver. Consequently, patients with cirrhosis may have no abnormalities in laboratory tests.

Finally laboratory tests provide an important tool to assess the effectiveness of therapy in diseases like viral or autoimmune hepatitis or when injury has resolved after discontinuing a hepatotoxic drug. Serial determinations of liver enzymes are useful in identifying particular causes of liver injury. For example, ischemic necrosis will cause a marked elevation in the aminotransferases that returns to normal within a matter of days, whereas acute viral hepatitis will cause sustained elevations for several weeks. In the evaluation of patients for liver disorders, it is helpful to group these tests into general categories. We have found the following classification most useful:

- *Tests to detect injury to hepatocytes*: these include all the enzyme tests, of which the aminotransferases and alkaline phosphatase are the most useful.
- *Tests of the biosynthetic capacity of the liver*: included in this group are coagulation factors (prothrombin time/international normalized ratio (INR)) serum albumin, ceruloplasmin, ferritin, α_1-antitrypsin, and lipoproteins. These substances are synthesized in the liver and transported into the circulation.
- *Tests of the capacity of the liver to transport organic anions and metabolize drugs*: within this category, the serum bilirubin is the most useful. Other tests that assess clearance of organic compounds from the circulation by the liver include indocyanine green (ICG), bile acids, caffeine, lidocaine, and breath tests. These tests are rarely used in clinical medicine, but may have a limited role in some research studies.
- *Tests to detect fibrosis in the liver*: these include proprietary tests such as Fibrosure®, FibroTest®, and the Enhanced Liver Fibrosis® (ELF) test. These tests rely on the use of several biochemical markers that are mathematically combined to estimate the degree of fibrosis assessed by histopathology of the liver (see Chapter 12).
- *Tests that reflect chronic inflammation or altered immunoregulation*: these include specific autoantibodies and immunoglobulins, proteins that are made by B lymphocytes, not hepatocytes. Some of these tests may be helpful in diagnosing autoimmune liver diseases such as autoimmune hepatitis and primary biliary cirrhosis.

Tests for detection of injury to hepatocytes (serum enzyme tests)

The liver contains thousands of enzymes, some of which are also present in serum in very low concentrations. Most of these enzymes have no known function in the serum. They are distributed in the plasma and interstitial fluid and have characteristic half-lives of disappearance, usually measured in days. Little is known about their catabolism or clearance. The elevation of activity for a given enzyme in serum is thought to primarily reflect its increased rate of entry into serum from injured liver cells. Serum enzyme tests can be grouped into two categories: (i) enzymes whose elevation in serum reflects generalized damage to hepatocytes; and (ii) enzymes whose elevation in serum primarily reflects cholestasis.

Enzymes that indicate the presence of hepatocellular necrosis

Aminotransferases

The serum aminotransferases (formerly called transaminases) are sensitive indicators of liver cell injury and are most helpful in recognizing acute hepatocellular diseases like hepatitis. The activities of ALT, formerly serum glutamic-pyruvic transaminase, and aspartate aminotransferase (AST), formerly serum glutamic-oxaloacetic transaminase, in serum are the most frequently measured indicators of liver disease. These enzymes catalyze the transfer of the α-amino groups of alanine and aspartic acid, respectively, to the α-keto group of ketoglutaric acid. This reaction results in the formation of pyruvic acid and oxaloacetic acid (Fig. 2.1). Of the numerous methods developed for measuring ALT and AST activity in serum, the most specific method couples the formation of pyruvate and oxaloacetate – the products of the aminotransferase reactions – to their enzymatic reduction to lactate and malate. The reduced form of nicotinamide adenine dinucleotide (NADH), the cofactor in this reduction, is oxidized to nicotinamide adenine dinucleotide (NAD). Because NADH (but not NAD) absorbs light at 340 nm, the event can be followed spectrophotometrically by means of the loss of absorptivity at 340 nm.

Both aminotransferases are normally present in serum in low concentration. The precise source of these enzymes in serum has never been firmly identified, although presumably they originate in tissues rich in ALT and AST. AST is present in liver, cardiac muscle, skeletal

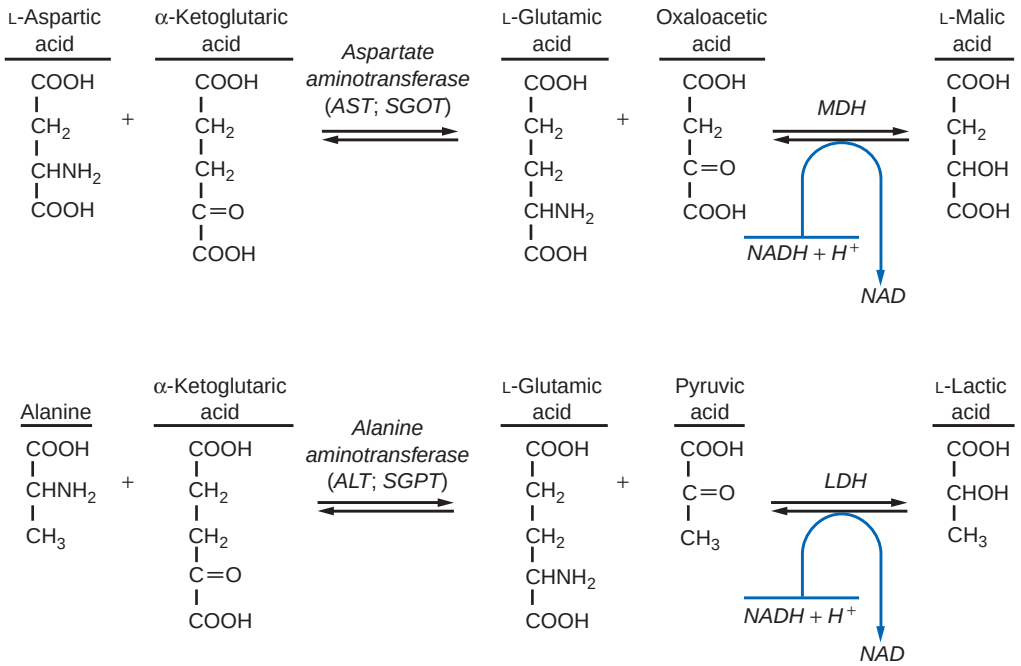

Figure 2.1 Enzymatic assay of aspartate aminotransferase (AST) and alanine aminotransferase (ALT). LDH, lactate dehydrogenase; MDH, malic dehydrogenase; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; SGOT, serum glutamic-oxaloacetic transaminase; SGPT, serum glutamic-pyruvic transaminase.

muscle, kidneys, brain, pancreas, lung, leukocytes, and erythrocytes, in decreasing order of concentration. ALT is present in highest concentration in the liver. ALT and AST both require pyridoxal 5′-phosphate as a cofactor, and both may be present in serum in apoenzyme as well as holoenzyme form [1]. In tissues, ALT is present in the cytosol; whereas AST occurs in two locations, the cytosol and mitochondria. The cytosolic and mitochondrial forms of AST are true isoenzymes and are immunologically distinct. Approximately 80% of AST activity in human liver is contributed by the mitochondrial isoenzyme, whereas most of the circulating AST activity in healthy individuals is derived from the cytosolic isoenzyme. Neither ALT nor AST has isoenzymes that are tissue-specific. Hence, isoenzyme analysis of serum ALT or AST seldom is useful. Patients with acute myocardial infarction and chronic alcoholic liver disease may be exceptions. Large increases in mitochondrial AST occur in serum after extensive tissue necrosis. Because of this, assay of mitochondrial AST has been advocated as an accurate test for the detection of myocardial infarction, but is not widely used. The level of mitochondrial AST is also increased in chronic, but not acute, alcoholic liver disease. AST and ALT levels are equally elevated in most hepatobiliary disorders, with the ALT level usually being somewhat higher than the AST level. ALT appears to be a more sensitive and specific test of liver injury than AST and is commonly used in epidemiologic studies to document the incidence of viral hepatitis.

Aminotransferase levels are typically elevated in all liver disorders (Tables 2.1 and 2.2). These include all types of acute and chronic hepatitis, cirrhosis, acute and chronic heart failure, various infections, metastatic carcinoma, and granulomatous and alcoholic liver diseases. The highest elevations occur in disorders associated with extensive hepatocellular injury, such as drug and viral hepatitis, acute ischemia, and exposure to hepatotoxins such as acetaminophen. Values are commonly in the range of several hundred to the low thousands, although values in the range of 10,000 to 15,000 IU/L (167–250 μkat/L[1] – see subsequent text) can occur in rare patients with viral hepatitis who make uneventful recoveries. Levels of aminotransferases are seldom elevated above 500 IU/L (8.34 μkat/L) in obstructive jaundice, in viral hepatitis in patients with acquired immune deficiency syndrome (AIDS), and in cirrhosis (Tables 2.1 and 2.2) [2].

The increase in the serum values of ALT and AST is related to injury to cells rich in the aminotransferases or

[1]SI units (Le Système International d'Unites) are gradually replacing other units to have one common, worldwide system for reporting scientific data. The SI unit for enzymatic reactions is the katal, abbreviated kat. It replaces the international unit (IU/L) and denotes moles of substrate converted per second. For example, to convert alkaline phosphatase in IU/L to SI units (μkat/L), multiply the IU/L value by 0.01667. The SI reference range for alkaline phosphatase is 0.5–2 μkat/L. This value may vary somewhat among laboratories.

Table 2.1 Evaluation of acute elevations in aminotransferases.

Diagnosis	Range of ALT (IU/L)	AST : ALT ratio	Additional tests
Viral hepatitis	N l–3,000	<1	Hepatitis serologies: HBsAg, anti-HCV, anti-HDV, HCV RNA, HBV DNA
Drug-induced liver injury	N l–15,000	>1	Acetaminophen level, acetaminophen adducts, serial determinations of aminotranserases
Ischemic necrosis	N l–10,000	>1	–
Rhabdomyolysis	N l–5,000	>1	CPK
Myocardial infarction	N l–400	>1	CPK, troponin
Sepsis	N l–400	<1	Blood, urine cultures
Acute biliary obstruction	N l–2,000	<1	Imaging
Aminita phalloides poisoning	N l–5,000	<1	–

ALT alanine aminotransferase; AST, aspartate aminotransferase; CPK, creatine phosphokinase; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; N, normal.

to changes in cell membrane permeability. The activity of any of the liver enzymes in serum reflects the rate of release of the enzyme from the liver into the circulation and the clearance of the enzyme from the circulation. The activity of AST and ALT in liver cells is more than 1,000 times greater than the activity in serum, so that, as liver cells die, the activity of aminotransferases increases in plasma. Under most circumstances the rate of clearance from the circulation remains relatively constant. An acute hepatocellular injury that takes place within a short period of time, such as necrosis due to acetaminophen poisoning, will result in a rapid rise in the serum levels of the enzymes as the enzyme activity from the dying cells enters the circulation. In patients with acetaminophen poisoning or ischemic injury, the peak level of AST exceeds that of ALT in the first 24 hours. Once there is no further injury to cells, the serum activity of both AST and ALT will return to the normal range. The rate of decline in the level of the enzymes depends on the clearance from the circulation, in much the same fashion as drugs are

Table 2.2 Evaluation of chronically elevated aminotransferases.

Diagnosis	Range of ALT (IU/L)	AST : ALT ratio	Additional tests
Viral hepatitis	N l–500	<1	Hepatitis serologies: HBsAg, anti-HCV, anti-HDV, HCV RNA, HBV DNA
Cirrhosis	N l–500	>1	Tests for advanced fibrosis, imaging
NAFLD	N l–300	<1	Imaging, elevated triglycerides, tests for insulin resistance
Cirrhosis	N l–300	>1	Tests for advanced fibrosis, imaging
Alcoholic liver disease	N l–400	>2	GGT, CAGE, or AUDIT questions, carbohydrate-deficient transferrin
Hemochromatosis	N l–200	>1	Ferritin, iron saturation, genetic testing
Autoimmune hepatitis	N l–2,000	<1	Antismooth muscle antibody, ANA, elevated IgG
Wilson disease	N l–2,000	<1	Ceruloplasmin, elevated serum copper, elevated urinary copper
Celiac disease	N l–100	<1	Tissue transglutaminase antibody, antiendomysial antibody
α_1-Antitrypsin deficiency	N l–100	<1	α_1-Antitrypsin phenotype
Hyperthyroidism	N l–200	<1	Elevated free T4, low TSH
Granulomatous liver disease	N l–500	<1	Various
Drug-induced liver injury	N l–2,000	<1	–
Myositis	N l–5,000	Usually >1	Elevated CPK, elevated aldolase
TPN	N l–300	<1	–

ALT alanine aminotransferase; ANA, antinuclear antibodies; AST, aspartate aminotransferase; CPK, creatine phosphokinase; GGT, γ-glutamyltransferase; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; IgG, immunoglobulin G; N, normal; NAFLD, nonalcoholic fatty liver disease; TSH, thyroid-stimulating hormone.

eliminated. ALT and AST are both catabolized by the liver with a resulting plasma half-life of 47 ± 10 hours for ALT and 17 ± 5 hours for AST [3]. The enzymes are presumably catabolized by cells in the reticuloendothelial system. Hepatic sinusoidal cells appear to be the main site for AST clearance. Almost no aminotransferases are present in urine and only a very small amount is present in bile. It is therefore unlikely that biliary or urinary excretion plays a role in the clearance of ALT or AST.

Chronic injury to the liver results in significant variability in the rate of release of enzymes into the circulation. Many studies have shown a poor correlation between the severity of necrosis or inflammation and the serum level of ALT. Since the plasma level of ALT is affected by both the rate of release of the enzyme into the plasma and the rate of clearance of ALT from the plasma, both parameters could potentially affect the plasma level of ALT. Unfortunately, there is little information regarding the effect of chronic liver disease on the plasma clearance of aminotransferases. The level of ALT in serum varies considerably over time in patients with chronic viral hepatitis [4], presumably as a result of variable degrees of inflammation and/or necrosis in the liver. Only rarely does the level of ALT in chronic viral hepatitis exceed 500 IU/L. Although the level of ALT is variable in patients with chronic hepatitis, there is not a consistent and predictable decline in the serum level as observed after acetaminophen poisoning or ischemia. These random fluctuations can easily be distinguished from the first-order decay in the level of AST and ALT seen after massive necrosis from drug-induced or ischemic injury helping to distinguish a short-term acute injury from a more chronic one.

For any laboratory test, the mean value ± 2 standard deviations (SD) in a presumably healthy population constitutes the normal range for those tests with a normal, Gaussian distribution. In the 1950s the standard range was established using 88 healthy individuals [5]. Testing on a larger population of over 12,000 volunteers defined the "reference range" for AST to be 13–31 IU/mL and for ALT to be 13–40 IU/mL [6]. The distribution of serum AST and ALT activity in healthy volunteers is asymmetric and does not follow a normal, Gaussian distribution. For serum ALT activity, the distribution is linear after a log transformation. Therefore, the normal range is more often defined by excluding the top 2.5% of the values from presumably healthy volunteers, rather than using the mean ± 2 SD [7]. Local clinical laboratories have also independently defined the range of "normal" ALT based on measurements in specific populations [7]. However, this approach may not accurately reflect the "true normal" values since there are many factors that can influence serum ALT activity, including gender, obesity, and the presence of undiagnosed liver diseases in asymptomatic individuals. Men have higher serum activity of ALT than women [6–9]. In recent years, considerable attention has been focused on the role of obesity as a factor contributing to a higher upper limit of the "normal" range for ALT. Nonalcoholic fatty liver disease (NAFLD) is widely recognized as the most common reason for abnormal liver enzymes in the population. Individuals with NAFLD may have only slight elevations in ALT. Failure to exclude them from a population used to define the "normal" range could lead a higher than expected upper limit. Since many diseases of the liver are asymptomatic in early stages, careful definition of the true normal range of ALT and AST is important in screening patients for the presence of liver disease.

In a cohort of 1,033 blood donors, the upper limit of the normal range of ALT was found to depend on body mass index (BMI) and gender; the authors therefore recommended adjusting the ULN for these factors to reduce the artificial heterogeneity in selecting blood donors [8]. Interestingly, an effect of alcohol consumption on ALT was not observed. Based on these findings, a value was recommended of 31 IU/L for the ULN in females with a BMI $<23\,kg/m^2$ and of 42 IU/L for males with a BMI $<23\,kg/m^2$, and of 44 IU/L for females with a BMI $>23\ kg/m^2$ and of 66 IU/L for males with a BMI $>23\,kg/m^2$. A similar study of 6,835 volunteer blood donors in Italy also identified gender and BMI as the primary factors that were associated with a higher ALT [9]. In addition, laboratory parameters indicating abnormal lipid or glucose metabolism were associated with a higher ALT, consistent with what is known about the risk factors for NAFLD. The authors recommended a ULN of 30 IU/L for men and 19 IU/L for women, based on the 95 percentile of subjects (top 5% were excluded). The sensitivity for identifying individuals with hepatitis C virus (HCV) viremia improved from 55% to 76.3% using these limits, compared with 40 and 30 IU/mL for men and women, respectively. Data from a Korean population of healthy, voluntary liver donors found a similar ULN threshold (29 IU/L in men and 22 IU/L in women for the 95 percentile) to those of other recent studies [10]. Using the 97.5 percentile would produce a ULN of 33 IU/L for men and 25 IU/L for women. The voluntary donors all had liver biopsies documenting normal histology (Table 2.3).

Beyond defining the normal range for a population, knowing the "true normal value" for serum ALT is important in making treatment decisions for diseases such as chronic viral hepatitis, particularly hepatitis B. Guidelines published by the American Association for the Study of Liver Diseases (AASLD), the European Association for the Study of the Liver (EASL), and the Asia–Pacific Association for the Study of the Liver (APASL) all use elevation in ALT above the ULN as a factor to

Table 2.3 Population studies of normal alanine aminotransferase (ALT).

Number of subjects	95% ULN	97.5% ULN	Variables affecting ALT	Reference
12,682	61 IU/L (men)	38 IU/L (men)	Age, gender, weight	Siest et al. [6]
Presumably healthy individuals				
	38 IU/L (women)	51 IU/L (women)	–	
Voluntary HCV-negative blood donors	36 IU/L (men)	–	BMI, triglycerides, by multiviariate analysis	Prati et al. [9]
3,856 men				
2,970 women	21 IU//L (women)	–	–	
1,085	42 (men with BMI <23 kg/m^2)	–	BMI, GGT	Piton et al. [8]
–	31 (women with BMI <23 kg/m^2)	–	–	
Voluntary liver donors with normal histology, 643 men	31 IU/L (men)	35 IU/L (men)	BMI, age	Lee et al. [10]
462 women	24 IU/L (women)	26 IU/L (women)	–

determine appropriateness for treatment of chronic hepatitis B [11–13]. In several of the guidelines, the panels recommend treatment based on values that exceed twice the ULN for ALT. The absolute value could be considerably higher if the ULN was 30 versus 19 or 40 versus 30 IU/L. The importance of defining the true normal ALT in considering treatment for chronic hepatitis B was addressed by a group of experts who recommended using 19 IU/L for women and 30 IU/L for men [14]. A population-based study in Korea, where there is a high prevalence of chronic hepatitis B infection, showed an increase in the relative risk of liver-related mortality in both men and women with an AST or ALT of greater than 20 IU/L [15]. The mean ALT activity in Japanese patients who achieved a sustained remission following treatment for chronic hepatitis C was 14.4 ± 3.2 IU/L for men and 9.9 ± 3.5 IU/L for women. These values were slightly lower than those of the healthy population although the reasons for this were unclear [16]. Of interest, serum ALT activity that is within the normal range may drop lower in response to oral nucleos(t)ide analog treatment of patients with chronic hepatitis B infection. These observations suggest that the true normal value in those individuals may be even lower than previously thought. The issue of what level of serum ALT activity should be considered normal in a population with chronic hepatitis has not been fully resolved.

There is a poor correlation between the extent of liver cell necrosis and the elevation of serum aminotransferases levels in chronic liver diseases. Similarly, absolute elevation of aminotransferase levels is of little value in predicting the outcome of acute hepatocellular disorders. Rapid decreases in serum aminotransferase levels are usually a sign of recovery from disease, but may be a poor prognostic sign in acute liver failure.

Elevated aminotransferase activity is among the first laboratory abnormalities to be detected in the early phases of viral hepatitis. In patients with jaundice due to hepatitis, the elevation of serum bilirubin level usually lags behind the increase in aminotransferase levels by approximately 1 week. Therefore, aminotransferase levels are frequently declining as the bilirubin level is increasing. Aminotransferase levels typically decline steadily during recovery from viral hepatitis. Secondary increases in aminotransferase levels or persistent elevation may indicate recrudescence of acute hepatitis or the development of chronic active hepatitis.

Hepatitis C is commonly associated with fluctuations in ALT and AST levels [4]. Some chronic hepatitis C patients with persistently normal ALT and AST levels have histologic evidence of chronic hepatitis on liver biopsy. The measurement of aminotransferases is one of the important means of evaluating the response to therapy for chronic hepatitis.

The AST : ALT ratio may be helpful in the recognition of alcoholic liver disease. If the AST is less than 400 IU/L (5.1 μkat/L), an AST : ALT ratio of more than 2 suggests alcoholic liver disease; a ratio greater than 3 is highly suggestive of alcoholic liver disease (Fig. 2.2) [17]. The increased ratio primarily reflects the low serum activity of ALT in patients with alcoholic liver disease [2]. This is secondary to a deficiency of pyridoxal 5′-phosphate in

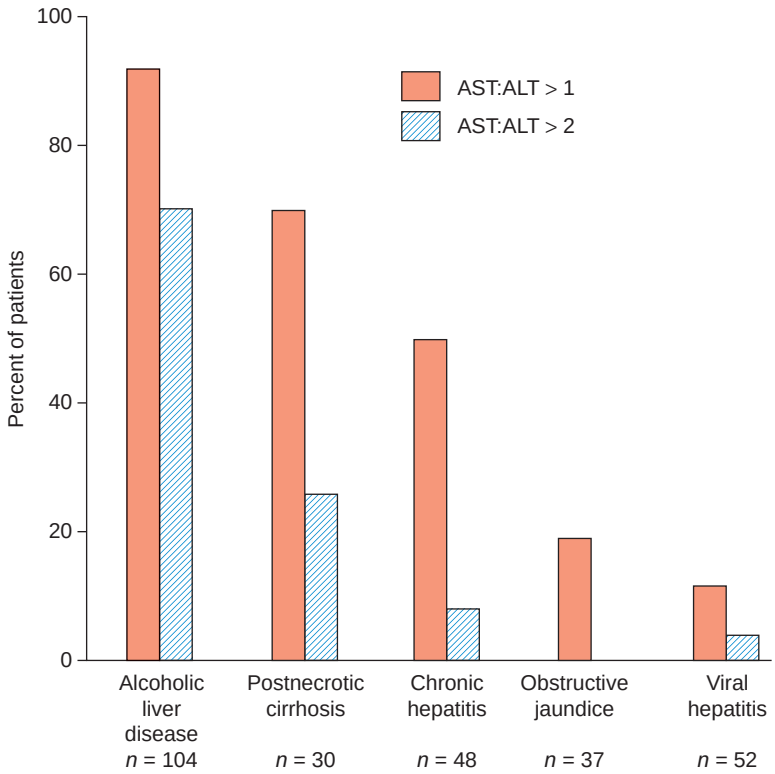

Figure 2.2 Percentage of patients with aspartate aminotransferase (AST): alanine aminotransferase (ALT) ratios greater than 1 and greater than 2. (Adapted from Cohen and Kaplan [17] with permission from Plenum.)

patients with alcoholic liver disease [1]. ALT synthesis in the liver requires pyridoxal phosphate more than AST synthesis does [1]. The altered AST : ALT ratio in the serum appears to reflect the altered ratios in the liver [2]. The less than expected increase in serum ALT and AST values in alcoholic liver disease – usually less than 200 IU/L (3.3 μkat/L) and 300 IU/L (5.1 μkat/L), respectively – cannot be explained simply by the decreased hepatic concentrations. This becomes evident whenever a patient with alcoholic liver disease has concomitant heart failure, viral hepatitis, or drug hepatotoxicity, particularly with acetaminophen; when this occurs, serum AST and ALT levels may soar to the thousands (>20 μkat/L). Despite striking elevations, the AST : ALT ratio remains increased and typical of alcoholic liver disease.

The AST : ALT ratio has been studied as a noninvasive indicator of cirrhosis in patients with chronic hepatitis C infection [18–21]. These studies have shown that an AST : ALT ratio greater than 1 indicates the presence of cirrhosis with a very high specificity (94–100%) but with a relatively low sensitivity (44–75%). Researchers identified a possible contributing factor to the AST : ALT ratio seen in both alcoholics and cirrhotics [22]. AST–immunoglobulin (Ig) complexes were studied in 128 patients with liver disease. AST was found to bind to Ig of the IgA class, but not to either IgG or IgM. This complex was seen in 41.8% of patients with chronic hepatitis, 62.2% of patients with cirrhosis, and 66.7% of patients with alcohol-related liver disease. The high level seen in the final group likely reflected the high levels of IgA seen in patients with alcoholic liver disease. The AST : ALT ratio was significantly higher in the patients with the AST–Ig complex, rather than those without, and this observation probably contributes to the higher AST : ALT ratio seen in patients with cirrhosis and alcoholic liver disease.

Elevated serum aminotransferase values are not specific for hepatobiliary disorders. They are also found in patients with severe cardiac and skeletal muscle damage. AST level is more often increased in patients with myocardial infarction than ALT, and is undoubtedly of cardiac origin. Marked increases in AST and ALT (>5000 IU/L) in patients with severe cardiac disease likely represent hepatic ischemia with centrilobular (zone 3) necrosis. AST and ALT values in muscle disease are typically less than 300 U/L (5.1 μkat/L) but have been reported to be much higher [23]. Except in instances of acute rhabdomyolysis, values rarely reach the range observed in patients with acute hepatocellular disorders. Serum AST and, occasionally, ALT activity can increase after vigorous exercise, with an AST level of greater than 1,000 U/L reported. In such cases the AST : ALT ratio is initially greater than 3 : 1, but the ratio rapidly approaches 1 : 1 given the shorter half-life of AST [23]. The ratio is typically close to 1 : 1 in patients with chronic muscle diseases or injury. This may

account for the slight, usually unexplained, increases in aminotransferase values observed among some runners.

Levels of the aminotransferases can be falsely elevated or diminished under certain circumstances. Drugs such as erythromycin and para-aminosalicylic acid can yield falsely elevated aminotransferase values if older colorimetric tests are used. Conversely, low AST values can occur in patients with uremia. These low values increase after dialysis; this finding suggests that a dialyzable inhibitor of the aminotransferase reaction is present in the serum of patients with uremia.

The cost-effectiveness of evaluating minimal elevations in ALT has been a subject of controversy. Many experts have argued that the lack of specificity of ALT and the number of conditions that do not require treatment, such as uncomplicated NAFLD, support a conservative approach to the evaluation and follow-up of these individuals [24–26]. However, several large epidemiologic studies have shown that an elevation in serum ALT activity is associated with an increase in the relative risk of death from chronic liver disease [15,27,28]. Some studies have also suggested that an elevation in serum ALT may predict an increased risk of overall mortality [15,27,29,30], whereas other studies have not found an association with increased risk of mortality from diseases other than liver ones [28]. Interestingly, a lower than normal ALT was also found to be associated with increased mortality and frailty in a geriatric population [31]. The increased mortality rate in this population appeared to be due to the association with frailty, a known risk factor for increased mortality in older individuals. Unfortunately, the disparities of opinion regarding the significance of minimal elevations of ALT are not likely to be resolved soon.

Other enzyme tests of hepatocellular necrosis

A number of other serum enzyme tests have been promulgated as being either more specific or more sensitive in the detection of hepatocellular necrosis than is the measurement of aminotransferases. Some of these enzymes are found only in liver tissues and, theoretically, the tests could be more specific for liver disease than are the aminotransferase tests. None of these enzymes have proved more useful in practice than the aminotransferase tests, and none are more widely used. Furthermore, some of these tests are not commercially available. A brief description of some of these enzyme tests follows.

Glutamate dehydrogenase

Glutamate dehydrogenase, a mitochondrial enzyme, is present primarily in the liver, heart, muscle, and kidneys. In the liver, it is present in its highest concentration in the centrilobular (zone 3) hepatocytes. Because of this location and the fact that the level is particularly elevated after acute right-sided heart failure, serum glutamate dehydrogenase was investigated as a specific marker for liver disorders that primarily affect centrilobular hepatocytes, such as alcoholic hepatitis. An initial report suggested that glutamate dehydrogenase may be a sensitive and relatively specific marker for alcoholic hepatitis, but this has not been confirmed [32].

Isocitrate dehydrogenase

Isocitrate dehydrogenase (ICDH), a cytoplasmic enzyme, is present in the liver, heart, kidneys, and skeletal muscle. Its activity in serum parallels that of the aminotransferases in acute and chronic hepatitis, but it is less sensitive. Although elevations in serum ICDH are relatively specific for liver disorders, increased levels have also been reported in disseminated malignant disease without detectable hepatic involvement. Like glutamate dehydrogenase, ICDH is predominantly found in hepatocytes in the centrilobular zone [33]. The measurement of ICDH does not yet offer any diagnostic advantage over the measurement of aminotransferases.

Lactate dehydrogenase

Lactate dehydrogenase (LDH) is a cytoplasmic enzyme present in tissues throughout the body. Five isoenzymes of LDH are present in serum, and are readily separated by various electrophoretic techniques. The slowest migrating band predominates in the liver. This test is not as sensitive as aminotransferase tests in the detection of liver disease and has poor diagnostic specificity, even when isoenzyme analysis is used. The LDH test is more useful as a marker of myocardial infarction and hemolysis. Marked elevations in serum LDH are sometimes seen in patients with acute liver failure due to ischemia or to infiltration of the liver with tumors such as melanoma or small cell carcinoma of the lung.

Sorbitol dehydrogenase

Sorbitol dehydrogenase is a cytoplasmic enzyme predominantly present in the liver; only relatively low concentrations are found in the prostate gland and kidneys. The activity of sorbitol dehydrogenase in serum parallels that of the aminotransferases in hepatobiliary disorders [34]. The measurement of sorbitol dehydrogenase appears to be less sensitive, however, and values may be normal in cirrhosis and other chronic liver disorders. The instability of this enzyme in serum further limits its diagnostic usefulness.

Enzymes for the detection of cholestasis

Alkaline phosphatase

Alkaline phosphatase is the name given to a group of zinc metalloenzymes that catalyze the hydrolysis of a large number of organic phosphate esters, optimally at an

alkaline pH. The alkaline phosphatases of different tissues are true isoenzymes because they catalyze the same reaction, but differ in certain physicochemical properties [35]. Most of the alkaline phosphatase isoenzymes of clinical interest are coded by one gene: the liver/bone/kidney enzyme, also known as *tissue-unspecific alkaline phosphatase.* They have the same immunologic properties and amino acid sequence. Their unique physicochemical properties are conferred by the different carbohydrate and lipid side chains added by post-translational modification. A second gene codes for intestinal alkaline phosphatase; a third gene codes for placental alkaline phosphatase and an isoenzyme made in certain cancers, the Reagan isoenzyme; and a fourth gene encodes a placental-like isoenzyme [36].

The precise function of alkaline phosphatase remains unknown. Alkaline phosphatases are found in the membrane of bone osteoblasts, the canalicular membranes of hepatocytes, the brush border of mucosal cells of the small intestine, the proximal convoluted tubules of the kidney, the placenta, and white blood cells [37]. In rat liver, alkaline phosphatase appears to have an active role in downregulating the secretory activities of the intrahepatic biliary epithelium [38]. In bones, the enzyme appears to be concerned with calcification, although its precise function is unknown. At other sites, it may participate in transport processes, but its actual physiologic purpose is largely unknown. There is good evidence that serum alkaline phosphatase in the normal adult is primarily derived from three sources: the liver, bone, and intestinal tract. The liver and bone are the major sources [39]. Contribution from the intestine (approximately 10–20%) is of importance, primarily in individuals with blood groups O and B, and the blood level of alkaline phosphatase is enhanced after the consumption of a fatty meal [40]. Studies with infused placental alkaline phosphatase have shown that the circulating enzyme appears to behave as other serum proteins do. The half-life is 7 days, and clearance from the serum is independent of the functional capacity of the liver or the patency of the bile ducts. The sites of degradation are unknown.

In the 15–50-year-old group, mean serum alkaline phosphatase activity is somewhat higher in men than in women (Fig. 2.3). In contrast, among individuals older than 60 years, the enzyme activity of women equals or exceeds that of men, and both sexes have somewhat higher values than younger adults [41]. The reasons for these differences are not known. In children, serum alkaline phosphatase activity is considerably elevated in both sexes, correlates well with the rate of bone growth, and appears to be accounted for by the influx of enzyme from osteoid tissue. Serum alkaline phosphatase in healthy adolescent males may reach mean levels three times greater than in healthy adults, without implying the presence of hepatobiliary disease. Enzyme activity in serum may double late in normal pregnancy, primarily because of the influx of placental phosphatase. Although elevation of serum alkaline phosphatase activity is observed in various hepatobiliary diseases, similar elevations are seen in disorders of bone characterized by increased osteoblastic activity, and normally occur during growth and pregnancy. The intestinal tract may occasionally and the kidneys may rarely be the sources of an elevated serum enzyme level [42].

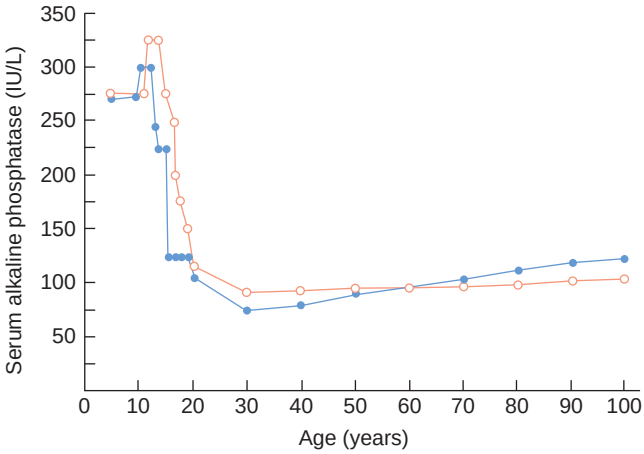

Figure 2.3 Normal serum alkaline phosphatase values at various ages for men (open circles) and women (closed circles). (Multiply by 0.01667 to convert to SI units, μkat/L.) (Data from Clarke and Beck [104] and Wolf [105].)

Identification of the specific isoenzymes of alkaline phosphatase could be helpful if an elevated serum alkaline phosphatase level is the only abnormal finding in an asymptomatic individual, or if the degree of elevation is higher than expected in the clinical setting. Although alkaline phosphatases derived from the liver, bone, intestine, and placenta have different electrophoretic mobilities [43], unfortunately electrophoresis and other methods of testing such as stability after heating are not sufficiently accurate to provide reliable differentiation of the isoenzymes. Therefore, the best substantiated approach to identifying the source of an isolated elevation in alkaline phosphatase is to measure the activity of enzymes that are released in parallel to liver alkaline phosphatase – such as serum leucine aminopeptidase, 5′-nucleotidase, and γ-glutamyltransferase (GGT) (Fig. 2.4). The levels of these enzymes, discussed later, are not elevated in bone disorders but only in those patients with liver dysfunction or, in the case of leucine aminopeptidase and 5′-nucleotidase, possibly in pregnancy. An increase of these enzymes in the serum of nonpregnant patients indicates that an elevated serum alkaline phosphatase is caused at least in part by hepatobiliary disease. In contrast, the lack of an increased level of 5′-nucleotidase in serum in the presence

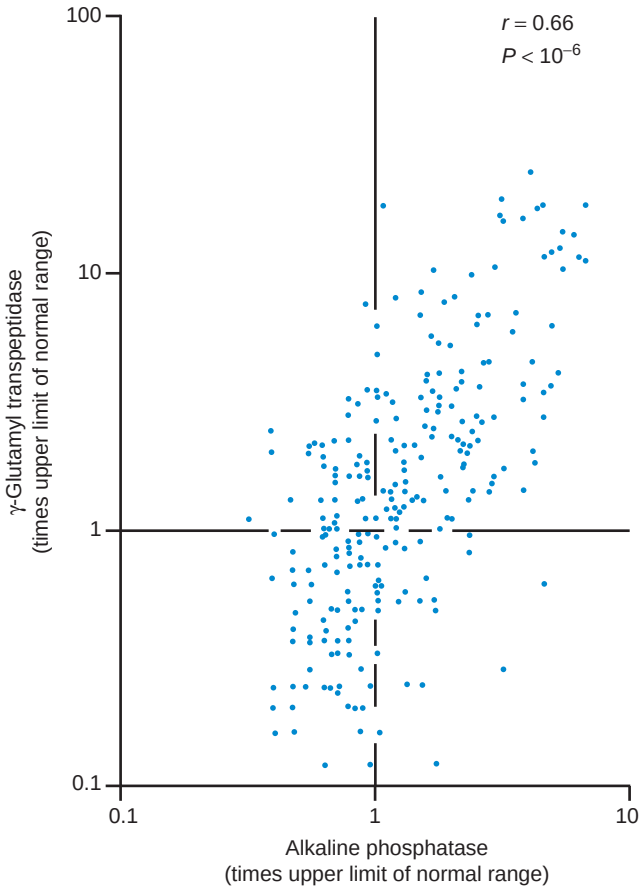

Figure 2.4 Correlation between serum γ-glutamyltransferase (GGT) and serum alkaline phosphatase levels in 245 healthy subjects and patients with hepatobiliary diseases. The units on the abscissa and ordinate are the logarithms of the multiples of the upper limits of normal for each test. Each point represents one patient. Although the correlation between the logarithmic values of the population is good ($r = 0.66$), a considerable variation exists between the percentage of GGT and alkaline phosphatase elevations in individual patients. (Reproduced from Whitefield et al. [106] with permission from British Medical Journal.)

of an elevated level of alkaline phosphatase does not rule out liver disease, because these enzymes do not necessarily increase in parallel in early or modest hepatic injury.

Hepatobiliary disease leads to an increased serum activity of alkaline phosphatase that is paralleled by a striking increase in hepatic enzyme activity. The increased hepatic activity cannot be accounted for by the biliary retention of alkaline phosphatase [44]. Most evidence suggests that this elevation primarily occurs because of enhanced translation of mRNA rather than increased synthesis of mRNA in the liver, with subsequent release of the phosphatase into the circulation (44,45]. This process appears to be mediated by the action of bile acids, which induce the synthesis of the enzyme and may cause it to leak into the circulation, perhaps by the disruption of hepatic organelles and the solubilization of phosphatase bound to such membranes [45]. The precise manner in which the phosphatase reaches the circulation is unclear. In some patients with cholestasis, small vesicles that contain many basolateral (sinusoidal) membrane enzymes – including alkaline phosphatase – still bound to these membranes have been found in serum [46]. These observations may explain the delayed elevation of serum alkaline phosphatase after acute obstruction of the biliary tract.

The principal value of serum alkaline phosphatase in the diagnosis of liver disorders is in the recognition of cholestatic disorders. Approximately 75% of patients with prolonged cholestasis have alkaline phosphatase values increased four-fold or greater. Such elevations occur in both extrahepatic and intrahepatic obstruction, and the extent of the elevation does not differentiate the two. There is essentially no difference among the values found in obstructive jaundice due to cancer, common duct stone, sclerosing cholangitis, or bile duct stricture. Values are similarly increased in patients with intrahepatic cholestasis due to drug-induced hepatitis, primary biliary cirrhosis, rejection of transplanted liver, and, rarely, alcohol-induced steatonecrosis. Values are also greatly elevated in hepatobiliary disorders in patients with AIDS (e.g., primary sclerosing cholangitis due to cytomegalovirus infection and tuberculosis with hepatic involvement) [47].

Lesser increases in alkaline phosphates activity – up to three times the upper limit of normal – are nonspecific and may occur in all types of liver disorders (including viral hepatitis, chronic hepatitis, cirrhosis, and infiltrative diseases of the liver) and congestive heart failure.

Isolated elevations of hepatic alkaline phosphatase or a disproportionate elevation compared with the results of other tests, such as the measurement of aminotransferases and serum bilirubin, may occur in partial bile duct obstruction due to gallstones or tumor, as well as in infiltrative disease (such as sarcoidosis, hepatic abscesses, tuberculosis, and metastatic carcinoma) [39]. The mechanism is unknown, but probably represents local areas of bile duct obstruction with induction and leakage of hepatic alkaline phosphatase into serum, from these obstructed areas. An elevated serum alkaline phosphatase level in patients with primary extrahepatic cancer does not necessarily imply metastasis to the liver or bone. Some cancers secrete their own alkaline phosphatase into serum or cause leakage of hepatic alkaline phosphatase into serum by an unknown mechanism [48].

Moderate elevations in the level of alkaline phosphatase of hepatic origin can occur in disorders that do not directly involve the liver, such as stage I or II Hodgkin disease, myeloid metaplasia, congestive heart failure, intra-abdominal infections, and osteomyelitis [48]. Certain families may also have increased levels of serum alkaline phosphatase that are genetic in origin [42].

Finally, extremely low levels of alkaline phosphatase can be present in patients with fulminant Wilson disease complicated by hemolysis [49,50].

5′-Nucleotidase

5′-Nucleotidase specifically catalyzes the hydrolysis of nucleotides such as adenosine 5′-phosphate and inosine 5′-phosphate, in which the phosphate is attached to the 5-position of the pentose moiety. 5′-Nucleotidase is found in the liver, intestines, brain, heart, blood vessels, and endocrine pancreas. In the liver, the enzyme is primarily associated with canalicular and sinusoidal plasma membranes. The physiologic purpose is unknown. In most laboratories, 5′-nucleotidase activity is assayed by the use of adenosine 5′-phosphate as a substrate, and the measurement of either the released inorganic phosphate or the free adenosine. The presence of alkaline phosphatase in serum complicates the assay because it also hydrolyzes the 5′-nucleotide substrates. Corrections for alkaline phosphatase activity can be made in two ways: (i) preliminary incubation of serum with appropriate concentrations of ethylenediaminetetra-acetic acid, which selectively inactivates only alkaline phosphatase; or (b) assay in the presence and absence of nickel (Ni^{2+}), a heavy metal that specifically inhibits 5′-nucleotidase. In most clinical laboratories, free inorganic phosphate is measured. A unit of 5′-nucleotidase activity is designated as an equivalent to the amount of enzyme that liberates 1 mg of phosphate per 100 mL of serum per hour. These units are analogous to the old Bodansky units of alkaline phosphatase activity and are expressed as such. In most series of healthy adults, the serum 5′-nucleotidase level ranges from 0.3 to 3.2 Bodansky units, and is not clearly influenced by sex or race. Values are substantially lower in children than in adults, increase gradually with adolescence, and reach a plateau after 50 years of age.

Serum values of 5′-nucleotidase are primarily elevated in hepatobiliary disease with a spectrum of abnormal values similar to that for alkaline phosphatase. The parallel behavior of these two enzymes in hepatobiliary disease probably reflects their similar subcellular location in hepatocytes [51]. Both enzymes are bound to bile canalicular and sinusoidal membranes, and must be solubilized to gain access to the circulation. Bile acids may act as detergents and solubilize them. In experimental bile duct obstruction in rats, bile acid concentrations rapidly reach levels sufficient to disrupt plasma membranes and solubilize both these enzymes. The same may occur in hepatobiliary disorders in which any degree of cholestasis develops [51].

The results of most studies indicate that alkaline phosphatase and 5′-nucleotidase are equally valuable in demonstrating biliary obstruction or hepatic infiltrative and space-occupying lesions. In selected patients, however, the level of one enzyme may be elevated and that of the other normal. Although the coefficient of correlation between the two enzymes is high, the values may not increase proportionately in individual patients [52].

Most data suggest that the 5′-nucleotidase and serum alkaline phosphatase are of equal value in differentiating obstructive from parenchymal liver disease. All investigators have shown some overlap in 5′-nucleotidase values in obstructive and hepatocellular jaundice. Some investigators have found this overlap to be small, and have concluded that this assay is equal to or better than the measurement of serum alkaline phosphatase for differentiating these two types of jaundice. Others have reported that the measurement of alkaline phosphatase has greater selective value [52].

Conflicting data have been reported for values of 5′-nucleotidase activity in serum during normal pregnancy. Some investigators have found an increase in enzyme activity in the third trimester, and others have reported no change during pregnancy. It is not clear whether these experiences are accounted for by differences in the methods used to measure 5′-nucleotidase activity. The major advantage of 5′-nucleotidase over the nonspecific alkaline phosphatase measurement in serum is enhanced specificity. Most studies show that the serum level of 5′-nucleotidase does not increase in bone disease; in the few instances in which an increase was observed, it was of low magnitude [52]. This is in striking contrast to results with alkaline phosphatase [52].

The greatest value of the 5′-nucleotidase assay is its specificity for hepatobiliary disease. An increased serum 5′-nucleotidase level in a nonpregnant individual suggests that a concomitantly increased serum alkaline phosphatase level is of hepatic origin. A normal nucleotidase level in the presence of an elevated serum alkaline phosphatase level does not rule out the liver as the source of the elevated phosphatase level. The level of one enzyme may occasionally be normal and the other elevated in liver disease.

Gamma-glutamyltransferase

γ-Glutamyltransferase catalyzes transfer of the γ-glutamyl group from γ-glutamyl peptides such as glutathione (GSH) to other peptides and to L-amino acids. GGT is present in many tissues in cell membranes, including the ductular side in the proximal tubule of the kidneys, intestine, and epididymis. A lower activity of GGT is found in the pancreas, liver, spleen, heart, brain, and seminal vesicles. GGT plays an important role in the hydrolysis of GSH and may also play a role in amino acid transport across membranes as part of the γ-glutamyl cycle. Within the liver, GGT is localized predominantly on biliary epithelial cells and on the apical membrane of hepatocytes. Although the activity of GGT in liver

is relatively low in comparison to kidney and other tissues, the liver is the predominant source of the enzyme in the serum. Serum enzyme values are usually comparable for men and women, although some investigators have found higher values in men [53]. Children more than 4 years old have serum values of healthy adults. Serum enzyme activity does not increase during the course of normal pregnancy. The normal range is 0–30 IU/L (0–0.5 μkat/L).

Elevated serum GGT enzyme activity is found predominantly in diseases of the liver, biliary tract, and pancreas [53]. Abnormal values appear in approximately the same spectrum of hepatobiliary diseases as for alkaline phosphatase, leucine aminopeptidase, and 5′-nucleotidase. Some investigators find the GGT test more sensitive than alkaline phosphatase and leucine aminopeptidase tests in the detection of liver disease [53]. Others find little difference in sensitivity between GGT and alkaline phosphatase tests. A reasonably good, albeit far from perfect, correlation exists between GGT levels and those of 5′-nucleotidase and alkaline phosphatase in liver disease (Figs 2.4 and 2.5). The mechanism underlying the elevation of GGT in hepatobiliary diseases remains uncertain, but solubilization and release of membrane-bound GGT is one possible mechanism. Alternatively, death of biliary epithelial cells is another possibility [54].

High values of serum GGT are also found in patients who take medications such as barbiturates or phenytoin, or in those who ingest large quantities of alcohol [55,56], even when other serum enzyme and bilirubin values are normal. An isolated elevation in GGT level, or an elevation in GGT level out of proportion with that of other enzymes such as alkaline phosphatase or ALT, particularly in an asymptomatic patient, may be an indicator of heavy alcohol consumption. The induction of hepatic microsomal GGT by alcohol and other drugs may account for some of these observations. This is not the only explanation, however, because neither elevated serum GGT levels, nor a history of recent alcohol ingestion, correlates with hepatic GGT activity in patients with biopsy-proven alcoholic liver disease [57]. In addition, the alkaline phosphatase and hepatic GGT activities are similarly increased in patients with alcoholic hepatitis, yet serum GGT levels were 1,300% of normal while alkaline phosphatase serum levels were only slightly above normal [57]. Aside from its value in conferring liver specificity to an elevated alkaline phosphatase level and its possible use in identifying that a patient abuses alcohol, the measurement of serum GGT offers little advantage over aminotransferase and alkaline phosphatase testing in the evaluation of patients with suspected liver disease. In a prospective study with 1,040 nonselected inpatients, 139 patients (13.4%) had elevated serum GGT activity. Only 32% of these patients had hepatobiliary disease; the other 68% had other diseases that did not involve the liver [58]. The clinical value of GGT lies in its use in conferring organ specificity to an elevated value of alkaline phosphatase, because GGT activity is not elevated in patients with bone disease.

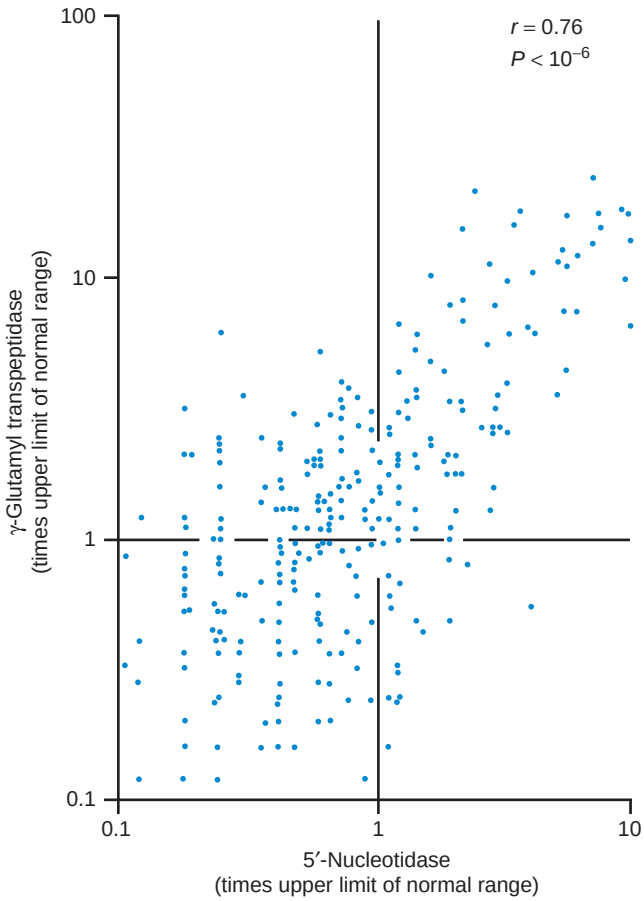

Figure 2.5 Correlation between serum γ-glutamyltransferase (GGT) and serum 5′-nucleotidase values in 245 healthy subjects and patients with hepatobiliary diseases. The units on the abscissa and ordinate are the logarithms of the multiples of the upper limits of normal for each test. Although the correlation between the logarithmic values of the population is good ($r = 0.76$), there is considerable variation between the percentage of GGT and 5′-nucleotidase elevations in individual patients. Leucine aminopeptidase

Leucine aminopeptidase, a proteolytic enzyme, hydrolyzes tissue amino acids from the N-terminal of proteins and polypeptides. It is most active when leucine is the N-terminal residue – hence, its name. Leucine aminopeptidase is found in all human tissues assayed; it has high activity in the liver, where it is primarily localized in the biliary epithelium. The function of this enzyme is not known, although it possibly involves hydrolysis of a peptide bond near an L-leucine residue, or the transfer of L-leucine from one peptide to another. The leucine aminopeptidase of normal serum, as a rule,

is electrophoretically homogenous and probably originates in the liver. In hepatobiliary disease, several peaks of activity are detected, and they probably represent isoenzymes.

The prevalent method for measuring serum leucine aminopeptidase involves α-leucyl-β-naphthylamine hydrochloride as a substrate; the liberated β-naphthylamine is assayed colorimetrically. Some evidence exists that the peptidase responsible for this reaction differs from the peptidases that hydrolyze other leucine compounds. Accordingly, in extrapolating data from one study to another, one should carefully consider the substrate used. Normal values when α-leucyl-β-naphthylamine is used usually range from 50 to 220 IU/L without a significant difference due to sex, age (18–75 years), or fed state.

Elevation in the leucine aminopeptidase level, like that of 5′-nucleotidase and to a lesser degree GGT, appears to be specific for liver disorders. The level of leucine aminopeptidase is not elevated in patients with bone disease [59], and enzyme values in children, although based on a small number of determinations, are comparable with those of adults. The only condition other than hepatobiliary disease known to result in an increase in this enzyme is pregnancy [59]. The level of serum leucine aminopeptidase progressively increases during gestation and reaches a peak at term. After delivery, the enzyme level falls, decreasing approximately 35% in 4 days. Electrophoresis of serum leucine aminopeptidase from pregnant women and from individuals with liver disease shows much overlap among the isoenzymes. This procedure is probably of no practical value in differentiating these two sources of the enzyme.

Serum leucine aminopeptidase testing is as sensitive as the measurement of alkaline phosphatase and 5′-nucleotidase in the detection of obstructive, infiltrative, or space-occupying lesions of the liver. Some investigators consider leucine aminopeptidase to be a more sensitive indicator of infiltrative diseases, rather than alkaline phosphatase, in nonjaundiced patients [59]. Contrary to the findings described in the original reports, pancreatic cancer without hepatobiliary disease does not cause an elevation in the level of serum leucine aminopeptidase.

Leucine aminopeptidase activity is elevated in most types of liver disease, but values are highest in biliary obstruction. Some investigators have promulgated it as a reliable test for differentiating obstructive and hepatocellular liver disease [56]. Others have observed a considerable overlap in values among patient groups, and found serum alkaline phosphatase to be at least as selective. The controversy regarding the specificity of measurement of leucine aminopeptidase as a test of biliary obstruction has never been resolved. Because of the availability of other equally sensitive, convenient, and specific tests, leucine aminopeptidase is not widely used. Its possible value is its specificity only for liver disease. In this regard, 5′-nucleotidase and GGT seem to have comparable merit.

Tests of the liver's biosynthetic capacity

Serum contains a complex mixture of proteins that have been extensively studied with various techniques. A schematic representation of the results of some of these methods is shown in Fig. 2.6. The liver is the main source of most of these serum proteins. The parenchymal cells are responsible for the synthesis of albumin, fibrinogen, and other coagulation factors, and most of the α- and β-globulins. γ-Globulins are an important exception, being synthesized by B lymphocytes [60].

In this section, we only discuss proteins used in the diagnosis of liver disease: albumin and coagulation factors, which are synthesized exclusively by hepatocytes. Additional diagnostic proteins include lipoproteins, ceruloplasmin (the blue copper-containing protein), ferritin, and α_1-antitrypsin.

Albumin

Albumin, which is quantitatively the most important plasma protein, is synthesized exclusively by the liver. Normal serum values range from 3.5 to 4.5 g/dL (35–45 g/L). The average adult has approximately 300–500 g of albumin distributed in body fluids, and synthesizes approximately 15 g/day (200 mg/kg/day). The synthesis rate may double in conditions in which rapid albumin loss or a decrease in serum albumin concentration occurs because of dilution, such as during the rapid accumulation of ascitic fluid [61]. Albumin has a long half-life, about 20 days. Approximately 4% is degraded each day, but little is known about the site of degradation. The serum level at any time reflects the rate of synthesis and degradation, and the volume of distribution. Albumin synthesis is regulated by changes in nutritional status, osmotic pressure, systemic inflammation, and hormone levels [61,62]. The precise mechanism is not entirely known, but appears to be related to the formation of albumin mRNA polysomes within the liver [62]. Substances that stimulate albumin synthesis cause individual ribosomes to bind to the albumin mRNA to form polysomes, which synthesize albumin more efficiently [62]. Amino acids such as tryptophan, phenylalanine, glutamine, and lysine function in this way and increase albumin synthesis in vitro [62]. Albumin synthesis is also stimulated by the amino acids that increase urea synthesis, that is, ornithine and arginine [63]. Ornithine serves as a precursor of the polyamine spermine, a compound that promotes polysome formation [63]. Corticosteroids and thyroid hormone stimulate albumin synthesis by increasing the concentration of albumin mRNA and transfer RNA in

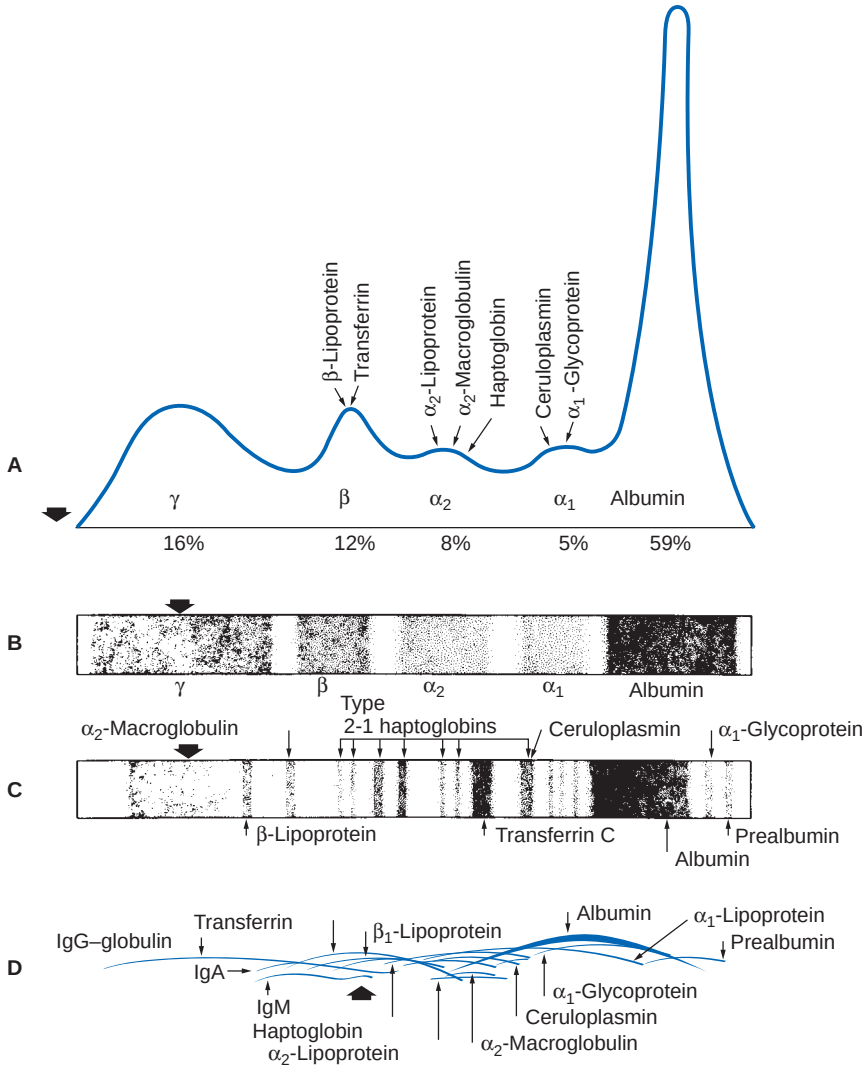

Figure 2.6 Schematic representation of the electrophoretic pattern of normal human serum in pH 8.6 buffer obtained with four methods: (A) tiselius or free boundary electrophoresis; (B) paper electrophoresis; (C) starch-gel electrophoresis; and (D) immunoelectrophoresis. (Reproduced from Putnam [107] with permission from Elsevier.)

hepatocytes either by increasing its synthesis or decreasing its degradation [64]. In vitro, alcohol decreases albumin synthesis by inhibiting the formation of polysomes [62], whereas inflammation decreases albumin synthesis [65] through the inhibitory effects of interleukin 1 and tumor necrosis factor [66].

Serum albumin levels tend to be normal in patients with liver disease such as acute viral hepatitis, drug-related hepatoxicity, and obstructive jaundice. Albumin levels of less than 3 g/dL associated with hepatitis should raise the suspicion of chronic hepatitis. Hypoalbuminemia is more common among individuals with chronic liver disorders, such as cirrhosis, and usually reflects severe liver damage and decreased albumin synthesis. One exception is patients with ascites, in whom synthesis may be normal or even increased, but serum levels are low because of the increased volume of distribution [61]. Heavy alcohol ingestion, chronic inflammation, and protein malnutrition can inhibit albumin synthesis. Hypoalbuminemia is not specific for liver disease and may occur in protein malnutrition of any cause, such as protein-losing enteropathy, chronic infection, or nephrotic syndrome. Serum albumin should not be measured when screening patients with no suspicion of liver disease. A study of patients consecutively examined in a general medical clinic, showed that in 56 of 449 patients in whom no indications for albumin measurement were present, the results were abnormal. However, in only two patients (0.4%) was the finding of any clinical significance [67].

Prothrombin time

Clotting is the end result of a complex series of enzymatic reactions that involve at least 13 factors. The liver is the major site of synthesis of 11 blood coagulation proteins:

- Factor I: fibrinogen [68].
- Factor II: prothrombin [69].

- Factor V: proaccelerin and labile factor [69].
- Factor VII: serum prothrombin conversion accelerator and stable factor [69].
- Factor IX: plasma thromboplastin component and Christmas factor [69].
- Factor X: Stuart–Prower factor [68].
- Factors XII and XIII: prekallikrein and high molecular weight kininogen.

Tissue factor (factor III) is present in subendothelial tissue, platelets, and leukocytes. Factor VIII is made in endothelial cells and the sinusoidal cells within the liver. The liver is involved in clearing some of the clotting factors from serum. The levels of components of the clotting mechanism are frequently abnormal in the course of hepatic disease [70]. These abnormalities can be assessed with tests in which one factor or the interplay of a number of factors is measured. The one-stage prothrombin time of Quick is one of the most useful tests available. It is used to measure the rate at which prothrombin is converted to thrombin. This occurs in the presence of a tissue extract (thromboplastin), calcium ions, and a series of activated coagulation factors (factors I, II, V, VII, and X), and is followed by the polymerization of fibrinogen to fibrin by thrombin (Fig. 2.7). The results may be expressed in seconds or as a ratio of the plasma prothrombin time to a control plasma time. A normal control is usually in the range of 9 to 11 seconds. A prolongation of 2 seconds or more is considered abnormal, and values of more than 4 seconds indicate a patient at risk of uncontrolled bleeding. The prothrombin time is prolonged if any of the involved factors are deficient, either singly, or in combination.

The INR is often used to express the degree of anticoagulation in patients receiving warfarin sodium (Coumadin®). The INR standardizes prothrombin time measurement according to the characteristics of the thromboplastin reagent used in the laboratory. The INR may not be the best expression of coagulation derangement in patients with liver failure, unless the same thromboplastin reagent is consistently used for measurement.

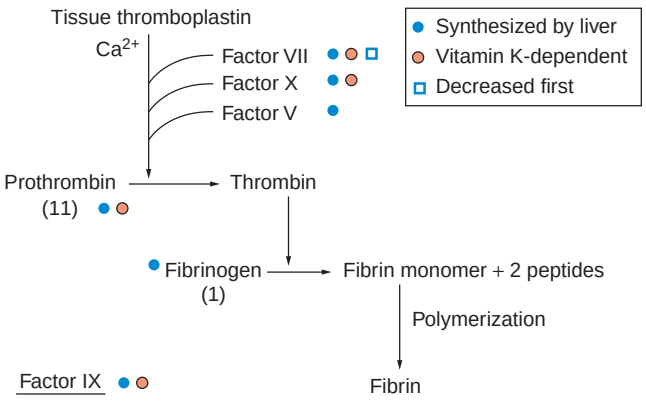

Figure 2.7 Factors involved in the Quick one-stage prothrombin time test.

Hepatic synthesis of biologically active forms of factors II, VII, IX, and X requires vitamin K for the γ-carboxylation of glutamic acid residues in these proteins. The γ-carboxylation step is a post-translational process that allows these proteins to bind Ca^{2+} avidly, a necessity for them to function as clotting factors [71]. The absence of vitamin K, the ingestion of vitamin K antagonists, or the presence of certain hepatic disorders (hepatocellular carcinoma) inhibits vitamin K-dependent carboxylation and allows the release of des-γ-carboxy (abnormal) prothrombin into serum [71]. This can be detected with a specific radioimmunoassay [72]. Healthy individuals have no des-γ-carboxy prothrombin in serum. Plasma levels of des-γ-carboxy prothrombin do not correlate with α-fetoprotein levels in patients with established hepatocellular carcinoma, but the two tests have a combined sensitivity of 85% [73]. The des-γ-carboxy prothrombin level can return to normal with excision of, or therapy for, hepatocellular carcinoma, and will increase again with a recurrence of the tumor [74]. However, elevated des-γ-carboxy prothrombin levels were detected only in 20% of hepatocellular carcinomas less than 3 cm in diameter; therefore, the measurement of this substance is not a satisfactory screening test [75].

A prolonged prothrombin time is not specific for liver disease and is seen in various congenital deficiencies of coagulation factors and in acquired conditions, including the consumption of clotting factors and ingestion of drugs that affect the prothrombin complex. In these instances, the underlying cause can usually be elucidated. When the aforementioned conditions are excluded, a prolonged prothrombin time may be the consequence of either hypovitaminosis K – as is found in patients with prolonged obstructive jaundice, steatorrhea, dietary deficiency, or an intake of antibiotics that alter the intestinal flora – or poor utilization of vitamin K owing to parenchymal liver disease. These two situations can usually be differentiated by means of parenteral administration of vitamin K_1. If the prothrombin time returns to normal or improves at least 30% within 24 hours of a single parenteral injection of vitamin K_1 (doses of 5–10 mg are usually given), it can be surmised that parenchymal function is good and that hypovitaminosis K was responsible for the original prothrombin time. In contrast, slight (if any) improvement occurs in most patients with parenchymal liver disease. Most patients with extrahepatic obstruction respond promptly to vitamin K. In patients with jaundice, the type of response to vitamin K_1 is therefore of some value in differential diagnosis. Observations of sluggish responses to vitamin K_1 – prolonged values are still recorded 24 hours before normalization at 48–72 hours in some patients with obstructive jaundice – and of good

responses among some patients with hepatocellular disease have been reported and complicate interpretation.

The prothrombin test is not a sensitive index of chronic liver disease because, even in severe cirrhosis, prothrombin levels can be normal or the prothrombin time only slightly prolonged. On the other hand, the test has high prognostic value, particularly for patients with acute hepatocellular disease. Prolongation of the prothrombin time to more than 5–6 seconds above the control value is the single laboratory test that draws attention to the possible development of acute liver failure in the course of acute viral hepatitis. Such a prolonged prothrombin time often precedes by days the manifestations of liver failure. Not all patients with abnormal prothrombin times of this extent have evidence of acute liver failure. Progressive shortening of the prothrombin time to normal usually precedes or accompanies other evidence of clinical improvement in the latter group. The degree of prolongation of the prothrombin time is a prognostic factor for patients with alcoholic steatonecrosis. A prothrombin time greater than 4 seconds above the control value occurred six times as often in a group of patients who died (60%) than in a group who survived (10%). In patients with hepatocellular disease, an abnormal prothrombin time, particularly one prolonged by more than 4–5 seconds that does not respond to parenteral administration of vitamin K_1, indicates extensive parenchymal damage and a poor long-term prognosis. The test is also used as an early predictor of outcome after acetaminophen overdose.

The prothrombin test is particularly important in the treatment of patients with liver disease. It allows assessment of the tendency to bleed before any contemplated surgical or diagnostic procedure, such as closed liver biopsy, splenic puncture, or transhepatic cholangiography. When the prothrombin time is prolonged, vitamin K_1 should be administered routinely in doses of 5–10 mg/day parenterally in up to three doses. It is difficult to identify the prothrombin time at which diagnostic procedures such as a needle biopsy of the liver are contraindicated, because the risk of bleeding has not been well correlated with the values of this test. Furthermore, vascular reactivity and coagulation factors, such as platelets, play an important contributory role. The prothrombin time can often be corrected by infusions of fresh frozen plasma in those situations in which surgery or procedures are required.

Tests of the liver's capacity to transport organic anions and to metabolize organic compounds

Bilirubin

See also Chapter 8.

Bilirubin metabolism

Bilirubin is a tetrapyrrole pigment derived from the breakdown of ferroprotoporphyrin IX (heme), an integral part of heme-containing proteins. Approximately 70–80% of the 250–300 mg of bilirubin produced each day is derived from the breakdown of hemoglobin in senescent red blood cells [76]. The remainder comes from prematurely destroyed erythroid cells in bone marrow and from the turnover of hemoproteins in tissues throughout the body [77]. The liver is the main source of the latter because of its high concentration of hemoproteins with relatively high turnover rates, such as cytochrome P_{450}. The initial steps leading to the formation of bilirubin occur in reticuloendothelial cells, primarily in the spleen and liver. The first reaction, catalyzed by the microsomal enzyme heme oxygenase, oxidatively cleaves the α-bridge of the porphyrin group, opens the heme ring, and produces equimolar amounts of biliverdin and carbon monoxide (Fig. 2.8) [78]. The second reaction, catalyzed by the cytosolic enzyme biliverdin reductase, reduces the central methylene bridge of biliverdin, converting it to bilirubin [79]. Bilirubin formed in the reticuloendothelial cells is lipid-soluble and almost insoluble in water. To be transported in blood, it must be solubilized, which is accomplished by reversible, noncovalent binding to albumin. Bilirubin is then transported to the liver, where it, but not the albumin, is taken up by hepatocytes in a process that involves carrier-mediated membrane transport (Fig. 2.9) [80]. Although several potential transporters have been identified, none has yet been cloned. In the hepatocyte, bilirubin is coupled to glutathione-*S*-transferases

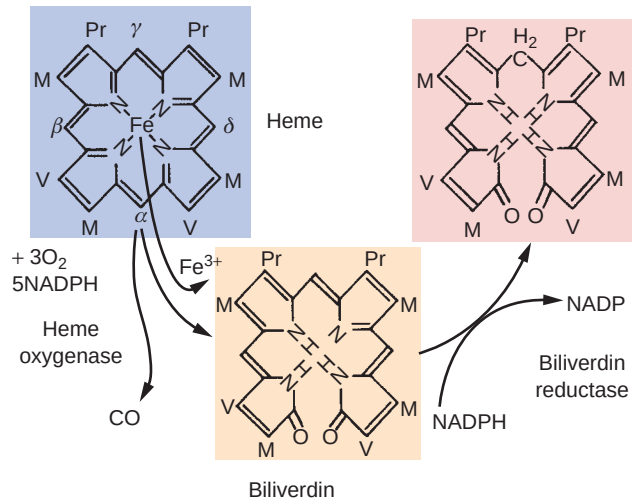

Figure 2.8 Formation of bilirubin from heme by the sequential actions of the enzymes heme oxygenase and biliverdin reductase. Figure 2.9 Scheme of bilirubin uptake, hepatocellular transport, and metabolism. Exogenous bilirubin is taken up by the hepatocyte at the sinusoidal membrane by an unidentified carrier protein (as depicted) or by transmembrane "flip-flop." The bilirubin is delivered to the endoplasmic reticulum by means of membrane–membrane transfer, with cytosolic-binding proteins serving as a potential means to preclude the diffusion of bilirubin back to the plasma. Heme generated within the liver from endogenous hemoproteins also gives rise to bilirubin. Glucuronidation occurs primarily within the endoplasmic reticulum. BR, bilirubin; E_1, heme oxygenase; E_2, biliverdin reductase; E_3, bilirubin uridine diphosphate glucuronosyltransferase 1. (Reproduced from Crawford et al. [109] with permission from Thieme.)

(formerly called ligandins). Bilirubin is then solubilized by means of conjugation to glucuronic acid; bilirubin monoglucuronide and diglucuronide are formed, both of which are called *direct-acting bilirubins*. The conjugation of glucuronic acid to bilirubin is catalyzed by an enzyme system in the endoplasmic reticulum of the hepatocyte that transfers glucuronic acid from uridine diphosphate–glucuronic acid to the acyl groups of the propionic acid side chains of bilirubin. The bilirubin conjugates are then actively transported from the hepatocyte into canalicular bile by an adenosine triphosphate-dependent transport process that is the rate-limiting step in hepatic bilirubin excretion. This process is mediated by a protein in the bile canalicular membrane called *multidrug resistance-associated protein 2*. The conjugated bilirubins drain from the bile duct into the duodenum and are carried distally through the intestine. In the distal ileum and colon, the conjugated bilirubins are hydrolyzed to unconjugated bilirubin by bacterial β-glucuronidases. The unconjugated bilirubin is reduced by normal intestinal bacteria to form a group of colorless tetrapyrroles called *urobilinogens*. Approximately 80–90% of these products are excreted in feces, either unchanged or oxidized to orange derivatives called *urobilins*. The remaining 10–20% of the urobilinogens are passively absorbed, enter the portal-venous blood, and are reexcreted by the liver. A small fraction, usually less than 3 mg/dL, escapes hepatic uptake, filters across the renal glomerulus, and is excreted in urine. The renal excretion of urobilinogen is complicated, partly because urobilinogen is a weak acid that passively diffuses across the renal tubule when in its undissociated form. The appearance of urobilinogen in urine depends on many factors, including urine pH and the rate of urine flow.

Measurement of serum bilirubin

The terms direct- and indirect-reacting bilirubin are based on the original van den Bergh method of measuring unconjugated bilirubin [81]. This method is still used in some clinical chemistry laboratories to determine the serum bilirubin level. In this assay, bilirubin reacts with diazotized sulfanilic acid and splits into two relatively stable dipyrryl azopigments that absorb light maximally at 540 nm. The direct fraction is that which reacts with diazotized sulfanilic acid in 1 minute in the absence of alcohol [81]. This fraction provides an approximate determination of the amount of conjugated bilirubin in serum. The total serum bilirubin level is the amount that reacts in 30 minutes after the addition of alcohol. The indirect fraction is the difference between the total and the direct bilirubin levels, and provides an estimate of the amount of unconjugated bilirubin in serum. With the van den Bergh method, the normal serum bilirubin concentration is usually less than 1 mg/dL (18 mmol/L). As much as 30% or 0.3 mg/dL (5.1 mmol/L) of the total is direct-reacting bilirubin [81]. Total serum bilirubin

Table 2.4 Differences between unconjugated and conjugated bile pigments.

Property	Unconjugated bilirubin	Conjugated bilirubin
van den Bergh reaction	Indirect (+ alcohol)	Direct
Water-soluble	−	+
Fat-soluble	+	−
Attachment to plasma albumin	+	+
Presence in icteric urine	−	+
Presence in bile	−[a]	+
Affinity for brain tissue	+	−
Association with hemolytic jaundice	++	±
Association with obstructive and hepatocellular jaundice	+	+++

[a]A small quantity of unconjugated bilirubin may be present in the common duct bile. There is a relative increase in unconjugated bilirubin in bile in conditions associated with severe unconjugated hyperbilirubinemia, such as Crigler–Najjar syndrome [7].
+, present or positive; –, absent or negative; ±, present or absent; ++, strong; +++, very strong.

concentrations are between 0.2 and 0.9 mg/dL (2.0–15.4 mmol/L) in 95% of a healthy population, and less than 1 mg/dL (18 mmol/L) in 99% [81]. Some differences in the properties of unconjugated and conjugated bilirubin are listed in Table 2.4.

Newer techniques for measuring serum bilirubin using high-performance liquid chromatography (HPLC) have contributed considerably to our understanding of bilirubin metabolism. First, they show that almost 100% of the serum bilirubin in healthy individuals, or those with Gilbert syndrome, is unconjugated, and less than 3% is monoconjugated bilirubin. Second, in patients with jaundice and hepatobiliary disease, the total serum bilirubin concentration measured with these newer, more accurate methods is lower than the values found with diazo methods [82]. This suggests that diazo-positive compounds distinct from bilirubin exist in the serum of patients with hepatobiliary disease. Third, the results of these studies indicate that in patients with jaundice and hepatobiliary disease, monoglucuronides of bilirubin predominate over the diglucuronides. Fourth, part of the direct-reacting bilirubin fraction includes conjugated bilirubin that is covalently linked to albumin [83]. This albumin-linked bilirubin fraction represents an important fraction of total serum bilirubin in patients with cholestasis and hepatobiliary disorders [83]. Albumin-bound bilirubin is formed in serum when hepatic excretion of bilirubin glucuronides is impaired, and the glucuronides are present in serum in increasing amounts. Because of its tight binding to albumin, the clearance rate of albumin-bound bilirubin from serum approximates the half-life of albumin (12–14 days) rather than the short half-life of bilirubin (approximately 4 hours). The prolonged half-life of albumin-bound bilirubin explains two previously unexplained enigmas in the care of jaundiced patients with liver disease: (i) that some patients with conjugated hyperbilirubinemia do not have bilirubinuria during the recovery phase of their disease; and (ii) that the elevated serum bilirubin level declines more slowly than expected in some patients who otherwise appear to be recovering satisfactorily. Late in the recovery phase of hepatobiliary disorders, all the conjugated bilirubin may be in the albumin-linked form. It is therefore not filtered by the renal glomerulus and does not appear in urine, although the serum bilirubin concentration is high. The value of conjugated bilirubin in serum decreases slowly because of the long half-life of albumin. The slow decline is unrelated to the actual rate of hepatic bilirubin metabolism.

Diagnostic value of serum bilirubin

The bilirubin normally present in serum represents a balance between the input from production and the hepatic removal of the pigment. Hyperbilirubinemia may therefore result from: (i) overproduction of bilirubin; (ii) impaired uptake, conjugation, or excretion of bilirubin; or (iii) regurgitation of unconjugated or conjugated bilirubin from damaged hepatocytes or bile ducts. One may anticipate that an increase in unconjugated bilirubin in serum results from overproduction or from impairment of uptake or conjugation, whereas an increase in the conjugated moiety is caused by decreased excretion or backward leakage of the pigment.

The total serum bilirubin level is not a sensitive indicator of hepatic dysfunction and may not reflect accurately the degree of liver injury. Hyperbilirubinemia may not be detected in instances of moderate to severe hepatic parenchymal damage or a partially or briefly obstructed common bile duct. This lack of sensitivity is partly explained by observations obtained in healthy persons given infusions of unconjugated bilirubin and in patients with uncomplicated hemolysis. These observations suggest that the capacity of the human liver to remove bilirubin from serum before hyperbilirubinemia occurs is at least two-fold greater than the daily pigment load (250–300 mg or 4,275–5,130 mmol) normally presented to this organ. This capacity may be even higher, according to the maximal rate of excretion of bilirubin into bile – approximately 55.2 mg/kg/day [84] – and the average amount of bilirubin formed from the destruction of senescent red blood cells, 3.9 mg/kg/day. In the steady state, the serum bilirubin concentration usually reflects the intensity of jaundice and the increase in total-body bile pigment. The serum bilirubin concentration may occasionally decrease transiently with the presence in serum

of substances such as salicylates, sulfonamides, or free fatty acids, which displace bilirubin from its attachment to plasma albumin and enhance the transfer of the pigment into the tissues [85]. Conversely, an increase in serum albumin concentration may induce a temporary shift of bilirubin from tissue sites into the circulation.

Total serum bilirubin concentration is seldom of value in specifying the cause of jaundice in individual patients because values among the various types of jaundice overlap considerably. On the average, uncomplicated hemolysis seldom causes a serum bilirubin value in excess of 5 mg/dL (85.5 mmol/L), and parenchymal liver disease or incomplete extrahepatic obstruction due to biliary calculi gives lower serum bilirubin values than those that occur with malignant obstruction of the common bile duct.

Few controlled studies have critically assessed the prognostic value of magnitude and duration of hyperbilirubinemia in liver disease. In general, the higher the serum bilirubin concentration in viral hepatitis, the greater the histologic evidence of hepatocellular damage and the longer the course of disease. Nevertheless, patients may die of acute liver failure with only a modest elevation in serum bilirubin level. The presence of concomitant hemolysis with overproduction of bilirubin and diminished glomerular filtration rate causing decreased excretion of the pigment may also confuse the issue by causing higher serum bilirubin values than would be expected for any degree of hepatocellular damage present. In acute alcoholic hepatitis, hyperbilirubinemia in excess of 5 mg/dL (85.5 mmol/L) is one of the findings that suggests a poor prognosis [86].

The major value of fractionating total serum bilirubin into unconjugated and direct-reacting moieties is in the detection of states characterized by unconjugated hyperbilirubinemia (Table 2.5). Such a diagnosis appears warranted when the serum level of indirect-reacting bilirubin is in excess of 1.2 mg/dL (20.5 mmol/L) and the direct-reacting fraction constitutes less than 20% of the total serum bilirubin value. Unfortunately, when the total serum bilirubin concentration is minimally elevated, it may be difficult to differentiate the cause of the bilirubin elevation. This difficulty reflects the inaccuracy of the diazo methods in differentiating conjugated from unconjugated bilirubin at low total serum bilirubin concentrations. This is one of the instances in which the newer, more precise methods of bilirubin determination may provide clinically useful information that is not attainable with the older diazo methods. This is particularly true in the detection of early or mild liver injury. Total bilirubin concentration may be normal in some patients with cirrhosis, hepatitis, hemochromatosis, congestive heart failure, and other disorders. An increase in the direct fraction above 0.3 mg/dL (5.1 mmol/L) should alert one to the possibility of mild liver injury. If the newer, more accurate techniques are used, conjugated bilirubin concentrations greater than 0.1 mg/dL (1.7 mmol/L) should be accurate in the detection of early liver injury, because bilirubin glucuronides are normally undetectable in serum, except in hepatobiliary disorders [82].

Table 2.5 Causes of unconjugated hyperbilirubinemia.

Cause	Mechanism
Hemolytic disorders	
Inherited: spherocytosis, elliptocytosis, glucose-6-phosphate dehydrogenase deficiency, sickle cell anemia	Overproduction of bilirubin
Acquired: microangiopathic hemolytic anemias, paroxysmal nocturnal hemoglobinuria, immune hemolysis	Overproduction of bilirubin
Ineffective erythropoiesis	
Cobalamin, folate and severe iron deficiencies, thalassemia	Overproduction of bilirubin
Drugs	
Rifampicin, probenecid	Impaired hepatic uptake
Inherited conditions	
Gilbert syndrome	Impaired conjugation
Crigler–Najjar, types I and II	Impaired conjugation
Neonates	
Neonatal (physiologic)	Overproduction of bilirubin, impaired conjugation, increased intestinal absorption
Breast milk	Impaired conjugation and increased intestinal absorption
Other	
Hematoma	Overproduction of bilirubin

The measurement and fractionation of serum bilirubin concentration in patients with jaundice does not differentiate accurately parenchymal (hepatocellular) from cholestatic (obstructive) jaundice. The accurate HPLC methods for measuring serum bilirubin show that the levels of both unconjugated and conjugated bilirubins are increased in hepatobiliary disease. No consistent pattern of elevation of these fractions differentiates hepatocellular from cholestatic liver disease [82]. Levels of both monoglucuronide and diglucuronide are elevated, with the monoglucuronides predominating.

Urinary bilirubin

The presence of bilirubin in the urine indicates the presence of hepatobiliary disease. Unconjugated bilirubin is

tightly bound to albumin, is not filtered by the glomerulus, and is not excreted into the urine. Consequently, only conjugated bilirubin is found in urine. This occurs only when conjugated bilirubin is in the serum, that is, when there is hepatobiliary dysfunction. The new, more precise methods for measuring serum bilirubin indicate that 100% of the serum bilirubin in healthy persons and those with Gilbert syndrome is unconjugated bilirubin. Measurable amounts of conjugated bilirubin in serum are found only in hepatobiliary disease. Because the renal threshold for conjugated bilirubin is low and the laboratory methods used can detect bilirubin concentrations as low as 0.05 mg/dL (0.9 mmol/L) of urine, conjugated bilirubin may be found in urine when the total serum bilirubin value is normal and the patient does not have clinical jaundice. This can occur early in the course of viral hepatitis or other hepatobiliary diseases when conjugated bilirubin first appears in the serum. Conversely, the urine can become free of bilirubin long before the level of conjugated serum bilirubin falls to normal in patients recovering from hepatobiliary diseases [83]. When this occurs, all the conjugated bilirubin is in the albumin-bound form and is not filtered by the glomerulus.

Bile acid tests

Although sensitive tests to measure serum bile acid concentration (see Chapter 9) have been available for more than 25 years, the role for these tests in the evaluation of patients with suspected liver disease remains uncertain. Bile acids are synthesized from cholesterol in hepatocytes, conjugated to glycine or taurine, and then secreted into bile. Serum bile acids are sensitive but nonspecific indicators of hepatic dysfunction. They allow some quantification of functional hepatic reserve.

Serum bile acid tests are most elevated in certain cholestatic liver diseases, such as primary biliary cirrhosis and primary sclerosing cholangitis. Serum bile acid levels are elevated in pregnant women, particularly in those with the pruritus of cholestasis. Serum bile acid levels are normal in patients with Gilbert syndrome and Dubin–Johnson syndrome, an observation that reinforces the separate pathways of transport for bilirubin and bile acids.

The attempt to improve the sensitivity and specificity of the serum bile acid tests with intravenous or oral tolerance tests has not proved successful. The ratio of cholic acid to chenodeoxycholic acid has also been considered a means of increasing the sensitivity and specificity of bile salt testing. Unfortunately, a marked overlap exists, both between the healthy control and various hepatic disease states. Serum bile acid tests offer the advantage of being highly specific indicators of liver dysfunction, but they are less sensitive than they were originally hoped to be and they are nonspecific in differentiating the various types of liver disease.

Clearance tests

Because serum bilirubin is an insensitive indicator of hepatic dysfunction and at low serum levels the measurement of total and direct bilirubin lacks biochemical precision, an effort was made to develop other tests of hepatic excretory capacity that were more sensitive and specific. The goal was to develop tests that could be used for more critical and specific evaluations of the excretory or detoxification capacity of the liver. Although these clearance tests are more sensitive than the serum bilirubin test, they have limited value because of their lack of specificity in diagnosing specific hepatobiliary disorders.

Dye clearance tests using sulfobromophthalein sodium (BSP) are not widely used because the test is difficult to perform and the substrate may be toxic and is no longer available. ICG dye is nontoxic and has a higher hepatic extraction ratio than BSP (70–96%). Ninety-seven percent of an administered dose is excreted unchanged in bile and the liver appears to be the only site of ICG clearance in humans. ICG is used primarily to estimate hepatic blood flow because the first-pass extraction of ICG by the liver is high. The elimination of ICG has been shown to correlate with mortality and morbidity after hepatic resections [87] and in intensive care unit patients [88].

Use of drug metabolism to assess liver function

Measurement of the clearance of drugs by the liver has the potential to provide an accurate method of measuring hepatic function. A number of candidate compounds have been studied in various clinical states, including acute and chronic viral hepatitis, cirrhosis from various causes, and before and after liver transplantation. Most of the compounds that have been studied, including aminopyrine, antipyrine, caffeine, and lidocaine, are metabolized by one or more of the isoenzymes of cytochrome P_{450}. Breath tests using ^{13}C- or ^{14}C-labeled aminopyprine as a way to measure the metabolism of aminopyrine are used infrequently although they have been available for more than 25 years in the United States. There are several reasons for this. They are less convenient to perform than are simple blood tests and the use of ^{13}C or ^{14}C isotopes is cumbersome and expensive.

Lidocaine is an example of a drug that is highly extracted by the liver (high first-pass effect) and oxidized by cytochrome P_{450} 3A/4A [89]. After intravenous administration, clearance of lidocaine is therefore a good measure of hepatic blood flow in healthy individuals. However, in patients with advanced liver disease, the compound is not highly extracted, most likely because of portal-venous shunting and changes in the intrinsic

activity of the P_{450} drug-metabolizing enzymes in the liver. Measurement of the appearance of metabolites of lidocaine (monoethylglycinxylidide or MEGX) in plasma has been used as a measure of hepatic function in patients with more advanced liver diseases, but the clearance of lidocaine can be altered by drugs that inhibit the specific isoenzymes of P_{450}. The MEGX test has been evaluated in a number of clinical situations: before and after liver transplantation [90], in patients with chronic hepatitis C with or without cirrhosis [91], and after prolonged treatment with pegylated interferon [92]. It has been shown to correlate well with histology but it is unclear whether it offers significant advantages over the model for end-stage liver disease (MELD) test [93]. The test requires HPLC, enzyme-linked immunosorbent assay (ELISA), or other methods of measuring MEGX.

Caffeine clearance and morning salivary caffeine levels

Caffeine clearance tests have been used to quantify functional hepatic capacity by asssessing the activity of cytochrome P_{450} 1A2, *N*-acetyltransferase, and xanthine oxidase [94]. Several variations in these tests have been described. In all studies, caffeine (200–366 mg) is taken orally. Early studies required that plasma caffeine concentrations be measured at multiple time points over 24 hours. In more recent studies, caffeine and its metabolites have been measured in 24-hour urine collections, in saliva, and in scalp hair. Results with these alternative methods are similar to those of the plasma clearance method. Overnight salivary caffeine clearance has been shown to correlate with ICG and galactose clearance and the aminopyrine breath test [95]. The measurement of a single level of caffeine in saliva in the morning after overnight abstinence was shown to correlate well with salivary caffeine clearance and is considerably easier to obtain [96]. Concomitant tobacco use is a confounding factor in these tests because it increases caffeine clearance [97]. The results of caffeine clearance tests correlate well with the ^{14}C aminopyrine test.

Tests used to detect fibrosis in the liver

Liver biopsy remains the standard for grading (inflammation) and staging (fibrosis) the severity of chronic liver disease. There is considerable interest in identifying biochemical markers that can be used as noninvasive surrogate markers for both liver fibrosis and inflammation to permit longitudinal assessment of disease progression as well as measuring responses to therapy. Thus far, no single biochemical test or marker has been identified as a perfect marker for fibrosis. A number of biochemical markers including hyaluronan, type IV collagen, procollagen III, and laminin have been studied. As discussed in Chapter 12 these tests are surrogates, not true biomarkers of fibrosis and their value is limited since they reflect the rate of matrix turnover rather than the deposition of matrix proteins. Multiparameter tests have also been examined; these include the well-studied FibroTest®, a multiparameter test that includes haptoglobin, bilirubin, GGT, apolipoprotein A-I, and α_2-macroglobulin [98]. Another multiparameter test is the ELF test that utilizes a diagnostic algorithm [99].

Tests used to detect chronic inflammation or fibrosis in the liver or altered immunoregulation

Immunoglobulins

Serum immunoglobulins are produced by stimulated B lymphocytes, and elevated levels in many patients with chronic liver disease are believed to indicate the impaired function of reticuloendothelial cells in hepatic sinusoids or shunting of portal-venous blood around the liver [100]. Antibodies directed against antigens of the normal colonic flora account for much of the increased serum immunoglobulin levels in patients with cirrhosis [100]. Because of portosystemic shunting, these antigens escape degradation by hepatic reticuloendothelial cells and reach lymphoid tissue outside the liver where they elicit an inflammatory response.

In most cases of acute hepatitis, immunoglobulin levels are normal or minimally increased. Mild to moderate hypergammaglobulinemia is present in many patients with chronic viral hepatitis or cirrhosis, while a striking increase in serum IgG suggests autoimmune hepatitis [101]. Diffuse polyclonal increases in IgG and IgM in most types of cirrhosis are nonspecific [101]. Increases in IgM levels suggest primary biliary cirrhosis, whereas increases in IgA may occur in patients with alcoholic cirrhosis or alcoholic hepatitis. Immunoglobulin levels are usually normal in patients with obstructive jaundice. Serial determination of serum IgG levels is useful in monitoring the response to immunosuppressive therapy in patients with autoimmune hepatitis. Hypergammaglobulinemia, with or without hypoalbuminemia, is not specific for liver disease and can be found in malignancy and chronic inflammatory diseases, particularly human immunodeficiency virus (HIV) infection.

Use of liver function tests

We have found it useful to order the tests listed in Table 2.6 during the initial encounter with a patient with jaundice or suspected liver disease. The use of these

Table 2.6 Liver function test patterns in hepatobiliary disorders and jaundice.

Type of disorder	Bilirubin	Aminotransferases	Alkaline phosphatase	Albumin	Globulin	Prothrombin time
Hemolysis	Normal	Normal	Normal	Normal	Normal	Normal
Gilbert syndrome	5 mg/dL; >85% due to indirect fraction No bilirubinuria	Normal	Normal	Normal	Normal	Normal
Acute hepatocellular necrosis (viral and drug hepatitis, hepatotoxins, acute heart failure)	Both fractions may be elevated; peak usually follows aminotransferases Bilirubinuria	Elevated, often >500 IU/L; ALT ≥ AST	Normal to three times normal	Normal	Normal	Usually normal; >5 seconds above control and not corrected with parenteral vitamin K suggests massive necrosis and poor prognosis
Chronic hepatocellular disorders	Both fractions may be elevated	Elevated, but usually <400 IU/L	Normal to three times normal	Often decreased	Increased γ-globulin	Often prolonged; is not corrected with parenteral vitamin K
Alcoholic hepatitis or cirrhosis	Bilirubinuria	AST : ALT >2 suggests alcoholic hepatitis or cirrhosis	–	–	–	–
Intrahepatic cholestasis	Both fractions may be elevated	Normal to moderate elevations; rarely >500 IU/L	Elevated, often over four times normal	Normal, unless chronic	γ-Globulin normal	Normal; if prolonged, is corrected with parenteral vitamin K
Obstructive jaundice	Bilirubinuria	Normal to moderate elevations; rarely >500 IU/L	Elevated, often over four times normal	Normal, unless chronic	β-Globulin may be increased	Normal; if prolonged, is corrected with parenteral vitamin K
Infiltrative diseases (tumor, granuloma)	Usually normal	Normal to slightly elevated	Elevated, often over four times normal	Normal	Usually normal; γ-globulin may be increased in granulomatous disease	Normal
Partial bile duct obstruction	–	–	Fractionate, or confirm liver origin with 5′-nucleotidase or γ-glutamyl transpeptidase	–	–	–

ALT, alanine aminotransferase; AST, aspartate aminotransferase.
From Kaplan [103] with permission from Elsevier.

tests, which include total and direct bilirubin, aminotransferases, alkaline phosphatase, albumin, globulin, and prothrombin time, as a battery improves accuracy in the diagnosis of liver disease and makes it unlikely that any case of clinically important liver disease will not be identified.

It is helpful to divide the causes of jaundice and liver dysfunction into the broad categories shown in Table 2.6, that is, disorders of bilirubin metabolism, acute parenchymal or hepatocellular disease, cholestasis, infiltrative diseases, chronic hepatocellular diseases such as cirrhosis, and others. Because the pattern of abnormalities may be similar in patients with infiltrative diseases and patients with partial bile duct obstruction, these two types of disorders are listed together.

Patients with hemolysis or Gilbert syndrome may have a total serum bilirubin level as high as 5 mg/dL (85.5 mmol/L). Bilirubinuria is absent and more than 85% of the bilirubin is in the indirect fraction using the van den Bergh reaction. Results of the remaining liver chemistry tests, listed in Table 2.6, are normal. An elevated reticulocyte count and/or a low serum haptoglobin level suggests hemolysis. If bilirubinuria is present and more than 20% of the elevation in bilirubin is in the direct-reacting fraction of bilirubin, Dubin–Johnson syndrome and Rotor syndrome should be considered. Serum bile acids levels are normal in Dubin–Johnson syndrome. Both Dubin–Johnson syndrome and Rotor syndrome are benign conditions that require no further investigation.

The serum aminotransferase levels are the most sensitive tests for detecting acute hepatocellular disorders, such as viral or drug-induced hepatitis. Aminotransferase levels greater than 500 IU/L (8.3 μkat/L) make such a diagnosis probable. Depending on the severity of the underlying hepatocellular disorder, the bilirubin level may be normal or elevated. If the bilirubin level is elevated, both the direct and the indirect bilirubin fractions will be elevated and bilirubinuria should be present. Alkaline phosphatase elevations as high as three times the upper limit of normal are common for patients with acute hepatocellular disorders; however, values greater than three times normal are unusual, except in some patients with drug-induced hepatitis. Serum albumin level is usually normal, and globulin levels are normal or minimally elevated. The prothrombin time is typically normal in most patients with viral or drug-induced hepatitis. Prolongation of the prothrombin time to more than 5 seconds above the control value and failure of prothrombin time to correct within 24–48 hours of parenteral administration of vitamin K suggest a poor prognosis. This should alert the clinician to the possibility of impending liver failure. If the liver function tests are typical of acute hepatitis, a careful medication history must be obtained along with serologic tests for viral hepatitis (see Table 2.1). The possibility of hepatic ischemia should also be considered.

Serial determinations of aminotransferases may prove useful in patients with acute hepatocellular disorders. For example, following acute necrosis due to acetaminophen poisoning, the level of AST will decline more rapidly than ALT assuming the injury does not continue. Based on the relative difference in the plasma half-life of the two enzymes, one would predict that the level of ALT would exceed that of AST within the next 1–2 days. The decline in serum activity follows first-order kinetics (Fig. 2.10). This conceptual explanation can be applied to other acute, short-term injuries to the liver, such as necrosis from other drugs, ischemia, blunt trauma to the liver, and transient injury from passage of common duct stones [102]. Therefore, serial determinations of AST and ALT can provide a clue as to whether an injury to the liver is due to acute necrosis or an ongoing injury, such as inflammation.

Liver enzymes may be highly insensitive in chronic hepatitis or cirrhosis. Patients with advanced postnecrotic or alcoholic cirrhosis may have shrunken livers and striking portal hypertension, yet have liver enzymes that are almost normal. Even those patients with active chronic diseases such as chronic hepatitis B or C, autoimmune hepatitis, alcoholic or NAFLD and hemochromatosis have relatively low levels of AST and ALT (<400 IU/L) (see Table 2.2). An AST : ALT ratio greater than 2 raises the possibility of alcoholic liver disease, and an AST : ALT ratio greater than 3 is highly suggestive of this possibility [17]. Alkaline phosphatase level is seldom helpful in the diagnosis of cirrhosis. While there may be clues – such as thrombocytopenia, an AST : ALT ratio greater than 1, low serum albumin, and prolongation of the prothrombin time – suggesting the presence of cirrhosis, a definitive diagnosis depends on demonstrating significant fibrosis in the liver. Although liver biopsy remains the most reliable test for cirrhosis, FibroTest and ELF may be considered as surrogate indicators in patients in whom there is concern for the presence of cirrhosis.

There is a characteristic pattern of liver function tests in cholestasis, although the routine laboratory tests listed in Table 2.6 do not differentiate intrahepatic and extrahepatic disorders. Alkaline phosphatase level is usually elevated out of proportion to the levels of other enzymes. Values four or more times greater than normal suggest some type of cholestasis. Depending on the severity of the underlying condition, the bilirubin level is either normal or elevated. If elevated, the direct fraction is increased and bilirubinuria is present. Aminotransferase levels are usually elevated, but values greater than 500 IU/L (8.3 μkat/L) are rare. Aminotransferase levels are usually less than 300 IU/L (5 μkat/L), unless the tests are performed within 24 hours of the development of acute bile duct obstruction due, for example, to the

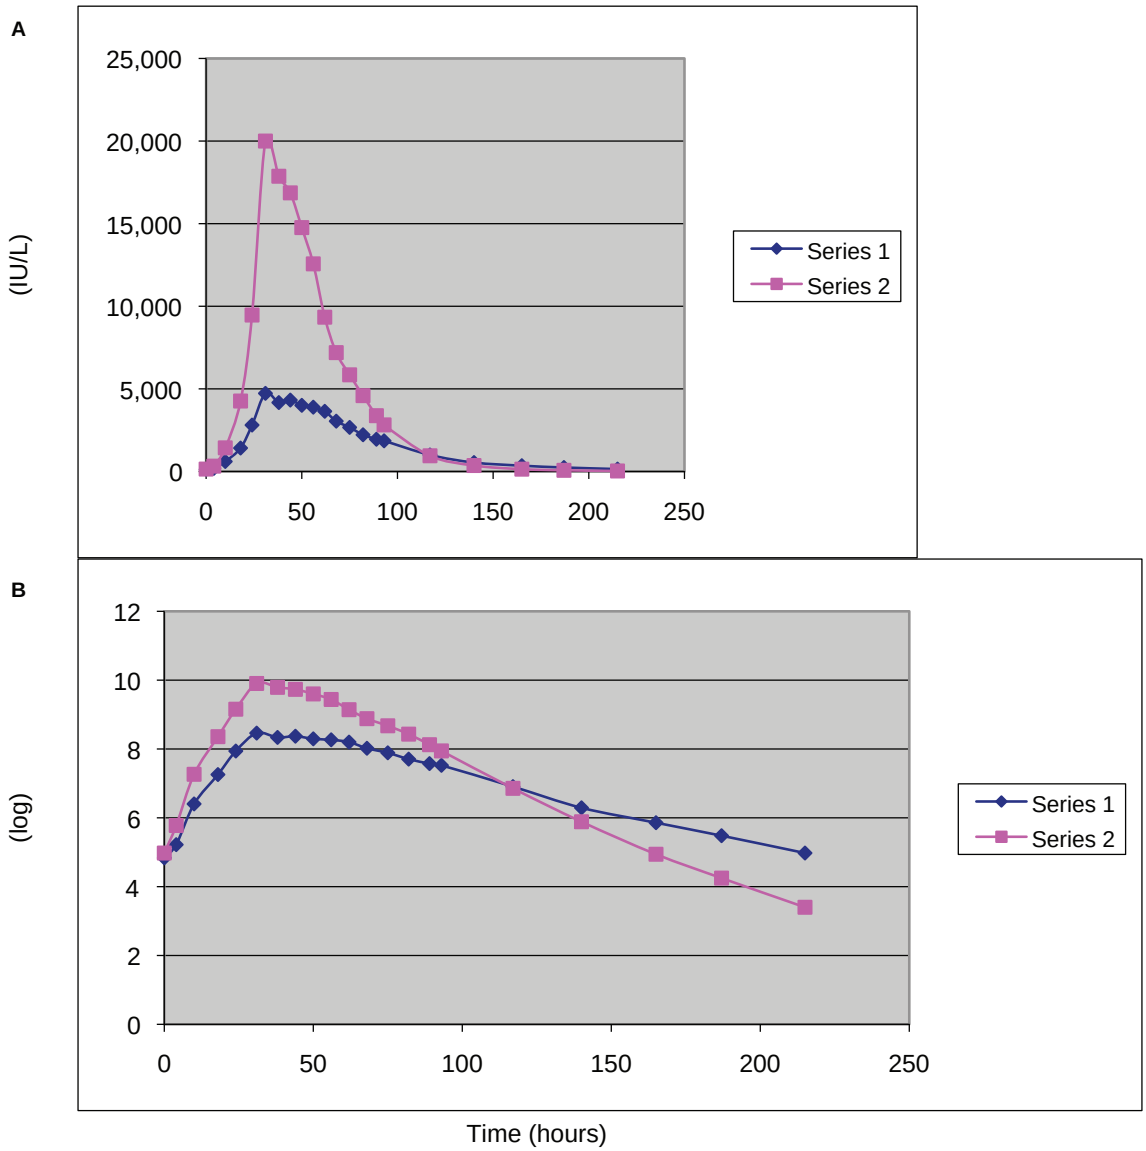

Figure 2.10 Kinetics of aspartate aminotransferase (AST) (pink, series 2) and alanine aminotransferase (ALT) (blue, series 1) following acute hepatic necrosis. AST and ALT are released into serum following acute hepatic necrosis. The level of both AST and ALT will decline over the next few days proportional to the half-life of the enzymes in the serum. The plasma half-life for ALT has been estimated to be 47 ± 10 hours and for AST, 17 ± 5 hours. Initially the AST is greater than the ALT, but 36–72 hours after an episode of acute hepatic necrosis, the ALT will be higher than the AST. (A) AST and ALT levels in IU/mL over time; (B) log AST and log ALT values over time.

passage of a common duct stone [102]. Albumin and globulin levels are usually normal. An increase in serum IgM in a patient with an elevated alkaline phosphatase suggests primary biliary cirrhosis. The antimitochondrial antibody test is helpful in this situation. The result is positive in 90–95% of patients with primary biliary cirrhosis, and is negative in patients with extrahepatic bile duct obstruction or sclerosing cholangitis. The prothrombin time is usually normal. If elevated, it is commonly due to vitamin K deficiency and should correct with parenteral administration of vitamin K.

Infiltrative liver diseases often only produce elevations in the alkaline phosphatase. Minimal elevations in aminotransferases may be observed, but the increase in alkaline phosphatase is much more dramatic. Measurement of 5′-nucleotidase or GGT can be used to confirm the hepatic origin of the alkaline phosphatase. The bilirubin level is almost always normal in infiltrative disease.

In summary, liver enzyme tests are useful in detecting liver disease in asymptomatic individuals and in evaluating patients with jaundice or other clinical evidence of liver disease. The pattern of abnormalities is often helpful

in classifying diseases of the liver and suggesting a direction for further evaluation, including serologic testing for hepatitis, genetic markers, ultrasound, computed tomography, magnetic resonance imaging, and percutaneous liver biopsy.

This paper demonstrates that the AST : ALT ratio is greater than 2 : 1 in alcoholic liver disease. The altered ratio is due, in part to a deficiency in pyridoxal phosphate. Addition of pyridoxal 5-phosphate to serum corrected the ratio in vitro.

Kaplan MM, Rhigetti A. Induction of rat liver alkaline phosphatase: the mechanism of the serum elevation in bile duct observation. *J Clin Invest* 1970;49:508.
This paper showed that the mechanism of the elevated serum alkaline phosphatase level in cholestasis is the induction of liver alkaline phosphatase and the leakage of liver alkaline phosphatase in serum. The authors clearly showed that the alternative theory popular at the time – that the liver clears alkaline phosphatase made in other organs from serum and excretes it into bile much as the liver excretes bilirubin – was incorrect. This paper resolved a controversy that had existed in medicine for more than 50 years.

Key concepts

- Although the standard percutaneous liver biopsy allows for a sample of only 1/50,000 of the liver parenchyma, it continues to serve as the gold standard in the diagnosis and management of liver disease.
- Percutaneous liver biopsy is a safe procedure, with a low mortality rate. Safety of the procedure can possibly be enhanced with the addition of ultrasound guidance or biopsy tract plugging techniques.
- In those with contraindications to percutaneous liver biopsy such as bleeding tendency or ascites, the transjugular approach is an alternative that offers the added benefit of portosystemic pressure gradient measurement.
- Diagnostic laparoscopy affords the clinician the ability to observe the gross appearance of the liver, perform directed biopsies, and obtain peritoneal tissue when indicated.
- While there are a number of noninvasive biomarkers and radiographic techniques in use to assess hepatic fibrosis, liver biopsy continues to have a role, although in a selected manner.

Liver biopsy has been used as a diagnostic tool since the late 1800s, when Paul Ehrlich performed the first percutaneous liver biopsy [1]. The described procedure was lengthy and precarious owing to a long hepatic puncture time. However in 1958, Menghini reported a "one second" technique that defined the procedure as we now know it [2]. Today, liver biopsy continues to serve as an important tool for those who diagnose and treat liver diseases. Biopsy specimens can provide prognostic information for several pathologic processes and the information gleaned can often be used to guide treatment decisions.

While percutaneous liver biopsy remains the most common practice, advances in radiographic and surgical techniques have allowed for the performance of liver biopsy via transvenous and laparoscopic routes, especially in patients with contraindications to a percutaneous approach. Alternatively, noninvasive techniques and serologic markers of liver histology are being validated, and in some cases may obviate the need for invasive procedures. In general, liver biopsies continue to be safe procedures, however infrequently life-threatening events can ensue.

Indications for liver biopsy (Box 3.1)

Abnormal hepatic biochemical tests and acute liver failure

Health care providers are frequently asked to evaluate patients with abnormal hepatic biochemical tests. Typically, the combination of a comprehensive history, physical examination, and laboratory analysis can yield a diagnosis. However, a small proportion of patients will have a negative workup and may require a histologic exam to determine a diagnosis. Histology in the majority of these cases will lead to a diagnosis of nonalcoholic fatty liver disease (NAFLD), however diseases such as primary and secondary biliary cirrhosis, autoimmune hepatitis, primary sclerosing cholangitis, and hemochromatosis have been identified through biopsy, when serologic studies were inconclusive [3]. The clear advantage to pursuing biopsy in this situation is the potential to recognize a disease process for which there is a specific treatment.

Liver biopsy is also indicated to identify the cause of acute liver failure when an obvious precipitant is not clear. The most recent guidelines on the management of

acute liver failure (ALF) recommend pursuing biopsy via the transjugular route when the etiology of ALF cannot be determined from history or serology alone [4]. In these cases, biopsy may identify entities such as diffuse malignancy, Wilson disease, autoimmune hepatitis, or viral infection.

Hepatitis C

Currently available treatment for chronic hepatitis C with pegylated interferon and ribavirin is associated with high costs, undesirable side effects, and modest response rates, especially in those with genotype 1 infection. Given these facts, candidates for hepatitis C virus (HCV) therapy need to be carefully selected. A pretreatment liver biopsy was for many years the norm. However, the role of liver biopsy in hepatitis C has been questioned over more recent years, with the advent of noninvasive markers of disease severity becoming more of a reality. Although there are several arguments for performing a liver biopsy in this population, the two main advantages to biopsy are to assess the necessity of antiviral therapy and to predict response to therapy [5].

The role of liver biopsy in prognostication and necessity of treatment is based on the premise that most patients with moderate inflammation from chronic hepatitis C develop cirrhosis within 20 years and nearly all patients with severe inflammation or bridging fibrosis develop cirrhosis within 10 years [6]. Patients with mild inflammation and/or minimal fibrosis have a low risk of progression to cirrhosis. Therefore, the urgency of treating someone with mild inflammation or minimal fibrosis is certainly not as great relative to treating someone with a more advanced histologic stage or grade. With the expectation that better tolerated agents may soon enter the arsenal for HCV therapy, it might make sense to delay treatment in less severe cases until better therapies are available.

Liver biopsy can help to identify a subset of patients with normal alanine aminotransferase (ALT) levels and significant histology that would benefit from therapy. Approximately 30% of patients with chronic hepatitis C have persistently normal ALT levels and only 42% develop peak levels twice the upper limit of normal [7]. Despite the fact that patients with normal ALT levels have been demonstrated to have significantly lower inflammation and fibrosis scores on liver biopsy examination than patients with elevated ALT levels, almost two thirds have evidence of portal fibrosis and 10% had bridging fibrosis [8]. Therefore, identification of those with clinically silent disease (i.e., those with normal serum aminotransferase levels) but histologic progression is critical for the treatment of a group at high risk of sequelae from HCV infection.

The presence of advanced fibrosis is also negatively associated with the probability of response to hepatitis C therapy. A recent study sought to examine the efficacy of peg interferon alfa and ribavirin therapy in patients with advanced fibrosis [9]. Sustained virological response (SVR) rates decreased according to level of fibrosis, such that in subjects without advanced fibrosis, SVR was 60% in patients with genotype 1 to 4, 51% in those with bridging fibrosis, and 33% in those with cirrhosis ($P = 0.0028$). The same trend held true for subjects with genotype 2/3. Lastly, liver biopsy may also reveal unsuspected cirrhosis, which would prompt initiation of a surveillance strategy for hepatocellular carcinoma and esophageal varices.

Although the information obtained from liver biopsy is useful, it is not mandatory to perform biopsy before treating hepatitis C. Biopsy is certainly more useful in guiding decision making for genotype 1 patients, since the treatment response rates are less than ideal and knowledge of their histologic risk of progression may influence the decision to treat or withhold therapy until better tolerated agents are available. In contrast, patients with genotype 2 or 3 may elect to undergo therapy regardless of findings on liver biopsy because the rates of sustained virological response are much better than seen in their genotype 1 counterparts.

Hepatitis B

The guidelines for initiating treatment of hepatitis B are largely based on the presence of abnormal transaminase levels and levels of viral replication. In many, antiviral therapy can be initiated without a pretreatment biopsy. Knowledge of underlying histology in those infected with hepatitis B can help guide treatment decisions when patients do not meet the guidelines and treatment may be of benefit. Liver biopsy should be considered in patients with modest elevations in transaminases based on the presence of hepatitis E antigen, viral load, and age [10]. Those with evidence of inflammation and/or fibrosis may benefit from initiation of therapy, which may lead to histologic improvement and subsequent clinical outcomes.

Nonalcoholic fatty liver disease

Nonalcoholic fatty liver disease represents a spectrum of liver disease ranging from minimal inflammation to cirrhosis. Most patients afflicted with NAFLD have a silent

course, marked by asymptomatic elevations in transaminases; however a subset can develop nonalcoholic steatohepatitis (NASH), a potentially progressive form that can evolve to cirrhosis, end-stage liver disease, and even hepatocellular carcinoma. The role of liver biopsy in NAFLD is primarily to distinguish between steatosis and NASH in order to offer more aggressive risk factor reduction to those with evidence of NASH, as well as to define the presence of cirrhosis, which would prompt initiation of cirrhosis care. Similar to other conditions, there exists a great deal of sampling variability in those with NAFLD, so biopsy likely represents a flawed gold standard for diagnosis [11].

Focal lesions

Focal hepatic lesions identified by radiographic techniques are often easily identifiable by their characteristic appearances. Diagnosis of specific liver masses is routinely made by radiography alone, and techniques and diagnostic experience have advanced to such an extent that biopsy is often unnecessary to make a diagnosis of the nature of the focal lesions. Biopsy becomes useful when there are atypical radiographic features.

Prior to pursuing biopsy for a mass lesion, it is crucial have an appreciation for the context in which the lesion arises. Clearly, a lesion arising in a patient with known cirrhosis makes hepatocellular carcinoma (HCC) a major concern. Biopsy of a suspected HCC is not without risk. HCCs tend to be highly vascular tumors so there is a risk of hemorrhage [12]. The risk of seeding the needle tract with tumor cells and causing spread of disease has been reported in up to 2.7–5% of cases of percutaneous biopsy [13]. Further there is a concern of sampling error when attempting to biopsy a small lesion that may give a false sense of security. Most importantly, the diagnosis of HCC can often be made readily in a patient with cirrhosis based on characteristic radiologic features.

Other lesions not characteristic on imaging such as adenomas, hemangiomas, focal nodular hyperplasia, cysts, abscesses, and lesions that are concerning for metastases, should only be considered for image-guided biopsy after careful review with a radiologist and an alternative imaging technique has failed to give a diagnosis.

Liver transplantation

Liver biopsy is helpful in making a specific diagnosis in both early and late allograft dysfunction. Diagnoses such as allograft rejection, viral infection (such as due to cytomegalovirus), drug-induced liver injury, bile duct injury, or recurrence of the original disease can be made with a liver biopsy. In addition, liver histology is helpful in determining the prognosis and course of recurrent hepatitis C-related fibrosis progression and clinical decompensation [14].

Considerations prior to percutaneous liver biopsy

Contraindications to having a percutaneous liver biopsy are listed in Box 3.2.

Coagulopathy/thrombocytopenia

Many patients undergoing liver biopsy have advanced liver disease complicated by coagulopathy and thrombocytopenia. Although the risk of major hemorrhage after liver biopsy is fairly low, hemorrhage remains the most feared complication of liver biopsy, despite the fact that there is no definitive correlation between risk of bleeding and level of coagulation abnormality. Traditionally, percutaneous biopsy has been avoided in patients with a prothrombin time elevated in excess of 4 seconds over control, an international normalized ratio (INR) greater than 1.5, or a platelet counts less than 60,000/μL. Prothrombin time, partial thromboplastin time, and platelet count should be measured within 4 weeks of biopsy. Patients with any of these derangements or a combination of them are typically sent for transjugular liver biopsy and given preprocedure fresh frozen plasma or platelet transfusions to correct coagulation abnormalities.

Patients taking oral anticoagulants should be counseled on discontinuation of the drugs at least 5 days before the biopsy, and a preprocedure prothrombin time INR is preferred to ensure that the INR is within acceptable limits. The indication for anticoagulation should be reviewed to ensure that discontinuation is appropriate and safe. Oral anticoagulation should not be restarted immediately, but can be resumed 48–72 hours after the biopsy since delayed bleeding has been reported in patients on

Box 3.2 Contraindications to percutaneous liver biopsy.

Absolute

- Uncooperative patient
- Bleeding tendency:
  - Prothrombin time (PT) ≥4 seconds over control or international normalized ratio (INR) >1.5
  - Platelet count <60,000/mm^3
- Inability to transfuse blood products
- Serious consideration of echinococcal disease
- Presumed hemangioma or other vascular tumors

Relative

- Ascites
- Obesity
- Infection in right pleural cavity and/or below right diaphragm

oral anticoagulants [15,16]. A recent study evaluated the role of aspirin in biopsy-related complications [17]. The authors reported that in over 15,000 image-guided core biopsies of many organs, aspirin did not seem to confer an increased risk of bleeding. Despite this new information, we still advise discontinuation of aspirin and nonsteroidal agents for approximately 7 days prior to the planned procedure, which may be restarted 48–72 hours after the procedure. Data are lacking on the management of newer antiplatelet agents; however, it would seem prudent that these agents be discontinued for a brief period of time before and after biopsy.

Ascites

The presence of ascites precludes percutaneous liver biopsy in many patients. The midaxillary approach is technically hindered as tense ascites causes a separation of the liver from the costal surface. Those with moderate ascites may be able to undergo a therapeutic paracentesis prior to biopsy, but in most cases a transjugular approach is used since many of these patients will have coexisting coagulation impairment.

Other contraindications

Successful percutaneous biopsy requires that the patient is able to cooperate with the procedure. Lack of patient cooperation may increase the risk of complications. Uncooperative patients needing biopsy should get biopsies via the transvenous routes using sedation. Marked obesity should also prompt a transjugular approach, as a percutaneous approach is hindered by adipose tissue. Patients suspected of having either infectious lesions or vascular lesions in the liver should not undergo routine percutaneous biopsy, as puncture of that tissue may cause dissemination of infection or hemorrhage.

Percutaneous liver biopsy

Technique

Percutaneous liver biopsy is the most common technique used to acquire liver tissue. Prior to setting up for the procedure, it is critical to confirm that the patient undergoing the procedure is an appropriate candidate. This entails a complete history and physical examination, a review of medications, and measurement of clotting parameters in order to assess for any contraindications to biopsy. A light meal at least 3 hours before the procedure may facilitate gallbladder emptying and reduce the risk of gallbladder puncture. Alternatively, an overnight fast can reduce the risk of aspiration in case of vomiting.

Prior to initiating the procedure, it is mandatory to clearly explain the procedure and any potential complications that could result from it. Written consent documenting this discussion with the patient and/or a proxy should be obtained. After this is accomplished it is appropriate to prepare the patient for the procedure.

Venous access should be established, preferably in the left arm, so that the patient can lie comfortably in the right lateral decubitus position after the biopsy. Patients are frequently anxious, and intravenous fentanyl and midazolam can alleviate apprehension, facilitate the procedure, provide some postprocedure relief of pain, and achieve some degree of amnesia. Most patients do well with approximately 50 μg of fentanyl and 2 mg of midazolam without impairment of their ability to cooperate with the biopsy. Older patients may require less sedation.

The patient should be positioned supine with the right hand placed under the head. The point of maximum liver dullness is percussed over the right hemithorax between the anterior and midaxillary lines and is usually found between the sixth and ninth intercostal spaces. In certain situations, it may be higher (e.g., obesity) or lower (e.g., emphysema). Dullness should be present in both inspiration and expiration as some patients may inadvertently take a deep breath during the procedure and thereby risk a pneumothorax. The routine use of real time ultrasound is helpful in establishing the best location for biopsy, and allows the operator the advantage of visualizing the liver during inspiration and expiration and identifying neighboring organs (i.e., lung, kidney, gut) that may be at risk of inadvertent puncture. The location for biopsy should be marked clearly, and then the area should be prepped and draped in a sterile fashion. A local anesthetic agent, such as 1% lidocaine is injected over the upper border of a rib, avoiding the intercostal nerve and vessels that run along the lower border. A small incision is made with a scalpel in order to accommodate the larger needle used to actually obtain the tissue. The biopsy needle should then be inserted at the incision site and the procedure performed.

Devices

Needles used to perform percutaneous liver biopsy are broadly categorized as aspiration needles (Menghini, Klatskin, and Jamshidi needles) and cutting needles (Vim Silverman and Tru-Cut needles and spring-loaded needles with triggering mechanisms). The aspiration-type devices are attached to a syringe. When the needle is inserted into the liver parenchyma, suction is applied to the syringe and tissue is aspirated into the needle for collection. The cutting-type needles, whether manual or automatic, employ a needle and outer cutting sheath that when propelled beyond the needle cuts and traps tissue within the needle hollow.

Different needles acquire various lengths and diameters of hepatic tissue. Comparisons of Menghini aspiration and Tru-Cut needles have shown increased

rates of tissue sample fragmentation with the aspiration needles compared with the cutting-type needles, especially in the presence of cirrhosis [18,19]. Likewise it has been reported that Tru-Cut biopsies were significantly longer (12 mm versus 8 mm; $P < 0.001$) and contain a greater number of portal tracts (16 versus 6; $P < 0.001$) than aspiration-type needles [18]. Amongst the cutting-type devices, it has been reported that the automated needles acquire slightly longer tissue samples (1.7 mm versus 1.5 mm; $P = 0.05$) [20]. It has also been noted that the nonautomatic cutting needles remain in the liver for a modestly longer time during the biopsy and may pose additional bleeding risk due to this added time [12]. Likewise, larger bore needles may confer a higher risk of bleeding [21].

Imaging

Ultrasonography can be used to guide the operator with respect to location for the percutaneous liver biopsy. Ultrasound can occur either in advance of the procedure, such that the biopsy site is "marked" by an ultrasonographer, or the ultrasound can occur in real time by the operator. The relative ease and availability of real time ultrasound have made its pre-biopsy use routine in some centers [22]. However, use of ultrasonography to guide a percutaneous biopsy is not mandatory. The lack of consensus on the matter is apparent in individual practice. A survey of 112 gastroenterologists associated with a major North American academic center revealed that over half performed liver biopsies without the use of ultrasound guidance [23]. Another survey found that 64% of gastroenterologists used ultrasound prior to biopsy [24].

To examine differences in diagnostic yield and safety, Lindor *et al.* performed a prospective, randomized study of 836 patients, who were randomized to either automatic or traditional cutting needles with or without ultrasound guidance [20]. Those who underwent pre-biopsy ultrasound had lower rates of hospitalization (2 versus 9; $P = 0.04$), lower rates of bleeding or hypotension (9 versus 18; $P = 0.07$), and lower frequency of pain requiring non-narcotic treatment (37% versus 50%; $P = 0.003$). There was no difference in pain requiring narcotic analgesia between those who had and did not have pre-biopsy ultrasonography. In contrast to these findings, a large British survey failed to demonstrate differences in major complications or pain between biopsies performed with and without ultrasonographic guidance [25]. With respect to diagnostic yield, a recent retrospective analysis of 205 patients who underwent liver biopsy found that there were no statistically significant differences between the specimens in terms of tissue fragmentation or number of portal tracts and central veins whether ultrasound guidance was or was not used [26]. Mean specimen length in the ultrasound-guided liver biopsy group was 12.58 mm and in the blind biopsy group was 16.22 mm ($P < 0.005$). Neither group experienced major complications.

Another prospective study showed that ultrasonography changed the site of liver biopsy determined by the percussion technique in as many as 15% of patients [27]. If the site had not been moved, what complications may have resulted is not known. A follow-up study showed that ultrasonography may not be of any greater utility in selected patients, such as those with difficult percussion, obesity, or chest wall deformity [28]. Ultrasonography was just as likely to mandate movement of the biopsy site in patients with these features compared with unselected patients.

Cost-effectiveness analysis has suggested that the use of ultrasonography to prevent major complications is cost effective [29]. The use of ultrasonography has resulted in better outcomes, is cost effective, and is already widely utilized. Given the fact that real time ultrasound is widely available, its use is preferred by many over blind percussion technique; however its use is not obligatory [30].

Plugged biopsy

While ultrasound guidance may provide a radiographic technique to enhance the safety of percutaneous biopsy, there is another technique that has been described. Plugged biopsies were first described in the mid 1980s and provide a technique whereby percutaneous biopsy may be considered in a patient with mild coagulopathy and/or ascites [31]. A recent trial studied the safety and efficacy of plugged percutaneous liver biopsies done with ultrasound guidance [32]. In 36 patients undergoing percutaneous biopsy, the needle tract was injected with a foam embolization particle. None of the patents had bleeding complications and specimens were adequate for diagnosis in all cases. Since then, transjugular biopsy has become a common approach for obtaining liver tissue in those with coagulopathy, and this technique has been compared with plugged percutaneous liver biopsy. One study reported bleeding requiring transfusion in two patients undergoing a plugged procedure [33]. The biopsy specimens obtained via the percutaneous route were significantly larger, although both techniques provided specimens adequate for diagnosis. More recently, the two techniques were again compared in a population with coagulopathy and/or ascites and neither group suffered complications of hemorrhage [34]. When available, plugged percutaneous biopsy may provide an alternative in those with mild coagulation abnormalities and ascites, especially given a low reported risk of bleeding and the potential of obtaining larger specimens.

Postprocedural considerations

After the successful completion of the biopsy procedure, the patient should be observed for a period of time with vital signs being taken every 15 minutes for the first hour, then every 30 minutes for the second hour. Conventionally, the patient should remain in the right lateral decubitus position during this time. The duration of observation after biopsy has been arbitrary for several years, with the recognition that postprocedural monitoring is to assess for complications related to bleeding – an event that if it occurs, should occur soon after biopsy. A recent retrospective evaluation of monitoring practices found that the majority of complications occurred within 1 hour postprocedure [35]. As recovery time decreased from 6 hours before 1997 to 1 hour in 2002, the major complication rate was 1.7% regardless of duration of observation. The majority of complications occurred within 1 hour during the observation period or within 24 hours after discharge. Based upon this study, it would be reasonable to conclude that a shorter observation time of 2 hours after ambulatory percutaneous liver biopsy is safe.

Adequacy of sample

A liver biopsy samples approximately 1/50,000th of the liver, and therefore may not be representative of the entire liver, especially given the fact that many diseases cause heterogeneous injury. Standard practice would mandate the presence of at least six portal triads in order to consider the specimen adequate for diagnosis in diffuse liver disease [36]. However, more recent data suggest that these criteria are inadequate for the grading of fibrosis and staging of inflammation in chronic liver disease.

A recent study in patients with chronic hepatitis B and C sought to examine the diagnostic yield of biopsies when the length and width of specimens were varied [37]. Shorter lengths of biopsy specimens yielded more mild estimates of inflammation grade, such that when only 1 cm of length was viewed 86.6% were interpreted as mild whereas when at least 3 cm of biopsy was viewed only 49.7% were graded as such. Similarly, more specimens were reported to show mild fibrosis with shorter length of specimens. As for the width, both grade and stage were significantly underscored in the 1 mm samples, regardless of their length. The study also reported that 11 portal tracts seemed to be the threshold below which disease grade and stage were significantly underestimated. Likewise, a biopsy of 2 cm in length and 1.4 mm in width tended to guarantee this number of portal tracts in 94% of cases. Another more recent study showed that intraobserver agreement was significantly better with longer length (2 cm) specimens than with shorter length (1.5, 10, or 5 mm) [38].

It has been reported that even large biopsy samples may not be reliable for the evaluation of NAFLD. A study examining two biopsies from patients with NAFLD, using large bore (16 gauge) cutting needles of average length 2 cm, showed surprising variability between the two biopsies, with 41% discordance rate for one or more stages [39]. However, a more recent paper showed that length of the biopsy sample positively correlated with the percentage of patients found to have definite NASH, such that 29% were diagnosed to have NASH in biopsies measuring less than 10 mm and 65% in biopsies measuring ≥25 mm [35].

We can therefore conclude that larger bore biopsies of longer length are desirable to reliably grade and stage chronic liver disease. However, liver biopsy must be regarded to some extent as a flawed gold standard for the evaluation of chronic liver diseases because of significant problems with sampling variability and the heterogeneous nature of liver diseases.

Complications of percutaneous liver biopsy

Complications resulting from liver biopsy range from pain, which is common, to more serious events such as bleeding, perforation of a neighboring organ, infection, or death, all of which are uncommon (Box 3.3). Sixty percent

[a] Symptomatic and asymptomatic.
[b] Asymptomatic.
Data from references [12,26,47–56,59–64,68–70].

of complications are recognized within 2 hours after the procedure, and 96% within 24 hours [21,40]. Fatal complications typically occur within 6 hours. A hospitalization rate of 1.4–3.2% for the management of complications following a liver biopsy has been reported, with pain or hypotension being the predominant cause [41,42]. Mortality after liver biopsy has been reported to vary from 0.0088% to 0.3% [12,43].

Up to 84% of patients experience pain after percutaneous biopsy, either at the biopsy site, in the right shoulder, or in both locations [44]. The pain is usually mild, dull, and responsive to analgesics. Pain medications are required in approximately one third of patients after biopsy, approximately one half of whom are given narcotics [45]. While pain typically resolves within a few hours of biopsy, one group found that it may persist up to 24 hours after biopsy [44]. Ongoing severe abdominal pain should alert the physician to the possibility of bleeding or peritonitis and warrants radiographic evaluation and/or hospital admission.

The most dreaded complication of liver biopsy is hemorrhage. Hemorrhage after liver biopsy can manifest as a free intraperitoneal bleed, intrahepatic or subcapsular hematoma, or hemobilia. The risk of fatal hemorrhage in patients without malignant disease is 0.04% and the risk of nonfatal hemorrhage is 0.16%. In those with malignancy, the risk of nonfatal hemorrhage is 0.4%, and 0.57% for nonfatal hemorrhage [12]. Risk factors for hemorrhage after liver biopsy include presence of malignancy, performance of multiple passes, advanced age, mycobacterial infection, requirement for pre-biopsy platelet transfusion, acute liver failure, cirrhosis, heparin administration on the day of biopsy, treatment with corticosteroids, use of nonsteroidal anti-inflammatory agents, use of large diameter needles, and when the procedure is performed by a less experienced operator [12,21,46]. Free intraperitoneal hemorrhage may be related to a laceration sustained during deep inspiration or to a penetrating injury of a large vessel. Significant intraperitoneal hemorrhage is manifest by abdominal pain, tachycardia, and hypotension. Typically, these symptoms develop within the first 2–3 hours after the procedure. Patients with these symptoms should ideally undergo radiographic imaging in order to confirm clinical suspicion. If hemorrhage is present, volume resuscitation must be undertaken immediately. If hemodynamic instability persists despite aggressive resuscitation over a couple of hours, then angiography with embolization of the bleeding site is the preferred approach to stop the bleeding. In some cases, surgical exploration is required. The use of prophylactic or rescue strategies such as plasma, fibrinolytic inhibitors, or recombinant factors can be considered, although their effectiveness and use has not been established in the situation of bleeding following a liver biopsy.

Intrahepatic or subcapsular hematomas have been reported in 0.59–23% of cases when ultrasonography is performed after a liver biopsy [47]. These are usually asymptomatic, and the frequency is similar in both laparoscopically guided and "blind" liver biopsies [48]. Large hematomas may cause pain, liver enlargement, tachycardia, hypotension, and a delayed drop in the hematocrit. Conservative treatment generally suffices, and angiography is rarely required.

Hemobilia is a rare complication of percutaneous liver biopsy that presents with the classic triad of right upper quadrant pain, jaundice, and gastrointestinal bleeding. In a series of 68,276 percutaneous biopsies, hemobilia occurred in only four (0.006%) procedures [21]. While some cases of hemobilia may present acutely, most present at least 5 days after the biopsy [49,50], an approximate time period for the erosion of a hematoma or pseudoaneurysm into a bile duct. Bleeding is usually arterial in origin, but can be venous. The severity ranges from life-threatening hemorrhage to occult bleeding with chronic anemia. Endoscopy may reveal blood flowing from the ampulla of Vater. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrates linear, irregular densities in the biliary tree and gallbladder that do not have the configuration of gallstones, and endoscopic sphincterotomy may facilitate the removal of these clots [51]. However, angiography is the preferred modality for diagnosis and embolization therapy.

Transient bacteremia has been reported in up to 13.5% of patients after liver biopsy [52]. This is usually of no clinical significance, although sepsis can sometimes occur in patients with biliary tract disorders. Evaluation of a post-transplant population (a high-risk group on immunosuppressive agents) found that of 1,136 percutaneous liver biopsies, only seven infections resulted [53]. No recommendations are currently available regarding prophylactic antibiotics for those with risk factors for endocarditis. Infection complications in the post-transplant patient are relatively more common in patients with biliary-enteric anastomosis, and antibiotic prophylaxis in such patients prior to the procedure appears prudent.

Other complications of liver biopsy include asymptomatic intrahepatic arteriovenous fistula, bile pleuritis, and bile peritonitis [54–57]. The most common cause of bile peritonitis is puncture of the gallbladder, which becomes apparent immediately and is characterized by severe pain and vasovagal hypotension. Bile peritonitis is also more likely if biliary obstruction is present. Pain may be followed by fever, abdominal pain, leukocytosis, and ileus. Ultrasonography or a computed tomography (CT) scan may identify an intra-abdominal collection of bile, and ERCP or biliary scintigraphy may demonstrate a bile leak. Surgery is indicated when clinical deterioration

occurs despite the administration of intravenous antibiotics, fluid, and pain control. Pneumothorax and hemothorax after liver biopsy often spontaneously resolve, and placement of a chest tube is seldom required.

Transjugular liver biopsy

Transjugular liver biopsy (TJLB) was first performed successfully in 1970 [58]. Since that time, it has continued to provide an alternative mechanism of obtaining liver tissue in patients with contraindications to percutaneous biopsy. Despite the fact that TJLB specimens have traditionally been thought of as inferior to those obtained by conventional methods, the transjugular approach offers the added benefit of being able to obtain a hepatic venous pressure gradient, a parameter which is increasingly recognized as an important clinical and prognostic marker.

Indications

Significant ascites and bleeding tendency are the most common indications for transjugular liver biopsy (Box 3.4) [59]. Bleeding is the most feared complication in patients undergoing liver biopsy, especially in those who have altered coagulopathy as a result of impaired synthetic function or thrombocytopenia. Coagulopathy, defined as a prothrombin time greater than 3 seconds over control and/or a platelet count less than 60,000 cm^3, accounts for almost half of all cases [59]. Due to the controlled circumstances of the transjugular approach, the risk of bleeding is minimal and appears to be safe even in those with congenital bleeding disorders when done on an outpatient basis [60,61].

TJLB has been shown to have a diagnostic and prognostic role in those with acute hepatic failure. A report of 17 patients with acute liver failure found that TJLB was technically successful in all patients and that there were no complications due to the procedure [62]. In those found to have submassive or massive necrosis, prognosis was poor. TJLB has also been reported to be safe and helpful in the early postoperative period after liver transplant due to coagulopathy or ascites [63]. Other common indications for TJLB are obesity, failure of percutaneous biopsy, or post liver transplant.

Box 3.4 Indications for transjugular liver biopsy.

- Ascites
- Coagulopathy
- Thrombocytopenia
- Fulminant hepatic failure
- Obesity
- Postoperative liver transplant
- Assessment of hepatic venous pressure gradient (HVPG)
- Refusal or failure of percutaneous biopsy

A clear advantage of the transjugular approach is the ability to measure the hepatic venous pressure gradient (HVPG). The measurement of the HVPG has a clear application in the management of portal hypertension. A reduction in the HVPG to a value under 12 or by 20% of baseline has been shown to reduce rates of variceal bleeding and mortality [64]. The measurement of HVPG will likely be used increasingly as its utility in the management of other conditions is demonstrated. For example, there is now evidence that knowledge of the HVPG may be informative in patients with hepatitis C. In a pretransplant setting, improved HVPG measurements have been demonstrated to relate to response to therapy of chronic hepatitis C [65]. In the post-transplant setting, HVPG measurement during TJLB was evaluated as a predictor for severe HCV recurrence after transplant [66]. An HVPG of 6 mmHg or greater was found to accurately identify patients at risk of disease progression after transplant. Additionally, it has been noted that patients with cirrhosis and increased HVPG measurements were at high risk of hepatic decompensation after resection of hepatocellular carcinoma [67].

Technique

Transjugular liver biopsy is performed under fluoroscopic guidance, often by an interventional radiologist, although hepatologists have performed it as well. As with percutaneous biopsy, modest amounts of conscious sedation can be used. The patient is placed in the supine position and is given supplemental oxygen via a nasal cannula. Pulse oximetry and electrocardiographic monitoring is recommended since the passage of the catheter through the heart can trigger cardiac arrhythmias.

A local anesthetic (1% lidocaine) is injected at the puncture site (typically the right internal jugular vein). Once the internal jugular vein is accessed, a sheath introducer is placed into the vein and, under fluoroscopic guidance, a catheter is advanced to the level of the right hepatic vein. Once the hepatic vein has been adequately visualized with venography, a biopsy needle is threaded down the catheter and advanced into the liver parenchyma. Two types of needles can used in TJLB: the Menghini (aspiration) or Tru-Cut (cutting) needle. The total procedure time is usually 30–60 minutes.

Specimens

The necessity of larger biopsy specimens containing a greater number of portal tracts for the evaluation of inflammation and fibrosis has called into question the adequacy of the specimens obtained from TJLB. Traditionally, these specimens have been noted to be suboptimal in size and subject to fragmentation owing to

the method by which they are obtained. However, smaller sample size and fragmentation problems have been overcome since aspiration techniques have given way to Tru-Cut TJLB methods [68]. While grading of inflammation and staging of fibrosis may be impaired in smaller samples, the ability to diagnose using these specimens (i.e., sample length at least 15 mm with at least six portal tracts) does not appear to be impaired.

The adequacy of Tru-Cut-type TJLB specimens was recently evaluated [69]. With three passes; the mean length of specimens obtained was 22 mm, with 65% of samples measuring over 20 mm. Twenty-six percent of specimens obtained had the requisite 11 complete portal tracts, which may limit the utility of TJLB specimens for accurate grading and staging of hepatitis. In a follow-up study, the consequence of doing four passes as opposed to three during TJLB was evaluated [70]. Performing four passes increased the percent of specimens containing at least 11 portal tracts to 40% (as compared to 26%; $P = 0.027$). There were no reported serious complications seen. It was thus concluded that when TJLBs are needed to assess grade and stage, four passes should be used.

Few studies have compared laparoscopic, transjugular, and percutaneous techniques. However, when compared with laparoscopic and percutaneous procedures, transjugular biopsies have been found to have significantly fewer portal tracts (average portal tracts 4.3 versus 11 and 11.7, respectively) [71]. Despite this fact, when these samples were evaluated to assess the grade and stage of chronic liver disease, the investigators did not find decreased levels of grade and stage reported compared with those biopsies obtained via percutaneous or laparoscopic routes.

The consistent observation that TJLB specimens yield decreased numbers of portal tracts may limit its use in the grading and staging of chronic liver disease, however when contrasted with the risk of percutaneous biopsy in those with contraindications, TJLB provides a valuable alternative for assessment of liver histology. Consideration should be given to performing four passes if an assessment of disease severity is the goal.

Complications

Complications due to TJLB are uncommon and range from arteriovenous fistula formation with hemobilia, to hematoma at the jugular access site (Box 3.5). In a recent review of over 7,000 transjugular biopsies, major complications occurred in 0.6% of cases. The majority of complications were intraperitoneal hemorrhage (15), hepatic hematoma (4), ventricular arrhythmia (4), and pneumothorax (4). Minor complications occurred in 6.6% of cases and typically were abdominal pain, fever, or subclinical capsular perforation. Eight deaths (mortality rate, 0.09%) occurred, five were due to hemorrhage and three were due to ventricular arrhythmia [59].

Box 3.5 Complications of transjugular liver biopsy.

- Hematoma at jugular access site
- Intraperitoneal hemorrhage
- Hepatic hematoma
- Ventricular arrhythmia
- Pneumothorax
- Abdominal pain
- Subclinical capsular perforation

Laparoscopic liver biopsy

Diagnostic laparoscopy can be performed for a variety of indications (Box 3.6). The major advantage of laparoscopy is that it allows for a direct visualization of the liver and affords us an opportunity to take directed biopsies. Diagnostic laparoscopy can be performed safely in patients with liver disease.

Indications

Due to the fact that percutaneous and transvenous biopsy methods are subject to sampling error, a laparoscopic approach can be used to study the gross appearance of the liver. A spectrum of macroscopic changes can occur in the presence of chronic liver disease. Whereas in patients with early disease the surface of the liver tends to appear smooth, in more advanced states the liver surface can appear granular. Cirrhosis is associated with diffuse nodularity and features of portal hypertension. In contrast to laparoscopic evaluation, it has been noted that percutaneously obtained liver biopsy specimens tend to understage the degree of fibrosis. In a study comparing histology with laparoscopic appearance of the liver, laparoscopic appearance was found to be 100% sensitive and 97% specific in identifying cirrhosis, compared with histological evaluation alone, which missed 6% of the cases of cirrhosis [72]. Liver biopsy, while specific for cirrhosis, may be associated with a 32%

Box 3.6 Indications for laparoscopic liver biopsy.

- Evaluation of liver disease after nondiagnostic radiologic examination
- Biopsy in patients with coagulopathy and/or thrombocytopenia
- Biopsy of discrete lesions difficult to access percutaneously
- Staging for primary hepatic tumors
- Evaluation of unexplained hepatomegaly
- Evaluation of unexplained portal hypertension
- When other less invasive modalities fail to provide a diagnosis

sampling error in the diagnosis of cirrhosis compared with laparoscopy [73].

Laparoscopy has been shown to enhance diagnostic yield not only in the case of cirrhosis, but in other disorders as well. Crantock et al. reported on 200 consecutive patients who underwent laparoscopy and biopsy [74]. Twenty-five patients had a malignancy diagnosed by the laparoscopically guided biopsy, eight of which were not seen on ultrasound prior to the laparoscopy. When compared with traditional histology, laparoscopy had >94% sensitivity and specificity at diagnosing fatty change, fibrosis, and inflammatory activity [72]. Laparoscopic appearance of the liver has also been evaluated as a prognostic indicator for treatment of chronic hepatitis C [75]. Worse macroscopic appearance was correlated with a lower sustained virological response.

When routine testing does not reveal a source for ascites, laparoscopy can be an invaluable tool for diagnosis. Laparoscopy can also identify the presence of multiple causes of ascites and is useful in obtaining peritoneal biopsies to confirm the diagnosis of malignancy or infection when suspected [76]. The diagnostic utility of laparoscopy and peritoneal biopsy has been demonstrated in several series and has determined the cause of ascites in up to 86% of cases of ascites of unclear etiology [77]. Special consideration should be given to the role of laparoscopy and peritoneal biopsy in those suspected of having tuberculous peritonitis. In a series of 14 patients with high protein content and elevated lymphocytes measured by paracentesis, all had negative Ziehl–Neelsen stains and culture of ascites after simple paracentesis [78]. Tuberculous peritonitis was only confirmed after laparoscopy demonstrated multiple white tubercles and adhesions. Biopsy specimens demonstrated caseating granulomas.

Laparoscopy can be used in the management of HCC. Diagnostically, a laparoscopic view of the liver surface may demonstrate changes suggestive of malignancy, such as hypervascular nodules and hyperemic, pigmented lesions [79]. Specific laparoscopic features, including the presence of irregular regenerative nodules, a high degree of nodular regeneration, and an atrophic right lobe, have been described to predict the development of HCC in patients with hepatitis C cirrhosis [80]. Therapeutically, laparoscopy can also be used in patients with suspected HCC to assess the extent of the primary lesion and to examine other areas for synchronous tumors [81]. In addition, it may be helpful to perform laparoscopy in patients with an elevated α-fetoprotein and unrevealing imaging studies.

Technique

Previously, patients undergoing diagnostic laparoscopic procedures were required to be admitted for observation after the procedure. Currently, outpatient diagnostic laparoscopy using conscious sedation has been demonstrated to be safe and effective [82]. Patients should receive oxygen via a nasal cannula and should be monitored during the procedure. Intravenous access is required to give conscious sedation.

With the patient in a supine position, the abdomen is prepped and draped. A Veress needle and trocar are usually placed in the left paramedian area; however, a right paramedian or subumbilical approach can be used in patients with an enlarged left hepatic lobe, splenomegaly, or previous splenectomy. A local anesthetic such as1% lidocaine is injected intradermally 2 cm above and to the left of the umbilicus. Then, a 16 gauge needle is inserted through the center of the wheal to the parietal peritoneum, which usually provokes some pain. Approximately 15–20 mL of 1% lidocaine is applied to the subcutaneous tissue and fascia within a 2 cm radius. It is important that sufficient local anesthesia be applied. A small incision is made in the center of the wheal, and the patient is asked to distend the abdominal wall without arching their back. The Veress needle is then inserted into the abdominal cavity. Aspiration with a 10 mL syringe may avoid air embolism or inadvertent entry into the intestines, both of which are rare complications [83].

Whereas carbon dioxide used for insufflation during therapeutic laparoscopy is a peritoneal irritant and provokes pain, the nitrous oxide commonly used for diagnostic laparoscopy is better tolerated [84]. Insufflation to an abdominal cavity pressure of 20 mmHg is accomplished by delivering 3–6 L of nitrous oxide through the Veress needle. A 20 mL syringe, half filled with saline solution, is then inserted and rotated within the abdominal cavity. Gas bubbles within the syringe indicate an unobstructed area for trocar placement.

The patient is then instructed to distend the abdomen, and the trocar is inserted into the peritoneal cavity. Two distinct "pops" confirm placement. An oblique-view laparoscope is then inserted into the abdominal cavity under direct vision. The area perpendicular to the scope is inspected for insertion-related damage. With the patient in the Trendelenburg position, the bladder and other pelvic structures can be visualized. Placement of the patient in the reverse Trendelenburg position allows thorough inspection of the right and left upper quadrants. A second trocar is inserted into the right midclavicular line to allow, via another laparoscope, inspection of the superior aspect of the right lobe and the delivery of accessory equipment, such as the biopsy needle and palpating probe. Liver specimens are obtained with a biopsy gun or, less commonly, a Tru-Cut needle from left of the falciform ligament, and the medial and lateral aspects of the right lobe to avoid sampling error. To avoid large blood vessels, a tangential approach to the liver left

of the falciform ligament is recommended. Pressure is applied with a palpating probe on both the biopsy sites to tamponade the bleeding site and establish hemostasis. Towards the end of the procedure, the initial trocar site (left of the umbilicus) is observed using the laparoscopic camera on the right side to look for any bleeding while the trocar is being removed. If bleeding occurs at the initial trocar site, an Avotin® pellet is inserted into the site to achieve hemostasis.

After the examination is completed, the trocar and biopsy sites can be closed with Steri-strips® or by sutures if a larger incision is made to accommodate larger trocars and laparoscopes. Patients are observed for approximately 18–24 hours postprocedure and discharged to resume regular activity in 3–4 days. Right shoulder pain for 6–8 hours after the procedure is common.

As with percutaneous and transvenous biopsies, patients should avoid nonsteroidal anti-inflammatory drugs and salicylate compounds for 1 week before and after the procedure. Recommendations for patients with clotting factor and platelet count abnormalities are similar to those of percutaneous liver biopsy. Recently, the use of recombinant factor VIIa before laparoscopic liver biopsy has been reported [85]. Moreover, mini-laparoscopy appeared safe in a small study of 61 patients with a platelet count less than 50,000/μL and/or an INR greater than 1.5; however most patients required the application of argon plasma coagulation directly to the liver to stop post-biopsy bleeding [86].

Advances in technology have allowed for the use of mini-laparoscopy, in which a smaller diameter trocar (1.9 mm) is used. This technique has been noted to be extremely safe, less invasive, and well tolerated by patients [87]. When compared with conventional laparoscopy, the mini-laparoscopic technique demonstrated similar success and had the advantage of a shorter procedure time [88]. When compared with a percutaneous approach, mini-laparoscopy has been noted to have the advantage of offering both macroscopic and histologic results that can improve the diagnosis of cirrhosis [89].

Laparoscopic ultrasonography is another technologic advance that has allowed for improved visualization of the liver parenchyma, targeted biopsies, and staging of both primary and metastatic hepatic lesions [90]. Performance of laparoscopic ultrasound can help to identify lesions not seen on conventional preoperative imaging and in this regard has been noted to help in avoiding unnecessary laparotomy [91]. Therapeutically, laparoscopic ultrasound can be used to direct radiofrequency ablation of unresectable lesions [92]. An exciting and recent technical advance involves an extension of the natural orifice transluminal endoscopic surgery (NOTES) procedure to perform a liver biopsy [93].

Box 3.7 Complications of laparoscopic liver biopsy.

- Pain
- Perforated viscous
- Hemobilia
- Splenic laceration
- Bleeding from biopsy site
- Ascitic fluid leak
- Abdominal wall hematoma
- Pneumoperitoneum and/or subcutaneous emphysema

Complications

A large series of 1,794 diagnostic laparoscopies done to evaluate abnormal hepatic biochemical tests, organomegaly, unexplained portal hypertension, and ascites reported that major complications occurred in only eight patients (0.44%) [83]. These major complications included perforation, hemobilia, splenic laceration, and bleeding from the biopsy site (Box 3.7). Minor complications included ascitic fluid leakage, abdominal wall hematoma, and postoperative fever. Subcutaneous emphysema and abdominal pain were observed in 31 patients (1.73%), and one death occurred.

Noninvasive markers of fibrosis

Liver biopsy remains the gold standard for histological assessment of liver disease. As the purpose of liver biopsy has changed from being simply a diagnostic test to a more comprehensive test that is able to provide pivotal information on prognosis and therapeutics, the role of liver biopsy remains central. However, because the procedure is invasive and associated with risk, and because it provides a flawed gold standard and because multiple biopsies may be necessary to chart the course of a disease, there is an obvious need to develop and use noninvasive markers of liver injury. There are currently several biochemical markers and radiographic techniques under evaluation to assess the degree of liver fibrosis in a variety of liver diseases.

Conclusions

Liver biopsy is a time-honored and safe method of evaluating diseases of the liver. Since the late 1800s, liver biopsies have aided practitioners with making accurate diagnoses. The role of biopsy has grown, and we can now glean information on prognosis and therapeutic options in a variety of liver diseases. It is clear that biopsy specimens may be subject to significant variability, and consideration should be given to that prior to performing a biopsy.

Table 3.1 Advantages and disadvantages of the different types of liver biopsy.

	Percutaneous	Transjugular	Laparoscopic
Advantages	Common procedure, widely available	Safe in those with bleeding tendency Safe in acute liver failure	Safe in those with bleeding tendency Macroscopic view Directed biopsy Peritoneal biopsy Can perform radiofrequency ablation
Disadvantages	Limited in specimen adequacy	Limited in specimen adequacy especially with suction-type needles	Infrequently performed by hepatologists in many countries Invasive
Special considerations	Ultrasound guidance Plugged biopsy	Hepatic venous pressure gradient measurement	Ultrasound guidance and evaluation Therapeutic interventions

Percutaneous biopsy continues to be the most common method of obtaining liver tissue. However, when contraindications to percutaneous biopsy exist, transjugular or laparoscopic approaches offer reasonable alternatives (Table 3.1). Complications related to liver biopsy while severe in some cases are fortunately rare and in most cases are able to be managed. While the future promises to include several noninvasive markers of liver injury, it is unlikely that liver biopsy will fall by the wayside.

CHAPTER 4

Noninvasive and Invasive Imaging of the Liver and Biliary Tract

Kunal Jajoo[1], *Kevin Mennitt*[2], *& Ira Jacobson*[3]

[1]Division of Gastroenterology, Hepatology, and Endoscopy, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

[3]Department of Gastroenterology and Hepatology, Weill Medical College of Cornell University, New York, NY, USA

Key concepts

- Ultrasonography is often the first hepatic imaging performed in patients with liver abnormalities, however it is limited by sensitivity and user dependence.
- Computed tomography (CT) and magnetic resonance imaging (MRI) are similar in sensitivity, however radiation is an issue with CT and MRI has lower spatial resolution.
- The role of positron emission tomography in liver imaging is still being investigated.
- Magnetic resonance imaging is very helpful in qualitatively and quantitatively assessing steatosis but none of the imaging modalities can accurately distinguish between steatosis and steatohepatitis.
- Magnetic resonance angiography and CT angiography have largely replaced diagnostic angiography. However catheter angiography still plays a role in equivocal cases and in conjunction with treatment.
- Endoscopic retrograde cholangiopancreatography has evolved into a primarily therapeutic procedure that allows for removal of common bile duct stones, palliation of obstructive jaundice, and treatment of biliary injury.
- Endoscopic ultrasound provides high resolution imaging of the hepatobiliary system that is complementary to cross-sectional imaging techniques and allows for fine needle aspiration for tissue or fluid acquisition.

Noninvasive imaging

Magnetic resonance imaging (MRI), computed tomography (CT), and ultrasound each have strengths and weaknesses in imaging the liver. Considerations to keep in mind are availability, clinical questions, radiation, contrast allergies, and the patient's overall health. Fortunately, technologic advances have made all of these modalities more widely available and accurate, decreasing the need for more invasive testing.

Ultrasound

Ultrasound is widely available and often the first study performed. However, relative to CT or MRI it has lower sensitivity for the diagnosis of metastatic lesions or detection of hepatocellular carcinoma (HCC). This sensitivity decreases with hepatic parenchymal abnormalities, especially cirrhosis and steatosis.

Ultrasound Doppler imaging is a method of quantifying blood flow, including direction, as well as assessing patency of vessels (Fig. 4.1). It is a fast method for the evaluation of vasculature in the post-transplant patient and monitoring for change. Doppler data can be displayed in a number of different ways including color, spectral, and power. Spectral Doppler is a tracing of the wave from peak systolic velocity, and resistive indices can be calculated. Ultrasound machines with these capabilities are standard and it is important for the clinician to indicate what questions need to be answered so that the appropriate examination is performed.

There are no absolute contraindications to ultrasound; it is very safe and without radiation. While it is recommended that the patient fast for 4–6 hours prior to the examination to decrease bowel gas, the exam can be performed at any time, with the knowledge that the images may be suboptimal in a patient who has just eaten. Morbidly obese patients can be a challenge to evaluate with ultrasound given the increased echogenicity of subcutaneous fat. Additionally, it should always be kept in mind that cirrhosis and steatosis also make the detection of liver lesions more challenging, such that a negative study may

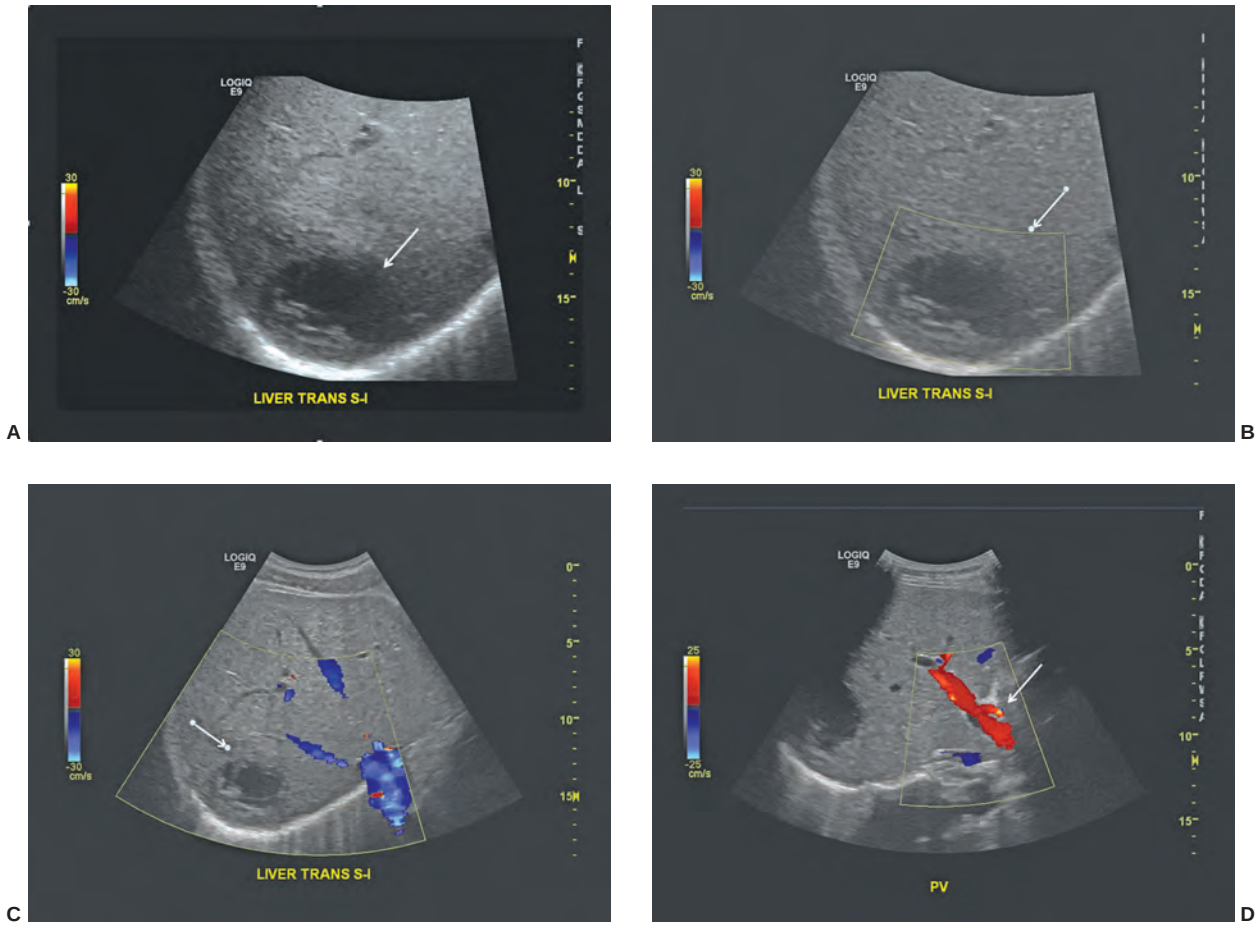

Figure 4.1 Ultrasound of the liver in a patient with hepatic abscess. (A) An irregular margined hypoechoic mass is indicated by the arrow. (B–D) Color Doppler shows no flow within the lesion (B), a patent hepatic vein (arrow) (C), and a patent portal vein (D).

still need to be followed with CT or MRI in a patient with high clinical concern of cancer.

Computed tomography

When CT was first introduced, images were obtained in a painstaking manner of one slice at a time and this is known as "conventional CT." Advances in technology have led to the ability to have the CT tube move in a continuous fashion to generate helical images. This is what is referred to as "multislice" or "helical CT." As a result, CT examinations can be performed rapidly to obtain images in multiple phases of contrast enhancement. Additionally, the acquired images are exceedingly thin (near isometric imaging) and can be manipulated to create sagittal, coronal, and 3D reconstructions (Fig. 4.2). This has become increasing important in evaluating potential living related liver donors, as accurate volumetric calculations can be made and the vasculature mapped.

Perhaps the greatest advance conferred by helical technology has been the ability to obtain post-contrast images in the arterial, portal-venous, and equilibrium (or parenchymal) phases. Hepatocellular carcinoma has an arterial blood supply such that intense enhancement occurs early. However, most metastatic lesions are seen in the later portal-venous or parenchymal phases. This multiphase imaging allows for both increased detection of lesions as well as characterization. The result is what is referred to as "temporal resolution."

It should be noted that while the CT examination only takes a few minutes (approximately 5 minutes with contrast injection), the patient's actual visit to the department will be much longer. Most centers advocate oral contrast to opacify the bowel. Patients are usually asked to ingest approximately 2 L of a barium or iodinated liquid suspension and the contrast is given 90–120 minutes prior to scanning to opacify the bowel. Patients should also be aware that an intravenous cannula will also be placed so that IV contrast can be given.

Relative contraindications include pregnancy, allergy to iodinated contrast, renal failure, or elevated creatinine, and patients with end-stage cirrhosis who are at risk

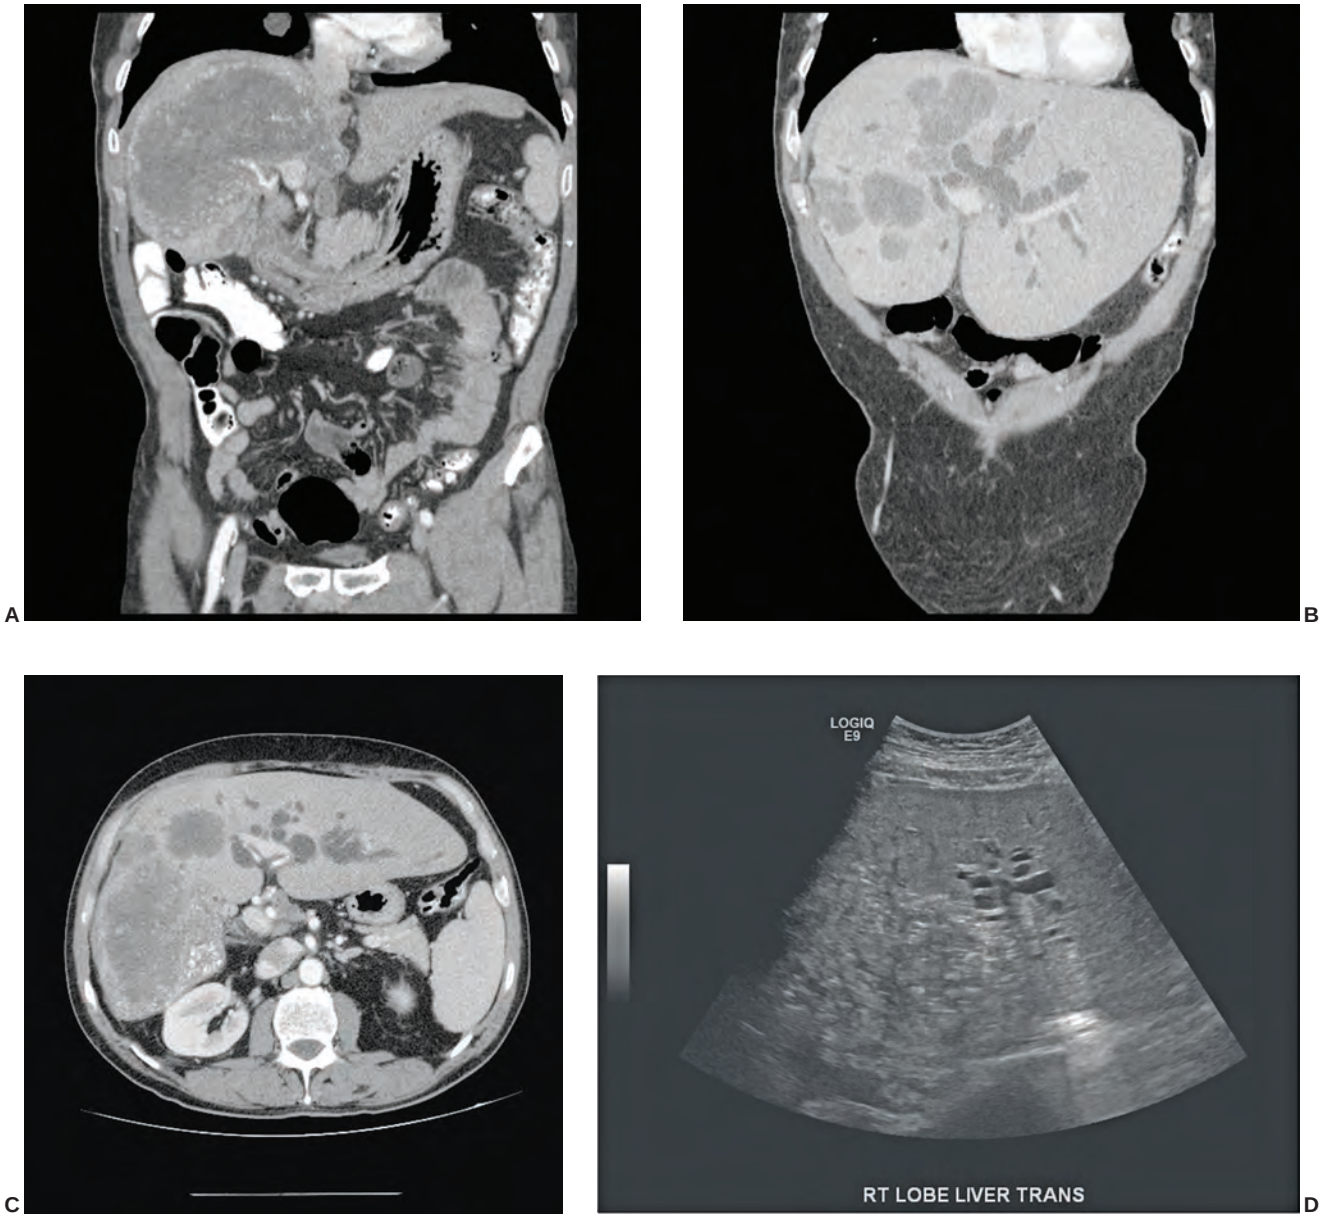

Figure 4.2 (A) Coronal contrast-enhanced CT image (reformatted from original axial images) showing a large partially calcified mass in the liver. Mucinous metastatic disease (from colon cancer) can contain dystrophic calcifications. (B) Coronal CT image from the same patient showing that not all of the metastatic lesions contain calcification, but that these are compressing and obstructing the intrahepatic biliary ducts. (C) Axial CT image showing all three findings: partially calcified mass, hypodense metastatic colonic carcinoma metastatic deposits, and secondary biliary dilatation. (D) Axial ultrasound image obtained as part of an evaluation for percutaneous biopsy and decompression of biliary obstruction.

for hepatorenal syndrome. A recent creatinine should be available prior to the patient receiving contrast.

Radiation and nephrotoxicity

Radiation from medical imaging has rightly become a major concern of patients, fueled in part by media coverage. While children and young women were initially the populations most thought to be potentially affected, with patients receiving multiple exams and living longer, radiation exposure is a concern for all patients and should be kept to the minimum possible [1,2].

The millisievert (mSv) is the unit for assessing the risk of cancer from an exam, known as the effective dose. Table 4.1 lists some common radiology examinations and their associated effective doses. As dose can be altered by the CT scanner used and the settings, it should be noted that the relative dose between imaging modalities is most important. While radiology departments should

Table 4.1 Radiation doses to organs from common radiologic procedures.

Procedure	Approximate order of increasing dose
Dental X-ray (brain)	1×
Chest X-ray (one view) (chest)	10×
Mammography (breasts)	300×
Abdomen CT in adult (stomach/gastrointestinal)	1,000×
Abdomen CT in infant	2,000×

CT, computed tomography.

have up-to-date policies ensuring a safe examination in terms of radiation dose, the radiologist is usually not familiar with the patient and may not know how many exams they have already had. Therefore, it is important for the patient's physician to be cognizant of the risk of radiation and weigh the risks and benefits of the procedure.

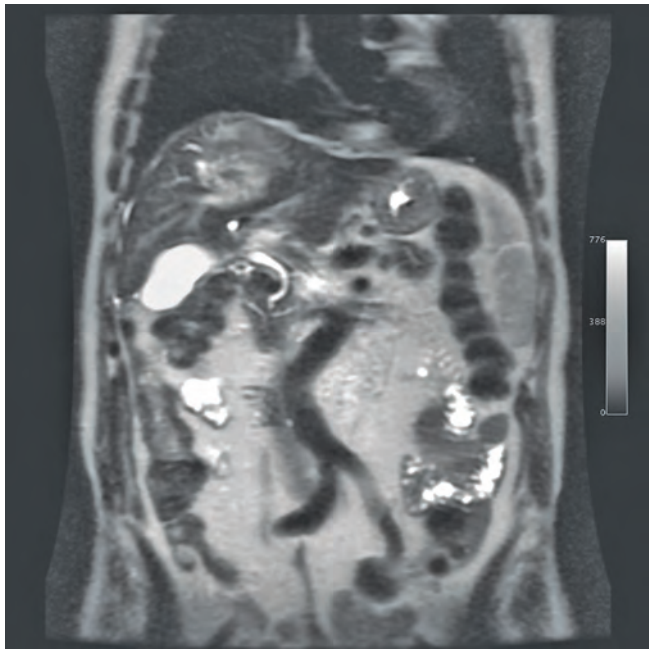
The newer iodinated contrast agents have osmolarity similar to that of blood. Early contrast agents were hyperosmolar but with the new near-osotonic agents decreased nephrotoxicity has been observed [3]. In patients with borderline renal function or in patients with renal insufficiency where the benefit of the exam outweighs the potential risk of contrast-induced nephropathy, *N*-acetylcysteine should be considered [4]. While some recent studies have questioned the utility of *N*-acetylcysteine in reducing contrast-induced nephropathy, it is safe and inexpensive and has not been shown to be of any harm to the patient [5].

Positron emission tomography

Positron emission tomography (PET) uses positron emitters attached to a molecule, such as glucose, to obtain a functional image. There are many positron emitters; however most are of limited clinical use because of their short half-life. Fluorodeoxyglucose (FDG) has a half-life of 110 minutes, which in practice is enough time for the pharmaceutical to be made and delivered. FDG is taken up by tissues with glucose metabolism. This glucose metabolism is generally high in cancers making them "FDG avid." However, other pathologies such as infection or inflammation will also have increased FDG uptake, which can cause diagnostic confusion [6].

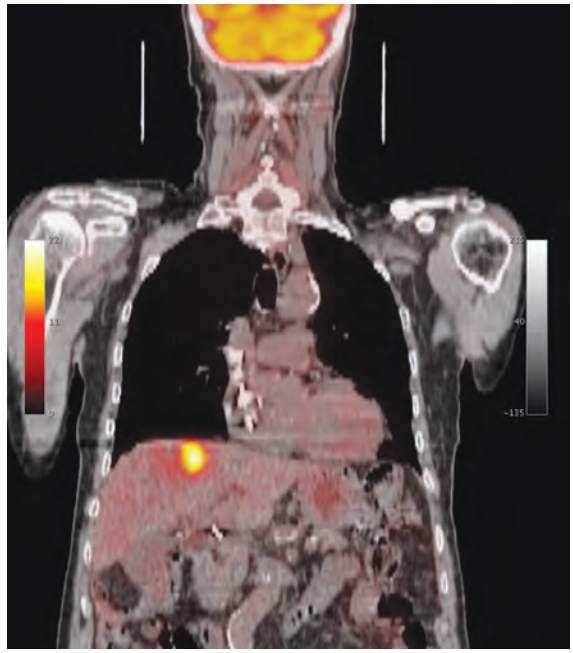
While PET alone can be used, it is more usual to use a PET-CT procedure, fusing a CT examination with overlaid PET images (Fig. 4.3). This improves anatomic localization of lesions and therefore accuracy of diagnosis. Additionally, it means that patients can obtain both studies during the same visit to the radiology department. In actuality the studies are performed separately, but with the patient on the same exam table.

PET-CT is particularly useful in metastatic hepatic lesions. Patients thought to have a solitary hepatic lesion are often found to have multiple lesions on PET [7]. Thus PET often changes the stage and management of patients. Currently in the United States, Medicare pays for PET in the staging of lung, lymphoma, and melanoma; the evaluation of recurrence in melanoma and colorectal cancers; and the initial evaluation of a solitary pulmonary nodule. It is hoped that this list will expand in the future as evidence supports this modality's wider utility.



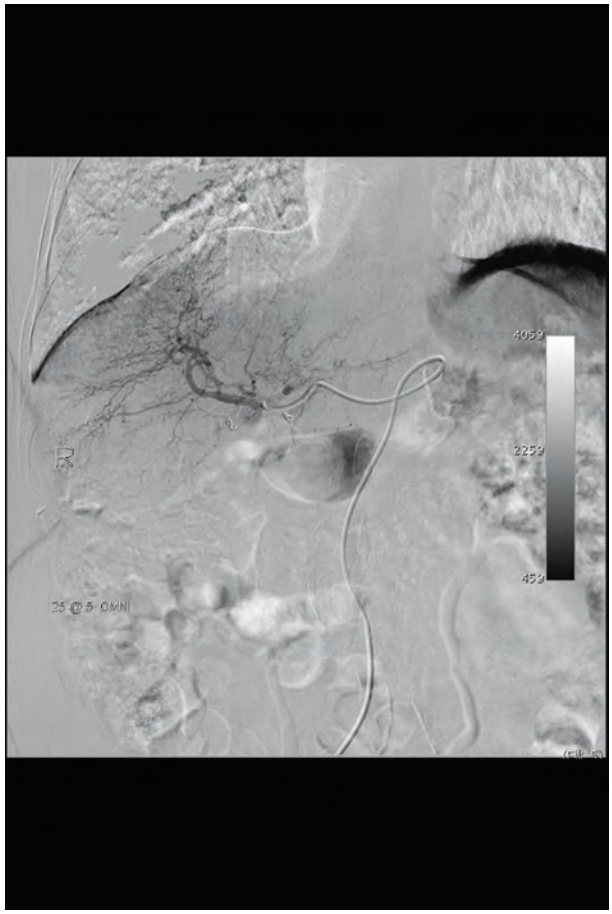
PET has been an immensely powerful tool in the diagnosis and treatment of certain tumors, such as lung and breast. Based on these experiences, it has been hoped that it would be as helpful in other cancers that are notoriously more difficult to detect and stage. Cholangiocarcinoma is one such neoplasm, which is often diagnosed after the window of opportunity for potential surgical resection. The literature has been scarce, presumably in part due to the relatively small number of cases, but a recent study indicated that PET is no better than CT alone for the detection of the primary cholangiocarcinoma [8]. This is disappointing as it was hoped that PET-CT might serve a surveillance role in patients with primary sclerosing carcinoma. However PET does appear to be clinically useful in the staging of patients with cholangiocarcinoma, as PET can better identify the involvement of regional lymph nodes and distant metastases [9].

PET has a relatively low detection rate for hepatocellular carcinoma, and more recently it has been suggested that it has limited utility in the post-transplant patient for recurrence surveillance [10,11]. Recent experience indicates that PET can be helpful in avoiding a clinically risky biopsy in cirrhotic patients with a known lesion. In this case, multiple lesions may be found and some may be more amenable to biopsy or the number of lesions may preclude treatment.



A PET-CT scan takes longer to perform than MRI, CT, or ultrasound, typically several hours. The patient will first have their blood sugar tested; elevated glucose in the blood competes with FDG and must be monitored. All patients should fast for 6 hours and diabetic patients should not take insulin prior to the exam. Patients should also refrain from exercising the day prior to the examination as the muscles will have greater than normal uptake.

Radiation dose



The increasing number of fused PET-CT scans performed, as opposed to PET alone, as well as the increasing utilization of PET, has raised concerns about its safety. The effective dose of PET-CT exceeds that of other clinically used imaging modalities [12].

A

B

C

Figure 4.3 (A) MRI of the liver of a patient with known colon cancer; the coronal T2 image shows a mass suspicious for metastatic disease. (B) The patient subsequently had PET-CT to assess for further disease and this fused image shows an area of glucose avidity consistent with metastatic disease in the liver. (C) The patient subsequently underwent catheter angiography for percutaneous embolotherapy.

Magnetic resonance imaging

Magnetic resonance imaging has been increasingly used in screening and follow-up in patients with metastatic hepatic lesions and HCC (Fig. 4.4). It is important to note that while image quality has improved with newer machines, it is essential that the imaging center's knowledge of scanning parameters is up to date as well. For instance, changes in time to echo (T_E), time to repetition (T_R), and number of excitations (N_{EX}) must be made if the MRI is 1.5T as opposed to 3.0T (strength of magnet) to maintain image quality and ensure patient safety [13]. The main advantages of MRI over CT and PET are the

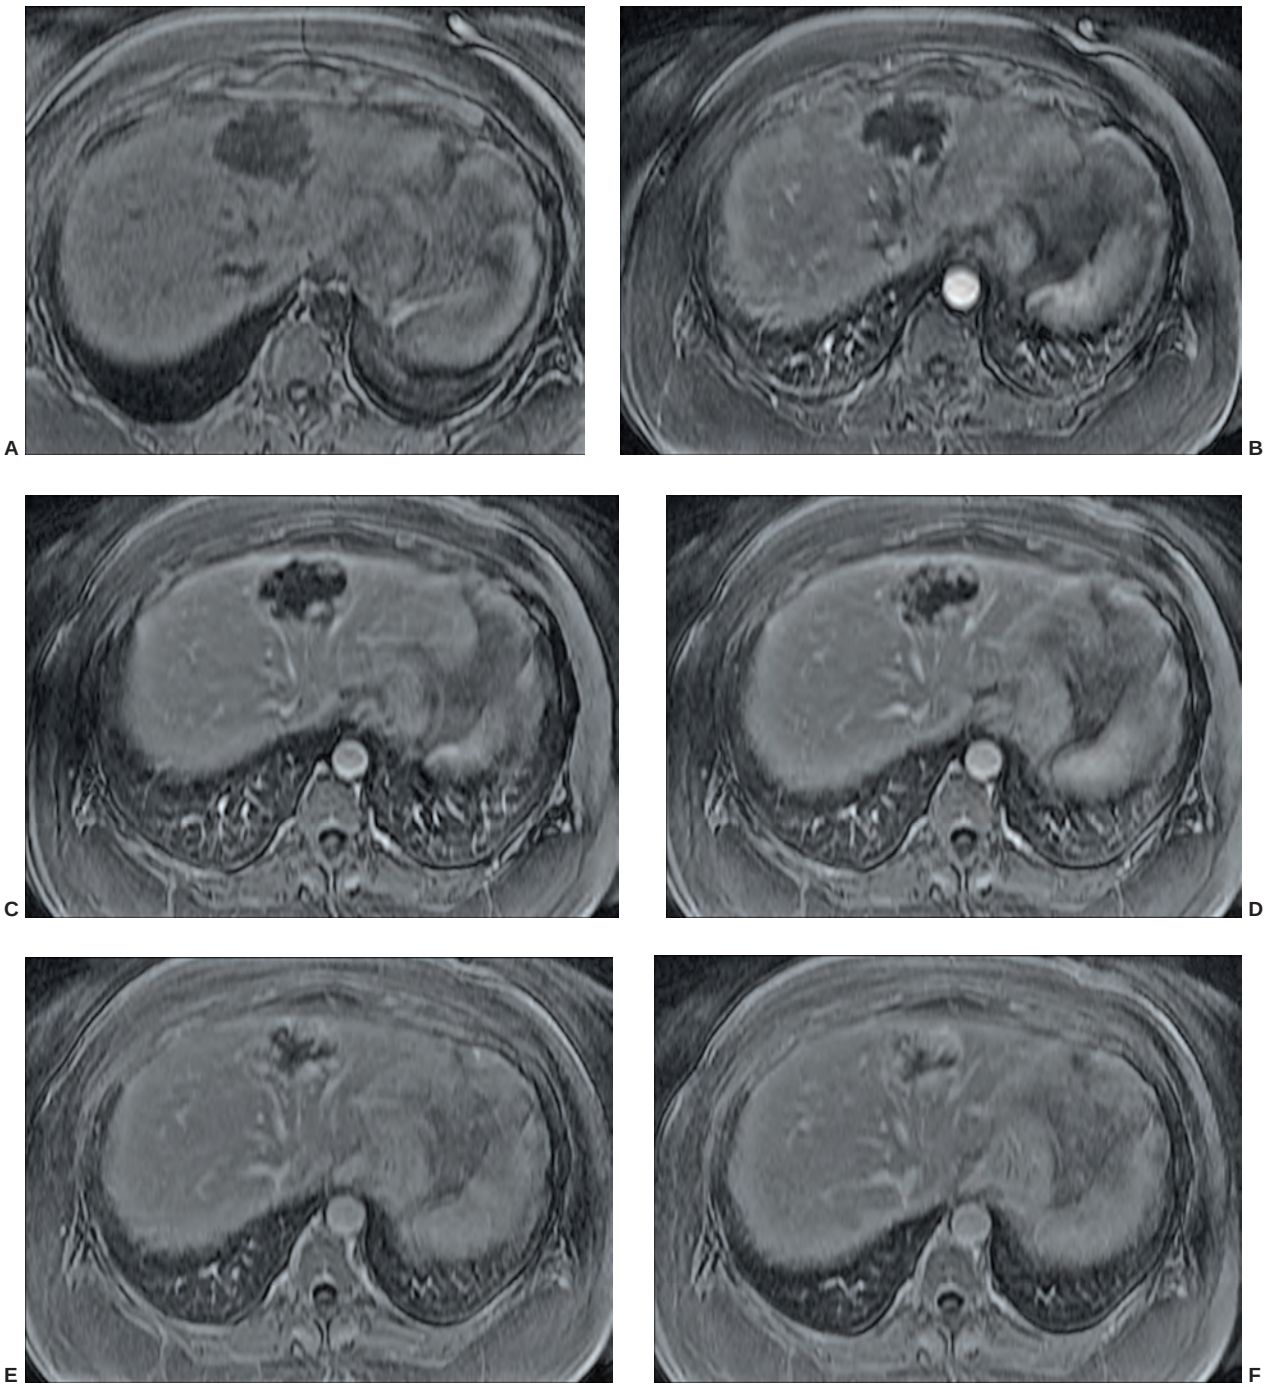


Figure 4.4 Dynamic contrast-enhanced MRI of the abdomen. A large lesion in the liver has a centripetal pattern of enhancement classic for hemangioma. Other lesions including neoplasms such as hepatocellular carcinoma and focal nodular hyperplasia have their own characteristic enhancement patterns. (A) Noncontrast; (B) early arterial phase; (C) late arterial phase; (D) portal-venous phase; (E) 90-second delay; (F) 5-minute delay.

lack of radiation and the use of relatively non-nephrotoxic contrast material (gadolinium). Compared to CT, MRI has higher contrast resolution, making lesions easier to identify, but lower spatial resolution, decreasing the conspicuousness of smaller lesions. Generally, contrast is administered during the MRI examination. The contrast agent is a form of gadolinium chelate that has a desirable safety profile when compared with iodinated contrast agents.

Contrast agents

The gadolinium-based agents can be classified into nonspecific gadolinium chelates, mixed vascular and hepatocellular-specific agents, and blood pool agents. Another group of contrast agents used in liver imaging are the superparamagnetic iron oxide particles, which are taken up by the reticuloendothelial system. For a number of reasons, including a slow infusion rate, they are not routinely used in clinical imaging.

Nonspecific gadolinium chelates are routinely used in all MRI examinations. After injection, the gadolinium distributes into the intravascular component and eventually reaches an equilibrium state between the vessels and extracellular space. As a result, tumor vascularity can be assessed. Lesions with increased vascularity appear "white" on T1-weighted images.

The perfusion/hepatocellular agents approved for use in the United States by the Food and Drug Administration (FDA) include gadobenate dimeglumine (MultiHance®, Bracco Diagnostics, Princeton, NJ) and gadoxetate disodium (Eovist®, Schering, Berlin). After distributing in the vascular interstitial compartment they are taken up by hepatocytes and excreted into the biliary system. Eovist has greater biliary excretion and is a more stable compound, however it is also more expensive, thus limiting its use [14]. In our practice, we routinely administer gadoxetate disodium during MRI examinations performed for the purpose of HCC screening. Since gadoxetate disodium is taken up by normal hepatocytes and excreted into the biliary system, it is useful in the detection of focal nodular hyperplasia (FNH) and its differentiation from hepatocellular adenoma [15]. Hepatocellular adenoma and FNH both enhance during the arterial phase of contrast-enhanced imaging. However, on delayed imaging, usually performed 20 minutes after the administration of gadoxetate disodium intravenously, the FNH will show greater enhancement than the surrounding normal hepatic parenchyma whereas the adenoma will show "wash out" or decreased relative enhancement [16]. This is because hepatic adenomas do not contain normal functional bile canaliculi, while FNH has bile ducts that may have decreased flow.

Gadofosveset trisodium (Ablavar®, Lantheus Medical Imaging, North Billerica, MA) has recently been approved by the FDA for magnetic resonance angiography as a blood pool agent. The role of Ablavar in the imaging of hepatic neoplasm has yet to be determined, so for now more conventional gadolinium preparations should be used. However, it is particularly useful in patients for whom the patency of the portal vein is in doubt after performing other imaging techniques such as ultrasound (Fig. 4.5).

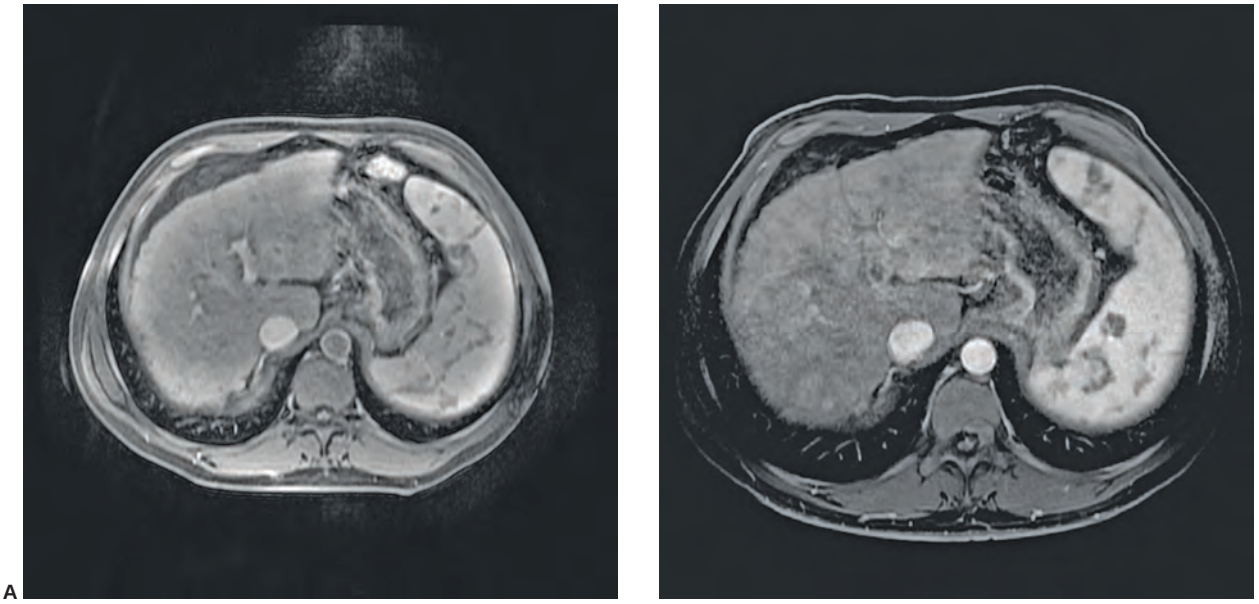

Figure 4.5 (A) MRI of the liver in a patient with a normal contrast-enhanced left portal vein. (B) Axial MRI with contrast showing tumor thrombus invading the main and right portal vein.

Recently, gadolinium chelates have been linked to nephrogenic sclerosing fibrosis when patients with impaired renal function are given high doses of gadolinium. The exact relationship of gadolinium to the development of nephrogenic sclerosing fibrosis is unclear, but caution should be used in this subset of patients [17,18]. Glomerular filtration rate (GFR) is routinely used to determine which, if any, gadolinium should be administered. For patients with a GFR greater than 60 mg/dL we simply adhere to the dosage allowed by the FDA and printed on the package insert. If the GFR is between 30 and 60 mg/dL we use the gadolinium preparation that has been shown to have the greatest stability, gadobenate dimeglumine [19]. In patients with a GFR of less than 30 mg/dL we do not administer gadolinium unless the benefits outweigh the risks. In all cases, a radiologist reviews the indications for MRI contrast before the examination is performed.

Summary of noninvasive techniques

Computed tomography and MRI are increasingly being used in evaluating patients with suspected or known liver neoplasms over ultrasound. The lack of radiation makes MRI more attractive, particularly in young patients. However, the speed of image acquisition in CT is particularly helpful in older patients or those for whom breath-holding and lying still are difficult or impossible. While CT generally requires approximately 5 minutes lying on a table, MRI takes about 15–20 minutes. The lower nephrotoxicity of gadolinium is also an advantage of an MRI examination over CT. In the selection of MRI scanners, it should be noted that so-called "open" scanners generate lower quality images as compared with the more widespread "closed bore" ones. Many manufactures now offer a compromise with a larger bore magnet, often marketed as large or wide bore. A knowledge of common contraindications to MRI is most important. It is widely appreciated that small internal ferromagnetic objects, such as pacemakers and aneurysm clips, are contraindicated in MRI. If there is any doubt, the wisest approach is to use a reference such as the free online resource mrisafety.com or to reference the manufacturer's web site. Any patient with internal foreign bodies should be brought to the attention of the radiologist prior to scheduling so that the appropriate assessment is done before the patient arrives at the MRI facility.

Noninvasive imaging: selected topics

Nonalcoholic fatty liver disease

Nonalcoholic fatty liver disease (NAFLD) occurs in about 20% of people in the United States and is the most prevalent type of liver disease (Fig. 4.6) [20]. Current evidence supports the concept that NAFLD can progress to progressive hepatic fibrosis with attendant complications, including HCC [21]. Therefore, a distinction has been made between the more commonly occurring steatosis alone, which has a relatively benign prognosis, and nonalcoholic steatohepatitis (NASH), which has greater potential for progressive fibrosis [22]. The challenge then is distinguishing between steatosis and steatohepatitis in the evaluation of patients with NAFLD.

Ultrasound is sensitive for the detection of parenchymal distortion resulting from steatosis and fibrosis. In patients with moderate to severe steatosis, one study showed ultrasound to be 100% sensitive but the positive predictive value was only 62% [23]. However, the

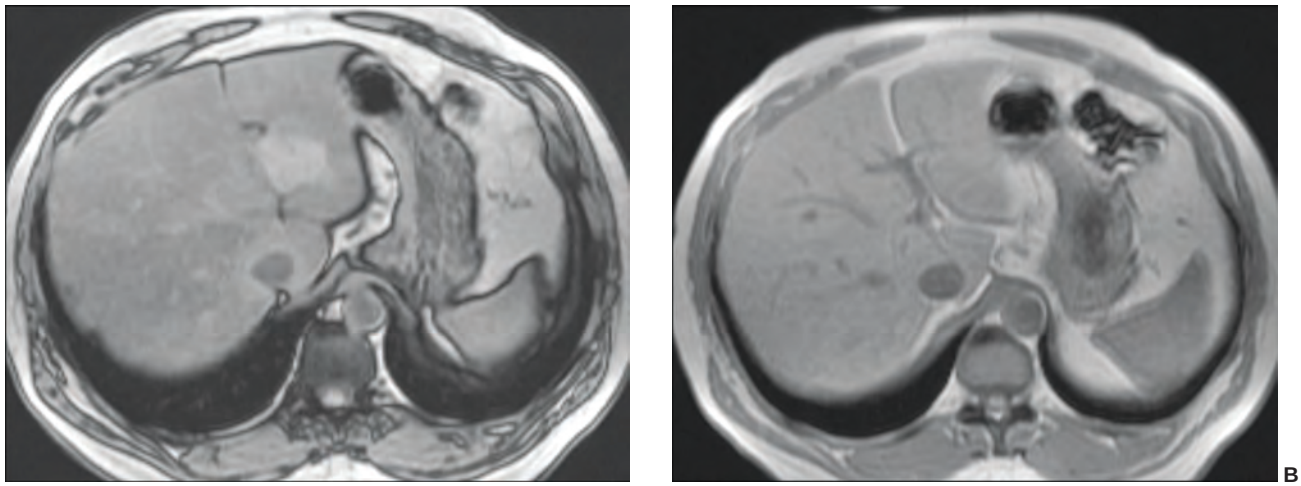

Figure 4.6 A common MRI technique to detect liver steatosis is to use in-phase and opposed-phase T1 gradient echo imaging. (A, B) Axial noncontrast images obtained at different times after the initial pulse. The image in (A) was obtained 2.1 ms earlier than the image in (B), and microscopic fat is demonstrated by loss of signal (darker) on image (A) as compared with (B).

increased echogenicity found in these and other disorders is nonspecific, limiting the accurate diagnosis of steatosis. It is widely accepted that if CT is used for the detection of steatosis, noncontrast images should be used as contrast increases the density measurements of the liver. Furthermore, the spleen is used for an internal reference and is a relatively vascular organ. MRI is the modality of choice given its sensitivity and lack of radiation. Additionally, MRI can quantify fatty deposition, which is particularly helpful in longitudinally evaluating patients during treatment [24,25]. Magnetic resonance spectroscopy is a more elegant technique for serial evaluation of steatosis, but is not as widely available or performed.

Therefore, in the absence of contraindications or expense considerations, MRI should be the initial imaging of a patient with suspected NASH. Unfortunately, distinguishing between NASH and NAFLD is more difficult. A prudent start begins with a history to discover any predisposing patient conditions, such as obesity or alcoholism. If the qualitative or quantitative MRI markers for steatosis do not normalize after change in lifestyle or diet or if there are no known risk factors, a biopsy may be warranted if physical exam and laboratory values do not reveal any clues to the etiology.

In practice, the simplest and most cost-effective imaging study to screen for steatosis is ultrasound. In a patient with steatosis and suspected liver neoplasm, MRI, given its greater lesion sensitivity and lack of radiation, should be considered [26].

Hepatic iron deposition

For many years, liver biopsy was the only way to assess hepatic iron status in patients with primary and secondary hemochromatosis. Routine CT and ultrasound are, in routine practice, ineffective in these patients. Furthermore, superconducting quantum interference device (SQUID) biomagnetic liver susceptometry testing is cumbersome and not widely available [27]. While the technique of quantifying iron using MRI is not new, there has been a recent increase in simple to use software packages and services, including those supplied by the MRI manufacturers themselves. Most importantly, the MRI methods have been validated by comparing them with liver iron concentration obtained by biopsy, the gold standard (Fig. 4.7) [28,29]. One company, Resonance Health, has marketed a product that will do everything but scan the patient and is FDA approved (Ferriscan®, Resonance Health, Claremont, Australia).

An added benefit of using MRI for liver iron concentration measurements is the ability to also quantify myocardial iron during the same MRI examination. In practice, screening for elevated iron deposition, as well as monitoring during chelation therapy, are routinely performed with MRI. Such a study does not require intravenous contrast and can be performed in less than 10 minutes, although a full liver MRI may be indicated to assess for other liver pathology.

Noninvasive hepatic vascular imaging

Ultrasonography is an excellent tool for the evaluation of hepatic vasculature. Routinely, hepatic imaging includes interrogation of the hepatic veins and portal vein, including velocity and direction of flow. This is particularly useful in evaluation for a transjugular intrahepatic portosystemic shunt (TIPS) procedure in cirrhotic patients. Prior to undergoing a TIPS procedure, a patient should undergo ultrasound with Doppler to assess the patency of the portal vein and hepatic artery. This exam is also

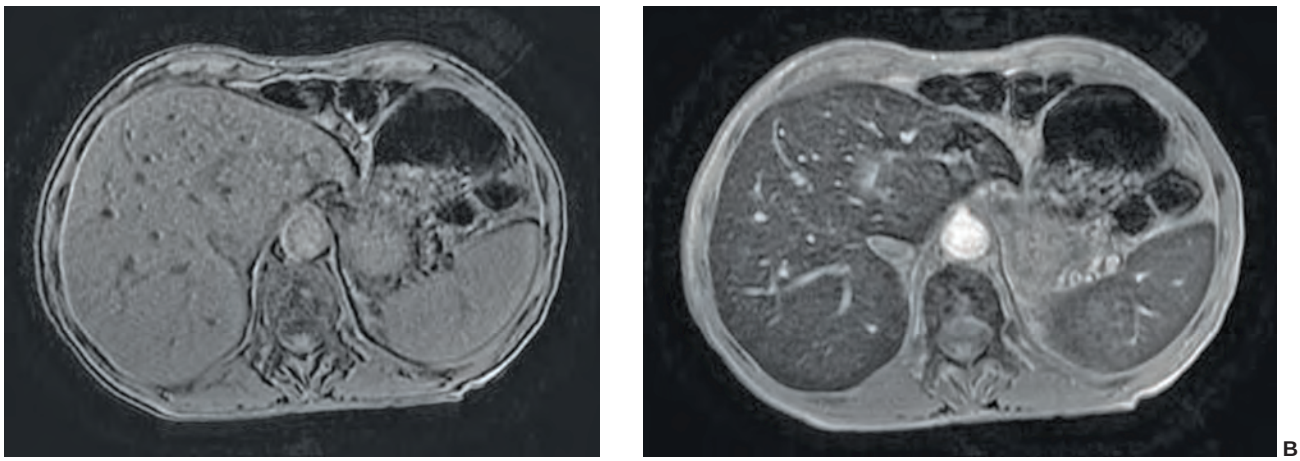

Figure 4.7 (A, B) Axial noncontrast MRI through the liver. A relatively simple MRI technique for quantifying iron in the liver utilizes the fact that the iron particles cause the signal in the liver to decrease the longer you wait to obtain the image. Image (A) was obtained milliseconds before (B), yet note how the liver signal (brightness) decreases from (A) to (B).

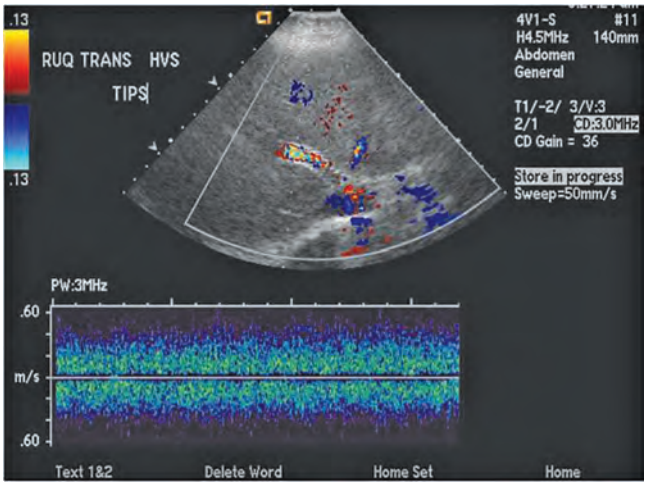

Figure 4.8 Axial ultrasound with spectral/color Doppler showing a patent TIPS.

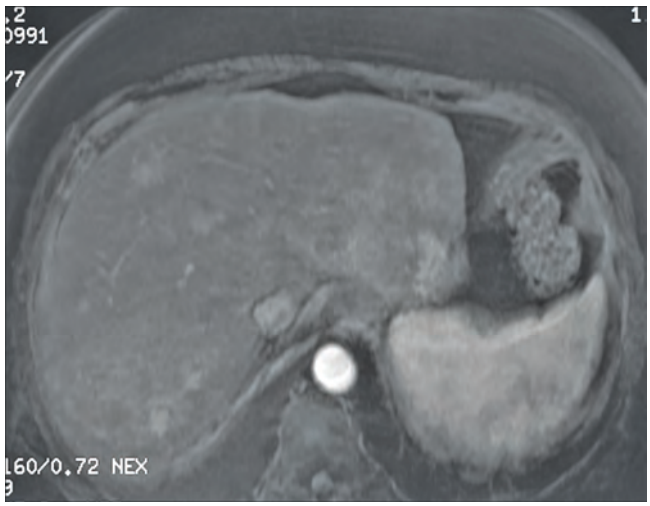

Figure 4.9 Axial post-contrast image through the liver during a late arterial phase (about 20 seconds after giving contrast) showing a transient hepatic enhancement difference. Patches of enhancement on this axial MRI image are the result of arteriovenous shunting.

useful in examining the hepatic veins and documenting any anatomic variants. Following a TIPS procedure, ultrasound is routinely used to assess the patency and flow within the graft. A Doppler technique can be used to document the velocity as well as direction of flow in the TIPS graft.

The metallic stents commonly used in TIPS cause artifacts on all imaging modalities, but ultrasound's ability to directly evaluate the blood flow is a distinct advantage (Fig. 4.8). A newer, expandable polytetrafluoroethylene-covered stent graft (Viatorr®, Gore, Flagstaff, AZ) has shown decreased artifact and, in a recent trial, good outcomes when evaluated with CT [30].

The increasingly rapid image acquisition of new CT and MRI machines has resulted in an increased number of visualized cases of so-called "transient hepatic enhancement difference". These are almost clinically insignificant areas in the liver where there is arteriovenous shunting and are usually only seen on arterial phase imaging. However, on CT or MRI after contrast, they appear as hypervascular regions in the liver, sometimes wedge-shaped and often peripheral and commonly mistaken for neoplasm (Fig. 4.9) [31]. Arteriovenous shunts can be seen in conjunction with neoplasm; however, in this case an actual mass is identified separate from the flow phenomena. The difficulty arises in patients who have undergone single-phase contrast-enhanced CT and MRI with an area of shunting detected. In those cases a repeat exam with multiphase image acquisition after contrast should clarify the issue. Diffusion-weighted imaging has also been used to distinguish benign or nontumorous shunting from more malignant causes.

In the evaluation of patency of the hepatic veins and portal vein, CT and MRI are superb. However, in rare cases these studies can be inconclusive. In our own experience, this occurs where there is documented portal vein thrombosis with recanalization in the past and current exams show possible revascularization of the portal vein. In these cases, we have found high resolution MRI after the administration of a blood pool gadolinium agent such as Ablavar to provide the information required. In any case of venous thrombosis, one should carefully inspect the arterial phase to assess for arterial enhancement within the vein that would indicate malignant thrombus (the neoplasm thrombus enhances earlier than a normal portal vein would expect to).

Screening for hepatocellular carcinoma

Screening for HCC commonly employs ultrasound, CT, and/or MRI, depending on the center. In Asia, in particular, there has been more interest and experience with using ultrasound. A recent review article details some of the newest ultrasound techniques, such as elastography, in the evaluation of patients with risk factors for development of HCC [32]. Despite higher financial costs, in the United States more attention has been focused on CT and MRI and faster image acquisition, and the development of novel contrast agents (particularly in MRI) have added to their appeal [33,34]. However, many physicians prefer to screen with ultrasound and then if there are abnormal findings obtain follow-up imaging with either CT or MRI.

A recently published study comparing the sensitivity of contrast-enhanced CT and MRI in detecting HCC lesions <1 cm found the sensitivity of CT to be 56–62% and the sensitivity of MRI to be 62–75% [35]. The sensitivity of ultrasound for the detection of small lesions

(<2 cm) has previously been shown to be lower than CT or MRI but a new study comparing contrast-enhanced ultrasound with MRI and CT found a 59% sensitivity for CT, 69% for contrast-enhanced ultrasound, and 76% for MRI [36]. Targeted ultrasound after positive CT or MRI showed that ultrasound without contrast had a detection rate of 36.4% for HCC lesions ≤1.0 cm, 77.6% for lesions between 1.1 and 2.0 cm, and 93.9% for lesions between 2.1 and 3.0 cm [37]. Overall, the literature suggests that MRI is most sensitive for the detection of small HCCs, with CT having slightly lower sensitivity. Ultrasound is most useful as an initial screening tool, however small lesions will be missed more commonly than if CT or MRI are utilized. Contrast-enhanced ultrasound shows promising initial results, however it is not widely used, particularly in the United States.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a challenging disease to diagnose and follow with imaging (Fig. 4.10) [38,39]. Magnetic resonance cholangiopancreatography (MRCP) techniques continue to improve. In fact, respiratory-gated volumetric techniques have resulted in 3D images of the intrahepatic and extrahepatic biliary system that rival traditional cholangiograms. In practice, endoscopic retrograde cholangiopancreatography (ERCP) and MRCP complement each other, with the former being more dynamic and user dependent and the later allowing for post-processing and reconstructions on a workstation [40].

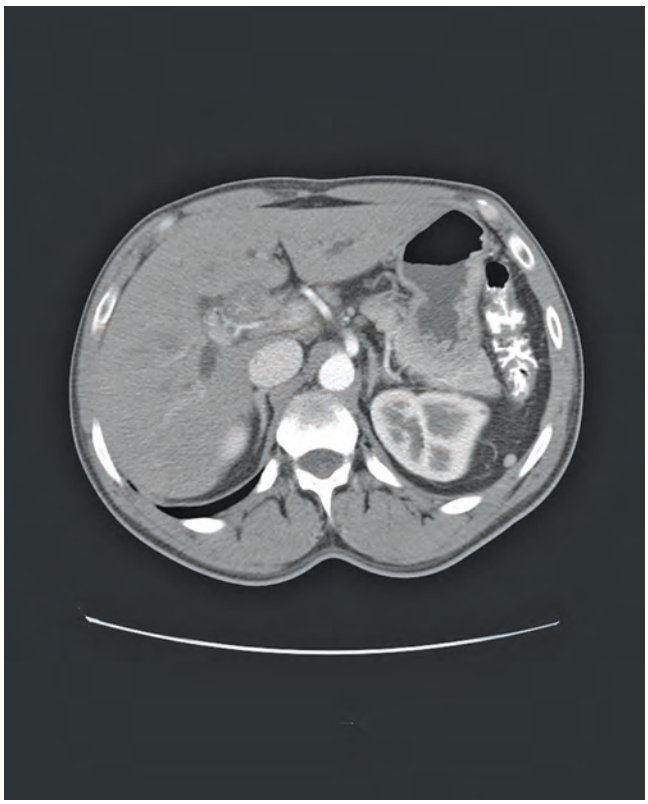

Figure 4.10 Cholangiocarcinoma complicating primary sclerosing cholangitis. Axial CT image through the liver showing dilated intrahepatic biliary ducts and a Klatskin tumor (dark nonenhancing region in the portohepatitis; the cholangiocarcinomas tend to mostly enhance late – minutes as opposed to seconds).

An advantage of MRCP is the ability to perform a complete dynamic contrast-enhanced liver MRI scan at the same time with little increase in duration of the procedure. Studies utilizing newer hepatocyte-specific gadolinium agents such as gadoxetate disodium are needed as these agents can be used to generate both post-contrast MRCP images as well to potentially improve neoplasm detection rates. Unfortunately, screening for cholangiocarcinoma remains disappointing and lesions detected may not alter ultimate prognosis [41]. ERCP, and its utility in patients with PSC, will be discussed more fully in a separate section.

Choledocholithiasis

For patients with laboratory and clinical findings suggesting choledocholithiasis or cholecystitis, ultrasound is rightfully the first study of choice. Ultrasound can readily detect gallbladder wall thickening and adjacent fluid collections suggesting inflammation from obstructed bilious contents. Calculi in the gallbladder and cystic duct are easily detected, however calculi in the common bile duct are often obscured by adjacent bowel gas. When choledocholithiasis is suspected, either a nuclear medicine biliary scintigraphy scan or MRCP may be helpful, The former provides physiologic information, including possible cholestasis and obstruction. Unfortunately, information such as the number and size of obstructing stones or strictures are not available. MRCP conversely provides direct visualization of calculi along with the number of stones and their position. This information is very helpful to the endoscopist or surgeon.

MRCP uses the same MRI equipment as a routine liver MRI scan. The magnetic resonance sequences are merely tailored to better image the biliary ducts. Gadolinium contrast is not essential but some radiologists prefer to administer it routinely as part of a total abdominal MRI examination (Fig. 4.11).

CT is not a primary imaging tool for the diagnosis of cholecystitis or choledocholithiasis in our practice. However, CT has become the initial study for many patients arriving in the emergency department with abdominal pain and many hospitals do not have 24/7 access to nuclear medicine or MRI equipment. Fortunately, most calculi are visualized on CT and secondary signs and complications (e.g., abscess, gangrenous gallbladder) are readily detected.

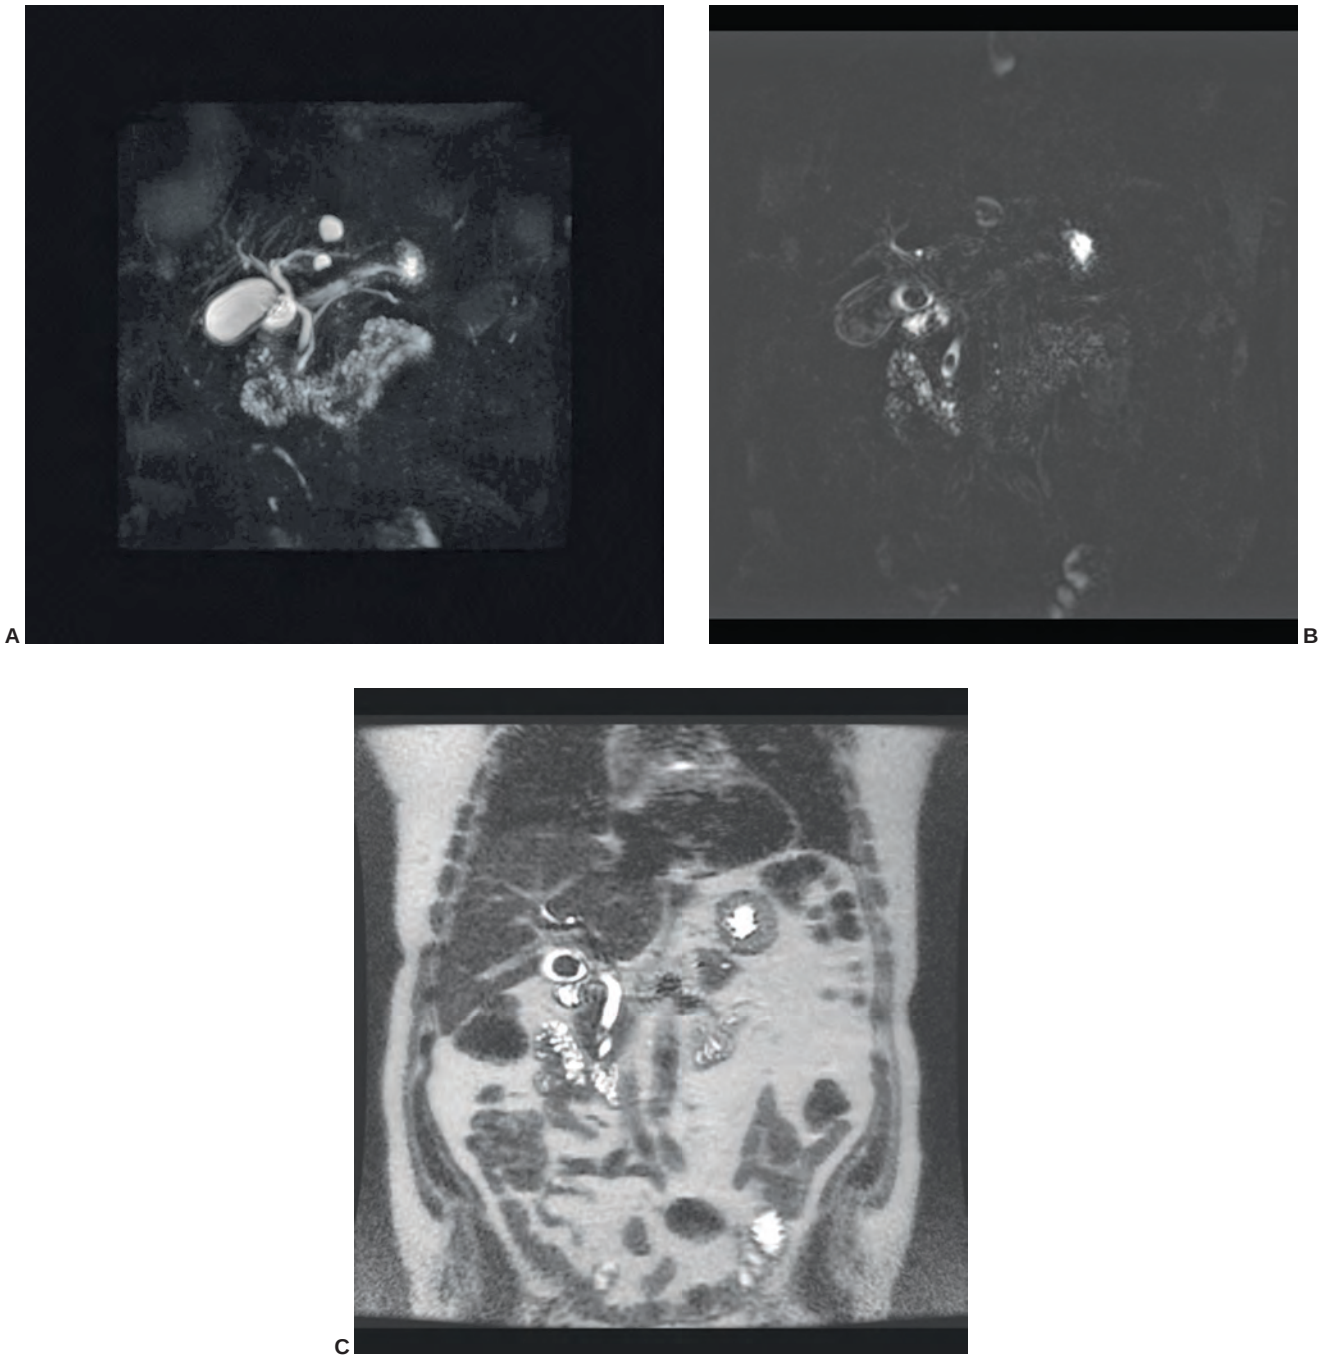

Figure 4.11 Choledocholithiasis. (A) The calculi in the gallbladder neck and common bile duct are difficult to see on this 3D reconstruction. (B) However, when only a portion of the 3D volume set is reviewed, the calculi are easily visualized. (C) A single coronal T2-weighted image also clearly shows the gallbladder neck and distal common bile duct stones.

Invasive imaging of liver and biliary disease

Noninvasive and minimally invasive imaging and procedures have undergone technologic advances in the past few years with noninvasive CT angiography (CTA) and magnetic resonance angiography (MRA) assuming larger roles in diagnosis, and catheter and percutaneous tools pushing the envelope of treatment.

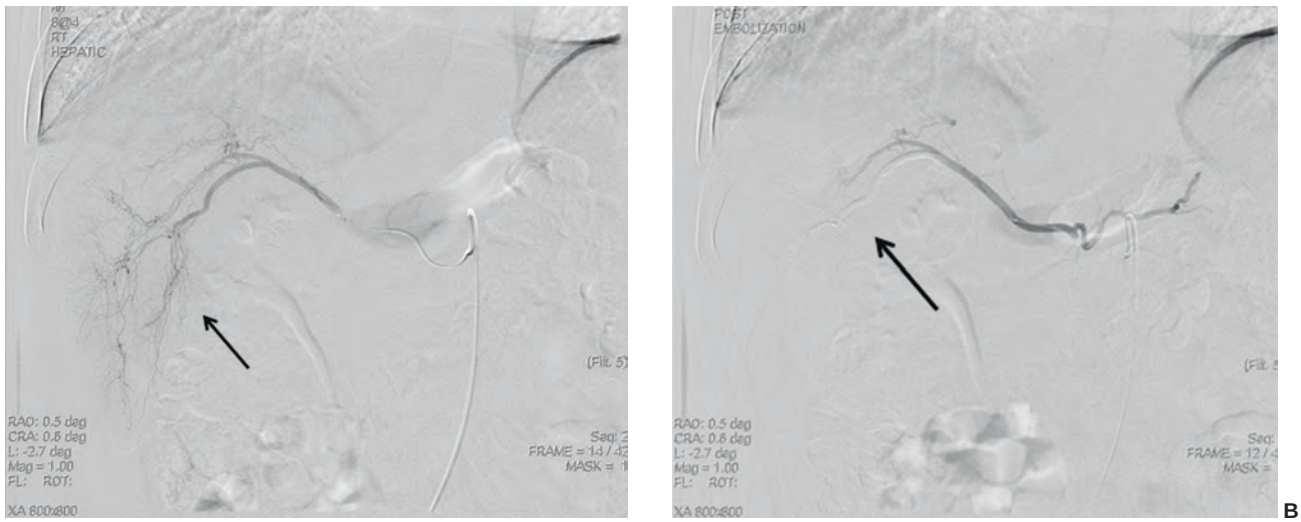
Many percutaneous interventional procedures have been developed to ablate hepatic malignancies, including hepatocellular carcinoma. While selective internal radiation therapy (SIRT) continues to develop, transarterial

chemoembolization (TACE) percutaneous ablative tools are more firmly established and are routinely used in radiology departments [42,43]. Recent experience with TACE suggests that it is not only helpful as a bridge until hepatic transplant can be performed but also as a course of treatment for those in whom surgery or transplant is contraindicated [44].

Angiography

Perhaps one of the largest changes in interventional radiology over the past decade has been the continued refinement of MRA, CTA, and Doppler ultrasound allowing high resolution imaging to replace catheter-based angiography. Aside from being noninvasive, these technologies are generally cheaper and also provide information outside the vessels. They can be performed as part of or concurrent with CT or MRI that is already being performed.

Hepatic arteriography



Hepatic arteriography continues to play a role in the state-of-the-art management of our patients with hepatic diseases. Catheter sizes continue to become smaller and more agile allowing the interventionist the ability to selectively inject very small vessels. In turn, this allows the rapid acquisition of images once contrast is administered such that a small area of the liver is evaluated. This is particularly helpful in cases where a MRA or CTA study is inconclusive. Further, if a suspected neoplasm is found it can be treated at the same sitting with catheter-guided embolotherapy (Fig. 4.12).

The contrast administered with catheter studies is the same used for CTA, thus care should be taken to minimize the contrast load if both procedures are done. In the past, patients with renal insufficiency who required catheter-based angiography may have received gadolinium chelate contrast as opposed to iodinated contrast to decrease the risk of contrast-induced nephropathy. However, given the association of nephrogenic systemic fibrosis (NSF) and large doses of gadolinium in the patient with renal insufficiency, this practice has become less common.

Portal and hepatic venography

There are several techniques the interventionist can use to opacify the portal vein (portography) including arteriographic portography, transvenous portography, transabdominal–transhepatic portography, and transabdominal–transplenic portography (Fig. 4.13). The latter two, as the names imply, require localization of the vein or spleen prior to the percutaneous introduction of a catheter. Thus they can be somewhat cumbersome. A catheter placed in the splenic artery via an initial femoral access is simpler – the contrast is injected and travels through the spleen into the splenic vein and then to the portal vein. There is very limited dilution of the contrast and excellent opacification of the portal vein is achieved through this indirect portography approach.

In practice, portography remains important as portal vein pressures can be obtained in the preoperative patient requiring either TIPS or surgical decompression. After TIPS, of course, the stent and portal vein can be easily catheterized via a transjugular approach. Prior to TIPS, portal pressure can be acquired by a transvenous approach. A catheter is introduced retrogradely into small splenic venous branches from an initial jugular approach. Wedge pressures are obtained after injection of carbon

(B) Post-TIPS portal venogram. A stent is identified traversing the right portal and hepatic veins. A repeat venogram demonstrates decreased collateral vasculature within the portal system.

dioxide. Contrast images of the portal vein can also be obtained by retrograde filling of small portal veins via their proximity to capillary veins. Improved techniques and operator experience have decreased complications, but systematic attention to detail and utmost care are essential to ensure patient safety [45].

Percutaneous transhepatic cholangiography

Similar to any percutaneous therapy, percutaneous transhepatic cholangiography (PTHC) is not without risks, including iatrogenic cholangitis, infection, and bleeding. Endoscopic methods of evaluating the bile ducts and, more recently, the continued improvement of MRCP techniques have led to a decrease in the number of PTHC procedures done. Most recently, certain gadolinium chelates such as gadobenate dimeglumine (MultiHance) and gadoxetate disodium (Eovist) have been developed and are partially excreted into the bile ducts. Delayed (20 minutes or later) T1 images produce contrast-enhanced bile ducts. However, this technique has not yet been proven to be superior to T2 MRCP sequences.

A patient who is to undergo PTHC should be properly prepped. This includes a thorough physical examination and history taking. In particular, signs of clotting disorder should be sought as well as uncovering any medications that may prolong the bleeding time. History of allergies should be also elicited and proper preprocedure antibiotic therapy should be administered to cover both Gram-positive and Gram-negative flora. Consultation with infectious disease professionals may be warranted for adequate prophylaxis.

Articles pictorializing the "characteristic" findings of benign versus malignant strictures and filling defects have been widely published. However, the accuracy of distinguishing these entities is far from satisfactory. Therefore, care should be taken to adequately scrutinize any pathology and make certain that air bubbles do not complicate the matter. In the presence of biliary obstruction, most radiologists choose to exchange the diagnostic catheter for a percutaneous drainage tube as there is often high pressure and inflammation as a result of the stasis. More definitive treatment can be attempted several days later, including internalization of the drain (Fig. 4.14).

Endoscopic imaging of the hepatobiliary system

Endoscopic imaging of the liver and biliary tree by ERCP and endoscopic ultrasound (EUS) complements the clinical information obtained by the radiologic modalities described above and allows for further evaluation and treatment of a variety of hepatobiliary abnormalities. Suspected choledocholithiasis can be confirmed or excluded by EUS and treated by ERCP with sphincterotomy. Biliary strictures seen on MRCP can be evaluated and sampled by ERCP with choledochoscopy to differentiate between

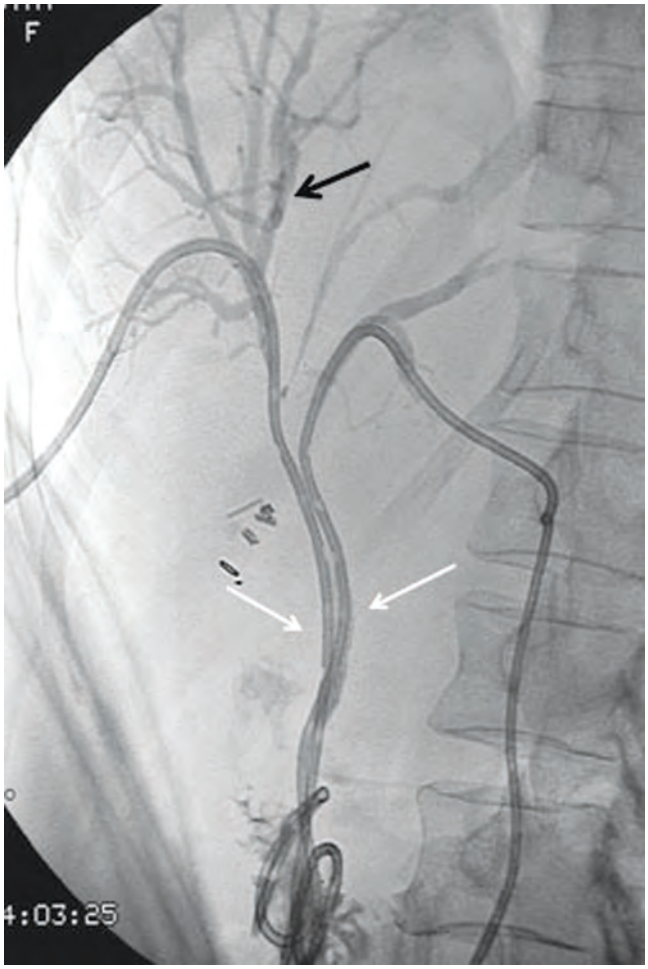

Figure 4.14 Patient with cholangiocarcinoma with intrahepatic biliary ductal dilatation (black arrow) who underwent percutaneous placement of biliary drains (left and right indicated by white arrows). The catheters drain both internally into the duodenum and externally.

benign and malignant processes, or further visualized by EUS and sampled by fine needle aspiration, depending upon the clinical situation. In this way, noninvasive radiologic imaging and minimally invasive endoscopic imaging can be used in conjunction to arrive at the final diagnosis and often provide the definitive therapy.

Endoscopic retrograde cholangiopancreatography

First described in 1968, ERCP provides minimally invasive access to the biliary tree and pancreatic duct to diagnose and treat a wide variety of pancreatobiliary diseases. The introduction of endoscopic sphincterotomy in 1974 allowed for the development of an increasing array of therapeutic modalities [46,47]. Technologic enhancements in MRI, particularly MRCP, have led to the evolution of ERCP from a diagnostic to a primarily therapeutic procedure. The following section will focus upon the use of ERCP in hepatobiliary disorders.

Hepatobiliary indications

Codified indications for ERCP have been set forth in a consensus statement by the National Institutes of Health (NIH) [48] and a practice guideline by the American Society of Gastrointestinal Endoscopy (ASGE) [49]. The primary indication for ERCP is the treatment of symptomatic biliary obstruction (Box 4.1). In patients who present with jaundice, the delineation between biliary obstruction and other forms of cholestasis is usually made based on clinical history and noninvasive imaging. When choledocholithiasis is found to be the likely cause of biliary obstruction, urgent ERCP for stone extraction is indicated (within 48 hours) when cholangitis or severe acute pancreatitis with persistent ampullary obstruction is present. ERCP is not indicated in mild or moderate acute gallstone pancreatitis without cholangitis [50,51].

In patients with biliary obstruction due to malignancy, ERCP is not required in all cases. Intractable pruritus, cholangitis, and cholestasis preventing the administration of chemotherapy are clear indications for biliary decompression by ERCP. Recent studies have demonstrated that routine ERCP for preoperative biliary decompression of malignant obstruction due to pancreatic cancer is not universally indicated as it is associated with increased morbidity [52,53]. In patients with malignant biliary obstruction who are deemed unresectable, endoscopic biliary decompression is safe and effective and results in less morbidity than palliative surgical by-pass [54]. Self-expanding metal stents are superior to plastic stents for this palliative application [55].

Endoscopic therapy is the preferred treatment modality for postoperative biliary leaks and strictures. The high volume of laparoscopic cholecystectomy and the increasing frequency of liver transplantation have been associated with an increased prevalence of these biliary disorders. Previously, altered surgical anatomy such as Roux-en-Y reconstruction, Whipple resection, and

Box 4.1 Indications for endoscopic retrograde cholangiopancreatography (ERCP).

- Obstructive jaundice
- Cholangitis
- Choledocholithiasis
- Severe acute gallstone pancreatitis with persistent ampullary obstruction
- Postoperative or traumatic biliary complications (i.e., leak, stricture)
- Evaluation of the sphincter of Oddi in patients with moderate to high suspicion of sphincter dysfunction

Billroth II anastomosis precluded or greatly hindered the ability to perform ERCP. With the advent of balloon enteroscopy, ERCP can be performed with a greater rate of success in patients with altered enteral anatomy [56].

Recurrent biliary pain or recurrent acute pancreatitis in the absence of gallstones or after cholecystectomy can be caused by sphincter of Oddi dysfunction (SOD). In patients with SOD who demonstrate elevated serum liver tests, a dilated common bile duct, and poor biliary drainage (type I SOD), endoscopic sphincterotomy is effective. In patients with one or two of these clinical findings (type II SOD), sphincter of Oddi manometry should be used to determine if basal sphincter pressures are elevated above 40 mmHg and only then should sphincterotomy be performed. Patients with SOD who do not demonstrate any of these objective findings (type III SOD) should be treated conservatively.

Complications

Endoscopic retrograde cholangiopancreatography carries a higher risk of complications than most other gastrointestinal endoscopic procedures. In 1991, a consensus conference was convened to establish a classification system of ERCP-related complications that would be used for future study (Table 4.2) [57].

In the largest single-center study to date [58], the outcomes of almost 11,500 ERCP procedures were analyzed for rate and predictors of complications. The overall complication rate was 4.0%, with severe complications in 0.36% of cases. Pancreatitis occurred in 2.6% of cases and bleeding in 0.3%. Independent predictors of complications by multivariate analysis included suspected SOD and biliary sphincterotomy. Independent predictors of post-ERCP pancreatitis included performance of a pancreatogram and suspected SOD. Severe complications were associated with co-morbid illness, obesity, choledocholithiasis, pancreatic manometry, and complex interventions. Placement of a prophylactic small diameter pancreatic stent and the presence of pancreatitis prior to the ERCP were each independent predictors of fewer overall complications. Perforation occurred in only 16 patients, too few to perform multivariate regression analysis.

Pancreatitis is the most common complication of ERCP. Patients present with epigastric pain radiating to the back and are found to have elevated serum pancreatic enzymes greater than three times the normal value. The rate of post-ERCP pancreatitis ranges from 1% to 7% in large studies. Elevation of serum amylase is common after ERCP and in the absence of concurrent abdominal pain is neither predictive nor diagnostic of post-ERCP pancreatitis [59]. In addition to the factors listed above, normal serum bilirubin, difficult or failed cannulation, history of post-ERCP pancreatitis, pre-cut sphincterotomy, pancreatic sphincterotomy, and younger age of patient have each been shown to be risk factors for post-ERCP pancreatitis in multivariate analysis [60].

A multitude of pharmacologic agents have been studied for the prevention of post-ERCP pancreatitis including corticosteroids, nonsteroidal anti-inflammatory drug (NSAID) suppositories, antisecretory agents such as octreotide and somatostatin, protease inhibitors such as gabexate and ulnistatin, and other medications with inconsistent results. Suppository NSAIDs such as diclofenac seem to have the most promise, including

Table 4.2 Grading system for the major complications of ERCP and endoscopic sphincterotomy.

Complication	Mild	Moderate	Severe
Pancreatitis	Amylase at least three times normal at more than 24 hours after the procedure, requiring admission or prolongation of planned admission to 2–3 days	Hospitalization of 4–10 days	Hospitalization of more than 10 days, hemorrhagic pancreatitis, phlegmon or pseudocyst, or intervention required (percutaneous drainage or surgery)
Bleeding	Clinical evidence of bleeding, hemoglobin drop <3 g, and no need for transfusion	Transfusion (4 units or less), no angiographic intervention or surgery	Transfusion (5 units or more), or intervention required (angiographic or surgical)
Cholangitis	>38°C for 24–48 hours	Febrile or septic illness requiring more than 3 days of hospital treatment or endoscopic or percutaneous intervention	Septic shock or surgery
Perforation	Possible, or only very slight leak, treatable by conservative management for 3 days or less	Any definite perforation treated medically for 4–10 days	Medical treatment for more than 10 days, or intervention required (percutaneous or surgical)

Adapted from Cotton et al. [57] with permission from Elsevier.

in meta-analysis [61], but its routine use has not been adopted to date. Placement of a prophylactic pancreatic duct stent during difficult procedures reduces the risk of pancreatitis and also reduces the risk of pancreatitis being severe should this complication occur. The optimal type of stent, and precise indications for use of this prophylactic measure, are yet to be determined [62].

Clinically significant post-sphincterotomy hemorrhage can occur in up to 2% of cases and can be seen as late as 10 days after the procedure. Thrombocytopenia, coagulopathy, and initiation of anticoagulants within 3 days of sphincterotomy are risk factors for post-sphincterotomy hemorrhage [63]. Aspirin and NSAIDs have not been shown to increase the risk of hemorrhage in this setting. There are insufficient published data to determine if antiplatelet agents such as clopidogrel increase this risk [64].

Perforation is rare during ERCP, reported in less than 1% of cases. Perforation can occur due to excess extension of a sphincterotomy, trauma from the endoscope, or migration of stents or guidewires. Bowel wall perforation is much more likely to occur in patients who have a history of biliary diversion surgery such as a Whipple resection [58]. Retroperitoneal perforation from sphincterotomy is the most common type of perforation resulting from ERCP, and can generally be managed conservatively with antibiotics and withholding oral feeding. However, surgery may be necessary for large perforations or for failure to improve after initial conservative management. Other infrequent complications of ERCP include cholecystitis, cholangitis, and papillary stenosis

Technique

Selective cannulation of the biliary tree requires high-volume training in order to opitimize the success rate and minimize the complication rate. ASGE training guidelines state that gastroenterology fellows must complete 180 ERCP procedures, with one half utilizing therapeutic modalities, to achieve competency. This generally requires 12 months dedicated to advanced techniques, either integrated within the traditional 3-year gastroenterology fellowship or, increasingly, in a dedicated additional (fourth) year advanced fellowship [65].

After obtaining informed consent by discussing the risks, benefits, and alternatives to the planned procedure, the patient is placed in the prone position with the head facing the endoscopist ("swimmer's position"). Sedation for ERCP varies broadly across regions ranging from moderate sedation with a benzodiazepine (midazolam) and a narcotic (fentanyl) to deep sedation with propofol to general anesthesia. There is an overall trend toward the more routine use of propofol and general anesthesia. Continuous monitoring of blood pressure, pulse rate, cardiac rhythm, and pulse oximetry is performed as in other endoscopic procedures. Additional respiratory monitoring by capnography has been shown to improve patient safety during ERCP [66].

The biliary tree is cannulated through the major papilla with a cannula or sphincterotome passed through a side-viewing duodenoscope. The duodenoscope allows an en face view of the major papilla, thereby facilitating visualization and cannulation (Fig. 4.15). The majority of patients will have a single ampullary orifice with a short common channel that bifurcates into the common bile duct and the main pancreatic duct. Conventional cannulation involves injection of contrast when the catheter is positioned toward the bile duct. An alternative method involves advancing a hydrophilic tip guidewire and achieving biliary cannulation prior to injecting contrast. We favor the latter approach as this has been shown

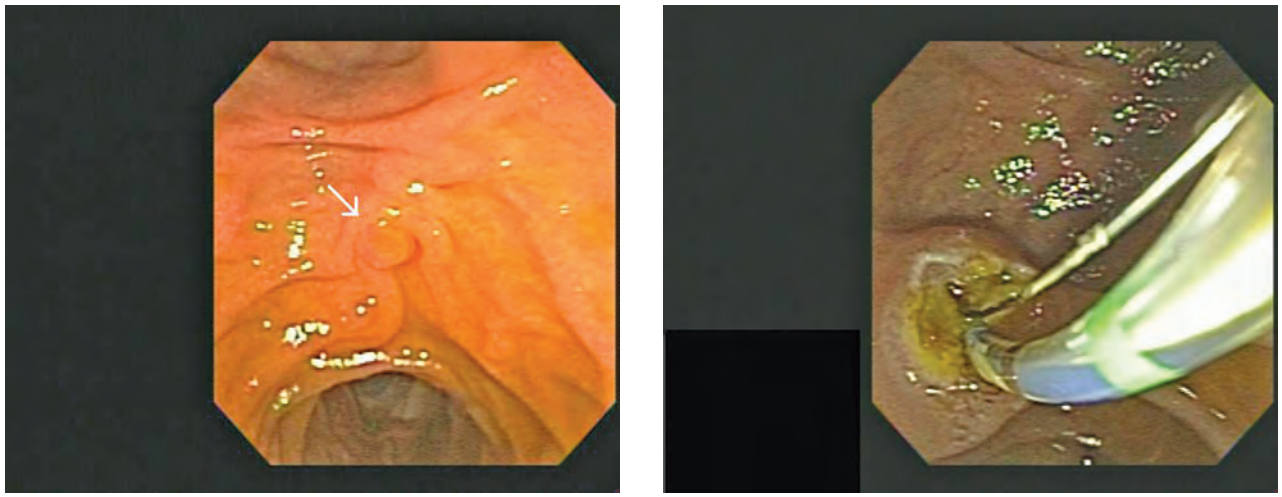

Figure 4.15 (A) Endoscopic view of a normal major papilla (white arrow). (B) Endoscopic view during sphincterotomy.

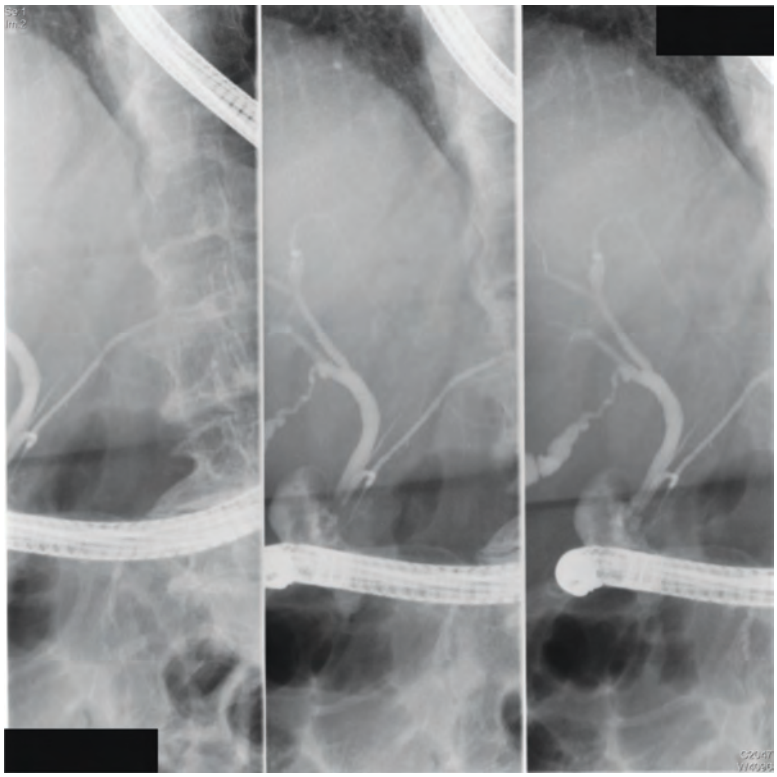

Figure 4.16 Normal ERCP image.

to decrease the risk of post-ERCP pancreatitis, likely by minimizing unintended contrast injection into the pancreatic duct and minimizing trauma to the papilla [67]. Once biliary access is achieved, sphincterotomy and additional therapeutic modalities can be utilized.

Much debate persists regarding the routine use of antibiotics to prevent infection in patients undergoing ERCP. Practice guidelines have been set forth by the ASGE and rely heavily upon expert opinion [68]. These guidelines recommend antibiotic prophylaxis be used when: (i) complete biliary drainage may not be achieved (hilar obstruction, primary sclerosing cholangitis); (ii) incomplete biliary drainage after ERCP; and (iii) drainage of post-transplant biliary strictures is being attempted. These guidelines do not recommend the use of prophylactic antibiotics when complete biliary drainage is expected or biliary obstruction is not suspected.

Cholangiogram

With the evolution of ERCP from a diagnostic to a primarily therapeutic procedure, an entirely normal cholangiogram is seen less frequently than previously. Despite this, it is important to fully understand the normal expected anatomy in order to interpret abnormalities. A scout film is obtained in many centers to demonstrate any tubes, drains, surgical clips, calcifications, or stents. The distal common bile duct fills readily once cannulation is achieved. The normal caliber of the common bile duct after contrast injection ranges from 3 to 9 mm. With the patient in the usual prone position the left main hepatic duct fills preferentially due to gravity. The patient's position may need to be altered or the cannula or a balloon selectively placed in order to achieve filling of the right posterior and right anterior ducts. The cystic duct insertion point can vary significantly from patient to patient (Fig. 4.16).

Choledochoscopy

Very thin endoscopes have been developed to allow direct visualization of the biliary tree (Fig. 4.17). These scopes are advanced through the working channel of the duodenoscope and into the common bile duct for additional evaluation of biliary strictures and treatment of large stones with choledochoscopy. The newest instruments are capable of four-way tip deflection with wheels analogous to those of the duodenoscope and have their own working channels to allow for intraductal biopsy and irrigation

Choledocholithiasis

In the National Health and Nutrition Examination Survey (NHANES III) of 1999, it was estimated that 20 million Americans have gallstone disease [69]. It is estimated that 15–20% of patients with gallstones will have or develop choledocholithiasis. The natural history of choledocholithiasis is not fully understood. While some patients can pass small common bile duct (CBD) stones

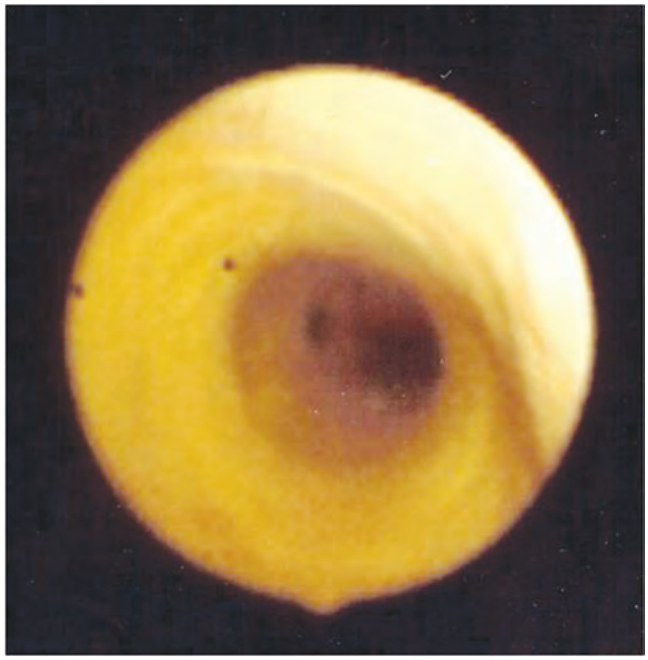

Figure 4.17 Normal endoscopic choledochoscopy.

without symptoms, others can develop life-threatening cholangitis and/or severe acute pancreatitis [70]. Determining which patients are most likely to have CBD stones allows for prompt treatment and avoidance of unnecessary ERCP and its attendant risks.

Several studies have evaluated the clinical predictors that indicate the presence of choledocholithiasis. The strongest predictors in patients with suspected CBD stone(s) include a dilated common bile duct on sonogram (>6 mm), advanced age, and pattern of liver enzyme elevation. In patients with clinically suspected choledocholithiasis whose serum liver enzymes normalized prior to ERCP, the likelihood of recovering a CBD stone at ERCP is less than 13%; whereas in patients with rising serum liver enzymes, the likelihood of a CBD stone is greater than 90% [71]. MRCP is highly sensitive and specific in detecting CBD stones and is particularly useful in those patients who demonstrate intermediate risk of having a CBD stone. A recent meta-analysis demonstrated that MRCP has a pooled sensitivity of 95% for the detection of biliary obstruction and 92% for the detection of a CBD stone. The accuracy of MRCP diminishes with stones that are smaller than 5 mm and in the presence of pneumobilia and surgical clips [72]. Endoscopic ultrasound demonstrates equally high sensitivity and specificity as MRCP, can prevent unnecessary ERCP [73], and is an excellent minimally invasive alternative for those patients who cannot undergo MRI due to the presence of a permanent pacemaker or automated implantable cardioverter-defibrillator.

In patients with choledocholithiasis seen on imaging or a high suspicion of such, as described above, ERCP with endoscopic sphincterotomy and stone extraction should be performed promptly. CBD stones are seen as a filling defect on an endoscopic cholangiogram (Fig. 4.18A). Sphincterotomy is performed by bowing the sphincterotome in order to bring the cutting wire into contact with the roof of the papilla and electrocautery is applied, generally with a blend of high cutting current and low coagulation current, along the direction of the bile duct. The bile duct is outlined by the longitudinal bulge above the ampullary orifice corresponding to the intramural

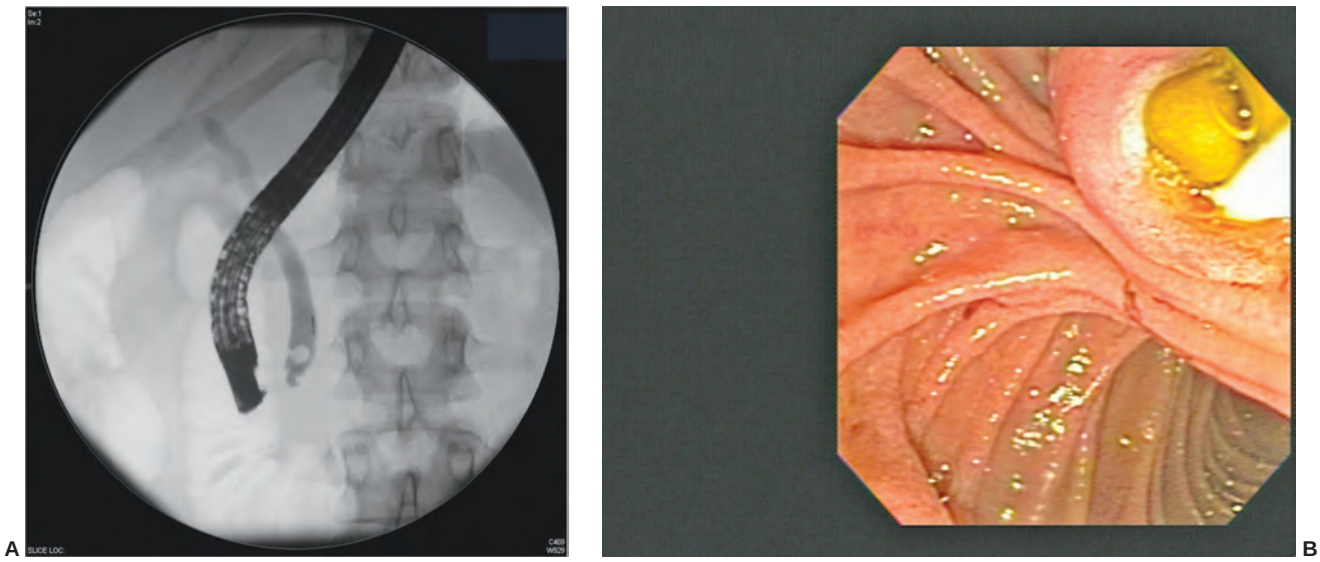

Figure 4.18 (A) ERCP demonstrating a distal common bile duct stone. (B) Endoscopic view of stone extraction.

Figure 4.19 ERCP showing obstruction at the hepatic hilum in a patient with cholangiocarcinoma. (Courtesy of Dr Savreet Sarkaria, Weill Cornell Medical College.)

portion of the distal bile duct [74]. In patients who are at increased risk of bleeding due to anticoagulants, antiplatelet agents, or cirrhosis, balloon sphincteroplasty can be utilized instead. This carries a higher risk of pancreatitis than endoscopic sphincterotomy (relative risk, 1.95) [75]. Once the sphincter is ablated, an extraction balloon or Dormia basket can be used to remove the stone (Fig. 4.18B). In difficult or multiple stones, mechanical lithotripsy with a crushing basket or electrohydraulic lithotripsy may be necessary. Alternatively, a plastic biliary stent can be placed to allow for slow fragmentation by mechanical erosion, which is removed in approximately 2 months. This has been shown to have a success rate of 90% in patients with multiple or large stones [76]. In patients who are deemed unfit for surgery, these therapeutic modalities significantly reduce the risk of recurrent biliary pancreatitis and cholangitis, but not cholecystitis.

Malignant biliary obstruction

Malignant biliary obstruction is generally detected by cross-sectional imaging performed in patients presenting with jaundice. This obstruction may be caused by cholangiocarcinoma within the bile duct (Fig. 4.19), adjacent pancreatic cancer (Fig. 4.20), or hepatic metastases obstructing the hilum or intrahepatic ducts. ERCP, often in conjunction with EUS, can be used to obtain a tissue diagnosis and treat these obstructing lesions. Once the level of obstruction is identified on cholangiography, a cytology brush can be used to sample the stricture for microscopic analysis. The cytologic yield is fairly low (~35%), but can be increased by using multiple brushes or adding intraductal biopsies. In addition, advanced imaging and molecular techniques have been developed to increase yield. These include choledochoscopy with a miniature scope advanced through the duodenoscope; intraductal ultrasound; digital image analysis (DIA); and fluorescence in situ hybridization (FISH). These

modalities significantly improve the diagnostic yield of indeterminate stricture sampling [77].

Endoscopic therapy of malignant biliary obstruction primarily involves stent placement for decompression. In patients who may be surgical candidates for resection, or for whom the clinical staging is incomplete at time of ERCP, 10 or 11.5 Fr temporary plastic stents are placed across the stricture. These stents generally occlude after about 3–4 months and must be replaced preemptively or removed at the time of surgery. In patients who are not candidates for resection and the diagnosis of malignancy is confirmed, self-expanding metal stents (SEMS) are placed across the obstruction for palliation. Metal stents have higher patency rates extending to 12 months and beyond and are cost-effective, averting the need for repeat ERCP stent change procedures. A multitude of SEMS are commercially available in various sizes. The size of the stent is determined by the endoscopist at the time of ERCP, taking into account the length and location of obstruction. Uncovered metal stents can occlude due to mucosal hyperplasia and tumor ingrowth, prompting the development of covered metal stents. In the studies available to date, there is a trend toward higher patency rates, but increased rates of stent migration and cholecystitis have been seen with covered metal stents [55].

Primary sclerosing cholangitis

Primary sclerosing cholangitis is an idiopathic, progressive cholestatic disease of the biliary tree that is characterized by diffuse structuring, dilatation, and beading of the bile ducts on cholangiography (Fig. 4.21). The vast majority of patients with PSC have concomitant ulcerative colitis. Conversely, approximately 5% of patients with ulcerative colitis will develop PSC. The inflammation and fibrosis of PSC results in cirrhosis and portal hypertension, and predisposes patients to cholangiocarcinoma, with a lifetime risk of 10–15%. This risk may be higher in patients with ulcerative colitis or cirrhosis [78,79]. The natural history of PSC is variable. In recent studies, the median time to death or liver transplantation is approximately 10–18 years from time of diagnosis [80,81]. ERCP was instrumental in the initial understanding of the disease, but MRCP has supplanted ERCP in the initial diagnosis of suspected PSC given the very low risk profile and equivalent diagnostic performance characteristics [82]. The major roles of ERCP in patients with PSC are in the diagnosis of suspected progression to cholangiocarcinoma and to provide biliary drainage in selected patients with dominant strictures (see below) or choledocholithiasis.

Figure 4.21 ERCP showing intra- and extrahepatic beading and stricturing of PSC. (Courtesy of Dr S. Ian Gan, Virginia Mason Medical Center.)

A clinical subset of patients with PSC will develop a dominant stricture leading to jaundice, pruritus, and recurrent bouts of acute cholangitis. This is felt to result in further progression of the disease. Endoscopic stricture dilatation and stent placement have been studied as minimally invasive treatment modalities for this type of symptomatic dominant stricture. Balloon dilatation and short- or long-term stent placement have been shown to result in improved liver chemistries, improved pruritus, and improved appearance of the cholangiogram [83,84]. Controlled prospective studies are not available, therefore it remains unclear which treatment modality has greatest efficacy. As discussed above, antibiotic prophylaxis should be given in patients undergoing ERCP for PSC. Unfortunately, this prophylaxis does not eliminate the risk of procedure-related cholangitis [85].

The nonoperative diagnosis of cholangiocarcinoma in patients with PSC can be elusive. Brush cytology during ERCP demonstrates a sensitivity of approximately 50%. Combining serum carbohydrate antigen 19-9 (CA 19-9) results, radiologic imaging, brush cytology, and molecular techniques such as DIA and FISH increases this sensitivity to 86% [86]. Despite these advances, screening for cholangiocarcinoma has not been demonstrated to improve outcomes in patients with PSC and routine screening is not recommended at this time.

Biliary complications of cholecystectomy

Laparoscopic cholecystectomy is one of the most common surgical procedures performed worldwide. Biliary leaks are more common with laparoscopic cholecystectomy than open cholecystectomy, occurring in approximately 1.1% of procedures. Most of these leaks occur from the cystic duct stump (Fig. 4.22), but biliary leaks can also occur from accessory bile ducts that enter the

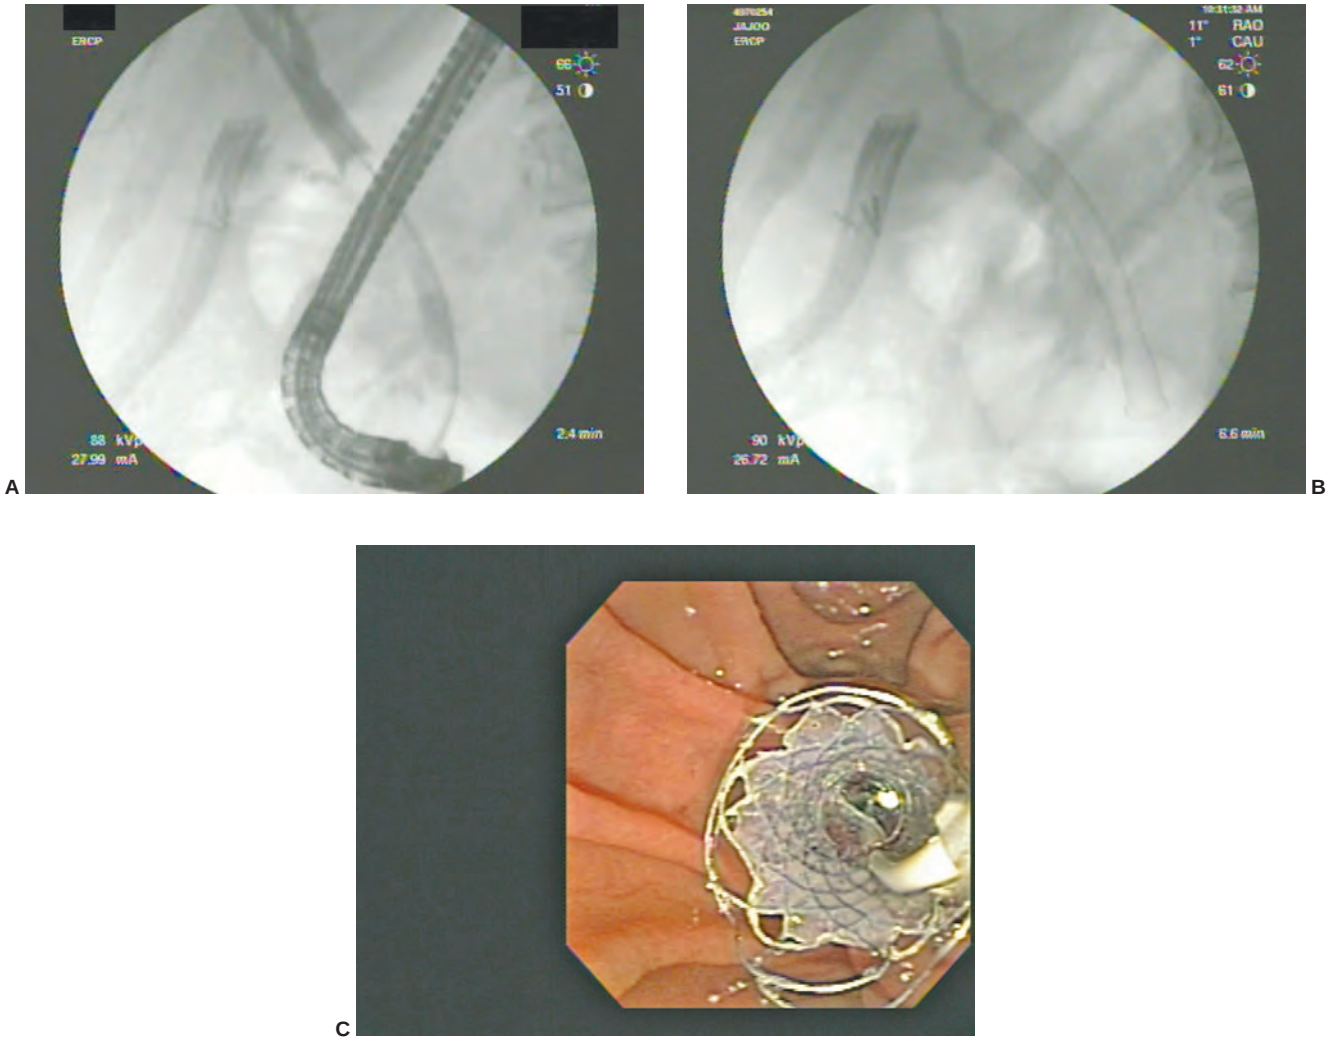

Figure 4.22 ERCP. (A) Bile leak from the cystic duct stump after laparoscopic cholecystectomy. (B) Covered SEMS placement to treat the bile leak. (C) Endoscopic view of covered SEMS deployment.

gallbladder bed (ducts of Luschka) or, less commonly, the common bile duct. Patients present with fever, right upper quadrant abdominal pain, and often an elevation in serum liver chemistries. Although this can be seen in the immediate postoperative period, the average time to presentation is approximately 5 days [87]. Bile leak can be diagnosed by transabdominal ultrasound, CT, or biliary scintigraphy scan. Once a postoperative biliary leak has been diagnosed or it is clinically suspected but imaging is nondiagnostic, ERCP is the primary modality for therapy and is effective in 90% of patients.

ERCP provides confirmation of the bile leak and readily demonstrates the location of the leak. Bile leaks are often associated with retained CBD stone(s), which can be identified and then treated by ERCP with sphincterotomy. The ideal initial endoscopic therapy for post-cholecystectomy bile leak has not been determined. The primary goal of any therapy for bile leak is to diminish the transpapillary pressure gradient and allow for preferential flow of bile into the duodenum instead of the site of leakage. This can be achieved by sphincterotomy alone, transpapillary stent placement, or both. When a retained stone is found, sphincterotomy is generally necessary for removal. If no stone or other obstruction is present, the less invasive approach of stent placement alone is effective [88]. The interval for stent removal is generally 4–6 weeks, though no controlled studies exist. Endoscopic sphincterotomy combined with nasobiliary drainage has also been shown to be effective in hospitalized patients and provides rapid diversion of bile flow, access for a follow-up cholangiogram, and obviates the need for repeat ERCP for stent removal [89]. Patient discomfort and the need for ongoing hospitalization have limited this approach. In patients who do not respond to these initial treatment

modalities, partially covered metal biliary stents have been shown to be very effective [90]. Rarely, surgical repair is required.

Postoperative biliary strictures are also seen as a complication of laparoscopic cholecystectomy as a result of unexpected ischemic injury or a misplaced surgical clip. Patients can present several years after surgery as the injury evolves into a stricture. These strictures are generally focal and can occur anywhere in the extrahepatic biliary tree above the level of the pancreas. Highly effective surgical, percutaneous, and endoscopic treatment options exist for the treatment of post-cholecystectomy strictures. The endoscopic route minimizes procedural morbidity and obviates the need for percutaneous drain placement. Stricture dilatation can be performed with a balloon dilator or graduated catheter dilator over a guidewire. At initial therapy, a plastic stent (8.5–10 Fr) is generally placed to provide drainage and allow for slow, constant dilatation. At times, several stents placed side by side are used to eliminate the stenosis. This may require multiple sessions at 2–3-month intervals over 1 year [91,92]. Recently, covered metal stents have been shown to be highly effective and safe in the management of benign biliary strictures and may be cost-effective by reducing the need for repeated procedures [93,94].

Complications of liver transplant

Biliary complications of orthotopic liver transplantation (OLT) include bile leak, strictures (Fig. 4.23), biliary casts, choledocholithiasis, and sphincter dysfunction due to denervation. Improvements in surgical techniques and organ selection have lead to a decrease in post-transplantation biliary complications; however, the overall rate of biliary stricture remains high at 10–15% and reaches 32% in living donor OLT [95]. Strictures may be more common in Roux-en-Y choledochojejunostomy anastomoses than in end-to-end choledocho-choledochostomy connections. It is postulated that these and additional biliary complications may be seen with the increased use of extended criteria donor grafts, split liver grafts, and other modalities used to compensate for the severe shortage of cadaveric grafts.

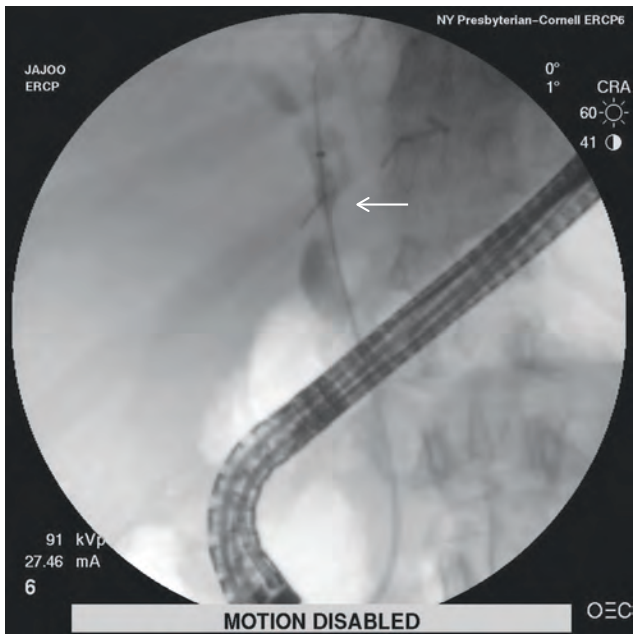

Figure 4.23 ERCP showing a stricture at a choledocho-choledochostomy anastomosis 3 months after orthotopic liver transplantation (white arrow).

Biliary leak generally occurs in the immediate post-transplant period and is treated as discussed above for post-cholecystectomy bile leak. Biliary leak in this setting can arise at the ductal anastomosis or at the insertion site of the T-tube, if one is placed. Endoscopic therapy with stent placement with or without sphincterotomy is effective and safe in the transplant setting.

Biliary strictures after liver transplantation are classified as either anastomotic or nonanastomotic strictures. Anastomotic strictures are related to technical aspects of the ductal reconstruction such as size mismatch between the donor and recipient, tension on the anastomosis due to distance between the cut ends, and bile leak at the anastomosis. Nonanastomotic strictures are often related to ischemia due to hepatic artery occlusion or prolonged ischemia times, immunologic injury due to rejection, and cytotoxic injury from bile salts [95].

Anastomotic strictures are more likely to respond to endoscopic therapy than nonanastomotic ones. Balloon dilatation and stent therapy are often required. Multiple stents may be used over months with a technical success rate approaching 90% [96]. Some authors have argued that balloon dilatation alone is sufficient and stent therapy only adds increased risk due to the possibility of stent occlusion [97]. Emerging data regarding the use of covered metal stents in the post-transplant setting are promising [93,98].

Choledocholithiasis can occur in the post-transplant setting due to stasis from a biliary stricture or related to alterations in bile composition resulting from the transplantation [99]. Biliary cast syndrome, in which sludge and debris from sloughed biliary epithelium results in obstruction, occurs in up to 18% of OLT patients, usually within the first year after surgery. Prolonged warm ischemia time and stricture formation are independent risk factors for cast formation [100,101]. ERCP is the treatment of choice for cast extraction, but success rates are lower than for stone extraction and up to 22% of patients with biliary casts will require repeat transplantation when endoscopic and percutaneous means of treatment fail [100].

Other benign biliary strictures

Chronic pancreatitis is associated with biliary strictures in up to 30% of cases [102]. Surgical biliary diversion was the mainstay of treatment for these strictures, but carries a high morbidity. Stent placement, including multiple side-by-side stents and covered metal stents, has been shown to be effective in biliary strictures due to chronic pancreatitis as in other benign biliary strictures [93].

Benign biliary strictures and leaks can also be seen as a result of blunt abdominal trauma or after nonsurgical interventional procedures such as TIPS. Ischemic strictures have been seen with hepatic artery infusions of antineoplastic agents and sclerosants such as 5-fluorodeoxyuridine and sodium morrhuate or ethanol. Endoscopic therapies as described above have demonstrated efficacy in these rare situations [103].

Endoscopic ultrasound

The close proximity of the biliary tree and liver to the stomach and duodenum allows for high resolution imaging of these structures by EUS. In addition, EUS allows for the visualization of these structures without the acoustic interference of intestinal gas and subcutaneous adipose that is inherent to transabdominal ultrasound. Fine needle aspiration (FNA) can be performed through the EUS scope to further enhance the diagnostic capability of this procedure.

Technique

Specialized endoscopic training is required to proficiently obtain and interpret EUS images. ASGE guidelines have been set forth [104] to serve as a basis for assessing competency and granting procedure privileges. This training should include a stepwise progression of FNA difficulty and adequate FNA experience. As with training for ERCP, EUS training may be best achieved during an additional fellowship year on therapeutic endoscopy.

After obtaining informed consent by discussing the risks, benefits, and alternatives to the planned procedure, the patient is placed in the left lateral decubitus position. Sedation for EUS is generally moderate sedation with a benzodiazepine (midazolam) and a narcotic (fentanyl). Increasingly, intravenous propofol sedation administered by an anesthesiologist or nurse anesthetist is utilized given the generally longer procedure time for EUS compared with general upper endoscopy. Continuous monitoring of blood pressure, pulse rate, cardiac rhythm, and pulse oximetry is performed as in other endoscopic procedures. Additional respiratory monitoring by capnography has been shown to improve patient safety during EUS [66]. Sequential EUS and ERCP can be performed safely on the same day with a risk profile similar to either procedure alone [105].

Two general types of echoendoscopes are available for EUS of the hepatobiliary anatomy: radial array and curvilinear array. Each of these has videoendoscopy capability in addition to an ultrasound transducer at the tip of the endoscope to allow for ultrasound imaging of the gastric and duodenal wall and surrounding structures. Radial array echoendoscopes provide a 360° image plane that is perpendicular to the long axis of the endoscope. This view is analogous to the axial images of a CT scan. The linear array echoendoscope provides a 120–150° image in the same plane as the long axis of the endoscope. This allows for direct sonographic visualization of instruments such as FNA needles as they are advanced through the enteral wall into the lesion being evaluated.

Complications

The complications of general endoscopy can occur with EUS, including sedation-related complications and rarely perforation. FNA carries a risk of bleeding and infection. The risk of bleeding is minimized by utilizing color flow ultrasound prior to advancement of the FNA needle to assess for the presence of blood vessels in the expected needle path. The risk of infection is minimal when solid lesions are sampled.

Indications for hepatobiliary EUS

A primary role for biliary EUS is the evaluation of choledocholithiasis. CBD stones can be difficult to diagnose, particularly in patients who do not demonstrate overt cholangitis or have fluctuating serum liver enzyme values. Transabdominal ultrasound and CT scans are highly specific for the finding of CBD stones, but lack high sensitivity. MRCP is highly sensitive and specific in the diagnosis of choledocholithiasis [72], but is limited for stones smaller than 5 mm. On EUS, CBD stones are seen as hyperechoic objects with shadowing within the anechoic duct (Fig. 4.24). EUS demonstrates similarly high test characteristics as MRCP (sensitivity 93% and 85%; specificity 96% and 93%, respectively) and both can help to avert the risks of unnecessary ERCP [106].

As discussed above, the differentiation between benign and malignant extrahepatic biliary strictures can be quite difficult. EUS with FNA has been shown to be sensitive and specific in the diagnosis of malignant biliary strictures, even when no mass was seen on cross-sectional imaging and ERCP with tissue sampling failed to provide a diagnosis [107,108]. Intraductal ultrasound, using a high-frequency catheter probe passed over a guidewire during ERCP, has also been used to provide additional imaging of indeterminate biliary strictures. EUS can be helpful in determining the cause of benign biliary strictures, such as chronic calcific pancreatitis (Fig. 4.25).

Solid liver lesions are generally approached by percutaneous means given the ready accessibility and safety

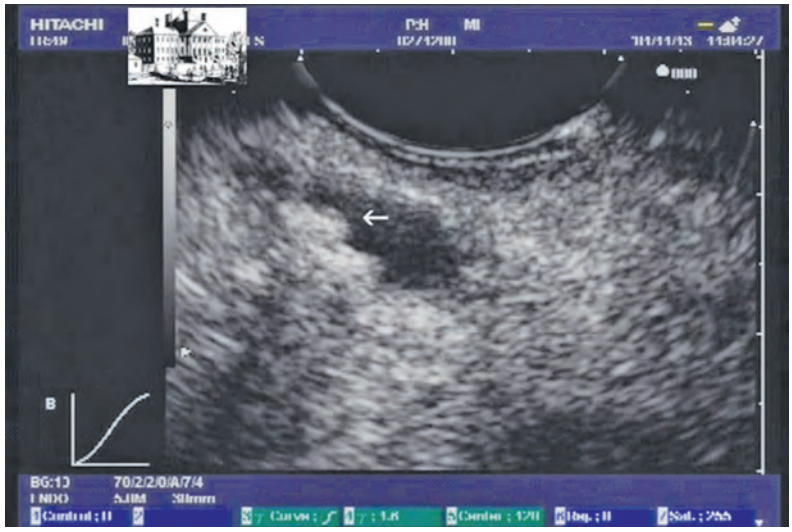

Figure 4.24 EUS demonstrating hyperechoic stones (white arrow) in the common bile duct.

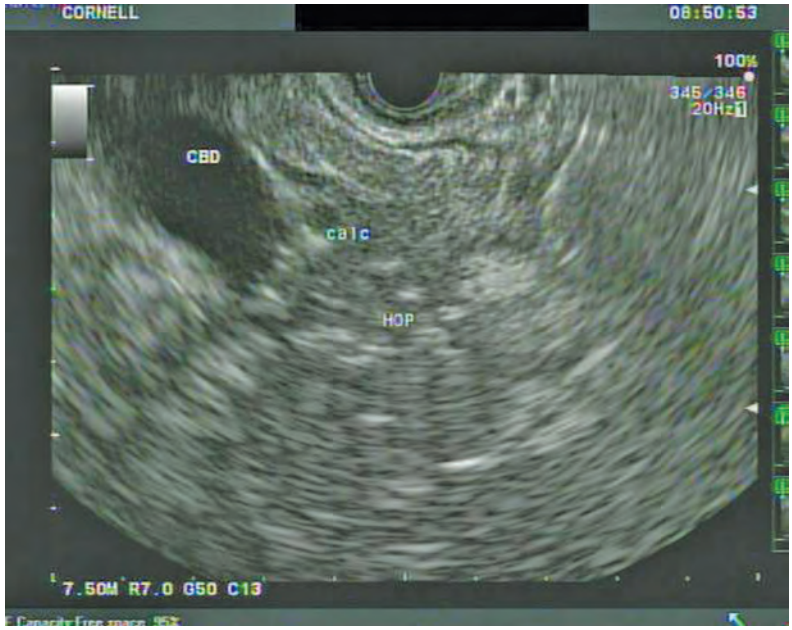
of this approach. EUS with FNA has been shown to be highly sensitive for solid liver lesions and demonstrates the ability to identify and diagnose lesions that may not have been seen on transabdominal ultrasound or CT scan [109]. In cases where metastatic disease is suspected despite negative radiologic imaging or the primary tumor requires EUS evaluation, EUS of the liver with FNA of any solid lesions is advised (Fig. 4.26).

EUS is also useful in the identification and sampling of ascites (Fig. 4.27). EUS can detect ascites that was not seen on other imaging studies such as transabdominal ultrasound and CT scan [110]. Paracentesis of suspected malignant ascites by EUS-FNA is highly sensitive and specific for malignancy (94% and 100%, respectively) and may significantly affect management decisions [111].

Portal vein thrombosis is generally diagnosed with noninvasive imaging such as transabdominal Doppler ultrasound or triphase CT scan. In cases of suspected portal vein thrombosis not identified by the usual means, EUS can provide the diagnosis with high sensitivity and excellent specificity (81% and 93%, respectively) [112]. Thrombus is generally seen as hyperechoic material within an otherwise hypoechoic or anechoic vessel.

As with the increasingly therapeutic focus of ERCP, the role of EUS has come to include interventional therapeutic indications that can avert surgical or percutaneous



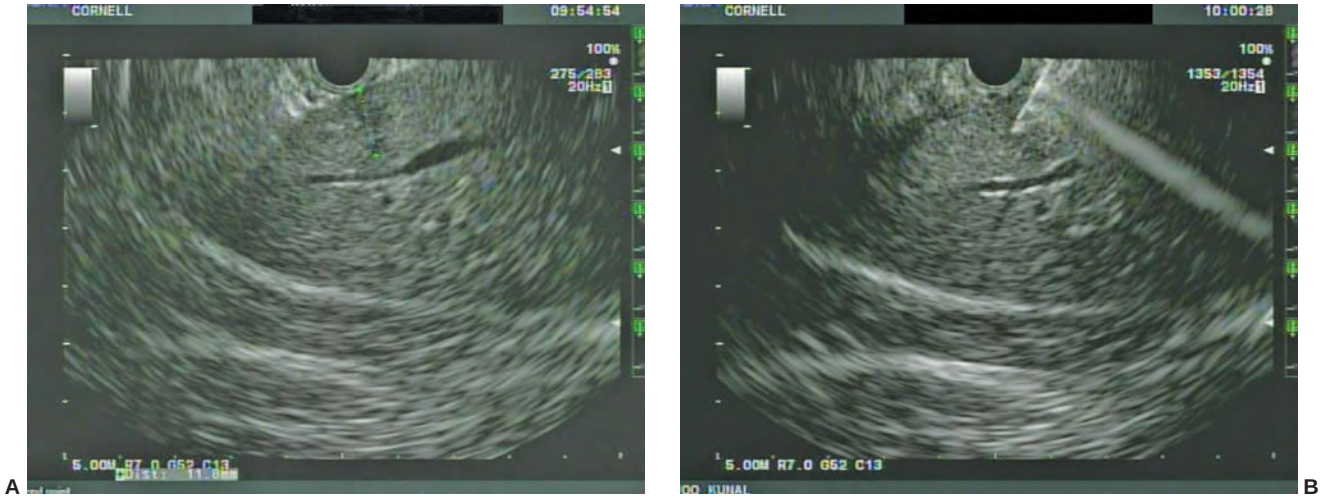


Figure 4.25 EUS showing obstruction of the distal common bile duct (CBD) due to chronic calcific pancreatitis (calc) in the head of the pancreas (HOP).

A B

procedures. In cases where transpapillary access to the biliary tree is not possible due to altered surgical anatomy or enteral obstruction, EUS with FNA access of the biliary tree can allow for antegrade placement of a biliary stent through the gastric or duodenal wall [113]. This has only been described in small series and requires further investigation.

PART II

General Considerations

CHAPTER 5
Physioanatomic Considerations

Ian R. Wanless
Department of Pathology, Dalhousie University, Halifax, Nova Scotia, Canada

Key concepts

- The branching pattern of large vessels and ducts is used for defining the segmental nomenclature used by radiologists and surgeons.
- Anomalies of the vessels and ducts are of importance to surgeons.
- Bile ducts are supplied by arteries. Arterial injury may lead to ischemic strictures of the ducts, especially after transplantation.
- The liver receives most of the splanchnic blood flow. After severe obstruction at any level of the hepatic vasculature, collateral channels become a source of bleeding and are partly responsible for hepatic encephalopathy.
- The microvasculature of the liver consists of small branches of portal and hepatic veins that interdigitate in a regular pattern, allowing the definition of parenchymal subunits called acini or lobules.
- Arterioles communicate with portal veins near the periportal end of the sinusoids. In cirrhosis, these communications dilate and therefore contribute to portal hypertension.
- Hepatocytes are exposed to gradients of nutrients and waste products leading to zonal metabolic specialization and zonal variation in susceptibility to ischemia and drug toxicity.
- The sinusoids are lined by fenestrated endothelial cells that lack basement membranes. This anatomy facilitates rapid exchange between plasma and hepatocytes.
- Hepatic lymph is formed at the sinusoidal level when there is increased sinusoidal pressure, especially with outflow obstruction. This lymph may accumulate as ascites.
- Sinusoidal macrophages (Kupffer cells) are important in host defense.
- Perisinusoidal stellate cells store vitamin A and, when activated, produce collagen that contributes to the pathogenesis of cirrhosis.
- There are two major anatomic forms of chronic liver disease: nodular regenerative hyperplasia and cirrhosis. These forms are determined by microvascular obliteration. In nodular regenerative hyperplasia, obliteration of portal veins is dominant. In cirrhosis, both portal vein and hepatic vein obliteration are prominent.
- Microvascular obliteration in cirrhosis is usually initiated by necroinflammation adjacent to terminal hepatic venules. Secondary congestion occurs in proximal tissue leading to parenchymal extinction and obliteration of portal veins, followed by angiogenesis, exacerbation of in–out imbalance, and a positive feedback loop that causes progression and slows regression of disease.

Anatomic knowledge is required for understanding normal hepatic physiology and the pathogenesis of disease. This chapter presents a summary of normal anatomy, some physiologic correlates, and a description of the major anatomic abnormalities found in human liver disease.

Surface anatomy

The liver is shaped like a wedge with its base against the right abdominal wall and its tip pointing to the spleen. The normal liver extends from the fifth intercostal space in the midclavicular line down to the right costal margin. It measures 12–15 cm coronally and 15–20 cm transversely. The lower margin can usually be felt below the costal margin during inspiration.

Transcutaneous puncture for liver biopsy is commonly located in the midaxillary line in the third interspace below the upper limit of liver dullness during full expiration, commonly in the ninth intercostal space. The median liver weight is 1,800 g in men and 1,400 g in women [1]. The adult liver weight is between 1.8% and 3.1% of body weight in 80% of individuals [2,3]. Liver weights in fetuses and children are relatively greater, being 5.6% at 5 months' gestational age, 4–5% at birth, and 3% at 1 year of age [4,5].

Impressed by the molding against adjacent organs, William Osler quipped that the liver was present only for packing purposes. Thus, the superior, anterior, and lateral surfaces are smooth and convex to fit against the dome of the diaphragm. The muscle bundles of the diaphragm often impress grooves in the superior surface. The costal margin often marks a transverse groove on the

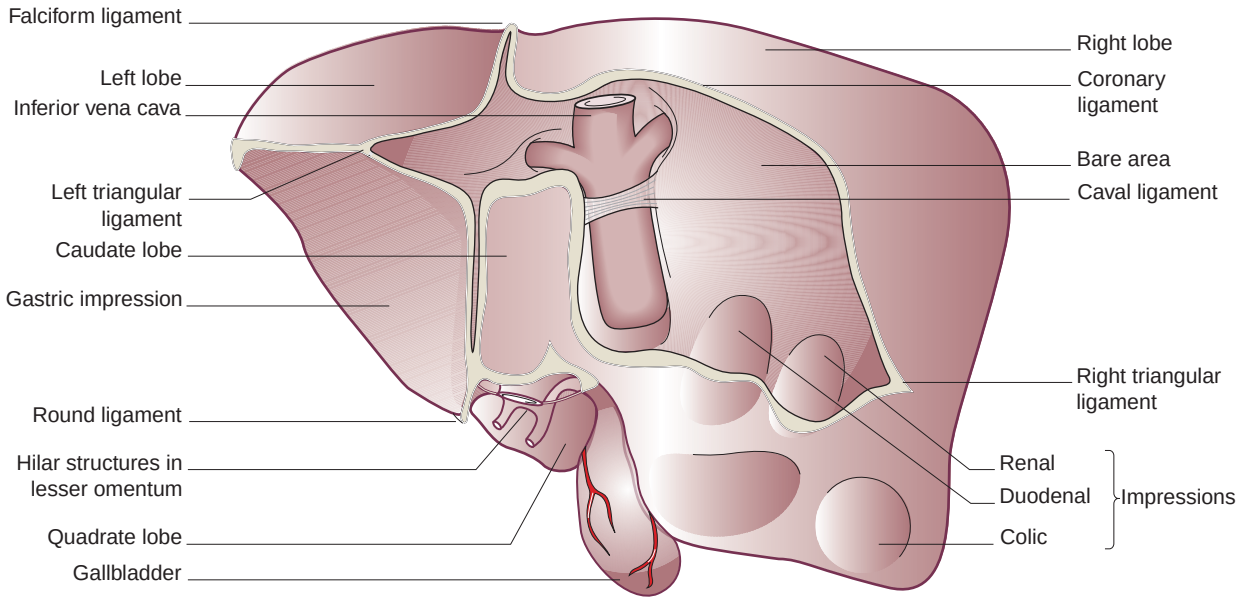

Figure 5.1 Posterior view of the liver. The marks impressed on the liver surface by neighboring organs mirror its topographic relations. (Reproduced from Wanless [207] with permission from Elsevier.)

anterior surface (corset deformity). The posterior surface has indentations from the colon, kidney, and duodenum on the right and the stomach on the left (Fig. 5.1). Deeper grooves, called fissures, are formed where extrahepatic vessels or cords press against the developing liver. Three of these structures, the umbilical portion of the left portal vein, the ductus venosus (ligamentum venosum), and the umbilical vein (ligamentum teres), form the umbilical fissure.

The liver is covered by the fibrous capsule of Glisson (or Walaeus). At the porta hepatis, the connective tissue of the capsule is continuous with the fibrous sheath, which invests the portal vessels and ducts and follows them to their smallest ramifications. The capsular peritoneum reflects onto the diaphragm and continues as the parietal peritoneum. The reflections form the coronary ligaments, the right and left triangular ligaments, and the falciform ligament (Fig. 5.1). These ligaments hold the liver firmly in its place and allow passage of the lymphatics, small vessels, and nerves. There is a large bare area where the liver is attached to the diaphragm and retroperitoneum. The vena cava, being retroperitoneal, lies on the bare area and is held to the liver by a ligament or bridge of liver parenchyma between the caudate and right lobes.

The falciform ligament connects the liver to the diaphragm and anterior abdominal wall. The lower free edge of the falciform ligament, called the round ligament, contains the obliterated umbilical vein. The falciform ligament ascends the anterior surface of the liver, joins the reflections of peritoneum left of the vena cava, continues posteriorly as the lesser omentum in the fissure of the ductus venosus, and finishes at the hilum. Thus, the falciform ligament anteriorly and the lesser omentum and umbilical fissure posteriorly divide the liver into the conventional right and left lobes.

On the posterior surface, the transverse portal fissure contains the hilar vessels and demarcates the conventional right lobe anteriorly from the caudate lobe posteriorly (Fig. 5.1). The quadrate lobe is the portion of the right lobe anterior to the transverse fissure and is delimited on the right by the gallbladder and on the left by the umbilical fissure.

The hepatoduodenal ligament connects the liver to the superior part of the duodenum. It is part of the lesser omentum, which sheathes the hepatic artery (HA), portal vein (PV), nerves, bile duct, and lymph vessels, all present within the porta hepatis. In the ligament the common bile duct lies to the right, the HA to the left, and the PV behind them. However, variations in the topography of the HA are common.

There are several variations in the gross anatomy and topography of the liver [6,7]. The relative size of the right and left conventional lobes is variable, being equal in size in 7% and greater on the left in 4% [7]. The Riedel lobe is a caudal prolongation of the right lobe, which may give a false impression of hepatomegaly (Fig. 5.2). The falciform left lobe is an elongated lobe that extends laterally and posteriorly like a scythe, found in 19% [7]. Extreme atrophy of the left lobe (4%) may be a result of vascular anomalies occurring early in life [8] or extinction of parenchyma occurring after acquired vascular obstruction. The left lobe may be attached to the rest of the liver

Figure 5.2 Liver with Reidel lobe, a prominent caudal extension of the right lobe.

by a narrow pedicle. Accessory livers may be found in the ligaments or mesentery or on the surface of the gallbladder, spleen, or adrenal glands [6]. Conversely, adrenal rests may be embedded in the right lobe, providing a source for the formation of intrahepatic adrenal cortical adenoma or myelolipoma [9].

Segmental anatomy

Division of the liver at the falciform ligament and umbilical fissure does not correspond to division based on branch points in the vascular supply. Surgical imperative has led to the search for functional divisions within the liver. The anatomic studies of Rex and others [10–13] demonstrated that the liver can be divided on a different plane into right and left livers (or hemilivers), each with its own blood supply and duct drainage. The right hemiliver comprises 50–70% of the liver mass. The liver can be further divided into a total of eight segments based on the vascular or bile duct distribution (Figs. 5.3 and 5.4) [7,13–17]. The segmental nomenclature devised by Couinaud has received the widest acceptance. This classification was based on the divisions of the portal veins. However, the branching of the PVs to the left lobe is irregular because of the entry of the umbilical vein, making it desirable to adopt a nomenclature based on the divisions of the arteries or ducts, as suggested by Strasberg [18]. This can be done without modification of the segments defined by Couinaud and rationalizes the diverse nomenclature used in different parts of the world. The Strasberg nomenclature is summarized in Figure 5.3 and Table 5.1.

Most hepatic resections can be achieved by division either on the Cantlie line (between the gallbladder and vena cava) or near the falciform ligament. Surgical dissection along the planes between segments is relatively bloodless. Because the segments do not have surface landmarks, small resections are usually performed without attempting to identify the segmental boundaries [17]. The segments vary greatly in size and shape among individuals [19], so that each operation is empirical and may be based on ultrasonography [20,21].

Embryology

The liver arises from the hepatic diverticulum of the foregut during the fourth week of gestation (Fig. 5.5) [7,22]. As the embryo develops, the blood supply to this region evolves in an elaborate fashion to deliver nutrients from three different sources in the sequence: yolk sac, placenta, and gut [7,18].

Hepatocyte precursors, the hepatoblasts, arise from endodermal cells at the advancing front of the diverticulum and invade the mesoderm of the caudal portion of the septum transversum. The vitelline veins traverse the region, bringing blood from the yolk sac and digestive tube to the heart. As hepatoblasts invade the mesenchyme, they disrupt the vitelline veins, tapping their blood supply. This supply is from the vitelline veins, segments of which later become the PVs. The hepatic bud is subdivided into cords by new capillaries called sinusoids. The sinusoidal flow coalesces into three major hepatic veins. At the time the main hepatic veins are developing, the entire liver is composed of only two lobules, and there is no artery and no left or right bile duct. As the hepatic and portal veins begin to branch, the branches interdigitate to remain equidistant from each other, and the parenchyma is subdivided into numerous lobules or acini. It has been suggested that the portal and hepatic vessels invade the most ischemic parenchyma, which is located at the nodal point of Mall, the point most distant from both PVs and hepatic veins [23,24].

The hepatoblast cords develop into anastomosing tubular structures with central bile canaliculi that eventually communicate with the bile ducts. Most hepatoblasts differentiate into hepatocytes, but those adjacent to the portal mesenchyme differentiate into a layer of duct progenitors called the ductal plate [25,26]. The ductal plate becomes bilayered and gradually forms segments with lumina. These segments form ducts that migrate away from the limiting plate to a more central location in the portal tracts near the portal vein. Portions of the ductal

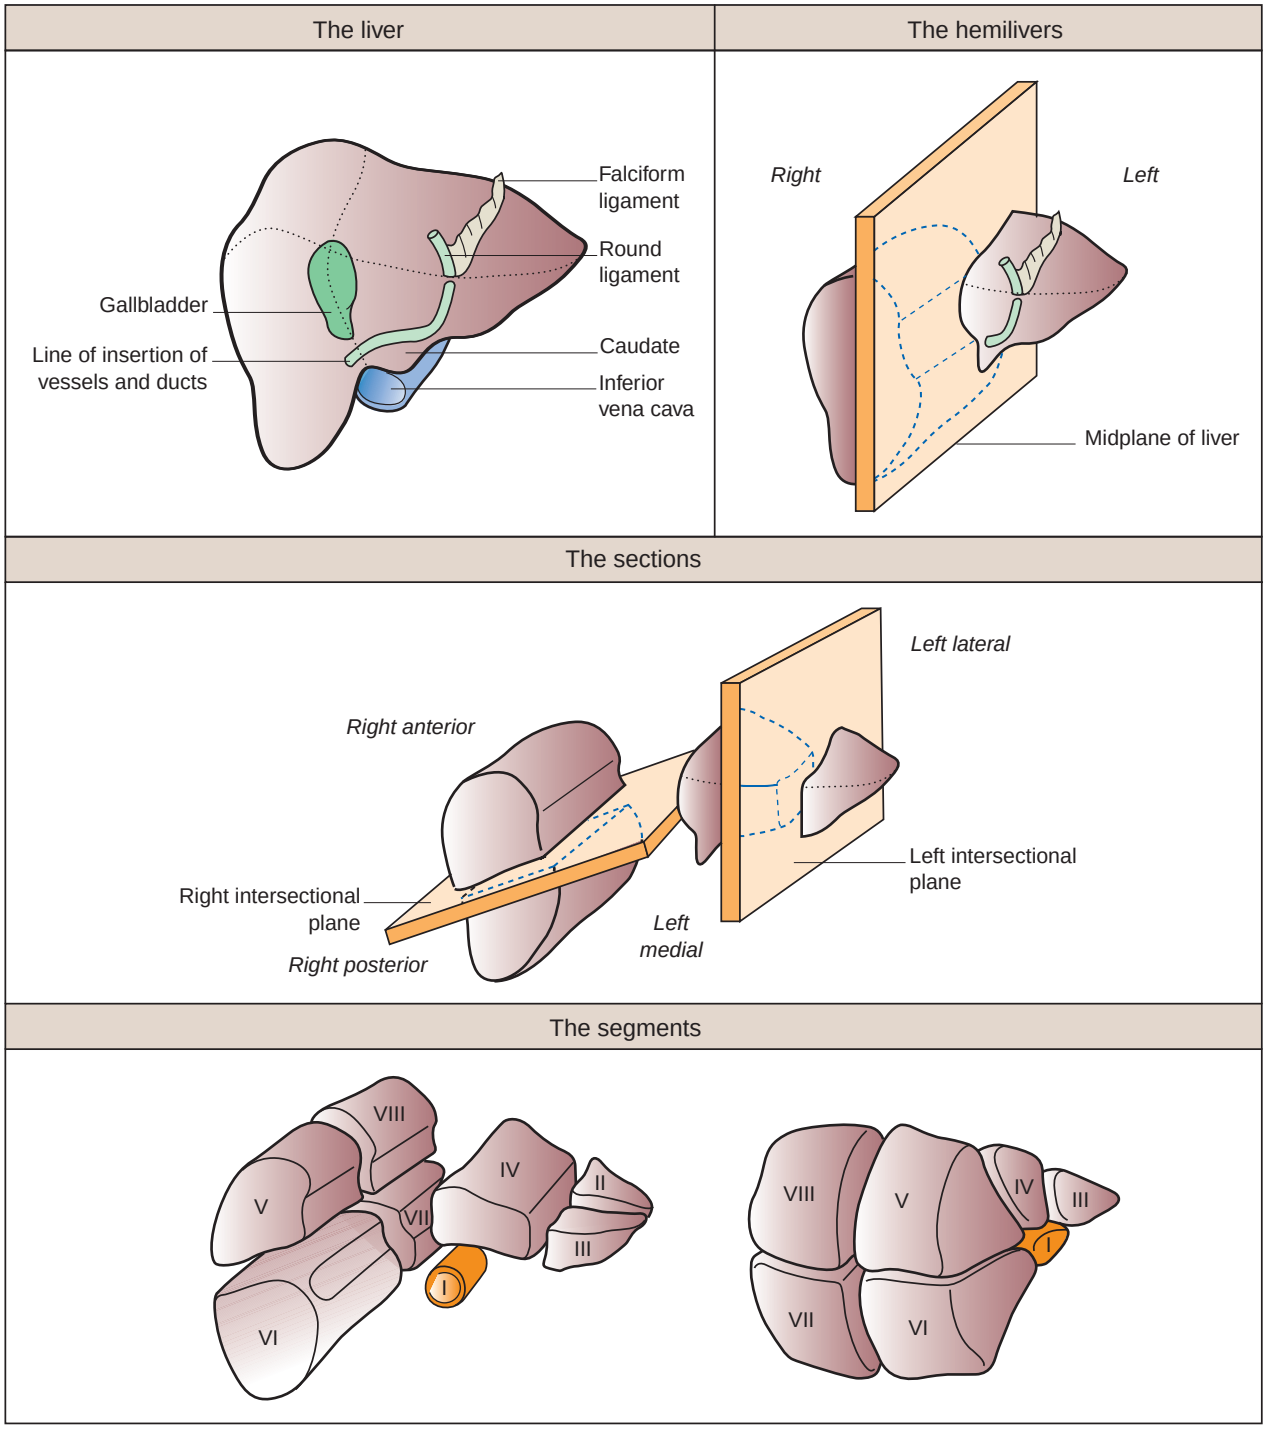

Figure 5.3 Schematic diagram of planes of division in the liver. The liver can be visualized as being divided into two hemilivers by the midplane of the liver. The hemilivers are each subdivided into two sections by right and left intersectional planes. Three of the sections are further subdivided into two segments each by intersegmental planes, based on the divisions of the ducts and arteries. The left medial section does not have a regular duct and artery division and is therefore called one segment (IV). However, for surgical convenience, it is subdivided into the posterior and anterior portions (segments IVa and IVb, respectively, not shown). The caudate lobe is a separate segment (I) that is not part of the four main sections. IVC, inferior vena cava. (Courtesy of Dr Strasberg; reproduced from Strasberg [18] with permission from Elsevier.)

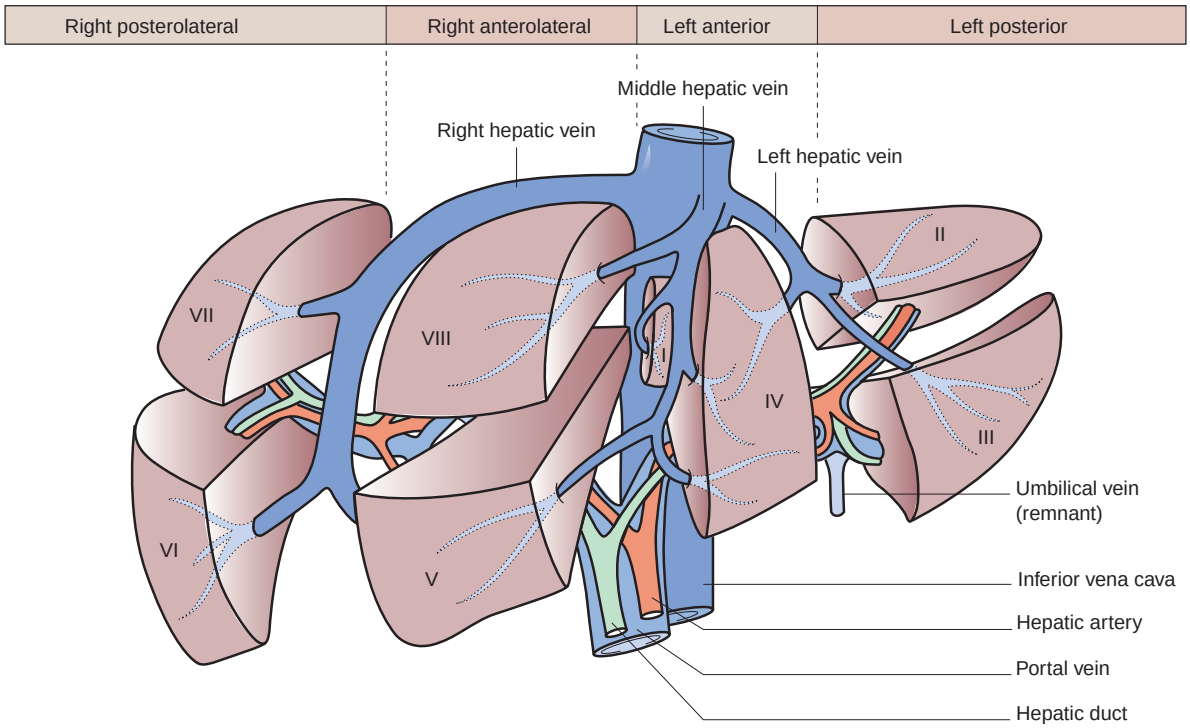

Figure 5.4 Schematic demonstration of the vascular relations of the segments. The segments are numbered using the nomenclature of Couinaud. The remaining elements of nomenclature are those of Strasberg. The midplane extends along the Cantlie line from the vena cava to the gallbladder. The middle hepatic vein runs in this plane. The right and left intersectional planes contain the right and left hepatic veins, respectively. Each section is supplied by one of the four major arteries and bile ducts. The portal pedicles and hepatic veins interdigitate, so they do not lie in the same planes except for the umbilical portion of the left portal vein and the umbilical vein (a medial branch of the left hepatic vein), both of which are found in the umbilical fissure (also known as the left intersectional plane). The *sections* of Strasberg coincide exactly to the *segments* of Healey and Schroy. The two *sections* of the right hemiliver correspond to the two right *sectors* of Couinaud. The tertiary structures of Strasberg and of Couinaud are called *segments*; these coincide to the *areas* of Healey and Schroy, except that segment IV is divided into two *areas* by these authors. (Drawn by M. Thompson; adapted from Wanless [206].)

Table 5.1 Nomenclature for resections of liver.

	Name of operation	
Portion of liver excised	**Strasberg**	**Couinaud, Goldsmith, and Woodburne**
Single segment	Segmentectomy (e.g., segmentectomy III)	–
Two adjacent segments	Bisegmentectomy (e.g., bisegmentectomy V, VIII)	–
Multiple segments	Segmentectomy (e.g., segmentectomy IV, V, VI)	–
One fourth of liver (e.g., left lateral section	Left lateral sectionectomy	Left lobectomy (segments II, III), left lateral segmentectomy
One half of liver, right hemiliver	Right hemihepatectomy (may or may not include segment I; e.g., right hemihepatectomy with segment I[a])	Right hepatectomy (segments V, VI, VII, VIII), right hepatic lobectomy
One half of liver, left hemiliver	Left hemihepatectomy	Left hepatectomy (segments II, III, IV), left hepatic lobectomy
Three fourths of liver, right hemiliver, and left medial section	Right trisectionectomy or right hemihepatectomy with left medial sectionectomy	Right lobectomy (segments IV, V, VI, VII, VIII, ± I), extended right hepatic lobectomy, right trisegmentectomy (Starzl)
Three fourths of liver, left hemiliver, and right anterior section	Left trisectionectomy or left hemihepatectomy with right anterior sectionectomy	Extended left hepatectomy, extended left lobectomy, left trisegmentectomy (Starzl)

[a]This comment also applies to left hemihepatectomy and the trisectionectomies.

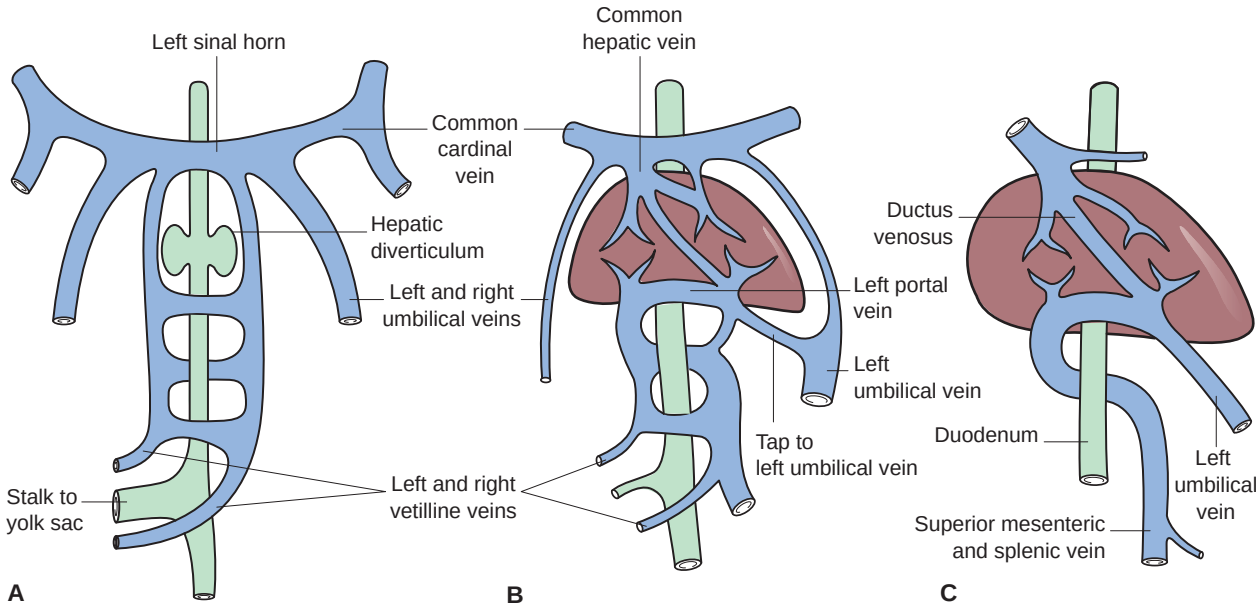

Figure 5.5 Drawing to show three stages in the development of the hepatic vasculature. (A) In the embryo, there are three paired venous beds that drain the placenta (umbilical veins), yolk sac, and intestinal tract (omphalomesenteric or vitelline veins), and the remainder of the body (cardinal veins). These beds converge on the sinal horns before entering the heart. The left and right vitelline veins are joined by three anastomoses to form a ladder-like structure with the intestinal tract intertwined. The extrahepatic portal vein develops from these vessels after selective obliteration of portions of the ladder (B, C). (B) The left vitelline vein receives a tap from the left umbilical vein. The intrahepatic segment of this tap becomes the umbilical portion of the left portal vein. Flow in this segment reverses after birth and supplies segments of the left hemiliver. As the liver develops, the venous drainage of the parenchyma becomes focused into two vessels, the future right and left hepatic veins, and later the middle vein (not shown), which usually drains into the left hepatic vein. The ductus venosus develops as a through-channel from the left portal vein to the common hepatic vein. The remainder of the portal vein blood perfuses sinusoids before reaching the hepatic veins. (C) The vasculature has been simplified with the removal of several segments including the most caudal anastomosis between the vitelline veins, the rostral portions of the left vitelline and left umbilical veins, and the right umbilical vein. The right lobe has grown faster than the left as the left lobe has lost the supply from the left vitelline vein and left umbilical vein blood is shunted through the ductus venosus. The left umbilical vein actually lies in the midline and later shifts to the right of midline.

plate resorb, leaving a complex anastomosing network of ducts that continues to simplify in the weeks after birth [27]. The common bile duct, left and right hepatic ducts, and gallbladder develop in the stalk region of the hepatic diverticulum. These ducts are continuous with the ductal plate in the cranial end of the diverticulum. As bile ducts develop, they become highly vascularized by arterioles and capillaries of the periductal plexus.

The liver occupies most of the abdominal cavity in the third month of gestation, in part because of large masses of sinusoidal hematopoietic cells. Thereafter, the right lobe grows faster than the left lobe but less than the rest of the body. The liver cell cords remain tubular until birth, when they begin to remodel into double-cell plates and finally into single-cell plates by 5 years of age. Hematopoietic cells are still found in the sinusoids at birth and are largely gone from the liver by 4 weeks of age.

The hepatoblast is a bipotential progenitor cell that is positive for cytokeratin CK19 and HepPar1. During organogenesis, these cells differentiate into hepatocytes (CK19-negative and HepPar1-positive) and small bile ducts (CK19-positive and HepPar1-negative) [26,28]. CK7 is expressed later and continues to increase in the weeks after birth. Severe injury to the adult liver causes a return to the pattern of expression seen in hepatoblasts. Thus, regenerating epithelial cells in the liver may have features of both ducts and hepatocytes [29].

Large vessels of the liver

The liver receives blood through the PV and through the HA, a branch of the celiac axis. Because the PV drains the blood of an area supplied by other branches of the celiac axis and by the superior and the inferior mesenteric arteries, the hepatic blood flow depends on the flow in these arteries [30].

Portal veins

The PV is an afferent nutrient vessel of the liver that carries blood from the entire capillary system of the digestive tract, spleen, pancreas, and gallbladder. It is constant in length, but the branches are variable (Fig. 5.6) [31,32]. The PV is formed behind the neck of the pancreas by the

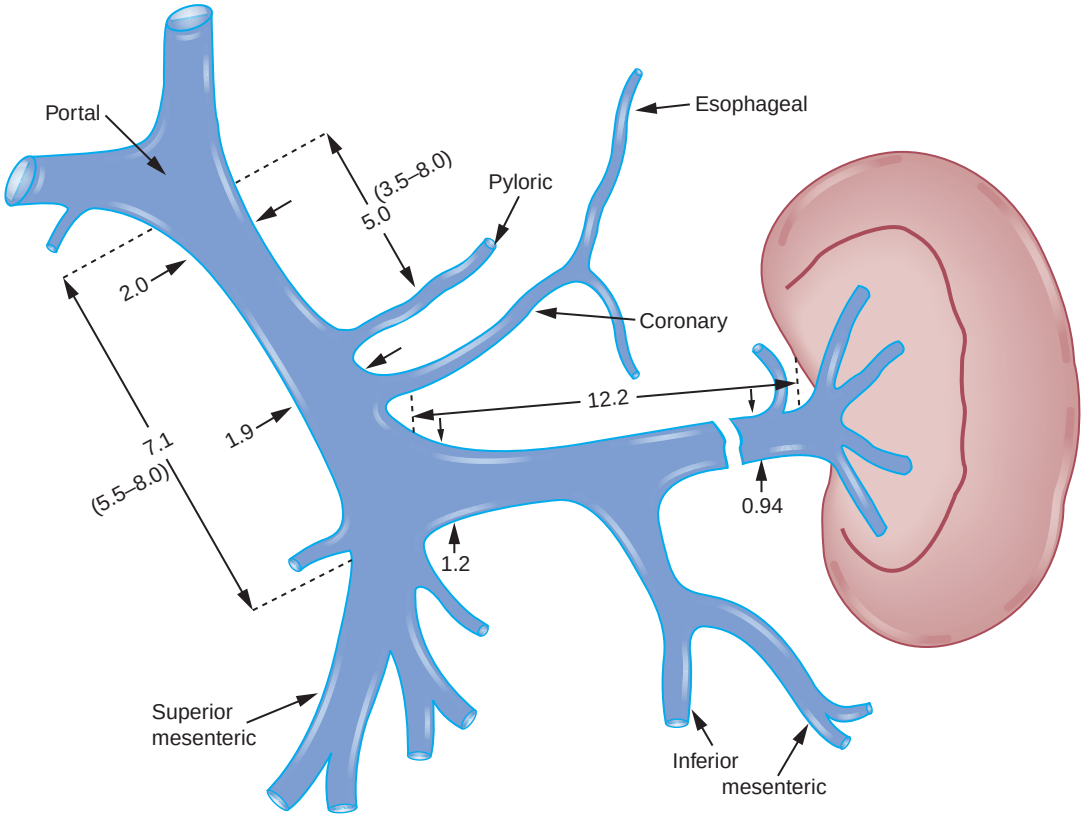

Figure 5.6 Measurements of the portal vein and its main branches, in centimeters. (Reproduced from Gilfillan [31] with permission from American Medical Association.)

confluence of the splenic and superior mesenteric veins. It also receives the superior pancreaticoduodenal vein, the left gastric (coronary) vein, and the cystic vein. Usually the upper 5 cm of the PV is devoid of major branches, allowing easy surgical dissection.

The splenic vein commences with five to six branches that return the blood from the spleen and unite to form a single nontortuous vessel. In its course across the posterior abdominal wall, it grooves the upper part of the pancreas, from which it collects numerous short tributaries. It runs close to the hilum of the left kidney and terminates behind the neck of the pancreas, where it joins at a right angle the superior mesenteric vein. Because of its nearness to the vessels of the left kidney, the splenic vein can be anastomosed to the renal vein. Its tributaries are the short gastric veins, the pancreatic veins, the left gastroepiploic vein, and the inferior mesenteric vein. In the distal splenorenal shunt operation, the short gastric veins are used for collateral drainage of the gastroesophageal varices.

The superior mesenteric vein carries blood from the small intestine, ascending colon, and transverse colon. The inferior mesenteric vein returns blood from the area drained by the superior and the inferior left colic and the superior rectal veins.

An important tributary of the portal trunk is the coronary vein. It runs upward along the lesser curvature of the stomach, where it receives some esophageal veins. In patients with portal hypertension, these enlarge to form varices.

The portal trunk runs in the hepatoduodenal ligament in a plane dorsal to the bile duct and the HA and divides into two lobar veins before entering the portal fissure. The right lobar vein, short and thick, receives the cystic vein. The left lobar vein, longer and smaller, is joined by the umbilical vein and the paraumbilical veins. It connects by the venous ligament with the inferior vena cava. The left lobar vein gives branches to the quadrate lobe and also to the caudate lobe before entering the parenchyma at the left end of the porta hepatis. A separate branch may arise near the bifurcation to supply the caudate lobe. This vein is easily injured during dissection. The paraumbilical veins arise from the umbilical portion of the left PV and travel in the round ligament, where they may become evident as umbilical varices in the presence of portal hypertension. The umbilical vein is easily recanalized in infants, allowing access for blood sampling and angiographic visualization of the portal system.

In addition to the main PV and its branches, the liver receives other veins from the splanchnic circulation, the

parabiliary venous system of Couinaud [33]. This highly variable plexus includes several veins that arise from the pancreaticoduodenal or pyloric veins and drain into the PV or directly into the inferior surface of segment IV and less often into other segments. This plexus provides examples of the metabolic effects of proximity to insulin source. Veins arising from the pancreatic region carry blood with high insulin levels and pyloric veins carry low insulin blood. Because insulin determines the propensity of liver to store triglycerides, the anatomy of these veins could explain some examples of focal fatty liver and focal fatty sparing [34].

Anomalies of the portal-venous system are relatively rare. The anterior segment of the right liver occasionally is supplied by a branch of the proximal left PV [35]. Preduodenal PV may be a result of persistence of the most caudad anastomotic channel between the vitelline veins (see Fig. 5.5). It may be associated with duplication of the PV, annular pancreas, duodenal diaphragm, or intestinal malrotation producing duodenal obstruction [36]. Congenital absence of the PV is associated with portosystemic shunting, as the superior mesenteric vein and the splenic vein drain directly to the vena cava or left renal vein, usually separately [37]. This may be associated with hepatoblastoma or nodular hyperplasia of the liver (often simulating a neoplasm), cardiac anomalies, and biliary atresia. The ductus venosus rarely remains patent after infancy and is associated with hypoplasia of the intrahepatic PV branches, nodular hyperplasia of the liver, atrial septal defect, and hyperammonemia [38].

Atresia of the PV may be a congenital malformation often associated with other vascular anomalies or a response to neonatal injury such as omphalitis or PV thrombosis [39]. When PV thrombosis occurs in the neonatal period the vein does not grow so that in adulthood it appears as a thin fibrous cord (hypoplasia or agenesis). A thrombosed PV may develop numerous irregular intraluminal channels in addition to a leash of collaterals in the porta, giving a radiologic appearance called cavernous transformation of the PV.

Hepatic veins

There are three main hepatic veins. The middle and left veins unite before entering the vena cava in 65–85% of individuals [7,40]. In 18%, there are two right hepatic veins draining into the vena cava [21]. In another 23%, there is a separate middle or inferior right hepatic vein draining segments V or VI, respectively. The veins have variable branching patterns. There are axial veins with four to six orders of dichotomous branching at acute angles, as well as numerous much smaller branches nearly at right angles (Fig. 5.7).

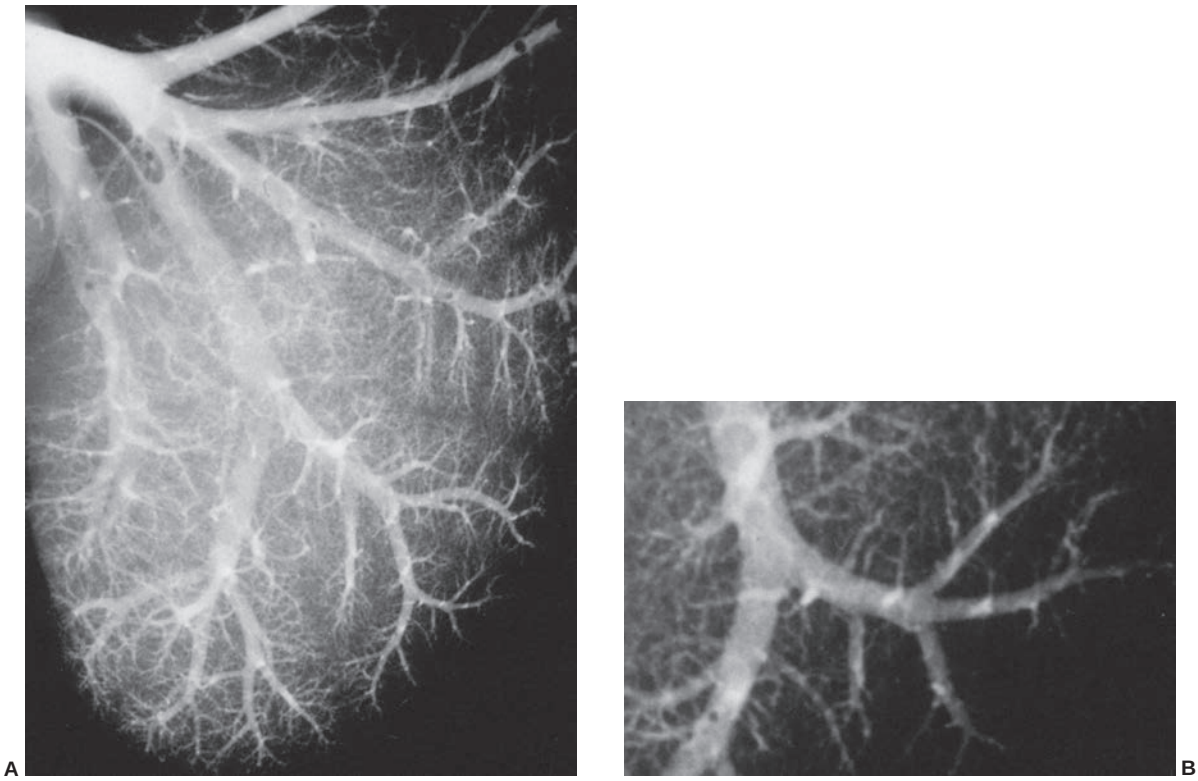

Figure 5.7 Hepatic veins shown on a postmortem angiogram. The major rami branch dichotomously and receive smaller branches nearly at right angles (see magnified portion on right).

The caudate lobe and adjacent parenchyma are usually drained by one or two small veins directly into the vena cava caudal to the main hepatic veins. When thrombosis of the main hepatic veins occurs, the veins of the caudate lobe are often spared, allowing survival and compensatory hyperplasia of this lobe [41]. Anastomoses between branches of the hepatic veins are uncommon in normal liver [42] but may be more frequent in the presence of diseases with portal hypertension [43]. Anastomoses of veins to other lobes become enlarged and may be mistaken for the original hepatic veins on Doppler interrogation. Partial recanalization occurs, often leaving webs in the hepatic veins or vena cava. These webs were formerly thought to be congenital, although now most are considered to be acquired [44,45].

Hepatic arteries

The common HA is the second major branch of the celiac axis [46]. It courses to the right along the upper border of the pancreas in the right gastropancreatic fold, which conducts the artery to the medial border of the hepatoduodenal part of the lesser omentum. It ascends in front of the PV in 91% of humans and to the left of and behind the bile duct in 64% of cases. It gives off the left and the right HAs to supply the corresponding hemilivers, The right and left HAs each divide into two arteries that supply the right anterior and posterior sections and the left medial and lateral sections, respectively. The middle HA arises from the left or right HA and supplies the quadrate lobe.

The cystic artery arises from the right HA in the upper part of Calot's triangle (formed by the cystic duct, common hepatic duct, and inferior surface of liver). The cystic artery divides into a superficial branch that is distributed to the peritoneal surface of the gallbladder and a deep branch that supplies the attached wall of the gallbladder and adjacent liver. In 75% of cases, the artery is single, and in 25%, there are two arteries with separate origins of the deep and superficial branches.

Anomalies of the HA are frequent, occurring in half of individuals [47]. Angiographic studies of the HA have demonstrated that the course of the arterial branches in the hilum deviates markedly from those of the PV, and in some cases the arteries may even cross the segmental fissures [48]. However, the more distal arterial branches follow the PVs closely, "climbing along them like a vine on a tree" [49].

Anomalies of the HA have gained new importance because of the advent of transplantation, aggressive resections, and intra-arterial chemotherapy. The most important anomaly is a right HA arising from the superior mesenteric artery to supply the entire right liver (14%) [50]. As this vessel may appear in Calot's triangle it is at risk during cholecystectomy. The left HA arises from the left gastric artery in 14–25% of people [46,50,51]. This vessel enters the liver at the left end of the hilum and may fail to be ligated during resections, leading to hemorrhage. Each of the aberrant arteries may be the only HA so that their injury can damage the liver severely. The PV and HA to segment IV may cross to the left of the umbilical fissure before turning medial and thus may be injured during left lateral segmentectomy. Ducts or small vessels cross this fissure in 20% [14].

There are extensive communications between the ultimate and penultimate branches of the right, the middle, and the left HAs in the umbilical fossa and in the region around the caudate lobe. The HA is provided with collateral flow through its anastomoses with arteries arising from the celiac axis and superior mesenteric artery. Anastomoses between the left and right HAs may occur. The main collaterals of the common HA are the right and left gastrics, right and left gastroepiploics, gastroduodenal, supraduodenal, retroduodenal, superior and inferior pancreaticoduodenals, aberrant HAs, and inferior phrenic arteries [52].

If ligation of an artery is necessary for the control of hemorrhage, ligation of the left or right artery is safe. Ligation of the HA proximal to potential collaterals such as the right gastric artery or gastroduodenal artery is better than ligation of the proper HA. After ligation of an HA, anastomotic channels enlarge and reestablish flow within a day [53].

Hepatic collateral circulation

Portal hypertension leads to the development of intra- and extrahepatic venous collaterals (Fig. 5.8) [54,55]. Extrahepatic collaterals are important, because when dilated to form varices, they are susceptible to rupture and massive bleeding. Varices in the submucosa of the gastrointestinal tract are most often a problem, especially in the esophagus and stomach but also in the rectum and duodenum and at ostomy sites.

Dilated umbilical or paraumbilical veins are found in 11% of patients with cirrhosis (veins of Sappey) [56]. They may cause a venous hum and caput medusa at the umbilicus (Cruveilhier–Baumgarten syndrome). Their presence implies high pressure in the left PV and therefore intrahepatic vascular obstruction. The direction of flow in lower abdominal wall collaterals is caudad if the inferior vena cava is obstructed, as in some patients with Budd–Chiari syndrome.

Varices may be found at sites where the gastrointestinal tract or pancreas becomes retroperitoneal or adherent to the abdominal wall because of pathologic processes. These "veins of Retzius" establish connections between the portal bed and the ascending lumbar azygos and renal and adrenal veins.

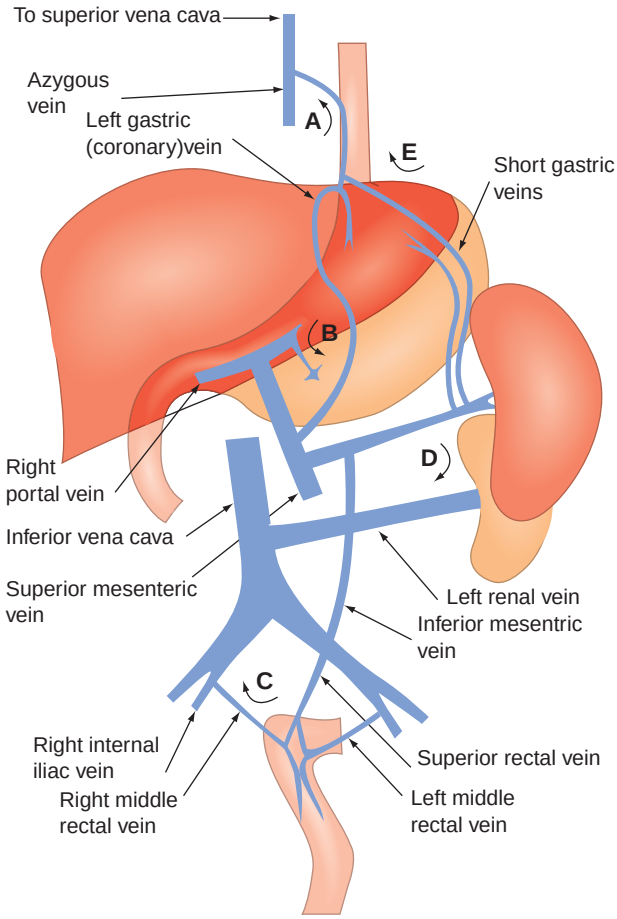

Figure 5.8 Diagram of the portal circulation. The most important sites for the potential development of portosystemic collaterals are shown. (A) Esophageal submucosal veins, supplied by the left gastric vein and draining into the superior vena cava via the azygous vein. (B) Paraumbilical veins, supplied by the umbilical portion of the left portal vein and draining into abdominal wall veins near the umbilicus. These veins may form a *caput medusa* at the umbilicus. (C) Rectal submucosal veins, supplied by the inferior mesenteric vein via the superior rectal vein and draining into the internal iliac veins via the middle rectal veins. (D) Splenorenal shunts, created spontaneously or surgically. (E) Short gastric veins communicate with the esophageal plexus. (Reproduced from Wanless [206] with permission from Elsevier.)

Within cirrhotic parenchyma, shunts are formed by anastomoses between smaller branches of the portal and hepatic veins, as discussed later [57]. These shunts allow blood to by-pass the sinusoidal exchange surface, leading to functional impairment. This effect is made worse by the creation of large shunts. In addition, any procedure that decreases portal flow to the sinusoids increases the likelihood of thrombosis, further increasing intrahepatic resistance. Titration of these benefits and liabilities is an important feature of surgical management. Large spontaneous shunts may be beneficial in lowering portal pressure and should not be disturbed without due consideration.

Portosystemic shunting appears to be responsible for reduced peripheral vascular resistance, possibly through the enhanced release of nitric oxide [58]. Dilated vascular channels in the lungs lead to intrapulmonary shunting with hypoxemia and increased cardiac output.

Lymphatics

Lymphatic channels are divided into deep and superficial networks [42,59,60]. The former run parallel to the branches of the portal vessels and hepatic veins, and the latter are found in the capsule. There are numerous anastomoses between these networks through small branches percolating through the capsule. The superficial lymphatics from the convexity form a dense network that coalesces into 14 groups of lymphatic trunks that drain through the coronary and falciform ligaments, through the diaphragm, and into the esophageal and xiphosternal nodes. From the undersurface of the liver, they drain into hepatic hilar nodes. The deep lymphatics following the portal tracts reach the hepatic nodes at the left side of the porta hepatis, and the lymphatics along the hepatic veins drain to lymph nodes near the vena cava. The portal lymphatic trunks drain 80% of the hepatic lymph.

Lymphatics can be identified by positive endothelial staining with antibodies to podiplanin (D2-40), Prox-1, and LYVE-1 [60]. Basement membranes, pericytes, and smooth muscle cells are scanty or absent [61]. The larger lymphatic vessels and trunks have valves; the walls contain smooth muscle cells.

The formation of lymph is discussed in the microanatomy section.

Nerves

The liver has a rich sympathetic and parasympathetic innervation [62]. Fibers derive from lower thoracic ganglia, the celiac plexus, the vagi, and the right phrenic nerve to form the plexuses about the HA, PV, and bile duct. The majority of fibers are organized into the anterior and posterior trunks, which enter the liver at the hilum. A few fibers enter at the hepatic veins and ligaments. The arteries are innervated mainly by sympathetic fibers. The bile ducts are innervated by both sympathetic and parasympathetic fibers. Unmyelinated sympathetic fibers send branches to individual hepatocytes in zone 1. Nerve discharges are propagated from one hepatocyte to another through gap junctions [63].

Most hepatic nerve fibers are aminergic or peptidergic, with a few cholinergic fibers; while intra-acinar cholinergic fibers have been found to occur in the guinea pig. Immunohistochemical studies have demonstrated many

other substances in some hepatic nerve fibers, including vasoactive intestinal peptide, neuropeptide Y, glucagon, somatostatin, neurotensin, and calcitonin gene-related peptide. The effects of nerve stimulation are partially mediated by prostaglandins synthesized in nonparenchymal cells of the liver. There may be local baroreceptors capable of detecting sinusoidal hypertension and leading to reflex renal artery vasoconstriction [64,65]. Afferent nerves may be responsible for pain when the liver is distended.

Stimulation of the nerve bundles around the HA and PV results mainly in a sympathetic discharge that alters metabolism and hemodynamics of the liver [66]. Glucose and lactate output are increased. Ketone and urea production, ammonia uptake, oxygen consumption, arterial and portal blood flow, and bile flow are reduced. Sympathetic nerve stimulation may exacerbate the effect of toxins [67]. Parasympathetic stimulation is thought to increase glycogen synthesis and reduce glucose release. Hepatic parasympathetic activity has an important effect on skeletal muscle insulin resistance [68]. Nerve action is modified by prevailing levels of hormones, especially insulin and glucagon.

Denervation experiments have demonstrated depletion of hepatic norepinephrine, altered blood flow response to stress, a decrease in cholesterol and phospholipid output, a decrease in progenitor cell number and function, altered glycemic control and feeding behavior, and sodium retention [69,70]. The clinical importance of nerve function is uncertain. After transplantation, the denervated state of the liver persists [71], although functional abnormalities appear to be minor [69]. These include increased liver blood flow, decreased postprandial PV flow, a decrease in hepatic progenitor cells, insulin resistance with postprandial hyperglycemia, hyperphagia, and loss of hepatic pain response.

Biliary system

The biliary system includes the bile canaliculi, intrahepatic and extrahepatic bile ducts, peribiliary glands, gallbladder, and ampulla of Vater [28]. The intrahepatic ducts begin at the bifurcation of the common hepatic duct.

Large ducts and gallbladder

The nomenclature of the large intrahepatic ducts will vary with the system used for naming the hepatic subunits (see above). Each hepatic segment has a bile duct that drains into a sectoral duct that drains into the right or left hepatic duct, which drains the right or left hemilivers, respectively. Caudate lobe drainage is variable, with ducts usually entering both the right and left ducts. The junctions of the segmental, hepatic, and common hepatic ducts are also highly variable [72]. The right and left hepatic ducts join to form the common hepatic duct at the right end of the portal fissure. The common hepatic duct is 1–5 cm long (mean, 2 cm), is 0.4–1.3 cm in diameter (mean, 0.66 cm), and is situated to the right of the hepatic artery and in front of the PV [73]. It is joined by the cystic duct at its right side to form the common bile duct (ductus choledochus) that runs another 5–8 cm to the ampulla of Vater. The supraduodenal part of the common bile duct lies in the right border of the lesser omentum. The pancreatic part of the common bile duct passes retroperitoneally behind the first portion of the duodenum. It then runs in a groove on the posterior surface of the head of the pancreas, anterior to the inferior vena cava. At the left side of the duodenum, it is joined in 70–85% of cases by the pancreatic duct (of Wirsung) and forms a common channel of variable length [74]. When a dilatation is present, it is called the ampulla of Vater [75]. The common channel resides within an elevation of the duodenal mucosa called the major papilla (of Vater).

The sphincter of Oddi consists of circular muscle fibers that surround the common bile duct in its course through the duodenal wall [76]. Circular muscle fibers are also present around the end of the pancreatic duct and around the tip of papilla; longitudinal fibers are also present. The sphincter of Oddi is inhibited by cholecystokinin, assisting the expulsion of bile into the duodenum. An elongated common channel has been associated with congenital bile duct dilatation [77]. Bile reflux may occur after papillotomy or surgical anastomoses with the intestine, resulting in recurrent cholangitis.

The gallbladder is a receptacle that receives up to a liter of bile daily, concentrating it by sodium-coupled water transport, and expelling it on stimulation by cholecystokinin. The gallbladder is a pear-shaped sac with a volume of 30–70 mL, measuring 3 cm wide and 7–10 cm long. Its parts are designated as the fundus, body, and neck. It lies on the undersurface of the right liver lobe, with the fundus projecting beyond the inferior border of the liver where the lateral margin of the rectus crosses the costal margin. The body is directed upward and to the left. Posteriorly, the fundus and body are in close relation with the transverse colon and duodenum, respectively. Gallstones can perforate into these viscera. The neck of the gallbladder is curved anteriorly and, when enlarged, forms the so-called Hartmann pouch. The mucosa of the neck forms a spiral valve of Heister that continues into the cystic duct. The spiral valve has the function of regulating bile flow into and out of the gallbladder. The cystic duct measures 4–65 mm in length (mean, 30 mm) and 4 mm in average diameter [78].

The arterial supply of the bile ducts comes mainly from many branches of the common HA, especially the retroduodenal artery and the right HA [46,79]. The gallbladder

may be supplied by one, two, or three arteries. The cystic artery usually arises from the right HA. The veins of the gallbladder are variable, draining into the liver at the gallbladder bed or into veins from the common bile duct but eventually draining into branches of either the left and/or right PV [7]. The lymph vessels of the gallbladder, hepatic ducts, and upper parts of the common bile duct empty into lymph nodes of the hilum. Those of the lower common bile duct drain into nodes near the head of the pancreas.

Nerve fibers supplying the extrahepatic ducts and gallbladder derive mainly from the sympathetic hepatic plexus laced around the hepatic artery. These also receive filaments from the right and left vagus nerves. Some nerve fibers deriving from the plexus can be seen running along the common bile duct. Sparse ganglion cells are present in the muscularis and the mucosa of the gallbladder. Nervous connection with the spinal system is brought about by fibers from the right phrenic and musculophrenic nerves. Because these nerves derive from the third or fourth cervical nerve, the anatomic basis for shoulder pain in gallbladder disease is evident. Vagal stimulation causes gallbladder contraction [80].

Histology of the bile ducts and gallbladder has been reviewed by Frierson [81] and Nakanuma et al. [28]. The walls of the extrahepatic ducts are formed by fibrous tissue with elastic fibers; smooth muscle is scanty or absent [82], except at the lower end of the common duct where muscle rings are conspicuous. The gallbladder wall contains abundant smooth muscle and little fibrous tissue. Rokitansky–Aschoff sinuses are outpouchings of the gallbladder mucosa through defects of the muscularis and are found in almost all gallbladders having calculi. The ducts of Luschka are small ducts in the areolar tissues of the hepatic surface of the gallbladder. These ducts communicate with intrahepatic bile ducts, but not usually with the gallbladder cavity, and may leak hepatic bile after cholecystectomy.

The mucosa has numerous papillary folds in the gallbladder, distal pancreatic duct, distal common bile duct, and ampulla. The mucosa of the bile ducts and gallbladder consist of a single layer of columnar epithelium and a lamina propria. A few goblet cells are present, especially in the ampulla. Somatostatin-containing cells may be present in the ampulla, a possible source for the development of somatostatinomas arising at this site.

Mucus-secreting accessory glands (peribiliary glands) are in the lamina propria of the gallbladder neck and extrahepatic bile ducts and adjacent to the large intrahepatic ducts [83].

Intrahepatic ducts

The intrahepatic ducts have been defined as ductules (less than 0.02 mm), interlobular ducts (0.02–0.1 mm), septal ducts (0.1–0.4 mm), and large ducts (more than 0.4 mm) [28]. These measurements are approximate, as the definition is also dependent on relation to the segmental boundaries and on histologic pattern.

The large and septal bile ducts have a well-demarcated dense fibrous wall and high columnar epithelium with basal nuclei and small mucin droplets. These ducts express blood group antigens. Interlobular ducts are located near the center of portal tracts and have minimal or no fibrous investment, and the epithelium is low columnar or cuboidal and lacks mucin. There is a periodic acid–Schiff (PAS)-positive basement membrane. Ductules are located near the limiting plate and have cuboidal epithelial cells. The presence of a few ductules may be considered normal, but large numbers are a feature of cholestatic or regenerating liver. Throughout the biliary tree, each duct is usually accompanied by an artery of similar diameter, a helpful guide when evaluating the absence of ducts.

The peribiliary glands accompanying large intrahepatic and septal ducts may be located within the walls (intramural) or form clusters outside the fibrous wall (extramural). Intramural glands are mucin rich, and extramural glands may be mucinous or serous, rarely with focal pancreatic acinar differentiation. Peribiliary glands are hypertrophied in patients with clonorchis infestation and may be the origin of some cholangiocarcinomas arising in that disease [84]. These glands may form retention cysts at the hilum in cirrhosis, portal vein obstruction, and polycystic kidney disease [85], rarely causing obstructive jaundice [86].

Intrahepatic bile ducts are the site of injury in many diseases, resulting in duct destruction, secondary cholestasis, and eventually cirrhosis in severe cases. In primary biliary cirrhosis, ducts up to 0.3 mm in diameter are destroyed by an immune process. In primary sclerosing cholangitis, the most severely involved ducts are extrahepatic and large intrahepatic ducts with less severe duct destruction in the smaller branches. Ducts less than 0.1 mm are the focus in chronic allograft rejection, graft-versus-host disease, Alagille syndrome, and reactions to a variety of drugs and toxins. Neonatal biliary atresia, polycystic liver disease, and several other syndromes may be a result of a variety of insults to the developing ducts at the ductal plate stage [87].

The peribiliary vascular plexus is hypertrophied in livers with cirrhosis or with PV obstruction and is especially prominent in congenital hepatic fibrosis, where it may fill on portal venogram and appear to form a duplication of the portal tree [86].

Variations and surgical implications

A portion of the right liver may drain into the left duct system in 6% of cases [7]. In 25%, a branch of the right

duct drains into the left duct [88]. The common hepatic duct may receive accessory hepatic ducts. If the common hepatic duct is absent, the right and left hepatic ducts may run separately and join close to the duodenum; the right duct receives the cystic duct. Other variations include a main duct draining into the gallbladder, the cystic duct draining into the right hepatic duct, and the right hepatic duct draining into the cystic duct [7,72,89,90]. The cystic duct usually enters the bile duct at an angle but may run parallel or curve behind the duct in a spiral fashion. The relations of the large ducts and vessels near the hilum are variable, but the peripheral branches of these structures run together within portal tracts.

Because ducts depend on arterial supply, ischemic necrosis, with or without stricture, may occur in the large bile ducts after transplantation, especially if the hepatic artery is compromised. Duct strictures, rupture, and infarction of the gallbladder have also been found after hepatic arterial injection of alcohol or chemotherapeutic agents, possibly because of injury to the peribiliary vascular plexus [28].

Numerous conditions are characterized by congenital or acquired anomalies of the duct system. Aberrant biliary ducts, the vasa aberrantia, form anastomoses between the gallbladder and small ducts in the adjacent liver. These ducts are liable to leak bile after cholecystectomy. Accessory mucus-secreting periductal glands are located all along the duct system. These may develop retention cysts that, rarely, encroach on the duct lumen to produce obstructive jaundice [86]. Congenital dilatation of the intrahepatic and/or extrahepatic ducts, known as choledochal cysts, is a rare cause of cholangitis or obstructive jaundice, usually presenting in childhood (see Chapter 42). Caroli disease is a subset of this condition, with dominant dilatation of the intrahepatic ducts. Congenital fibrocystic disease occurs in a variety of anatomic patterns, often with coexistent renal disease. Von Meyenburg complexes, clusters of dilated ducts within the portal tracts, are markers for adult polycystic kidney disease and polycystic liver disease [91]. Biliary atresia, the absence or obliteration of the extrahepatic bile ducts, is one of the most common causes of cirrhosis in childhood.

Anomalies of the gallbladder have been reviewed [92]. Absent gallbladder and double gallbladder are rare (0.05% and 0.02%, respectively). Duplication may be accompanied by two separate cystic ducts. Agenesis is associated with other congenital defects of the intestines or bones. Bilobed, hourglass-constricted gallbladders and those with a folded fundus (phrygian cap), persistent septum, or diverticulum favor retention and inflammation. The gallbladder can be completely buried in liver substance (intrahepatic gallbladder) or attached loosely to it by a mesentery (floating gallbladder). An ectopic gallbladder may be found attached to the left hepatic duct. Ectopic gastric mucosa within the gallbladder predisposes to perforation or hemorrhage.

Microanatomy

Normal human histology

When viewed histologically, the normal liver displays a uniform arrangement of portal tracts separated by parenchyma composed of hepatocellular plates and sinusoids. Terminal hepatic venules are located equidistant from portal tracts. The portal tracts contain arteries, ducts, nerves, and PVs in a connective tissue stroma (Fig. 5.9). Stroma within the portal tracts normally contains a small number of macrophages, plasma cells, and lymphocytes.

Although often called portal triads, the number of each of these elements varies with the size of the tract. In a study of needle biopsies, the average number of profiles per portal tract was 2.3 ducts, 2.6 arteries, and 0.7 veins [93]. The average minimum diameters were 13 μm for ducts, 12 μm for arteries, and 35 μm for PVs. In normal infants, the number of ducts per portal tract is less than in adults. The average number of portal tracts in adults was 19 per biopsy, with a mean biopsy length of 1.8 cm, although the interpretation of liver biopsies requires an assessment of sampling error. Biopsies obtained by the transjugular route were half this size, and in fibrotic

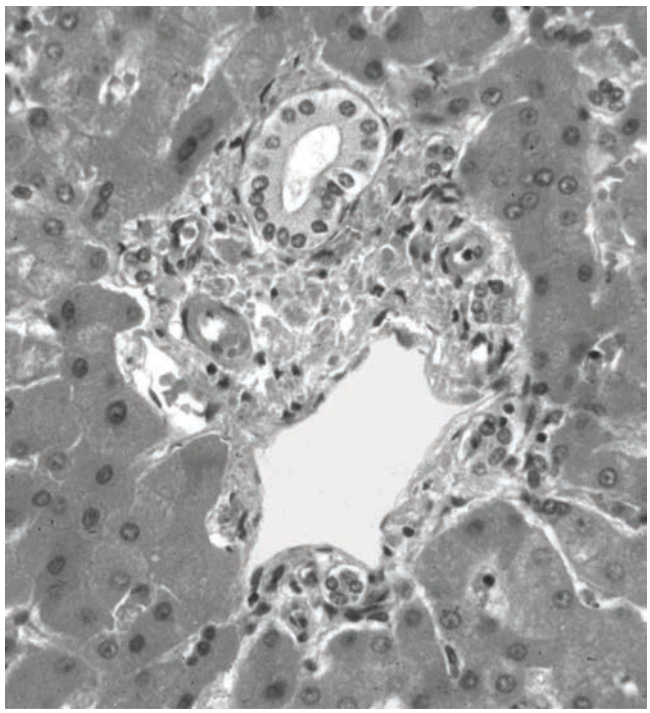

Figure 5.9 Normal portal tract from a human liver, showing several small ducts, two arteries, a portal vein, and occasional lymphocytes. Hematoxylin and eosin (H&E).

conditions the number of portal tracts available was often less than half a dozen.

Hepatocytes

Hepatocytes comprise 65% of the cells in the liver and 80% of hepatic volume. Hepatocytes are polyhedral with a central spherical nucleus. They are arranged in plates one cell in thickness, with blood-filled sinusoids on each side of the plates (Fig. 5.10) [94]. The cytoplasmic membrane has specialized domains providing a canalicular region on the lateral walls and numerous microvilli on the sinusoidal (basolateral) surfaces. The canalicular domains of adjacent hepatocytes are bound together by tight junctions to form bile canaliculi that coalesce and ultimately drain into ducts within portal tracts. Hepatocytes are also attached by gap junctions that have a role in transmission of nerve impulses from zone 1 to zone 3. Normal and abnormal ultrastructure of hepatocytes has been reviewed elsewhere [95,96].

Hepatocytes can be identified by evidence of albumin or α-fetoprotein synthesis using molecular techniques. It is more convenient to use immunohistochemical techniques. HepPar1 (carbamoyl phosphate synthetase), arginase-1, and CK18 stain the cytoplasm of all hepatocytes [97,98]. Glutamine synthetase stains the cytoplasm of hepatocytes near the terminal hepatic venules and regenerating hepatocytes [99,100]. Polyclonal carcinoembryonic antigen (CEA) and CD10 stain bile canaliculi. Alpha-fetoprotein, glypican-3, HSP70, and p28/gankyrin are often expressed in malignant hepatocytes [97,101,102].

Endothelial cells and sinusoids

The length of a human sinusoid varies between 223 and 477 μm. The diameter of the sinusoids can vary from 6 to 30 μm and can increase to 180 μm when necessary. Zone 1 sinusoids are smaller than those in zone 3 [103]. Caliber depends on active contraction of endothelial cells and stellate cells as well as passive distension [104]. Leukocytes are large compared with sinusoidal diameter, so that blood flow compresses the sinusoidal wall, promoting exchange between plasma, subendothelial fluid, and hepatocytes [103].

The sinusoidal surface is covered with a layer of endothelial cells to enclose the extravascular space of Disse (Fig. 5.10). Hepatic sinusoids differ from systemic capillaries in that the endothelial cells are fenestrated, subendothelial basement membrane material is scanty, Weibel–Palade bodies are absent in most species, and intercellular junctions are absent, permitting passage of large macromolecules including lipoproteins but not chylomicrons [94,105]. Fenestrations are grouped into clusters called sieve plates. The mean fenestration diameter in the rat is 150–175 nm, occupying 6–8% of the endothelial surface area [105]. The fenestrations can change in size in response to various stimuli, including pressure, neural impulses, endotoxins, alcohol, serotonin, and nicotine [106]. They are large in zone 1 and smaller and more numerous in zone 3. Agents that disrupt actin filaments can almost double the number of fenestrations within minutes [106]. The permeability of fenestrations has been studied with marker particles. In the rat, liposomes 400 nm in diameter are readily engulfed by hepatocytes. The ability to traverse fenestrations may depend on deformability or surface charge of the particles [107].

Sinusoidal endothelial cells also differ from continuous endothelial cells in their immunohistochemical phenotypes. Factor VIII-related antigen, *Ulex europaeus* agglutinin I binding, PECAM-1, CD34, and 1F10 are features of continuous endothelial cells but not sinusoidal endothelial cells [108]. Sinusoidal endothelial cells express low affinity Fc γ-receptors (CD32, FcR), lipopolysaccharide-binding protein complex receptors (CD14), thrombospondin receptors (CD36), class II histocompatability receptors (CD4), and ICAM-1, stabilin-1, and stabilin-2 [109–111]. Stabilin-1 and stabilin-2 have roles in endocytosis of proteins by sinusoidal endothelial cells [112].

During embryogenesis, transition from a continuous to fenestrated phenotype occurs between 5 and 20 weeks' gestation [109]. The fenestrated phenotype partially reverts to the continuous endothelial phenotype in chronic hepatitis, cirrhosis, and hepatocellular carcinoma [110], including the expression of CD34, PECAM-1, and laminin receptors α6β1 and α2β1 [108,113]. Stabilin-2 expression is lost when the sinusoidal endothelium acquires CD34 expression [111]. These phenotypic changes may be an indication of arterialization of the sinusoids that occurs during the development of severe cirrhosis. Morphologically, cirrhosis may be accompanied by widening of the space of Disse, subendothelial deposition of collagen and basement membrane material, defenestration, and effacement of hepatocellular microvilli. These changes, often called "capillarization of sinusoids" [114] likely reduce transport across the sinusoidal walls and explain some of the hepatocellular dysfunction seen in cirrhosis.

Nitric oxide produced by hepatocytes, Kupffer cells, and sinusoidal and arterial endothelial cells may cause increased sinusoidal blood flow, thereby protecting the liver during various injuries [115–117]. Increased blood flow may be beneficial by preventing adhesion of leukocytes and platelets that might otherwise injure the endothelium [118]. Nitric oxide production may have a role in the hepatopulmonary syndrome [119] and hepatorenal syndrome [120]. Endothelin-1 is produced by activated stellate cells and causes these cells to contract [121]. Circulating endothelin-1 may have a role in the hepatorenal syndrome [120].

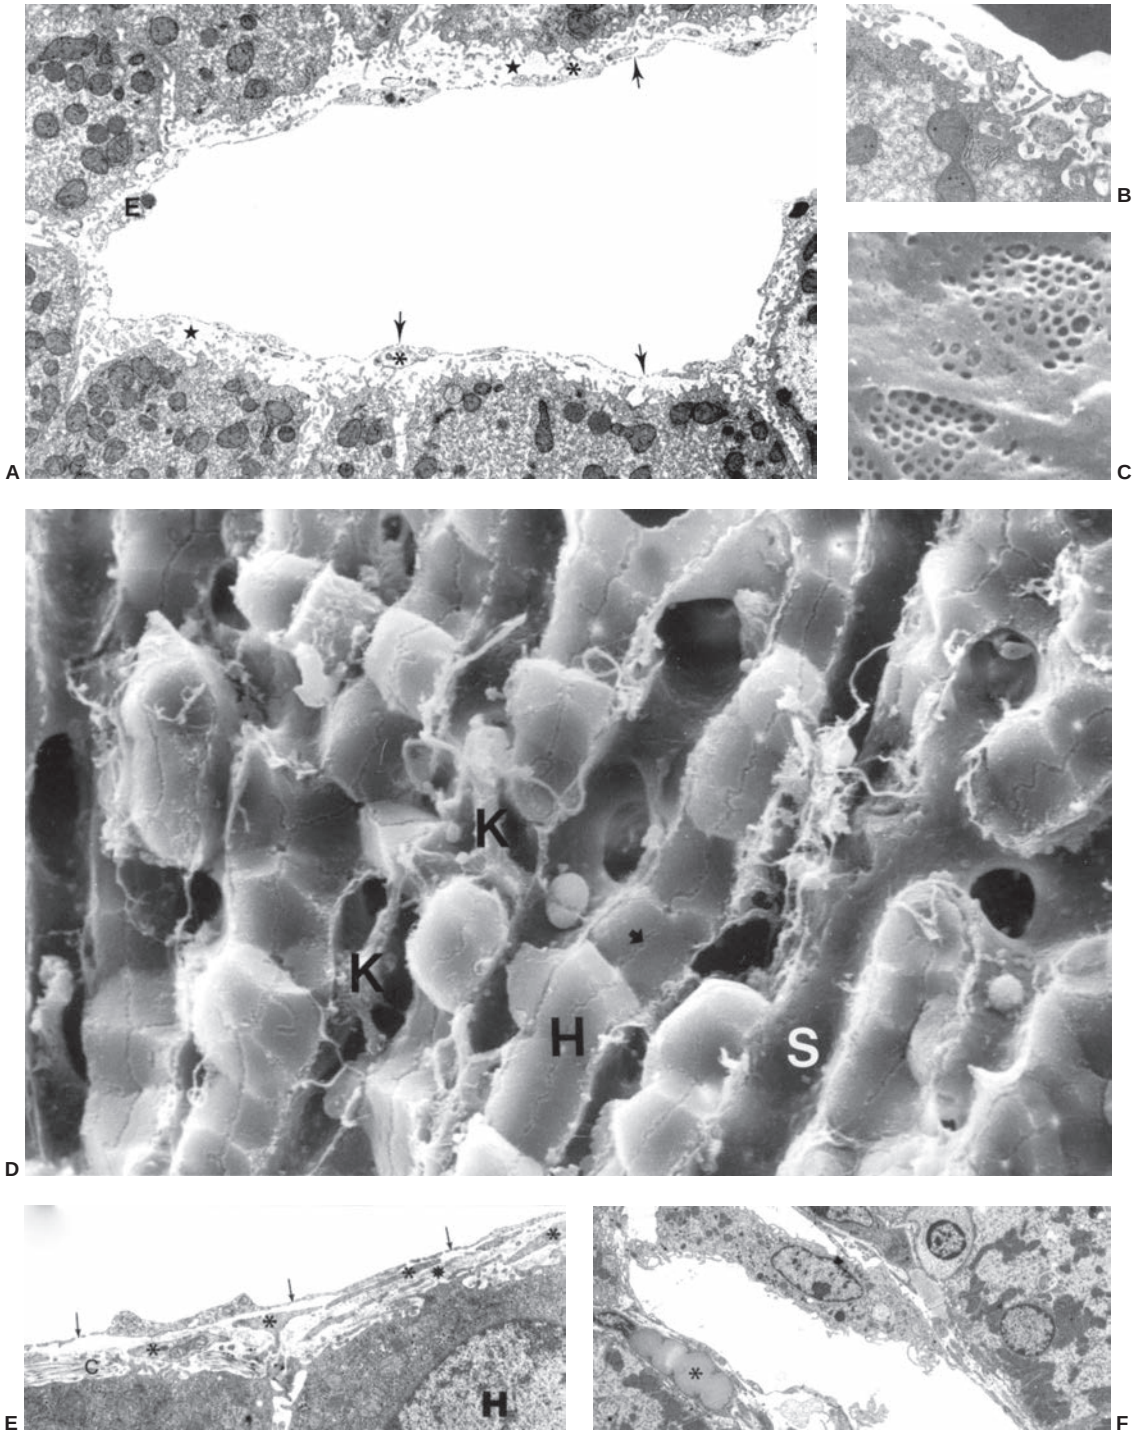

Figure 5.10 Ultrastructure of sinusoids. (A) Sinusoid showing endothelium (E) covering the subendothelial space of Disse (stars). This space contains stellate cell processes (asterisks) and hepatocellular microvilli. Note that the microvilli extend into recesses between hepatocytes. The endothelial cells are fenestrated (arrows). Transmission electron micrograph (TEM), original ×4,840. (B) Closer view showing endothelial fenestrations and microvilli of a hepatocyte. TEM, original ×10,000. (C) Endothelial fenestrations are clustered into sieve plates. Scanning electron micrograph (SEM), original ×29,400. (D) Hepatocellular plates are one cell in width with bile canaliculi (short black arrow) visible on the fractured edges of the plates. Hepatocytes (H), sinusoids (S), and Kupffer cells (K) are seen. Collagen fibers have been pulled from the spaces of Disse. SEM, original ×2,000. (E) The space of Disse (eight-pointed star) contains several stellate cell processes (asterisks) and collagen bundles (C). Endothelial fenestrations are labeled (arrows). H, hepatocyte nucleus. TEM, original ×6,000. (F) Sinusoid with a Kupffer cell in the lumen and a stellate cell containing lipid (asterisk) in the space of Disse. TEM, original ×2,000. (A, B, courtesy of Dr P. Bioulac-Sage. C, from Bioulac-Sage et al. [94] with permission from Springer-Verlag.)

Endothelial cell injury is important in endotoxemia, hypotensive shock, and cold perfusion of donor livers [122,123]. Donor livers may develop rounding-up and detachment of endothelial cells that may be responsible for some instances of primary nonfunction after transplantation [124,125].

It has been suggested that thickening of the space of Disse may contribute to poor transport of materials to the hepatocellular surface [126], as well as possibly contributing to portal hypertension [127]. Amyloid fibril deposition may widen the space of Disse dramatically and cause severe atrophy of subjacent hepatocytes. With severe amyloidosis, hepatomegaly, cholestasis, and noncirrhotic portal hypertension have been reported [128]. Cellular infiltration within the lumina of sinusoids occurs in Gaucher disease, mastocytosis, leukemias, and myeloproliferative disorders, but such infiltration does not correlate with clinical evidence of portal hypertension [129]. Obstruction of small veins is more likely to cause portal hypertension in these diseases, because sinusoids are distensible and able to regenerate [39].

Formation of lymph

Most hepatic lymph derives from the subendothelial space of Disse, and a minority, perhaps 10%, is formed by leakage from capillaries of the peribiliary plexus. The smallest recognizable lymph capillaries are found in the interstitial tissue in terminal portal tracts and adjacent to terminal hepatic venules (Fig. 5.11) [130]. The pathways that join these lymph capillaries to the space of Disse have been demonstrated [60]. It is believed that lymph percolates through the collagen and proteoglycan matrix located between the periportal hepatocytes and within the portal interstitium. Lymph could also flow in the matrix investing the portal inlet venules and arterioles that penetrate the limiting plate.

Because of the large endothelial fenestrations in sinusoidal (and presumably lymphatic) endothelial cells, there is little or no oncotic pressure gradient between plasma and subendothelial tissue fluid, and the protein content of hepatic lymph is approximately 80% that of plasma. With a very low oncotic pressure gradient, the main stimulus for the formation of lymph is sinusoidal pressure. A 1 mm rise in efferent pressure doubles hepatic lymph flow. The liver normally produces 1–3 L per day but this may increase to 11 L per day in cirrhosis or extrahepatic outflow obstruction [131]. Communications between small bile ducts and lymphatics may allow for the increased formation of lymph seen after biliary tract obstruction [132].

Biliary tree

The biliary tree begins with a network of bile canaliculi that empty into bile ducts via the canal of Hering (Fig. 5.12) [133]. The small bile ducts are supplied by

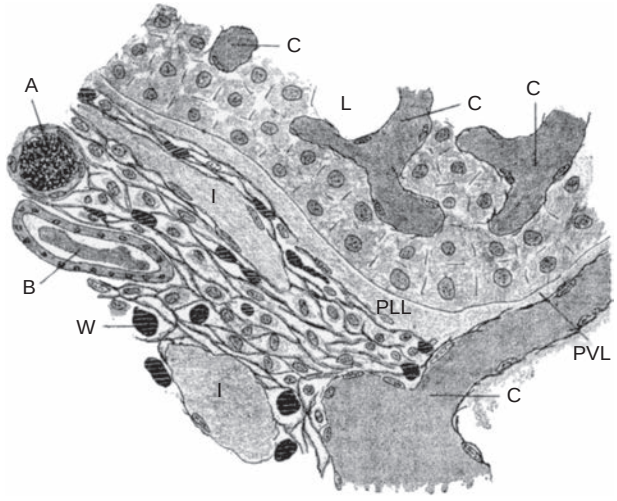

Figure 5.11 Mall's original drawing of portal and periportal tissue showing the space of Disse (perivascular lymph space, PVL), the space of Mall (perilobular lymph space, PLL), and a lymph vessel (l) after injection with gelatin. The space of Disse is continuous with the space of Mall. In life, the space of Mall may be a virtual space where lymph percolates among interstitial matrix fibers. Also shown are lobule (L), sinusoids (C), connective tissue fibers (W), bile duct (B), and artery (A). (Reproduced from Mall [130] with permission from Johns Hopkins University Press.)

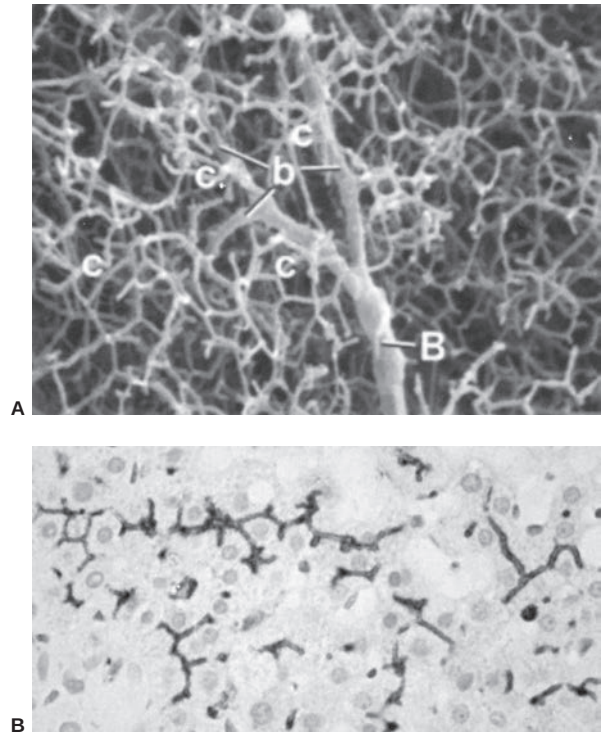

Figure 5.12 Bile canaliculi. (A) Scanning electron micrograph of a methacrylate injection cast of a rat biliary tree (×860). B, terminal twig of the bile duct; b, canal of Hering; c, bile canaliculi emptying into canals of Hering. (B) Photomicrograph of human liver stained for polyclonal carcinoembryonic antigen (CEA). CEA is present in the distribution of the bile canaliculi that could not be seen on H&E. A similar pattern may be seen with CD10 staining. (A, from Murakami et al. [208] with permission from Japanese Society of Histological Documentation.)

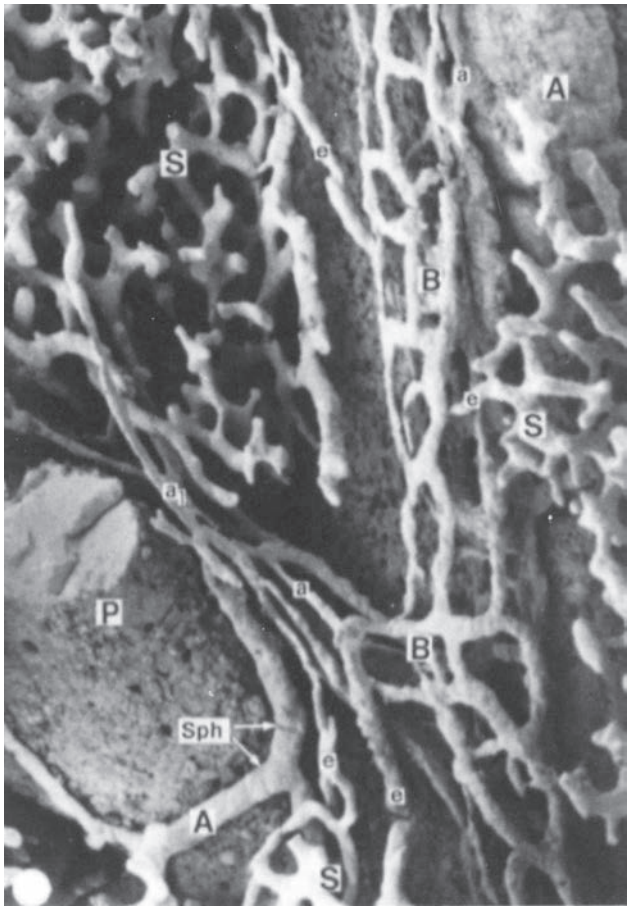

Figure 5.13 Scanning electron micrograph of cast blood vessels in the liver of a rhesus monkey. Peribiliary arterial plexus (B) receives blood from arterial branches (A) by means of afferent arterioles (a). The plexus supplies sinusoids (S) through efferent arterioles (e). Note the grooves indicating arteriolar sphincters (Sph). Arterioles (a_1) bypass the plexus and empty directly into sinusoids. P, portal vein. Methyl methacrylate cast, original ×135. (Courtesy of Dr T. Murakami, Okayama University.)

arteries (Fig. 5.13) [134]. Terminal branches of the hepatic artery supply a general capillary plexus within the portal tract, a peribiliary vascular plexus, and also empty directly into zone 1 sinusoids [135]. The general and peribiliary vascular plexuses eventually drain into sinusoids through capillary connections known as the "internal roots of the portal vein." The peribiliary vascular plexus has been divided into inner, intermediate, and outer layers. The inner layer has fenestrated endothelium, suggesting a role in water exchange. Similar fenestrated endothelium is found in the gallbladder mucosa.

Canaliculi have contractile and secretory properties. Canaliculi in isolated hepatocyte doublets have been shown to undergo rhythmic contraction thought to represent peristaltic activity in the intact liver [136]. These contractile functions are provided by a pericanalicular band of microfilaments composed of actin, myosin II, tropomyosin and α-actinin, and associated proteins, stabilized by a sheath of noncontractile intermediate filaments [137].

The cholangiocytes lining the small ducts transport water and solutes under hormonal control [138–140]. Peribiliary glands also participate in the concentration of bile. Chloride transport is dependent on the cystic fibrosis transmembrane conductance regulator (CFTR), explaining the decreased water content of bile, hepatolithiasis, and secondary biliary cirrhosis seen in some patients with cystic fibrosis. In polycystic liver disease there is a genetic abnormality in cholangiocytic cilia leading to disruption of fluid transport and cholangiocyte proliferation [141].

Stellate cells

The stellate cells (fat-storing cells or Ito cells) are located within the spaces of Disse. Their cytoplasmic droplets normally contain abundant vitamin A, mostly as retinoyl palmitate [142]. These cells can be identified by the presence of immunoreactivity for smooth muscle actin, transient autofluorescence, and histochemical affinity for gold and silver.

When activated by various cytokines, stellate cells are transformed into myofibroblast-like cells that have reduced vitamin A storage, increased content of myofilaments and α-smooth muscle actin, and increased expression of procollagen gene transcripts [143–145]. Stellate cells, in their activated state, are the principal hepatic fibroblasts. Evidence has been presented that many forms of hepatic injury activate hepatic macrophages and that these cells release cytokines capable of activating stellate cells. Stellate cells can also secrete matrix metalloproteinases that degrade matrix proteins. Activated stellate cells contract under stimulation by sympathetic discharge or endothelin-1 secretion. They also secrete angiogenic factors such as ang1 [146,147]. By these mechanisms, stellate cells could exacerbate portal hypertension.

Kupffer cells

Kupffer cells are the resident macrophages in the liver. They comprise more than 80% of tissue macrophages in the body and 15% of cells in the liver. Although capable of proliferation in situ, they are also recruited from the peripheral blood [148]. Kupffer cells reside in the sinusoids, with pseudopodia anchored to endothelial cells or occasionally hepatocytes. They may form part of the sinusoidal wall. Macrophages in the liver are important in host response to various injuries including that induced by toxins and infectious agents [149].

Liver-associated lymphocytes

A few lymphocytes are normally found in portal tracts and sinusoids, even after washout with saline. Portal

lymphocytes are 90% T cells with a CD4 : CD8 ratio of 1.6, whereas sinusoidal lymphocytes are 60% T cells with a CD4 : CD8 ratio of 0.4 and 30% natural killer (NK) cells (CD56+). Sinusoidal lymphocytes reside in the lumen adherent to Kupffer cells and endothelial cells [148]. Many sinusoidal lymphocytes are large, with cytoplasmic granules, and are also called pit cells because of the resemblance of the granules to grape seeds [150]. Pit cells are most numerous in zone 1 sinusoids. These cells are thought to have a role in killing tumor cells and virus-infected cells. The granules of pit cells contain perforin, a protein that injures cell membranes [150]. Traffic of lymphocytes and other leukocytes is largely controlled by chemokines elaborated during inflammatory reactions [151].

Stroma

Connective tissue stroma supports the capsule, the portal tracts from the hilum to periphery, and the sinusoidal walls. The composition of the stroma varies with location. Connective tissue of the capsule and portal tracts is mostly collagen type I and III and elastin. Reticulin fibers, defined by their histochemical affinity for silver, are largely composed of collagen type III and fibronectin [152]. They are located in the spaces of Disse, where they give tensile strength to the parenchyma. Type IV collagen forms a basal lamina around small vessels.

Many noncollagenous glycoproteins are in the matrix, including laminin, fibronectin, tenascin, entactin, vitronectin, undulin, osteonectin, and von Willebrand factor [153]. Laminin links basement membrane collagen to the integrins attached to endothelial cells and epithelial cells. Tenascin function is uncertain, but it is mitogenic for a variety of cell types. Vitronectin stimulates fibroblast migration. Von Willebrand factor is found within endothelial Weibel–Palade bodies and in basement membranes [153]. Proteoglycans bind to cells and matrix proteins and have roles in matrix–cell and cell–cell interaction.

In scarred livers, there is an absolute increase in many matrix proteins. The bulk of the scar tissue is type I collagen. After hepatocellular necrosis, the connective tissue framework is rapidly repopulated with hepatocytes in an orderly fashion. If regeneration is delayed, the deposition of collagen by stellate cells destroys the framework and prevents restitution to normal.

The stromal collagen is important to prevent tears in the blood vessels and sinusoidal walls. Focal rupture of reticulin leads to parenchymal hemorrhage and blood-filled cysts (peliosis hepatis) [154,155]. Mineral oil deposits are present in portal tracts and adjacent to hepatic venules in more than half of human livers and are usually accompanied by a slight mononuclear infiltrate [156].

Three-dimensional organization of the liver

The organization of the hepatic parenchyma has been conceptualized in two contrasting models: the acinus and the lobule [157–159]. Terminal PVs interdigitate with the terminal hepatic venules, with sinusoids bridging the gaps between these vessels. The terminal hepatic venules can be considered as being the center of a lobule or the periphery of several acini. The acinar approach is discussed in detail here.

The simple liver acinus is a small parenchymal mass, irregular in size and shape, arranged around an axis consisting of a terminal hepatic arteriole, portal venule, bile ductule, lymph vessels, and nerves that grow out together from a small portal field (Fig. 5.14). The simple liver acinus lies between two (or more) terminal hepatic venules with which its vascular and biliary axis interdigitate. In a 2D view, it occupies sectors of two adjacent hexagonal or pentagonal fields.

The plates and cords of the simple acini are in continuity with adjacent acini in three dimensions; there is no capsule separating the acini from one another. It can be assumed that the dividing line between the acini is the watershed of biliary drainage, so that each acinus empties its biliary secretion into the axial bile ductule.

A complex acinus is a clump of tissue composed of at least three simple acini whose axial channels branch in three dimensions from the preterminal stalk (Fig. 5.15). Each of its terminal branches forms the axis of a simple acinus. A sleeve of tissue composed of tiny clumps (acinuli) surrounds the preterminal channels. These acinuli are nourished by axial venules and arterioles branching off

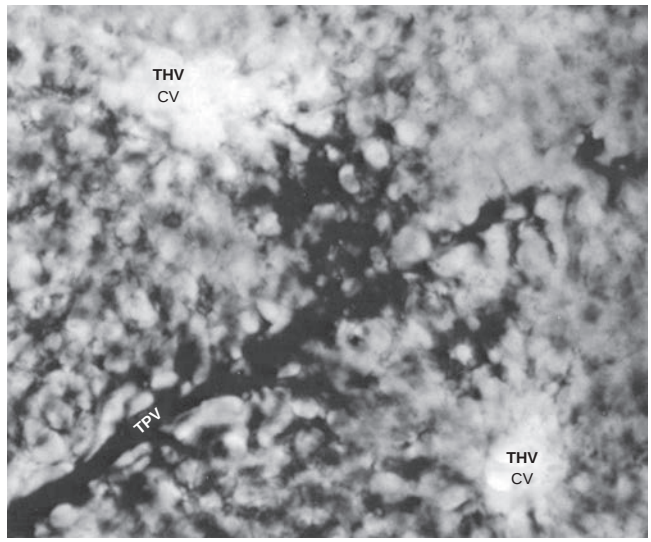

Figure 5.14 Liver acinus in a human. The acinus occupies sectors of only two adjacent hexagonal fields and reaches their central veins (CV). The terminal portal branch (TPV) is injected with India ink and runs perpendicular to the two terminal hepatic venules (THV) with which it interdigitates. Thick cleared section, original ×300.

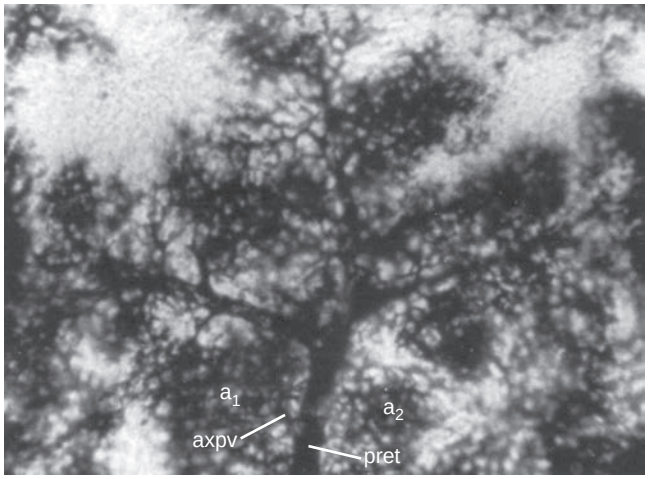

Figure 5.15 Complex acinus in a human. The sinusoids injected with India ink are supplied by three terminal portal branches and their parent preterminal vessel (pret). These portal venules help form the axial channels of a complex acinus cut longitudinally. The sleeve of parenchyma around the preterminal vessel is formed by acinuli (a_1, a_2). axpv, axial portal venule supplying the sinusoids of a_1. The poorly injected white areas (in the upper corners) are parts of zone 3 around the terminal hepatic venules, which are not shown. 150 μm thick cleared section, original ×88.

Figure 5.16 Group of acinar agglomerates in a human liver injected with India ink. Three large portal branches grow out in different directions from a portal space (PS). One of these runs diagonally through the field and represents the axis of an acinar agglomerate. From this portal branch, preterminal (1) and terminal (2) branches grow out and form the axes of complex and simple acini, respectively. 100 μm thick cleared section, original ×18.

the preterminal vessels. Structural and functional unity in a complex acinus can be demonstrated by injection of colored materials [160]. The axial vessels of the simple acini are always the same color as the parent vessels of the complex acinus. Three or four complex acini form larger clumps of tissue, the acinar agglomerates. Acini or acinuli also form a sleeve of parenchyma around the axial stem servicing the agglomerate.

The acinar agglomerate has unity because the main route of vascular supply and the biliary drainage are common to the whole clump as well as to its subdivisions. The hierarchy can be continued because several agglomerates are supplied by a single macroscopic portal tract. The PVs supplying agglomerates in the human liver are approximately 150 μm in diameter (Fig. 5.16) [160]. All branches of the hepatic vein interdigitate with HA and PV branches of similar order; this creates a hexagonal or pentagonal pattern when seen histologically in cross-section (Figs. 5.17 and 5.18).

The acinus is an ideal physiologic unit for the understanding of many vascular and biliary events in human biology (see discussion of cirrhosis below). The conceptual advantage of the acinus is that the blood supply of a portion of parenchyma and the bile duct draining that same parenchyma reside in the same portal triad. "Thus, structural, circulatory, and functional unity is established in this small clump of parenchyma" (Fig. 5.19) [161]. By contrast, the classic hexagonal lobule is supplied by several separate PV branches, arteries, and ducts, each of which also supplies other adjacent lobules [160].

McCuskey [162] notes that all the essential relationships are present within a smaller unit called hepatic microvascular subunits. The smallest useful unit is that in which there is a significant barrier to blood flow between adjacent units.

Recent studies show that PV blood is distributed by numerous small inlet venules, giving a portal supply that is more diffuse and less granular than that pictured by the original description of the acinus [157–159]. These analyses suggest that isobars of oxygen tension are

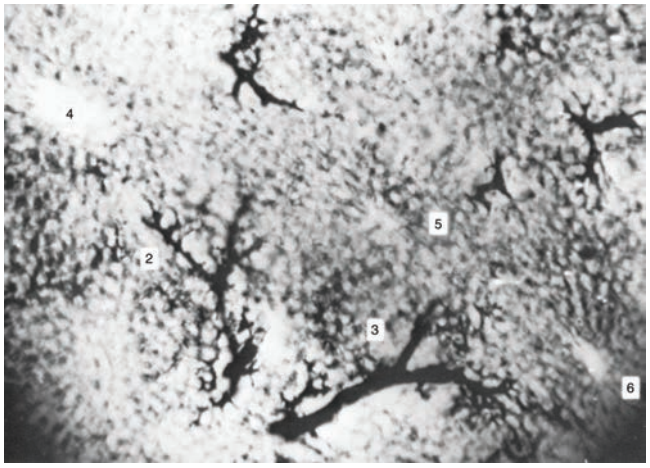

Figure 5.17 Interdigitation of portal and hepatic vein branches in a human liver injected with India ink. Two horizontal terminal portal branches (2, 3), forming the axes of acini, interdigitate with three vertical terminal hepatic venules (4, 5, 6), around which they arch. Thick cleared section, original ×110.

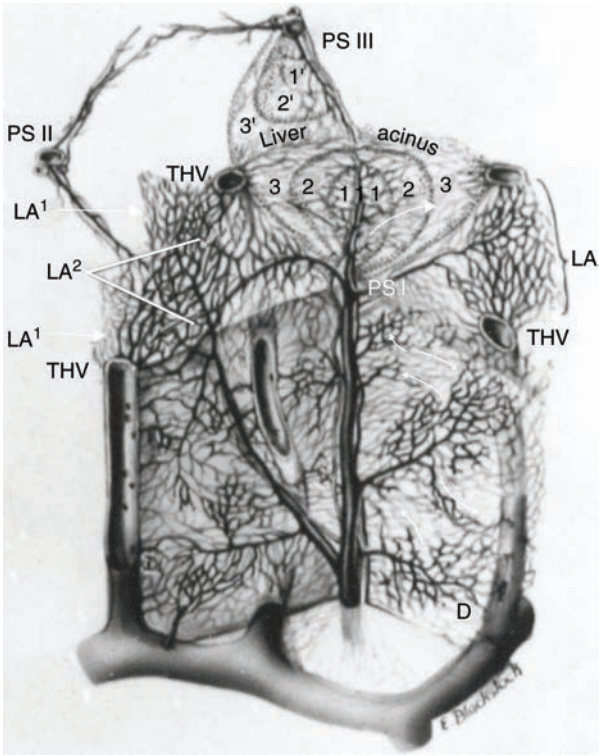

Figure 5.18 Vascular and biliary architecture of an acinar agglomerate and the relation of the acini to the adjacent hexagonal lobule. Note the arcuate courses of the terminal portal branches, the irregularly arranged simple acini, and the short portal vessels that form the axes of tiny acinuli constituting the mantle of parenchyma around the longitudinally cut portal space. Intercommunicating paths of acini and acinuli are shown by white arrows. D, channels of Deysach; LA, LA^1, simple liver acinus; LA^2, simple acinus penetrating a hexagonal field situated well above the level of origin of the acinus; PS I, PS II, PS III, portal spaces; THV, terminal hepatic venule; 1, 2, 3, circulatory zones of the simple liver acinus.

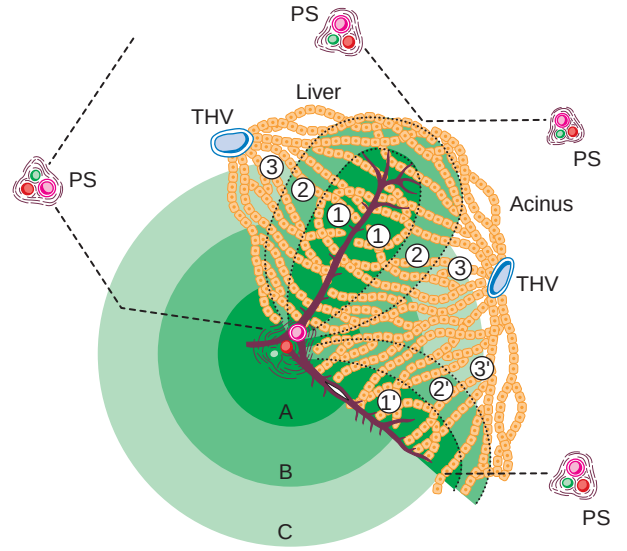

Figure 5.19 Blood supply of the simple liver acinus and the zonal arrangement of cells. The acinus occupies adjacent sectors of neighboring hexagonal fields. Zones 1, 2, and 3, respectively, represent areas supplied with blood of first, second, and third quality with regard to substrate, oxygen, and nutrients. These zones center around the terminal afferent vascular branches, terminal bile ductules, lymph vessels, and nerves and extend into the triangular portal field from which these branches crop out. Zones 1′, 2′, and 3′ designate corresponding areas in a portion of an adjacent acinar unit. In zones 1 and 1′, portal inlet venules empty into sinusoids. Note that zone 3 approaches the preterminal portal tract, nearly reaching the inner circle (A). PS, portal space; THV, terminal hepatic venules (central veins).

sickle-shaped (Fig. 5.20), with the parenchymal subunits being components of a hedge rather than individual grapes on a vine. Although parenchymal subunits are difficult to visualize in the normal human liver, they become evident in pathologic conditions such as nodular regenerative hyperplasia, in which there is a pruning of the portal-venous supply. As with a hedge, when individual portal units are pruned, the remaining units undergo hyperplasia to form an array of spherical units, revealing the underlying acinar structure. The hierarchical arrangement of simple, complex, and agglomerate acini can be appreciated in livers with prominent atrophy or necrosis [161]. In this century-long debate, it is useful to note that parenchymal subunits in the human liver do not exist. The debate concerns the best way to imagine their structure if they did exist.

Hepatocellular heterogeneity

The liver is anatomically situated to receive high concentrations of nutrients and certain hormones from the intestines and pancreas. Gradients of these substances, as well as oxygen and waste products, are found across the functional units of liver. These gradients are not constant but vary with cycles of feeding and exercise.

The position of hepatocytes within the acinus is reflected in the specialized functions of these hepatocytes (Fig. 5.21) [158,163–165]. Zone 1 hepatocytes are adapted to high oxidative activities, having numerous large mitochondria. Dominant processes in zone 1 are gluconeogenesis, β-oxidation of fatty acids, amino acid catabolism and ureagenesis, cholesterol synthesis, and bile acid secretion. Zone 3 is an ideal location for exergonic processes, including glycolysis and lipogenesis. There is a narrow rim of hepatocytes adjacent to terminal hepatic venules that remove ammonia from the blood by synthesizing glutamine. Zone 3 is also the site of general detoxification and biotransformation of drugs.

Metabolic zonation is accompanied by gradients of some anatomic features [161]. Mitochondria are larger and more numerous and lysosomes and Golgi are more abundant in zone 1. Smooth endoplasmic reticulum is more abundant and nuclear volumes are larger in zone 3. Endothelial fenestra are larger and less numerous in zone 1. Kupffer cells, large granular lymphocytes, stellate

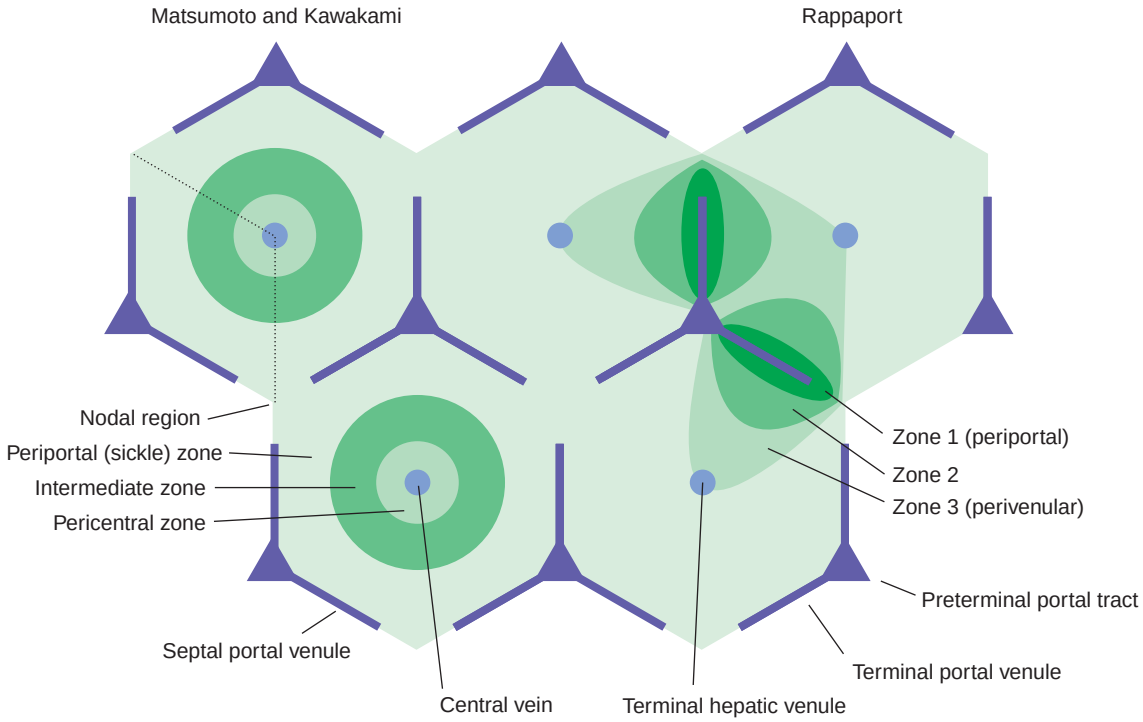

Figure 5.20 The acinar structure of the hepatic microcirculation, as conceived by Rappaport [160] and modified by Matsumoto and Kawakami [157]. In both models, the margins of the shaded zones represent planes of equal blood pressure (isobars), oxygen content, or other characteristics. The models differ in the shape of the isobars surrounding the terminal portal venules. The acinus is bulb-shaped, and the classic hexagonal lobule is comprised of several wedge-shaped portions (called primary lobules, indicated by dotted lines, upper left), which have cylindrical (sickle-shaped) isobars. The nodal region is the nodal point of Mall [23]. (Reproduced from Wanless [207] with permission from Elsevier.)

cells, and sympathetic nerve endings are all more numerous in zone 1. There are also gradients in the composition of matrix proteins [166].

The control of metabolic zonation has been found to operate at the pretranslational level, with a few exceptions. Thus the gradients of the enzyme protein and the enzyme mRNA tend to parallel each other. Enzyme expression usually varies during the feeding cycle or changes in oxygen tension, and the zonation is said to be dynamic. It is likely that many signals interact to produce dynamic zonation. Glucose and oxygen gradients each have an effect on various enzymes, and these gradients are interdependent [167,168]. Genes in the Wnt/β-catenin pathway appear to mediate metabolic zonation [169,170].

Stable zonation that does not vary with metabolic signals is a result of intercellular or cell–matrix interactions. For example, glutamine synthetase activity may depend on close approximation of hepatocytes with some element of the venules [164,171]. Glutamine synthetase expression becomes undetectable in late cirrhosis [99] possibly because of the destruction of hepatic venules and secondary necrosis of zone 3 hepatocytes during the development of cirrhosis [100].

Clinical importance of hepatocellular heterogeneity

Metabolic heterogeneity is responsible for zonal injuries that are of diagnostic value to the pathologist. The distribution of necrosis and steatosis in response to chemical injury is often zonal. Sharply defined zone 3 necrosis is characteristic of toxicity from acetaminophen, *Amanita phalloides*, pyrrolizidine alkaloids, and various hydrocarbons such as halothane and carbon tetrachloride. Zone 1 necrosis has been found with allyl alcohol, phosphorus, and high-dose iron ingestion. Zone 2 toxicity is rare in humans but has been produced in animals with ngaione, furosemide, and beryllium. Cocaine toxicity in rodents may affect different zones depending on preexisting enzyme induction [172].

Systemic hypoperfusion generally produces zone 3 necrosis. This pattern may be altered by local factors. For example, in disseminated intravascular coagulation, zone 1 sinusoidal fibrin deposition causes maximum ischemia to be located in zone 1 or 2. Zone 2 necrosis has been reported in some patients with hypotensive shock [173]. Viral hepatitis usually produces spotty necrosis in all zones but often with an ill-defined zone 3 predominance. Yellow fever often produces zone 2 necrosis. Herpes virus

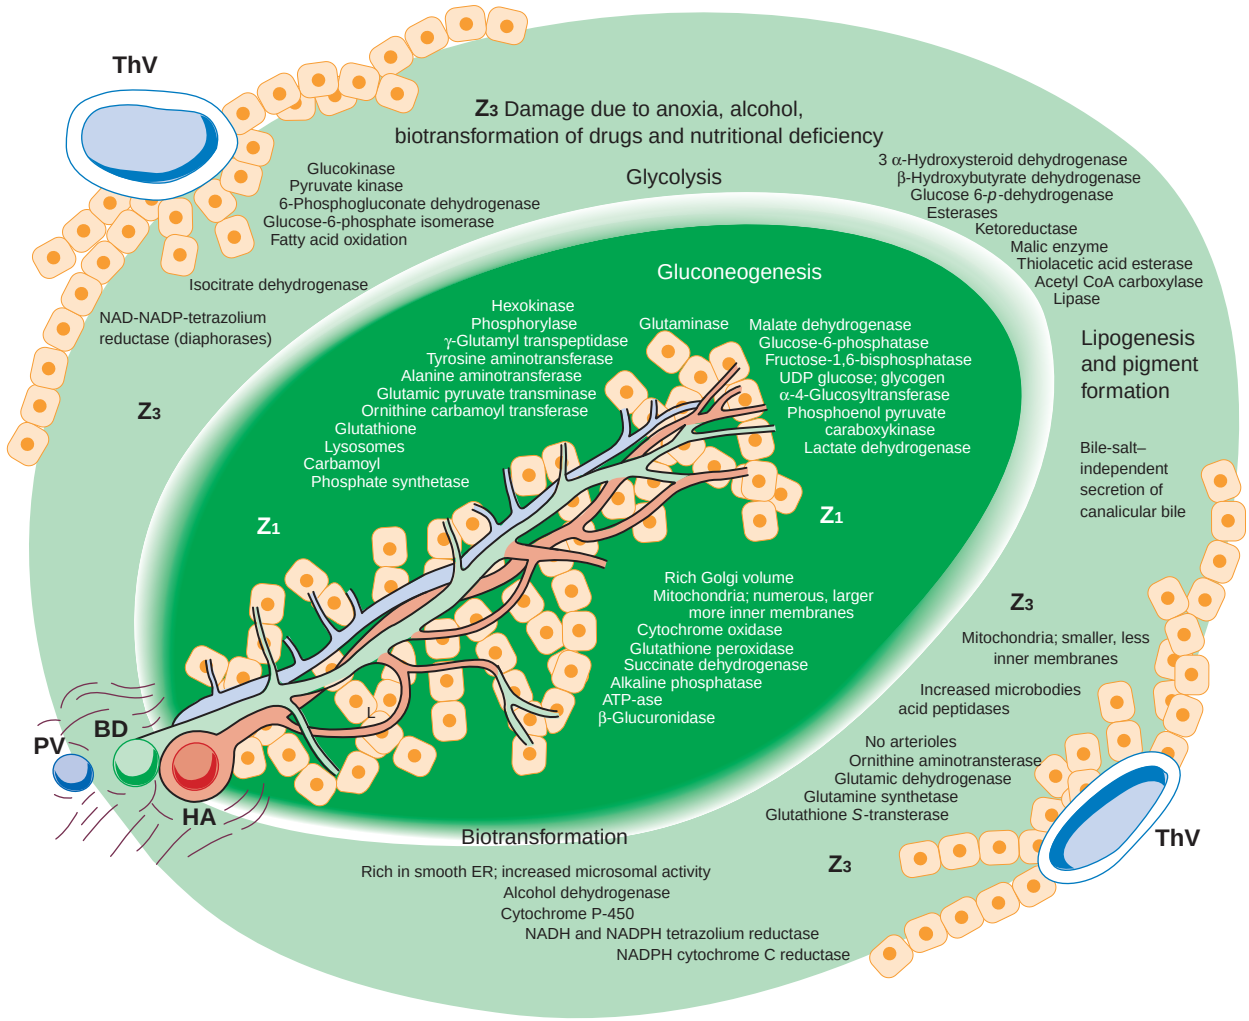

Figure 5.21 Schematic diagram of various metabolic processes that show zonal differences across the acinus. BD, bile duct; hep art, hepatic arteriole; PV, portal vein; ThV, terminal hepatic venule; Z1, periportal area; Z3, periacinar and perivenular area (the latter is derived from portions of zone 3 of several adjacent acini). For description, see text; for references see [161] and [164]. ATP, adenosine triphospate; CoA, coenzyme A; ER, endoplasmic reticulum; NAD, NADH, nicotinamide-adenine dinucleotide (and reduced form); NADP, NADPH, nicotinamide-adenine dinucleotide phosphate (and reduced form). (Adapted from Rappaport and Wanless [161] and Jungermann and Kietzmann [164].)

produces well-demarcated necrosis that does not follow a zonal distribution.

In hemochromatosis, hemosiderin is deposited predominantly in zone 1 hepatocytes. This is useful to distinguish hemosiderin from lipofuscin, the latter occurring predominantly in zone 3 hepatocytes. Proximity to a source of insulin favors the development of steatosis, as seen after instillation of insulin in the peritoneal cavity during dialysis, and decreased steatosis is seen in infarcts of Zahn, where PV supply to the tissue is obstructed.

Control of hepatic microcirculation

The terminal PVs supply sinusoids directly, giving a constant but sluggish blood flow [160,161]. In contrast, arterioles drain into terminal portal venules and zone 1 sinusoids, giving a pulsatile but small volume flow that appears to enhance sinusoidal flow, especially in periods of reactive arterial flow, as in the postprandial state. Groups of sinusoids shift their work asynchronously. The change from storage phase of inactive sinusoids to flow activity demonstrates at the microscopic level the function of the liver as a "venesector and blood giver of the circulatory system" [174].

Arterial flow varies inversely with PV flow. The mechanism of this *hepatic arterial buffer response* is based on washout of locally produced adenosine [175]. When portal-venous flow is reduced, adenosine accumulates and causes dilatation of the arterial resistance vessels; the reverse also occurs. The relative contribution of arterial and portal-venous flow varies between regions of the

liver and this varies with gravity and other physiologic variables [176]. The conductance of PVs increases with distention, causing portal pressure to be little altered by large changes in PV flow [177]. In addition to arteriolar tone, local control of the microcirculation may depend on the contraction state of sinusoidal endothelial cells and stellate cells [104].

Regional blood flow is of practical importance when investigating focal lesions such as focal nodular hyperplasia and neoplasms. The venous and arterial circulation can be differentially imaged by using computed tomography (CT) with arterial portography (CTAP) or CT with intravenous contrast injection. Cirrhotic nodules, dysplastic nodules, and small hepatocellular carcinomas may have a portal-venous supply and are usually isodense on contrast CT. Hepatocellular carcinoma, hepatic adenomas, metastases, and focal nodular hyperplasia are mostly supplied by arteries and are therefore hyperdense with contrast CT [178–181].

Physioanatomic aspects of human liver disease

Regeneration of hepatocytes

The normal liver maintains a constant mass that is determined by the needs of the host [182]. If a partial hepatectomy is performed, the organ grows to regain much of the original mass in 10 days in rodents and in a few weeks or months in humans [183]. If a liver is transplanted into a new host, the new liver grows (by mitosis) or shrinks (by apoptosis) to the size of liver expected for that host's body size. Hepatocyte dysfunction, such as chronic cholestasis in primary biliary cirrhosis or primary sclerosing cholangitis, appears to be a signal to initiate cell proliferation, as the liver may be twice the normal weight in the early stages of these diseases.

There is controversy concerning the source of hepatocytes participating in regeneration. The normal resting liver has a very low mitotic rate. After many types of injury, mitoses become readily visible in hepatocytes from all acinar zones. However, some labeling studies have suggested that mitosis is particularly active in the periportal region, giving rise to the hypothesis that hepatocytes are born in zone 1 and migrate in their lifetimes to zone 3 [184]. This "streaming liver" concept implies the presence of stem cells, now considered to be located in the smallest radicles of the biliary tree, the canals of Hering [133,185]. Cells in this location are thought to be able to differentiate into cholangiocytes and hepatocytes [186–188]. The direction of differentiation between these two compartments may be directed by the Wnt and Notch pathways [189]. It appears that the bulk of cell replacement, in acute and subacute injury models, is by panacinar mitosis. The stem cell and streaming liver mechanisms may be important in severe injury states [190]. The stem cell population may be replenished by cells migrating from bone marrow [182,191–193].

In normal human liver, half of hepatocytes are diploid and the remainder are polyploid [194]. One third of hepatocytes are binuclear. The processes of polyploidization and binucleation are irreversible so that polyploidy increases with age. These processes may protect long-lived hepatocytes against mutation. During a regenerative stimulus, binucleation and polyploidy decrease as binucleating growth is suppressed. Thus, after regeneration, freshly divided cells have small and uniform nuclei, in contrast to the polyploid resting cells.

Putative signals for initiation of the cell cycle in hepatocytes include hepatocyte growth factor (HGF), made in all the major types of nonparenchymal liver cells, epithelial growth factor (EGF), made in salivary glands and hepatocytes, transforming growth factor α (TGF-α), made in hepatocytes, and tumor necrosis factor (TNF) [195]. Endotoxin stimulates TNF secretion and TNF stimulates Kupffer cells to secrete interleukin-6, which is an important mediator of hepatocellular regeneration. HGF and TGF-β are bound to extracellular matrix [196]. Insulin and glucagon support hepatocyte growth in culture and in vivo, although they are not complete mitogens for hepatocytes. Although the details of this complex system are not fully understood, it is clear that cytokines and growth factors derived from multiple cells types are involved. Thus, gut-derived endotoxin, pancreatic hormones, activated Kupffer cells, and sinusoidal blood flow will influence hepatocellular regeneration [197].

Pathogenesis of chronic liver disease

Chronic liver disease is usually defined as hepatic injury lasting for at least 6 months. The late stages of chronic liver disease have often been divided in two clinicoanatomic forms: cirrhosis and noncirrhotic portal hypertension, the former associated with portal hypertension and hepatic dysfunction and the latter with portal hypertension and nearly normal function. While these categories are often sufficient for clinical management, the anatomic features allow further subdivision, which is necessary to interpret liver biopsies and understand the pathogenesis of progressing and regressing liver disease (Table 5.2). All types of chronic liver disease are associated with vascular obstruction and the various anatomic patterns in Table 5.2 can be explained by the distribution and severity of the obstructive lesions (Fig. 5.22).

Hemodynamic changes in the parenchyma can be understood in terms of inflow and outflow imbalance. When either inflow is increased (by hyperemia or angiogenesis) or outflow capacity is decreased (by hepatic vein obstruction), the tissue becomes congested and suffers

Table 5.2 Clinical and anatomic features of the major forms of chronic liver disease.

Anatomic diagnosis	Portal hypertension	Hepatocellular dysfunction	Parenchymal extinction and fibrous septa	Description of fibrous septa	Obliteration of small portal veins	Extrahepatic or large intrahepatic portal vein block	Obliteration of small hepatic veins
Cirrhosis, venocentric[a]	++	++	+++	Between hepatic veins, portal tracts not involved	+	– or +[d]	+++
Cirrhosis, micronodular	++	++	+++	Many, broad	+++	– or +[d]	+++
Cirrhosis, macronodular	+	+	++	Many, thin	++	– or +[d]	++
Cirrhosis, incomplete septal	+	+/–	+	Moderate, thin, or incomplete	++	–	+
Chronic obliterative microvascular disease	+	+/–	+/–	Thin or absent	++	–	+
Obliterative portal venopathy[b]	+	+/–	–	–	++	–	– or +
Extrahepatic portal vein obstruction[c]	++	+/–	–	–	++	++	–

Gradings are for typical examples but gradings can vary within each anatomic category.
[a] Also known as reversed-nodularity cirrhosis of Budd–Chiari syndrome.
[b] Often with nodular regenerative hyperplasia.
[c] For example, portal vein thrombosis, portal vein agenesis, or cavernous transformation of the portal vein.
[d] Present with secondary portal vein thrombosis.

injury. This injury involves all components of the tissue, including the portal veins, sinusoidal walls, hepatocytes, and hepatic veins. Congestive injury to the sinusoids leads to atrophy or parenchymal extinction. Congestive injury to the hepatic veins causes obstruction of these veins and a worsening of congestion and a positive feedback loop of parenchymal extinction. Congestive injury to the portal veins causes hepatic inflow to be converted from a predominantly low pressure venous supply to a high pressure arterial supply. Thus, the hemodynamic effects of chronic liver disease can be summarized as *in–out imbalance*, a state that leads to progressive destruction of parenchyma and evolution to cirrhosis [198].

The effects of these flow changes can be recognized histologically. When regions of parenchymal extinction occur, there is collapse of the architecture so that hepatic veins and portal tracts become approximated (Fig. 5.23). If parenchymal extinction lesions are sufficiently large, linear regions lacking hepatocytes are produced that are recognized as "fibrous" septa. Regeneration of hepatocytes adjacent to septa causes curved deformity of the septa. When numerous curved septa are present, the histologic pattern of cirrhosis can be appreciated. If obstruction is greater in portal veins than hepatic veins, tissue injury is not sufficient to cause extensive parenchymal extinction and the result is noncirrhotic portal hypertension, often with nodular regenerative hyperplasia [199].

The histologic appearance of the liver varies with time after injury. If chronic injury abates, as with successful suppression of viral activity or abstinence from alcohol, venous drainage sites improve and in–out imbalance resolves. This allows collagen to be resorbed and hepatocytes to fill-in septal regions [200]. Thus, micronodular cirrhosis can remodel progressively into macronodular cirrhosis, incomplete septal cirrhosis, and eventually a state of regressed cirrhosis (Figs. 5.23 and 5.24). Because portal vein obliteration is difficult to reverse, [201] patients with regressed cirrhosis commonly have noncirrhotic portal hypertension and a histologic appearance described as *chronic obliterative microvascular disease*.

The mechanism of vascular obstruction in chronic liver disease depends on the nature of the primary disease. In most forms of chronic hepatitis, portal and hepatic vein phlebitis occurs as a bystander effect of inflammation in adjacent tissue [202]. In Budd–Chiari syndrome thrombosis is important [203]. In chronic biliary disease, bile salt

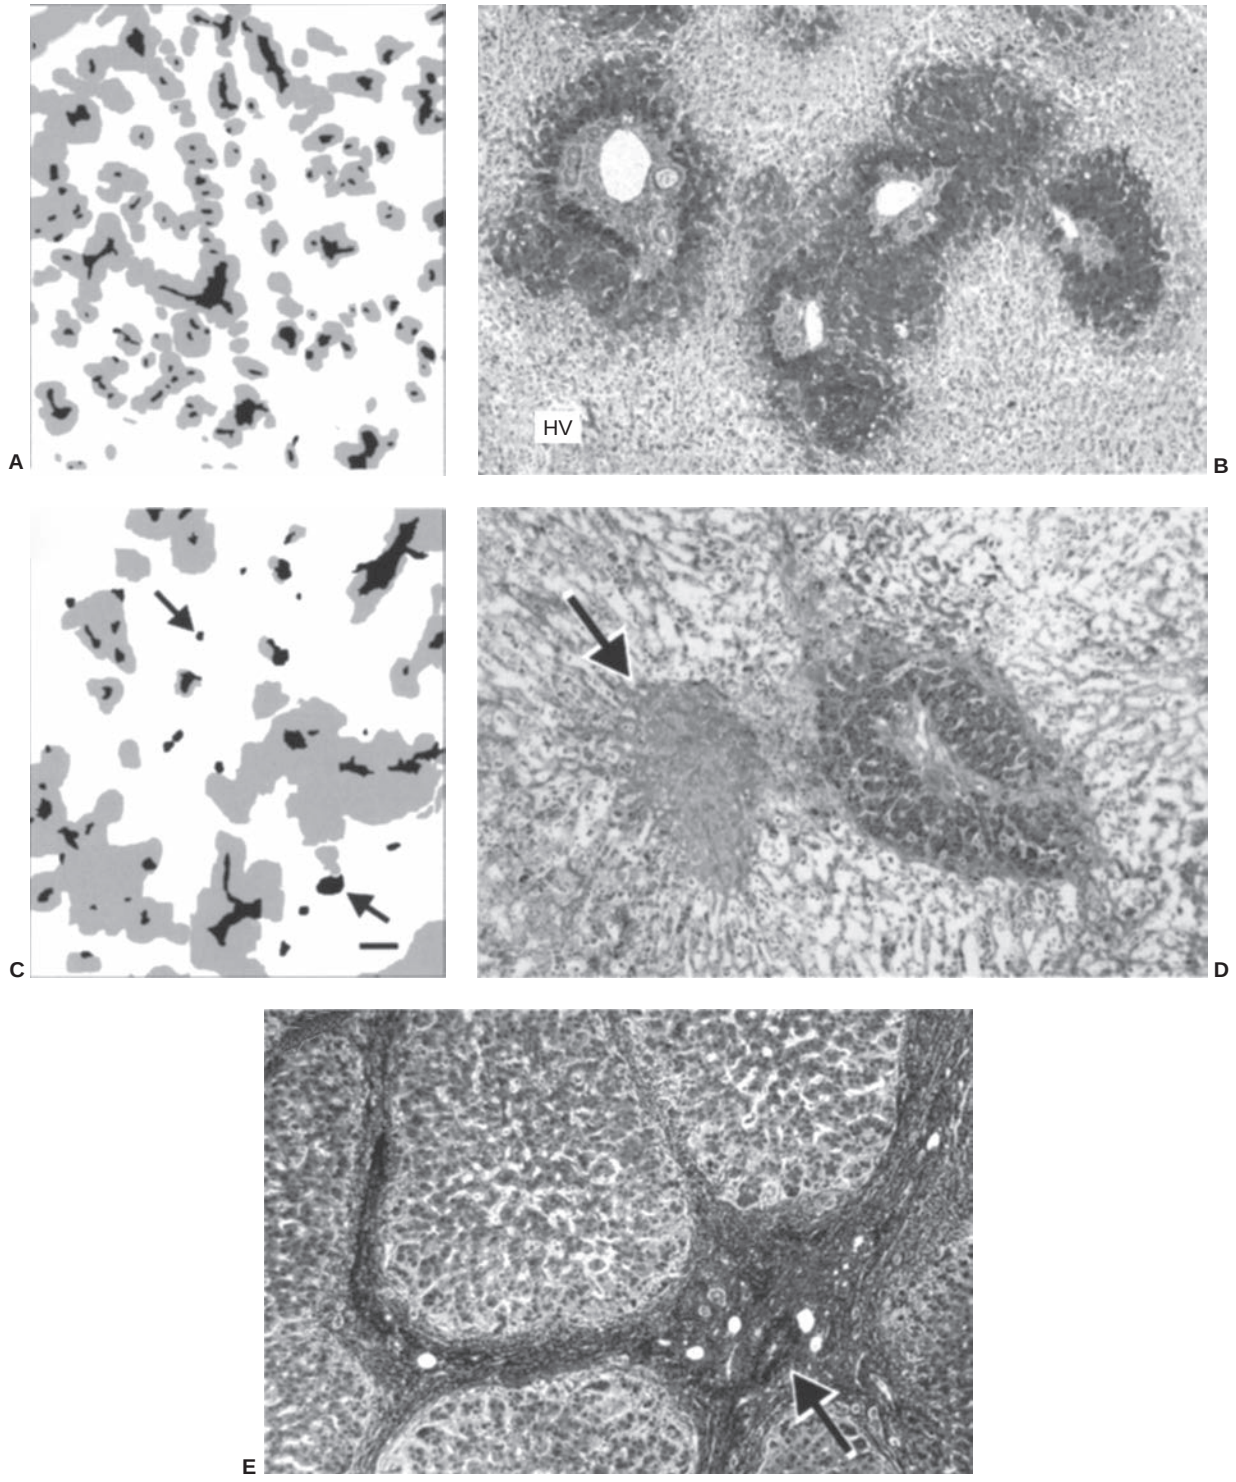

Figure 5.22 The histogenesis of cirrhosis. There are two basic types of cirrhosis, venocentric and venoportal. The type is determined by the distribution of vascular obstruction as illustrated by these examples with Budd–Chiari syndrome. (A, B) Venocentric cirrhosis occurs when parenchyma near obstructed hepatic veins (HV) shows contiguous cell loss (extinction) and fibrosis and cirrhotic nodules (dark tissue) contain portal tracts with patent veins. The periportal tissue survives because of retrograde portal vein drainage. (C, D) When hepatic vein obstruction is followed by portal vein obstruction, retrograde portal vein flow is not possible and the periportal tissue cannot support hepatocytes. This is shown in (C) where portal tracts (black) are usually accompanied by periportal tissue (gray) except in regions affected by portal vein obstruction (arrows) (bar = 1 mm). In (D) the arrow indicates a portal tract with an obstructed portal vein and absent periportal tissue. (E) Venoportal cirrhosis occurs when portal tracts are incorporated into the septa located adjacent to the cirrhotic nodules. Arrow shows obliterated portal vein. (B, D, E) Elastic-trichrome stain. (Adapted from Tanaka and Wanless [203] with permission from Elsevier.)

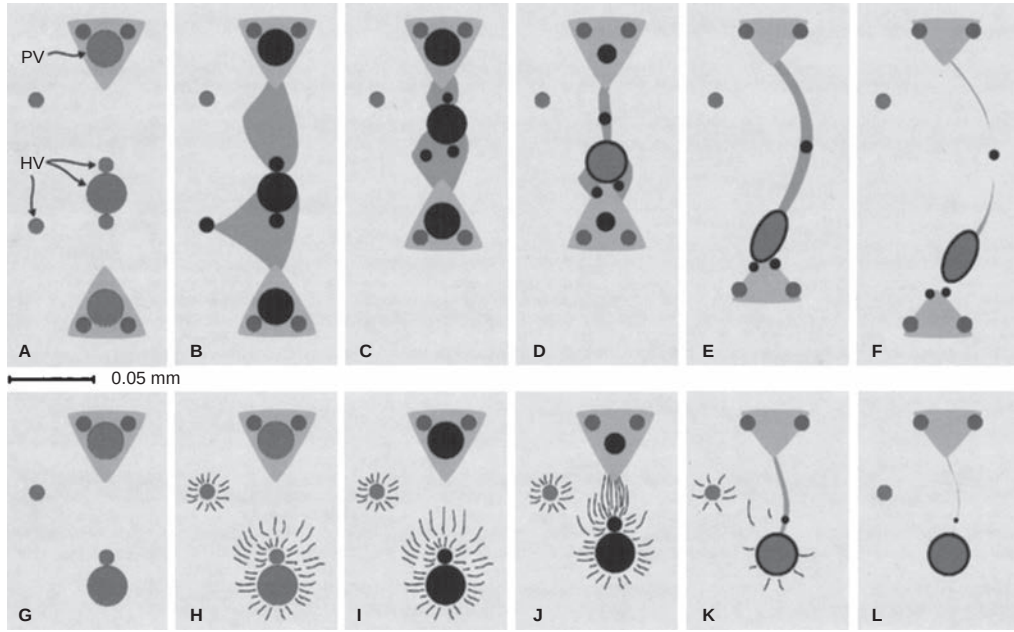

Figure 5.23 Diagram of tissue remodeling in chronic hepatitis (A–F) and in alcoholic liver disease (G–L) during the development and regression of cirrhosis. Normal acini are shown in (A) and (G) with the sequence of events leading to small regions of parenchymal extinction in the following panels. Obstructed veins are shown as black circles. (B) Obliteration of small portal and hepatic veins occurs early in the development of cirrhosis in response to local inflammatory damage. The supplied parenchyma becomes ischemic. (C, D) Ischemic parenchyma shrinks and is replaced by fibrosis (process of parenchymal extinction). The shrinkage is accompanied by close approximation of adjacent vascular structures. (E) Septa are deformed and stretched by expansion of regenerating hepatocytes. (F) As septa are resorbed, they become delicate and perforated before disappearing. Trapped portal structures and hepatic veins are released from the septa and are recognizable as obstructed and ectopic remnants. Note the absence of portal veins. In alcoholic disease (G–L), the sequence of events may differ from other forms of chronic liver disease. (H) Sinusoidal fibrosis is often prominent in advance of parenchymal collapse, leading to a pericellular pattern of fibrosis. (I, J) Inflammation and fibrosis lead to hepatic and portal vein obliteration with secondary condensation of preformed sinusoidal collagen fibers into a septum. (K, L) After prolonged periods of inactivity, sinusoidal fibrosis and septa are resorbed. HV, hepatic vein; PV, portal vein. (Adapted from Wanless et al. [200] with permission from College of American Pathologists.)

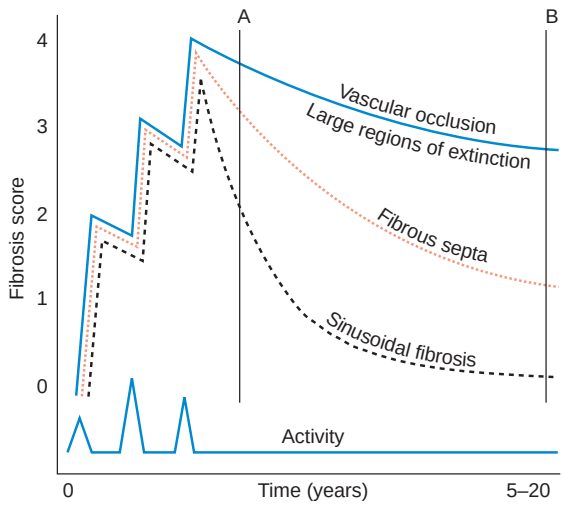

Figure 5.24 The time course of the histologic features of cirrhosis in relation to periods of activity. After cessation of activity, various histologic features regress at different rates. The balance of histologic features varies with the duration of low activity disease, for example between time points A and B. At time B cirrhosis cannot be diagnosed histologically, although vascular obstruction (especially of portal veins) and clinical portal hypertension may remain. (Reproduced from Wanless [209] with permission from College of American Pathologists.)

injury is likely responsible for the hepatic vein obliteration and portal inflammation may explain the PV obliteration. In established cirrhosis of any etiology, stasis and reversed flow commonly lead to portal vein thrombosis. Congestive hepatic venopathy may cause parenchymal extinction even if the original disease is inactive [204,205]. In nodular regenerative hyperplasia and some forms of noncirrhotic portal hypertension, portal vein obstruction occurs by local portal inflammation or thrombosis.

The significance of these thrombotic and congestive mechanisms is that they point to possible therapeutic strategies. Antithrombotic therapy is often recommended in patients with obvious thrombotic disease such as Budd–Chiari syndrome and portal thrombosis [206] but may also be beneficial in selected patients with other types of progressive liver disease. Congestive venopathy might be ameliorated by β-blockers or by portacaval or transhepatic shunt procedures.

CHAPTER 6
Bilirubin Metabolism and Jaundice

Allan W. Wolkoff[1] *& Paul D. Berk*[2]

[1]Marion Bessin Liver Center and Division of Gastroenterology and Liver Diseases, Albert Einstein College of Medicine, New York, NY, USA
[2]Department of Medicine, Division of Digestive and Liver Diseases, Columbia University College of Physicians and Surgeons, New York, NY, USA

Key concepts

- Bilirubin is the final degradation product of heme, which is the prosthetic group of numerous important hemoproteins involved in oxygen transport (e.g., hemoglobin) or metabolism (e.g., P450 cytochromes). The conversion of heme to bilirubin involves two enzymatic steps: opening of the heme ring by heme oxygenase to form biliverdin, with the release of both carbon monoxide (CO) and iron, and reduction of biliverdin to bilirubin by biliverdin reductase.
- Normal adults produce a mean of 4 mg of bilirubin per kilogram body weight per day. Degradation in the reticuloendothelial system of the hemoglobin of dying erythrocytes generates 80–85% of daily bilirubin production. The remainder has multiple sources, including ineffective erythropoiesis in the bone marrow and the turnover of short-lived, nonhemoglobin hemoproteins including the various P450 cytochromes. Because synthesis and degradation of these cytochromes occurs throughout the body, both heme biosynthesis and the heme oxygenase/biliverdin reductase pathways are widely distributed.
- Bilirubin was long considered simply a biologic waste product. However, biliverdin and bilirubin have antioxidant properties, CO is important in cell signaling, iron plays a key role in the generation of reactive oxygen species, and both heme biosynthesis and heme degradation are tightly regulated. These observations suggest that, hemoglobin degradation aside, heme synthesis and degradation throughout the body may play a role in cellular antioxidant defenses.
- Bilirubin formed in the periphery is kept in solution during transit to the liver by very tight binding to albumin. Once at the liver, it is transported from the plasma to bile by four distinct steps: hepatocellular uptake; binding to specific intracellular proteins; conversion to a water-soluble form by conjugation to glucuronic acid by the uridine diphosphate (UDP) glucuronosyl-transferase isoform (UGT1A1); and the adenosine triphosphate (ATP)-dependent, carrier-mediated transport of the resultant bilirubin monoglucoronides (BMGs) and diglucuronides (BDGs) across the canalicular domain of the plasma membrane into the bile canaliculus.
- Jaundice is the yellow-orange discoloration of skin, conjunctivae, and mucous membranes that results from an elevated concentration of bilirubin in plasma. Hyperbilirubinemias are usually classified into those that are predominantly unconjugated and those that are mainly conjugated. The latter often, in fact, involve elevations of both the conjugated and unconjugated bilirubin fractions. Instances of hyperbilirubinemia in which other common hepatic biochemical tests are normal often reflect familial hyperbilirubinemias; the combination of hyperbilirubinemia with abnormalities of other hepatic biochemical tests suggests an acquired condition.
- The plasma unconjugated bilirubin concentration reflects a balance between bilirubin turnover and hepatic bilirubin clearance (C_{BR}). Unconjugated hyperbilirubinemia can result from increased bilirubin turnover (e.g., hemolysis), decreased bilirubin clearance (e.g., neonatal hepatic immaturity, familial unconjugated hyperbilirubinemias), or situations in which both processes are occurring (neonatal immaturity in infants with glucose-6-phosphate dehydrogenase (G6PD) deficiency).
- Reduced levels of UGT1A1 on either a congenital (Gilbert and Crigler–Najjar syndromes) or acquired (administration of certain human immunodeficiency virus (HIV) protease inhibitors) basis and shunting of blood around the hepatic parenchyma in cirrhosis are the most frequent causes of a reduction in hepatic bilirubin clearance. Hereditary (Dubin–Johnson syndrome) or acquired (hepatocyte injury) deficiencies of the canalicular transport system, or obstruction to the flow of bile down the biliary tract, are the principal causes of conjugated hyperbilirubinemia.
- Application of molecular technology has led to extensive progress in understanding the pathogenesis of the familial hyperbilirubinemias. Thus, Gilbert syndrome and types I and II Crigler–Najjar syndrome were long considered separate diseases, with separate patterns of inheritance. It is now recognized that they all reflect autosomal recessive disorders characterized by mutations of different severity in the gene encoding UGT1A1. Similarly, Dubin–Johnson syndrome is now known to reflect an inherited abnormality in *MRP2*, encoding an ATP-dependent canalicular plasma membrane transporter for bilirubin conjugates and a number of other non-bile-acid organic anions. Of the five familial hyperbilirubinemias, only Rotor syndrome remains unexplained in terms of molecular pathogenesis.

Bilirubin, a reddish-yellow heme degradation product, is produced principally from the breakdown of the hemoglobin of senescent red blood cells and is eliminated from the circulation by the liver. Jaundice, derived from the French *jaune* (yellow), is the yellow-orange discoloration of the skin, conjunctivae, and mucous membranes that is a consequence of an elevated concentration of bilirubin in plasma. Although mild hyperbilirubinemia may be clinically undetectable, jaundice becomes apparent at plasma bilirubin concentrations of 3–4 mg/dL. The threshold for its recognition depends on the patient's normal pigmentation, the lighting conditions under which the observation is made, and the particular fraction of plasma bilirubin that is elevated. Optimal interpretation of an elevated plasma bilirubin concentration is based on an appreciation of its metabolism, and in particular, its sources and disposition. These are the subject of this chapter.

Sources, structure, and plasma transport of bilirubin

Bilirubin production from heme

Bilirubin is the final, common end-product of the metabolism of heme, the moiety found in hemoglobin, myoglobin, and other hemoproteins (Fig. 6.1). The formation of bilirubin is the result of a multistep, enzymatic process in which the porphyrin ring of heme is first opened at the α-bridge carbon in a stereoselective, enzymatic oxidative process carried out by the microsomal enzyme heme oxygenase. This step leads to the release of an iron atom and to the formation of equimolar quantities

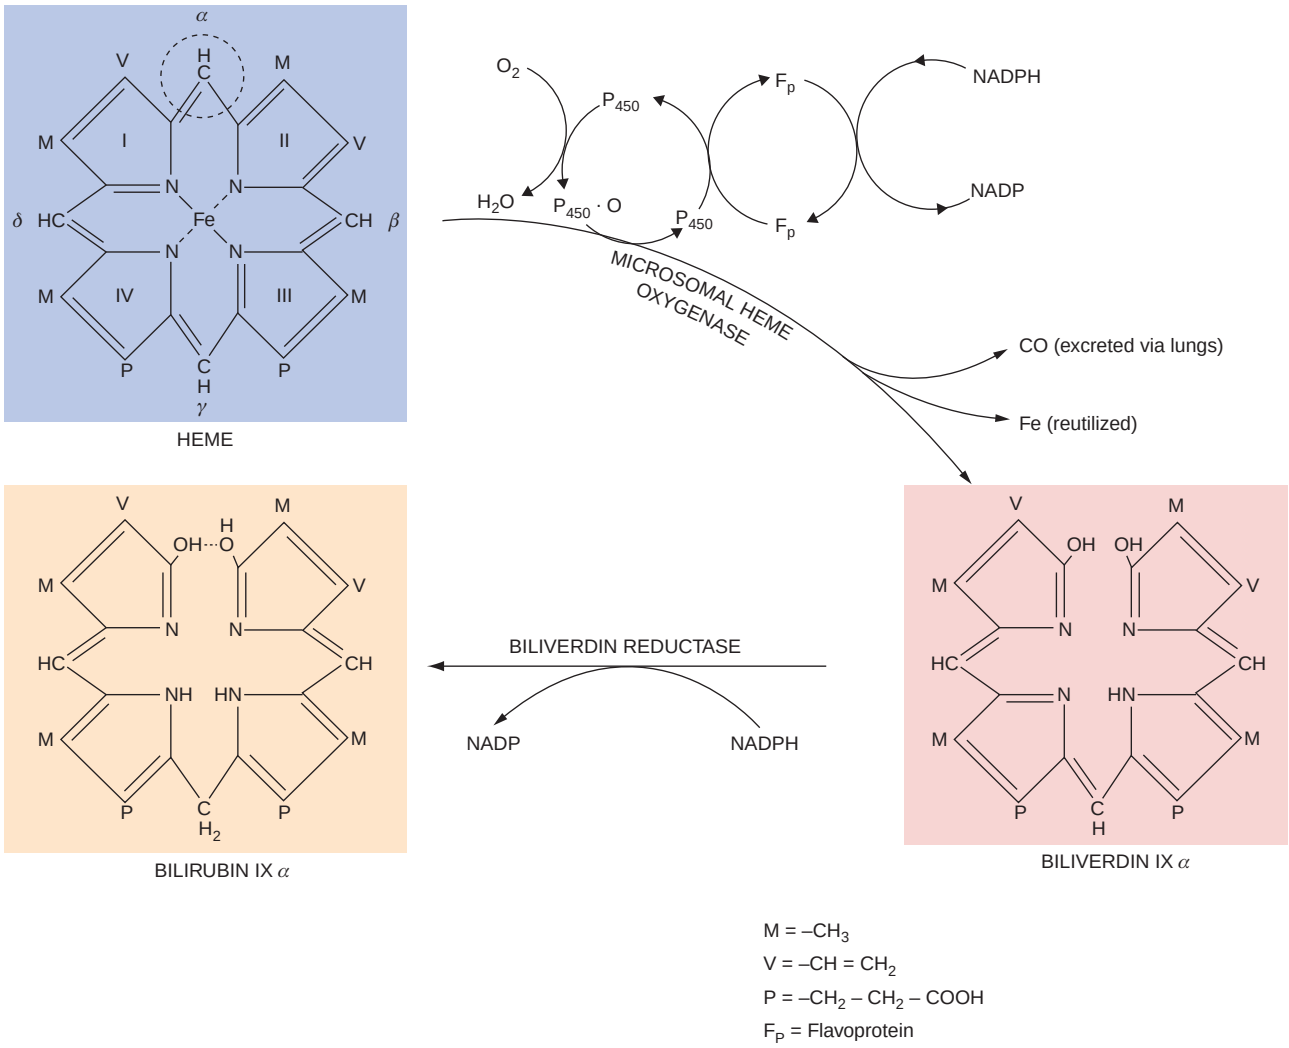

Figure 6.1 Pathway for the degradation of heme to bilirubin. Stereospecific opening of the heme macrocycle at the α-bridge carbon by the microsomal enzyme heme oxygenase results in the formation of equimolar amount of biliverdin and carbon monoxide. Biliverdin is subsequently reduced to bilirubin by the enzyme biliverdin reductase. NADP, NADPH, nicotinamide adenine dinucleotide phosphate (and reduced form). (Reproduced from Berk et al. [268] with permission from Elsevier.)

of biliverdin, a green tetrapyrrolic pigment, and carbon monoxide [1]. Biliverdin is a water-soluble pigment that is readily excreted unaltered by the liver. It is the principal bile pigment in many amphibia, fish, and birds. However, it does not readily cross the placenta. Accordingly, most mammals rapidly and quantitatively convert biliverdin to the reddish-yellow pigment bilirubin through a reaction that is catalyzed by the enzyme biliverdin reductase [2–4]. Heme oxygenase is present in macrophages throughout the reticuloendothelial system, including Kupffer cells of the liver, and certain epithelial cells including hepatocytes and renal tubular cells [1]. Biliverdin reductase is widely distributed in many cells throughout the body, including macrophages [1,2]. The major sites of bilirubin production are the spleen and other compartments of the reticuloendothelial system, which degrade the hemoglobin of senescent and injured red blood cells. However, the degradation of heme to bilirubin can occur in many sites, including macrophages that migrate into hematomas containing extravasated hemoglobin. Because both heme oxygenase and biliverdin reductase are present in macrophages, the sequential steps in the conversion of heme to bilirubin are readily visualized at the edges of any bruise, where the purplish to green to yellow color changes reflect the conversion of extravasated and deoxygenated hemoglobin first to biliverdin and then to bilirubin.

Possible cytoprotective effects of the heme oxygenase/biliverdin reductase pathway

Heme oxygenase and biliverdin reductase were initially considered to function solely as a heme degradative and waste disposal pathway. However, the widespread distribution of these enzymes in cells outside the reticuloendothelial system, the tight control of heme oxygenase activity achieved through the presence of both an inducible (HO-1) and a constitutive (HO-2) form of the enzyme, and the important biologic effects of the several products of heme degradation led to a growing interest in this pathway [5]. Both biliverdin and bilirubin proved to be potent antioxidants under certain circumstances, and hyperbilirubinemia was reported to have various protective clinical effects (e.g., against ischemic heart disease; reviewed in [1,5]). Carbon monoxide (CO) functions as both a signaling molecule and an important vasoactive regulator; and the iron released during heme degradation contributes to various forms of cellular cytotoxicity by facilitating the formation of reactive oxygen species (ROS). These findings suggested that cells might have evolved fine control over the heme oxygenase/biliverdin reductase pathway specifically to regulate CO production for signaling and heme consumption and the generation of bilirubin and biliverdin for their roles in counteracting *intracellular* oxidative and nitrosative stress [5,6]. The existence of a specific intracellular oxidation/reduction cycle in which lipophilic ROS oxidize bilirubin to biliverdin, which is then re-reduced by biliverdin reductase, was postulated [7] and debated [8]. It was claimed that such a cycle, analogous to the GSH/GSSG (glutathione (reduced form)/glutathione (oxidized form)) cycle for detoxifying soluble oxidants, could potentially permit bilirubin to destroy a 10,000-fold excess of oxidants [7]. However, more recent studies cast serious doubt on the existence and functioning of the proposed intracellular bilirubin/biliverdin redox amplification cycle [2,9]. Although both bilirubin and biliverdin clearly can exhibit antioxidant properties under certain conditions in vitro and extracellularly, it is increasingly doubtful that such conditions occur intracellularly, or that the intracellular oxidation of bilirubin results in its specific, quantitative conversion to biliverdin, which is an essential requirement for the functioning of the proposed cycle.

Quantitative aspects of bilirubin production

In normal human subjects, bilirubin production averages ~4 mg/kg body weight/day (6 μmol/kg body weight/day) [10]. Hemoglobin from senescent or injured erythrocytes is the source of 80–85% of the heme that is eventually catabolized to bilirubin (Fig. 6.2). The remainder

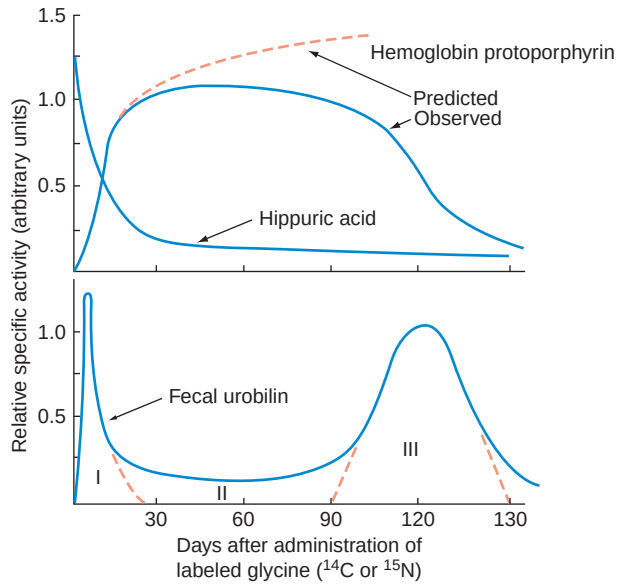

Figure 6.2 Relative specific activities of hemoglobin protoporphyrin, fecal urobilin (stercobilin), and hippuric acid after administration of labeled glycine. The early labeled peak of stercobilin is derived from ineffective erythropoiesis and the turnover of heme enzymes; the late peak reflects the death of senescent erythrocytes. The observed specific activity of hemoglobin protoporphyrin is less than that predicted from the continued availability of labeled glycine for hemoglobin synthesis as determined from the hippuric acid curve. This suggests some random loss of labeled erythrocytes, which may be the source of fraction II of labeled stercobilin. (Reproduced from Berk et al. [268] with permission from Elsevier.)

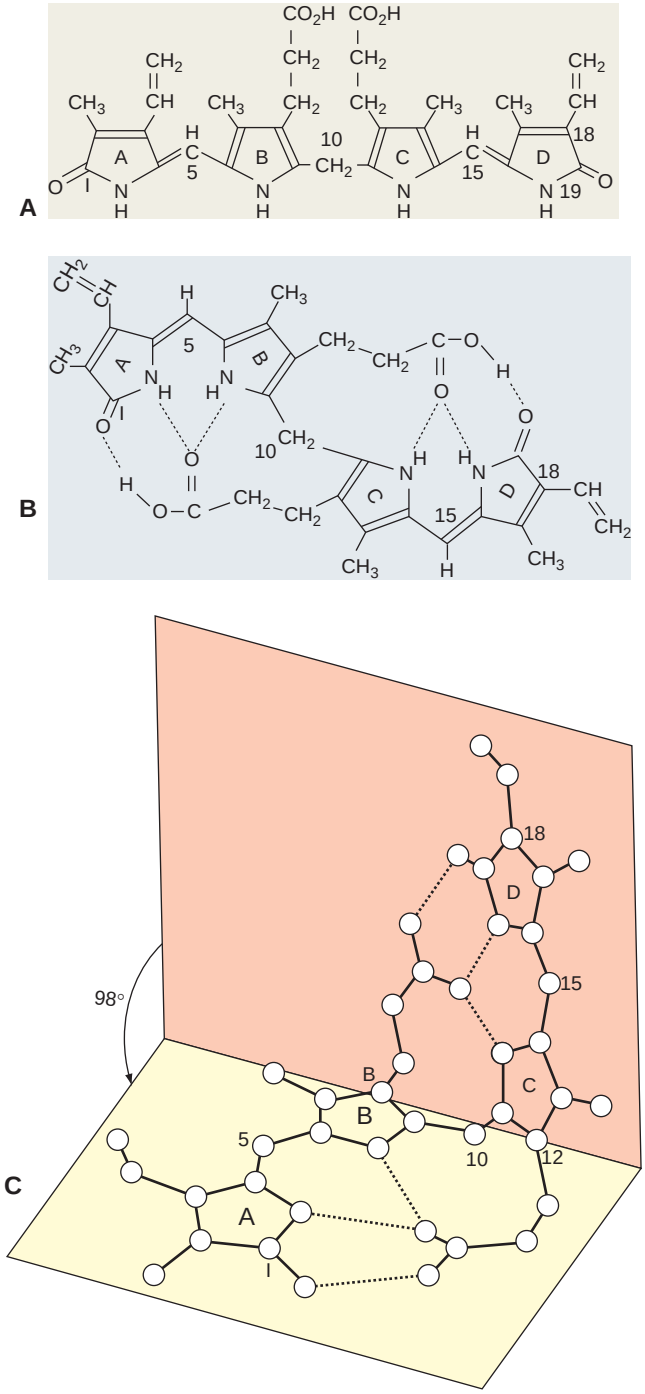

Figure 6.3 Structure and conformation of bilirubin. (A) Conventional "linear tetrapyrrole" structure of the naturally occurring isomer of bilirubin, designated bilirubin IXα. The oxygen functions on the A and D rings are depicted as the lactam tautomers, and the bridge carbons at positions 5 and 15 are shown in the Z configuration. In this configuration they and their attached hydrogens project toward the substituted β-positions on the adjacent pyrrole rings, just as in the protoporphyrin ring from which bilirubin is derived. (B) Planar representation of the 3D conformation of the bilirubin molecule, showing hydrogen bonding (. . .) between each of the –COOH side chains and the –C=O and =NH groups of the end rings (rings A and D) of the opposite half of the molecule. These hydrogen bonds hold the molecule in a rigid 3D conformation.

has multiple sources, including a component of ineffective hemoglobin production in the bone marrow and the turnover of short-lived, nonhemoglobin hemoproteins including the various P450 and b_5 cytochromes, catalase, and peroxidase [11–15]. In normoblastic hemolytic anemias, the bone marrow can increase red blood cell production as much as eight-fold [16], leading to a corresponding increase in the component of bilirubin production derived from erythrocytes [12]. Under these conditions, the amount of bilirubin derived from ineffective erythropoiesis in the marrow may increase in absolute terms, but the proportion of bilirubin production due to ineffective erythropoiesis remains unchanged [12]. By contrast, major increases in the fraction of bilirubin production derived from ineffective erythropoiesis may occur in megaloblastic anemias such as those associated with either folate or vitamin B_{12} deficiency, the thalassemias, and certain dyserythropoietic anemias [12]. Increased bilirubin production also occurs in disorders of heme biosynthesis, including the hereditary erythropoietic porphyrias and lead poisoning [12,13,17]. Finally, administration of phenobarbital and other drugs increases the turnover of heme enzymes, notably hepatic cytochrome P450 isoforms, with a resulting increase in bilirubin production (see below) [14,15,18].

Structure of bilirubin-IXα

Naturally occurring bilirubin is designated bilirubin-4Z,15Z-IXα. This designation indicates that it is derived from protoporphyrin isomer IX, the isomer found in heme and hemoproteins such as hemoglobin, by cleavage of the porphyrin macrocycle at the α-bridge carbon and that the stereochemical arrangement at the 5- and 15-bridge carbons is in the Z configuration (Fig. 6.3) [19,20]. This configuration allows the formation of internal hydrogen bonds between the propionic acid side chain on the B ring and polar groups on the D ring, and between the propionic acid on the C ring and polar groups on the A ring [21]. Although bilirubin is frequently depicted as a linear tetrapyrrole, these hydrogen bonds in fact fix the molecule in a rigid, "ridge tile" configuration [22]. This configuration blocks exposure of the molecule's polar groups to aqueous solvents and of the central bridge carbon to attack by diazo reagents, and is therefore the basis both for bilirubin's hydrophobic behavior and its slow (indirect) diazo reactivity [23,24].

Figure 6.3 (*continued*) (C) Three-dimensional representation of bilirubin-IXα. The molecule takes the form of a ridge tile (i.e., a tile that fits along the top of a roof), with the ridge line defined by the carbons at positions 8, 10, and 12. Rings A and B lie in one plane, and C and D lie in another, with the interplanar angle being approximately 98°. (Reproduced from Berk et al. [268] with permission from Elsevier.)

Other bilirubin isomers

A number of structural (Fig. 6.4A, D) and configurational (Fig. 6.4B, C) (stero)isomers of bilirubin are of either physiological or clinical interest. Opening of the protoporphyrin-IX ring at bridges other than the α-carbon can occur nonenzymatically, leading to the formation, after reduction, of bilirubin-IXβ, -IXγ, or -1Xδ, respectively (Fig. 6.4A) [25,26]. Stereoisomerization at positions 4 and 15 can lead to formation of -4Z,15E and -4E,15E stereoisomersas illustrated in Fig. 6.4C and D [19,20,27].

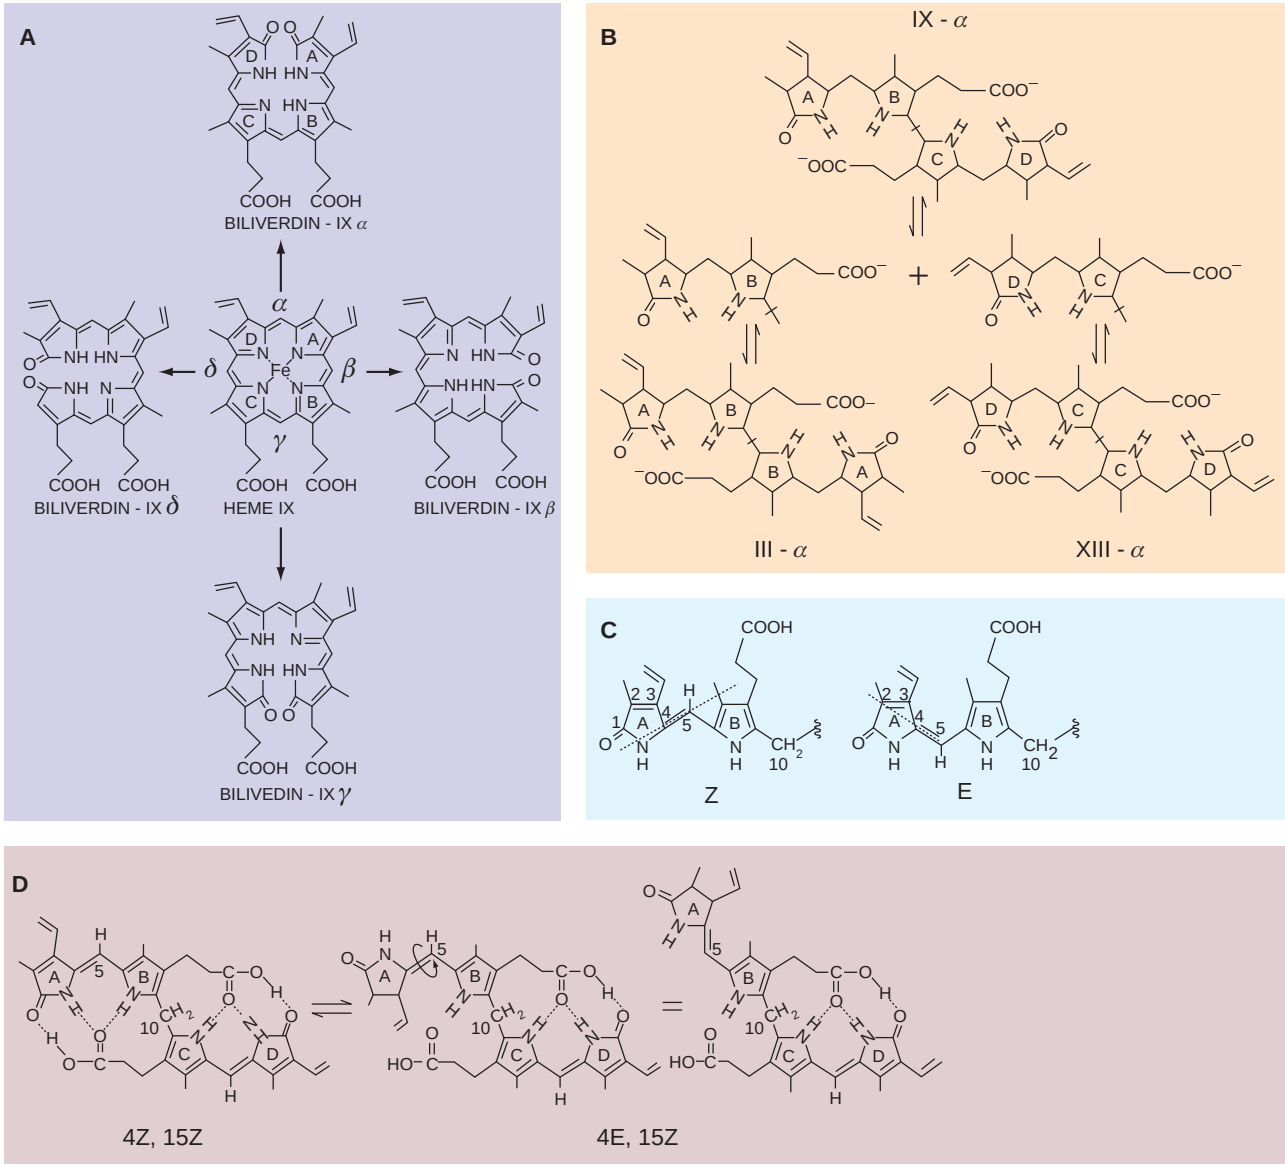

Figure 6.4 Bilirubin isomers. (A) Formation of α-, β-, γ-, and δ-isomers of biliverdin by nonenzymatic cleavage of the protoporphyrin ring of heme at the α-, β-, γ-, and δ-bridge carbons, respectively. (B) Dipyrrolic scrambling. This process involves the nonenzymatic dissociation of the bilirubin tetapyrrole into dipyrrolic units, which may then reassemble at random into symmetric (bilirubin-IIIα and -XIIIα) and nonsymmetric (bilirubin-IXα) tetrapyrroles. When this process occurs in a mixture of the C8 and C12 isomers of bilirubin-IXα monoglucuronide, final products will include -IIIα, -IXα, and -XIIIα isomers of both unconjugated bilirubin and its mono- and diglucuronides. (C) Nomenclature of the Z and E configurational isomers of bilirubin. If a plane is erected perpendicular to the page along the 4,5 double bond (illustrated by the dashed lines), the B ring may be together (German: *Zuzammen* (Z)) on the same side of the plane or on opposite sides (*Entegegen* (E)) of the plane from the NH group in the A ring. In the Z configuration, the meso hydrogen at position 5 is *trans* to the A-ring lactam hydrogen, while in the E configuration it is *cis*. (D) E,Z isomerization at the 4,5 double bond. In the 4Z,15Z configuration, the molecule is rigidly hydrogen bonded. In the 4E,15Z configuration, the A-ring nitrogen and oxygen groups are not spatially available to form hydrogen bonds with the C12 propionic acid side chain. Because of free rotation about the C5–6 bond, the two 4E,15Z structures are equivalent. Analogous geometric isomerization may occur at the 15,16 double bond. (Reproduced from Berk [269] with permission from Elsevier.)

None of these isomers can form the internal hydrogen bonds characteristic of bilirubin-4Z,15Z-IXα. Accordingly, they behave as more polar molecules, with rapid (direct) diazo reactivity, and can be excreted in bile without conjugation [28–30]. Finally, under certain conditions in vitro, the two nonidentical halves of the bilirubin molecule can dissociate and then reassemble at random [27]. This results in formation of two symmetric isomers, designated bilirubin-IIIα and -XIIIα, in addition to the asymmetric -IXα isomer; the ratio of -IIIα : -IXα : -XIIIα molecules formed is approximately 1 : 2 : 1 (Fig. 6.4B). Bilirubin-IIIα and -XIIIα *can* form internal hydrogen bonds. They are, therefore, relatively nonpolar, react slowly with diazo reagents, and require conjugation as a prerequisite to biliary excretion [31–33]. Recognition of the existence and properties of these various bilirubin isomers has increased understanding of the biologic properties of the naturally occurring -4Z,15Z-IXα form, and of the processes involved in its elimination by the liver. However, only the -4Z,15E and -4E,15E photoisomers, which are formed and readily excreted without conjugation during phototherapy of neonatal jaundice [19,20, 29,30], are of clinical significance.

Bilirubin in plasma

Although the bilirubin molecule contains two carboxyls and several other polar groups, internal hydrogen bonding involving these polar moieties constrains the molecule in a rigid, nonpolar and therefore highly insoluble conformation. As an otherwise insoluble molecule, bilirubin formed in the periphery is transported to the liver tightly bound to albumin, at concentrations that far exceed its solubility in protein-free aqueous solutions [34,35]. Adult human albumin has one high-affinity binding site for bilirubin and at least one class of lower affinity sites. Experimental measurements of the affinity of bilirubin for albumin have varied considerably with the methods employed [34], but estimates of a K_d for the high-affinity site have been in the μM range using several different approaches [34,36,37]. The determination of these estimates has been based on the assumption that the affinity of bilirubin for albumin is constant, and is independent of the albumin concentration. Under this assumption, until the bilirubin : albumin molar ratio in the circulation exceeds 1 : 1, virtually all of the bilirubin present would be bound to the high-affinity site on albumin, and the unbound bilirubin concentration would remain extremely small. This small, unbound bilirubin concentration [38] is, nevertheless, considered to be an important driving force for hepatocellular bilirubin uptake (see below). Under this model, if the 1 : 1 molar ratio of bilirubin to albumin is exceeded, the unbound bilirubin concentration increases rapidly with further increases in total bilirubin. In the neonatal period, increased levels of unbound bilirubin can cross the blood–brain barrier, leading to the serious neurologic consequences of kernicterus [39–42]. Similar neurotoxicity may, rarely, occur in adolescents and adults who develop sufficiently high concentrations of unconjugated bilirubin to exceed the critical 1 : 1 bilirubin : albumin molar ratio [43]. This is, in fact, the only clinically significant potential toxicity of hyperbilirubinemia. Since a normal albumin concentration is ~4 g/dL (600 μM), and a 1 mg/dL bilirubin concentration represents 17.1 μM, the critical 1 : 1 bilirubin : albumin molar ratio is usually exceeded in otherwise healthy adults only at bilirubin concentrations at or in excess of 35 mg/dL. In catabolic states in which hypoalbuminemia exists, however, the 1 : 1 ratio may be exceeded at much lower bilirubin concentrations, for example, less than 17 mg/dL in the presence of an albumin concentration of 2 g/dL. Although models of bilirubin binding to albumin that assume a constant affinity independent of the albumin concentration have been the basis for predictions of bilirubin concentrations at which the risk of kernicterus increases, several recent studies have challenged the basic assumptions of the model. Such studies have reported that the affinity of bilirubin for albumin actually varies inversely with the albumin concentration [38,44], making calculation of the critical unbound bilirubin concentration, and hence the risk of kernicterus, even more uncertain than previously. However, the most rapid changes in affinity reportedly occur at quite low albumin concentrations, with only relatively minor further changes occurring as the albumin concentration is increased above 150 μM [44]. Thus, the impact of this new observation on bilirubin to albumin binding within the physiologic range of albumin concentrations, and hence on the risk of kernicterus, has yet to be definitely determined, and may be very small. A variety of xenobiotics may displace or otherwise influence the binding of bilirubin to albumin. The resulting increase in the free bilirubin concentration may increase the risk of kernicterus in susceptible individuals [39,45–47].

Hepatic disposition of bilirubin

Since bilirubin is a potentially toxic waste product, its hepatic disposition is designed to eliminate it from the body via the biliary tract. Transfer of bilirubin from blood to bile involves four distinct but interrelated steps: hepatocellular bilirubin uptake, binding to specific intracellular cytosolic proteins, conjugation with glucuronic acid, and canalicular excretion (Fig. 6.5).

Bilirubin uptake

The fenestrated endothelium that lines the hepatic sinusoids provides the bilirubin–albumin complex with ready

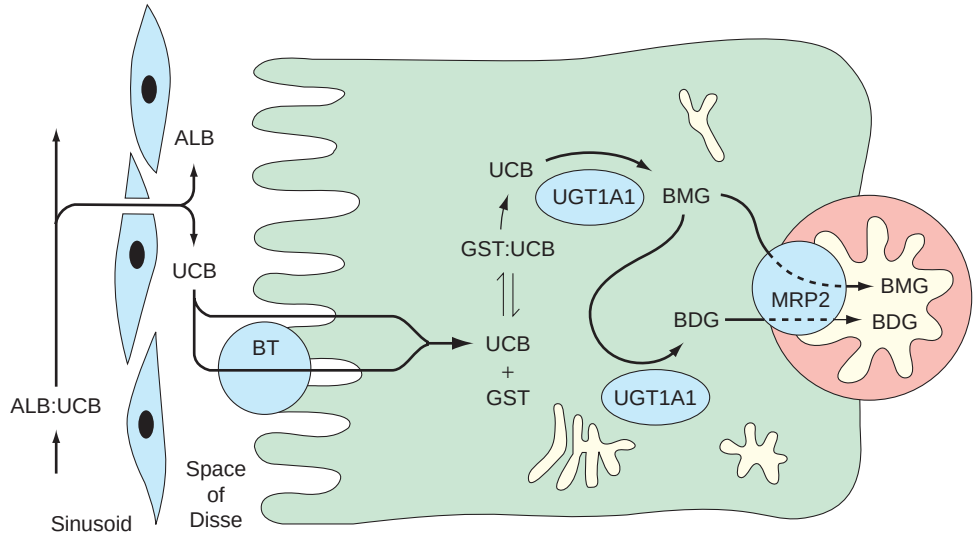

Figure 6.5 Hepatocellular transport of bilirubin. Efficient transfer of bilirubin from blood to bile is dependent on normal sinusoidal architecture, plasma membrane transport processes, and intracellular binding and conjugation. Albumin-bound bilirubin in sinusoidal blood passes through endothelial cell fenestrae to reach the hepatocyte surface, entering the cell by both facilitated and simple diffusional processes. Within the cell it is bound to glutathione-*S*-transferase (GST), and conjugated by bilirubin–uridine diphosphate (UDP) glucuronosyl-transferase (UGT1A1) to mono- and diglucuronides, which are actively transported across the canalicular membrane into the bile. ALB, albumin; BDG, bilirubin diglucuronide; BMG, bilirubin monoglucuronide; BT, proposed bilirubin transporter; MRP2, multidrug resistance-associated protein 2; UCB, unconjugated bilirubin. (Reproduced from Berk and Wolkoff [69] with permission from McGraw-Hill.)

access to the extrasinusoidal space of Disse, where it can come into direct contact with microvilli lining the sinusoidal surface of the hepatocytes [48–50]. In this setting, bilirubin dissociates from albumin and is transported across the hepatocyte plasma membrane into the cell. Numerous in vivo studies of bilirubin uptake kinetics in animals, in isolated, perfused livers, isolated hepatocytes, and plasma membrane vesicles, have all indicated that bilirubin uptake is concentrative, saturable, and competitively inhibited by other organic anions such as sulfobromophthalein (BSP), implying a protein-mediated, facilitated uptake process [51–60]. Subsequent reports, however, showed that BSP and bilirubin uptake could be dissociated under certain conditions, implying the existence of both shared and separate transport processes [55]. Despite an intensive search, the putative bilirubin transporter has not yet been identified, and several candidate transporters [61], including such historical ones as BSP/bilirubin-binding protein (BSP/BR-BP), organic anion-binding protein (OABP), bilirubin translocase (BTL) [56], and the more recently reported human transporter SLC21A6 [57,58] have failed to withstand closer scrutiny. Recent studies have also identified a purely passive, nonsaturable bilirubin uptake process, but its relative magnitude compared with the saturable process remains to be determined [59]. Although transporter mediated unconjugated bilirubin uptake has yet to be definitively identified, it appears that unconjugated bilirubin may be exported from the hepatocyte by the human drug resistance-associated protein MRP1 [60]. MRP2 mediates conjugated bilirubin export.

Intracellular binding

Once within the cell, bilirubin partitions between the cytosol and the lipid bilayer of various intracellular membranes. As with bilirubin binding to albumin in plasma, the cytosolic bilirubin fraction is kept in solution at concentrations that far exceed its aqueous solubility by binding as a nonsubstrate ligand to a number of proteins, of which the most abundant and best characterized are members of the glutathione-*S*-transferase (GST) superfamily [62–65]. This family includes a large number of homodimeric and heterodimeric proteins, previously referred to as ligandins [66], that are principally responsible for bilirubin binding. Kinetic analyses suggest that binding to these proteins is not involved in the initial process of cellular bilirubin uptake, but does increase net bilirubin sequestration by decreasing bilirubin efflux from the cytosol back into the space of Disse [63]. The GSTs have been postulated to play a specific role in presenting bilirubin to the microsomes for conjugation.

Bilirubin glucuronidation

The aqueous insolubility of bilirubin reflects the rigid, highly ordered, molecular structure conferred by internal hydrogen bonding that prevents solvent access to polar components of the molecule. Subsequent conjugation

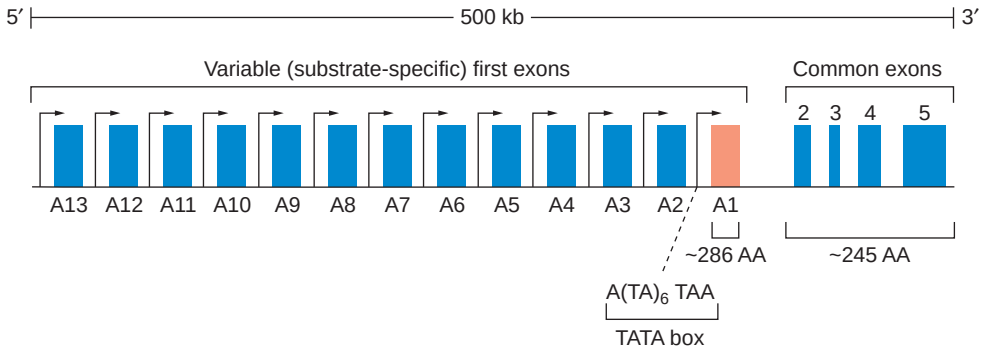

Figure 6.6 Structural organization of the human *UGT1* gene complex. This large complex on chromosome 2 contains at least 13 substrate-specific first exons (A1, A2, etc.), each with its own promoter, that encode the *N*-terminal substrate-specific 286 amino acids of the various *UGT*-encoded isoforms, and common exons 2–5 that encode the 245 carboxyl-terminal amino acids common to all of the isoforms. mRNAs for specific isoforms are assembled by splicing a particular first exon such as the bilirubin-specific exon A1 to exons 2–5. The resulting message encodes a complete enzyme, in this particular case bilirubin–uridine diphosphate (UDP) glucuronosyl-transferase (UGT1A1). Mutations in a first exon affect only a single isoform. Those in exons 2–5 affect all enzymes encoded by the UGT1 complex. (Reproduced from Berk and Wolkoff [69] with permission from McGraw-Hill.)

with glucuronic acid residues disrupts this internal hydrogen bonding, rendering the resulting monoglucuronide and diglucuronide conjugates highly soluble in aqueous solutions. The enzyme responsible for bilirubin glucuronidation is the UDP-glucuronosyl-transferase isoform UGT1A1, which is encoded by the *UGT1* gene on chromosome 2 [67,68]. This gene has a complex structure and mutations within it are recognized as the cause of three different disorders characterized by unconjugated hyperbilirubinemia: Gilbert syndrome and types I and II Crigler–Najjar syndrome. The *UGT1* gene (Fig. 6.6) consists of 13 exons (designated A1–A13) each of which encodes a distinct, substrate-specific binding site for one of the multiple protein isoforms produced by this single gene locus [69]. Initiation of RNA transcription at each of these 13 exons is controlled by a separate promoter element immediately upstream of its unique exon. Alternative splicing fuses one of these upstream exons with the four exons (exons 2–5) common to all UGT1 protein isoforms. Exon A1 and the four common exons code for the UGT1A1 protein that is responsible for glucuronidation of bilirubin (Fig. 6.6) [68,70].

Canalicular excretion of bilirubin

Bilirubin glucuronides are transported across the apical plasma membrane into the canaliculus by an ATP-dependent process mediated by a membrane protein initially called canalicular multispecific organic anion transporter (cMOAT), but now designated multidrug resistance-associated protein 2 (MRP2) (see Fig. 6.5) [71–73]. MRP2 is a member of the MRP gene family, other members of which pump drug conjugates, as well as unmodified anticancer drugs, out of cells. In mouse models, effective MRP2 function requires the presence of at least one additional protein, radixin, which localizes to the canalicular membrane and directly binds the carboxy-terminal cytoplasmic domain of MRP2 [74].

Fate of bilirubin in the gastrointestinal tract

Conjugated bilirubin excreted in bile passes through the small intestine without significant absorption and reaches the colon intact [75–77]. There, it is both deconjugated, presumably by bacterial β-glucuronidases [78] and degraded by other bacterial enzymes to a large series of urobilinogens and other products [79,80], the nature and relative proportions of which depend in part on the bacterial flora [79,81,81]. Because of this variability, quantitation of fecal urobilinogen excretion does not provide an accurate measure of heme degradation and bilirubin formation [83] and has largely been abandoned as a clinical test for hemolysis or ineffective erythropoiesis.

Some urobilinogen is reabsorbed from the colon, resulting in small but measurable concentrations of urobilinogen in plasma [84]. Most of this is reexcreted by the liver, but a small fraction is eliminated by the kidney. Increased urinary excretion of urobilinogen is a consequence of an increased plasma level. This in turn may reflect either increased bilirubin production, with a consequent increased formation and enterohepatic circulation of urobilinogen, or decreased hepatic clearance of urobilinogen. Hence, an elevated urine urobilinogen excretion does not distinguish between hemolysis and liver disease [85].

In the neonatal period, the presence of increased levels of intestinal β-glucuronidase [79,86] may result in the presence of appreciable amounts of unconjugated bilirubin within the distal small intestine and upper colon.

Absorption from these sites can give rise to a significant enterohepatic circulation of unconjugated bilirubin [75,76,79], which has been implicated as a contributing factor to physiologic jaundice of the newborn and to the further increase in plasma bilirubin concentrations seen in neonates with intestinal obstruction, delayed passage of meconium, or fasting [78]. In severe unconjugated hyperbilirubinemias such as those occurring in Crigler–Najjar syndrome type I or in the jaundiced Gunn rat (see below), a similar enterohepatic circulation may result from unconjugated bilirubin being excreted both in bile [87,88] and directly across the intestinal lumen into the gut [87]. Efforts to reduce unconjugated hyperbilirubinemia in such situations by interrupting the enterohepatic circulation of unconjugated bilirubin with the use of agents such as oral agar, charcoal, or cholestyramine have had at best limited and inconsistent success [78,79,89]. Recent reports suggest that oral administration of calcium phosphate with or without the lipase inhibitor orlistat may be an efficient means to interrupt bilirubin enterohepatic cycling to reduce serum bilirubin levels [90–92].

Bilirubin in the urine

Because of its very tight binding to albumin, the free fraction of unconjugated bilirubin in plasma is too small to permit efficient ultrafiltration at the glomerulus. Consequently, unconjugated bilirubin never appears in urine no matter what its plasma concentration. By contrast, bilirubin conjugates are appreciably less tightly bound to albumin. In the presence of cholestasis, whether secondary to hepatocellular injury or ductal obstruction, bilirubin conjugates formed in the hepatocyte are diverted back to the circulation, where their weaker albumin binding and larger free fraction permit excretion by the kidney, principally by glomerular filtration [93–97]. A small degree of tubular reabsorption has been demonstrated, but tubular secretion apparently does not occur [97]. The presence of bilirubin in the urine is an absolute indicator of conjugated hyperbilirubinemia.

Clinical physiology of bilirubin

The quantity of unconjugated bilirubin in plasma, and hence the plasma unconjugated bilirubin concentration, reflects a balance between two processes: bilirubin production and hepatic bilirubin clearance (Fig. 6.7) [10,12,48,98]. This balance is indicated by the relationship:

$$BR \cong BRT/C_{BR}, \quad (6.1)$$

where BR represents the plasma unconjugated bilirubin concentration, BRT is plasma bilirubin turnover (which closely approximates bilirubin production), and C_{BR} is the rate of clearance of unconjugated bilirubin from plasma by the liver. Measurement of C_{BR}, which has units of mL/min/kg, is a quantitative test of hepatic function that is, conceptually, analogous to creatinine clearance, a widely used measure of renal function. Both BRT and C_{BR} can be calculated from the area under the curve of an injected tracer dose of radiolabeled unconjugated bilirubin [10,12,98,99]. Alternatively, the bilirubin production rate can be estimated by isotope dilution from the specific activity of fecal bile pigments following intravenous injection of radiolabeled bilirubin [11,100], or from measurements of the excretion rate of carbon monoxide [101,102]. While estimates of BRT and C_{BR} by any of these methods are not available as routine clinical measurements, an appreciation of the physiologic implications of these two variables is very useful in interpreting data that *are* readily available in clinical settings. Specifically, Eq. (6.1) indicates that BR is directly proportional to the rate of bilirubin turnover and inversely related to hepatic bilirubin clearance in a manner analogous to the relationship between glomerular filtration rate and serum creatinine. Moreover, starting from any given baseline values

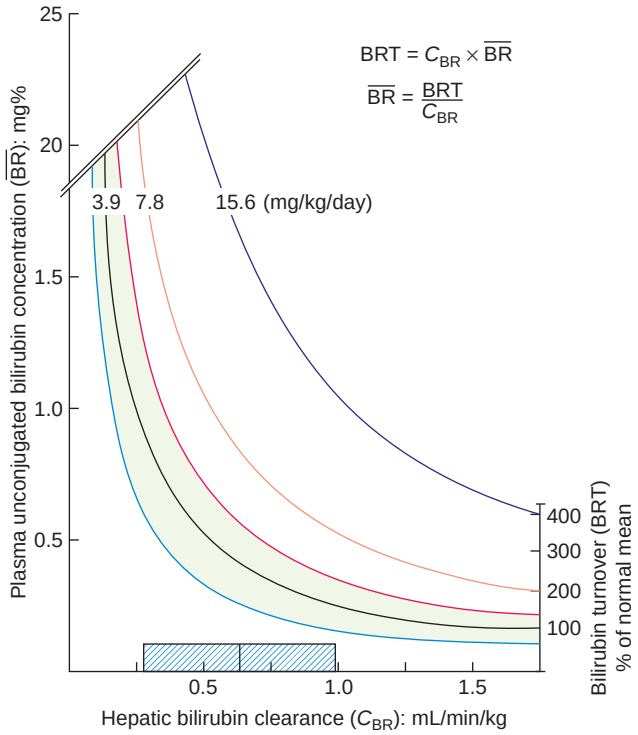

Figure 6.7 Relationship between plasma bilirubin turnover (BRT), hepatic bilirubin clearance (C_{BR}), and plasma concentration of unconjugated bilirubin ($\overline{BR}$). The stippled area represents the normal range for bilirubin turnover; the striped bar on the horizontal axis is the normal range (mean ± 2 standard deviations) for hepatic bilirubin clearance. (Reproduced from Berk et al. [98] with permission from American College of Physicians.)

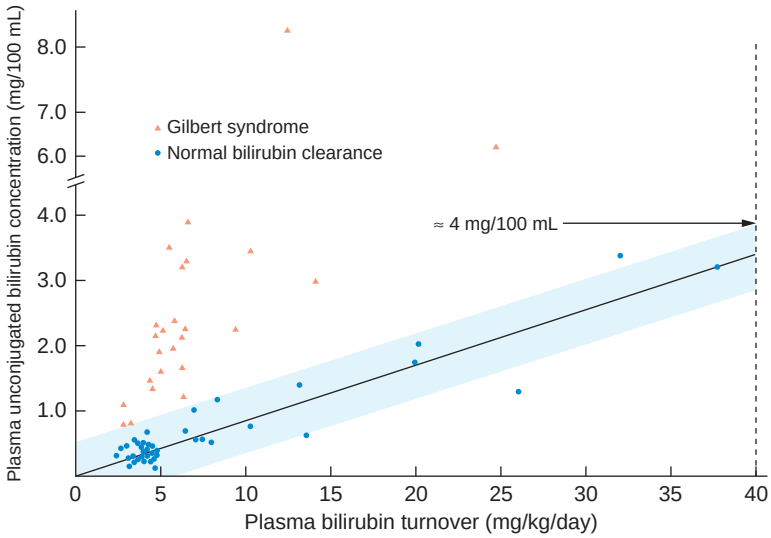

Figure 6.8 Relationship between plasma bilirubin turnover and the plasma concentration of unconjugated bilirubin. Normal plasma bilirubin turnover is up to 5 mg/kg body weight/day. Higher values indicate increased bilirubin production, usually from hemolysis. When hepatic bilirubin clearance is within the normal range, the plasma unconjugated bilirubin concentration increases linearly with increases in bilirubin turnover, as indicated by the regression line (stippled area represents ± 2 standard errors of the estimate about the regression line). Extrapolation of the regression line to the maximal rate of steady-state bilirubin production indicates the highest level of unconjugated hyperbilirubinemia that can result from sustained hemolysis in an individual with normal hepatic bilirubin clearance. Since the bone marrow can only increase erythrocyte production by about eight-fold in response to hemolysis, the maximum sustainable rate of bilirubin turnover is ~40 mg/kg/day, and the corresponding value of plasma unconjugated bilirubin is 4 mg/dL. (Reproduced from Berk et al. [98] with permission from American College of Physicians.)

for BRT and C_{BR}, a change in either BRT or C_{BR} will result in a corresponding fractional change in BR. The fractional change in BR will be directly proportional to any fractional change in BRT and inversely proportional to a fractional change in C_{BR} (Figs 6.7 and 6.8) [12,98]. As a result, for any given level of bilirubin production, equal *fractional* changes in hepatic bilirubin clearance can have dramatically different effects on plasma bilirubin concentrations, depending on the initial absolute value of C_{BR}. For example, when bilirubin turnover is normal (~4 mg/kg/day), reducing bilirubin clearance from a normal mean value of ~0.70 mL/min/kg to a lower mean value of ~0.35 mL/min/kg (a reduction of ~50%) will approximately double serum bilirubin, increasing it by ~0.4 mg/dL (from 0.4 to 0.8 mg/dL). This increment may well go unnoticed clinically. By comparison, in a patient whose hepatic clearance is already reduced a corresponding 50% reduction in bilirubin clearance, for example from 0.1 to 0.05 mL/min/kg, will again double the bilirubin concentration. In this instance, however, the interval increase, by ~2.7 mg/dL, will be sufficient to be clinically detectable. Similarly, doubling bilirubin production will double the plasma concentration of unconjugated bilirubin. The absolute magnitude of the increase, in mg/dL, will depend on the value of C_{BR}.

Measurement of plasma bilirubin concentration

Plasma bilirubin is typically measured in clinical laboratories by some modification of the diazo reaction first described by van den Bergh and Müller in 1916 [103] (reviewed in [104]). In this procedure, unconjugated bilirubin in the sample reacts slowly with the diazo reagent (for example, diazotized sulfanilic acid) because the central bridge carbon, which is the site of the attack by the reagent, is rendered sterically inaccessible by the internal hydrogen bonding within the molecule (see Fig. 6.3). In the presence of ethanol, caffeine, or other "accelerators" that disrupt the internal hydrogen bonding, the central bridge carbon becomes more readily accessible to nucleophilic attack and the unconjugated bilirubin molecule reacts more rapidly and completely. Similarly rapid diazo reactivity is displayed by conjugated bilirubin, in which esterification of propionic acid side chains with glucuronic acid prevents hydrogen bond formation and exposes the central bridge carbon. Accordingly, the "prompt" or *direct-reacting bilirubin* in serum or plasma, considered a measure of the amount of conjugated bilirubin present, is determined a short time interval (30–60 seconds) after the addition of the diazo reagent to the sample in the absence of an accelerator. The *total bilirubin* concentration, a measure of both unconjugated and conjugated bilirubin, is typically measured at some more prolonged interval (for example, 30–60 minutes) after the addition of an accelerator substance. The *indirect-reacting bilirubin*, calculated as the total minus the direct-reacting bilirubin, is widely used as a proxy for the amount of unconjugated bilirubin in the sample [104].

Bilirubin can also be estimated in biologic fluids by direct spectrophotometry because of its intense absorption band at approximately 450 nm [33,105]. The method is rapid, requires very small samples, and is therefore often used in neonatal nurseries or in amniotic fluid analyses [106] in which sample availability is limited. The method is nonspecific because turbidity and other yellow-orange materials such as carotenoids interfere. Various devices designed to measure bilirubin levels transcutaneously without blood sampling, by reflectance and/or

spectrophotometry, are widely used in neonatal nurseries (e.g., [107]). Accurate alternative methods also exist for quantification of individual bilirubin species [108, 109], including bilirubin conjugates covalently bound to plasma proteins (i.e., δ-bilirubin, see below), not only in plasma but also in bile, urine, and other biologic fluids [110–114]. As they are rarely employed outside research laboratories, a description of these technologies is beyond the scope of this review.

Normal ranges

Using conventional, diazo-based, analytic procedures, the upper limit of normal for *total plasma bilirubin* has been reported to be anywhere between .1.0 and 1.5 mg/dL (17–26 μM), and that for the indirect-reacting fraction from 0.8 to 1.2 mg/dL (14–21 μM) [85,104,115,116]. Differences reported reflect both variations in analytic methods and whether the 95% or 99% confidence limits were used to define the normal range. They also reflect the fact that bilirubin concentrations in the normal population exhibit a log-normal (skewed to the right) rather than a Gaussian (bell-shaped) distribution, which must be accounted for in establishing appropriate normal limits [115].

Many studies have set the upper limit of normal for the *indirect-reacting fraction* at 1.0 mg/dL (17.1 μM), in close agreement with limits predicted on theoretical grounds from a knowledge of the distributions of plasma bilirubin turnover and hepatic bilirubin clearance rates in a normal population [115]. When the total plasma bilirubin concentration is normal, the normal direct-reacting fraction (a proxy for conjugated bilirubin) was traditionally reported to be <0.1 mg/dL, or at most <0.2 mg/dL [104]. Because unconjugated bilirubin does react, albeit slowly, with diazo reagents even in the absence of an accelerator, even this small direct-reacting fraction *overestimates* the miniscule amounts of conjugated bilirubin actually present [117]. Consequently, the calculated indirect-reacting bilirubin *underestimate*s the amount of unconjugated bilirubin present. The proportional magnitude of these errors is greatest at total bilirubin concentrations within or near the normal range. Nevertheless, at virtually any total bilirubin level, if the direct-reacting fraction was <15% of the total, the bilirubin in the sample could be considered essentially all unconjugated. Unfortunately, the errors involved appear to be greater with autoanalyzer methods currently in widespread use than they were with the manual methods used in the past. "Normal" values for direct-reacting bilirubin have been creeping upward over the years even as more precise chromatographic methods demonstrate that the actual amounts of conjugated bilirubin in normal serum or plasma are vanishingly small. An informal survey several years ago suggested that few large laboratories in the New York metropolitan area set an upper limit of normal for direct-reacting bilirubin as low as 0.2 mg/dL. The most commonly reported upper limit was 0.3 mg/dL, with limits of 0.4–0.8 mg/dL being reported not infrequently. Such latitude can lead to considerable error in interpreting the direct- and indirect-reacting fractions as conjugated and unconjugated bilirubin. Because the presence of even modest amounts of true conjugated bilirubin in serum should alert the clinician to the possibility of significant hepatobiliary pathology, this distinction is of more than academic interest [118]. Since conventional bilirubin glucuronide conjugates are water-soluble and bind relatively loosely to albumin, they are readily filtered at the glomerulus and excreted in the urine. Accordingly, uncertainty about the clinical significance of a mildly elevated direct-reacting bilirubin can often be clarified by a simple dipstick test for bilirubin in the urine. Even minimal degrees of conjugated hyperbilirubinemia are associated with bilirubinuria. A negative dipstick test in the presence of a modestly elevated direct-reacting fraction suggests either the presence of δ-bilirubin (see below) or an artifact of the diazotization procedure.

With prolonged conjugated hyperbilirubinemia, some of the conjugated bilirubin in plasma binds *covalently* to albumin and produces what is designated the delta (δ) bilirubin fraction [111–114]. Although δ-bilirubin gives a direct diazo reaction, it is not filterable by the glomerulus and does not appear in the urine; it disappears slowly from the plasma with the 14–21-day half-life of the albumin to which it is bound. δ-Bilirubin accounts for the sometimes slow rate at which conjugated (direct) hyperbilirubinemia resolves as hepatitis improves or biliary obstruction is relieved. Although δ-bilirubin is not easily measured, its presence can be inferred when an elevated direct-reacting bilirubin persists after bilirubinuria resolves.

Hyperbilirubinemia and jaundice

Hyperbilirubinemia is conveniently classified as *unconjugated (indirect-reacting)* or *conjugated (direct-reacting) hyperbilirubinemia.* In practice, pure conjugated hyperbilirubinemia is uncommon; in most cases an elevated plasma conjugated bilirubin is accompanied by an elevation of unconjugated bilirubin resulting in a mixed hyperbilirubinemia. In this setting, because the plasma level of conjugated bilirubin reflects renal as well as hepatic clearance of bilirubin conjugates, the ratio of conjugated to total bilirubin is usually not helpful diagnostically. *Another useful characteristic is whether hyperbilirubinemia is the only abnormality of hepatic function or whether other hepatic biochemical tests such as the activities of serum aminotransferases (aspartate aminotransferase (ALT), alanine aminotransferase (AST)), alkaline phosphatase, or γ-glutamyl-transferase are*

also abnormal. Absence of abnormalities of other hepatic biochemical tests is one of the features that helps to distinguish the *familial hyperbilirubinemias* from the majority of acquired cases of hyperbilirubinemia. However, certain forms of acquired hyperbilirubinemia such as acquired hemolytic disease and inactive cirrhosis may also occur in the absence of other biochemical abnormalities. The major causes of familial hyperbilirubinemia are listed in Box 6.1.

Causes and consequences of hyperbilirubinemia

Unconjugated hyperbilirubinemia

Unconjugated hyperbilirubinemia is the result of any process that increases bilirubin production, decreases bilirubin clearance, or results in both processes acting in concert [12,98,99]. The reference range for the plasma unconjugated (that is, indirect-reacting) bilirubin concentration is generally reported to be 0.3–1.0 mg/dL, although some laboratories set the upper limit at 1.2 mg/dL and occasionally as high as 1.5 mg/dL. Values above the reference range represent unconjugated hyperbilirubinemia. While scleral icterus may become detectable when the bilirubin concentration exceeds 2.5–3.0 mg/dL, many cases of unconjugated hyperbilirubinemia are subclinical and detectable only by measurement of the plasma bilirubin concentration.

Increased bilirubin production

Hemolysis and increased ineffective erythropoiesis are two of the most common processes responsible for increased bilirubin production. A large number of distinct hereditary hemolytic disorders have been described, and result from inherited hemoglobinopathies, enzyme deficiencies, or abnormalities in red blood cell membrane structure. There are also many acquired hemolytic conditions, ranging from pure, specific autoimmune hemolytic anemias to the shortened red cell life spans that accompany many chronic diseases. Excessive ineffective erythropoiesis may occur on a congenital basis, as in any subtype of congenital dyserythropoietic anemia [48], or on an acquired basis, in disorders such as erythropoietic porphyria, pernicious anemia, and lead poisoning [13]. Transfusion of old bank blood and massive hematomas or pulmonary infarcts can produce unconjugated hyperbilirubinemia by temporarily increasing bilirubin production. Excessive *hepatic* bilirubin production, while seemingly a potential cause of increased plasma bilirubin turnover, has not been convincingly documented as a cause for clinically evident hyperbilirubinemia. Although hepatic heme turnover has been reported to contribute as much as one quarter of total bilirubin production based on the labeling of plasma bilirubin after administration of radiolabeled heme precursors e (e.g., [119–121]), approximately half of hepatic-derived bilirubin is excreted into the bile without transit through the plasma [10,12,48,100,120,122]. This means that hepatic hemes contribute no more than ~12% of plasma bilirubin turnover. Studies documenting a significant discrepancy between the increase in bilirubin labeling from ^{3}H-or ^{14}C-labeled heme precursors and total bilirubin production suggest that that actual percentage is appreciably lower [123,124]. On this basis, hepatic heme turnover would have to increase many-fold in order to result in a clinically recognizable increase in the plasma unconjugated bilirubin concentration.

Unconjugated hyperbilirubinemia due solely to increased bilirubin production rarely exceeds 4 mg/dL, even in the face of brisk hemolysis (Fig. 6.8), and is generally well tolerated. However, subjects are at an increased risk for the development of pigmented gallstones.

Decreased bilirubin clearance

As noted above, four distinct processes are involved in hepatocellular bilirubin disposition, and each, if defective, can result in a decrease in hepatic bilirubin clearance. Although the precise mechanism(s) by which bilirubin is taken up by hepatocytes remains unclear, several drugs (e.g., rifampin, flavispidic acid, novobiocin, and various cholecystographic contrast agents) are reported to competitively inhibit the bilirubin uptake process (see [48]). The resulting unconjugated hyperbilirubinemia resolves with the cessation of the medication. Reduced hepatic bilirubin uptake (and net clearance) can also result from portosystemic shunting by which blood bypasses the hepatocytes. While this is most commonly thought of as

occurring through venous channels such as varices, it may also result from capillarization of the hepatic sinusoids – that is, the loss of sinusoidal endothelial fenestrae and increased perisinusoidal matrix deposition – that occurs in cirrhosis. It is also a consequence of an absolute reduction in hepatic blood flow, or from abnormalities in the net extraction of bilirubin from the circulation by hepatocytes.

Abnormalities in the binding of bilirubin to its cytosolic-binding proteins are at least a hypothetical basis for decreased bilirubin clearance. However, defective glucuronidation is a more common mechanism that results in reduced bilirubin clearance and consequent unconjugated hyperbilirubinemia. Delayed expression of UGT1A1 in neonates is primarily responsible for the physiologic jaundice of otherwise normal newborns. Peak serum bilirubin levels in this setting are typically less than 5–10 mg/dL between days 2 and 5 and decline to normal within 2 weeks. Higher neonatal bilirubin levels that predispose to kernicterus occur in the face of profound prematurity, Gilbert syndrome (see below), hemolysis, or both (e.g., [125]). Three familial disorders of bilirubin conjugation are well recognized: Crigler–Najjar syndrome types I and II and Gilbert syndrome. These are described in greater detail below. Although considered until recently as distinct disorders, these conditions are now all known to result from mutations of different functional severity in the bilirubin-conjugating enzyme UGT1A1. Acquired deficiency of UGT1A1 and consequent unconjugated hyperbilirubinemia also occurs with administration of certain HIV protease inhibitors such as indinavir and atazanavir (reviewed in [126,127]).

Conjugated hyperbilirubinemia

Conjugated hyperbilirubinemias typically reflect abnormalities in hepatocellular excretion of conjugated bilirubin or in biliary tract obstruction. Dubin–Johnson and Rotor syndromes are uncommon, heritable disorders of conjugated bilirubin excretion. In Dubin–Johnson syndrome, mutations in MRP2 result in deficient canalicular transport of bilirubin conjugates [72,128,129]. The molecular defect in Rotor syndrome remains unknown but produces a phenotype similar in many respects to that of Dubin–Johnson syndrome. In both disorders, general hepatocellular function is preserved and liver chemistries other than the bilirubin concentration are typically normal. Bilirubin concentrations in Dubin–Johnson and Rotor syndromes are most often between 2 and 5 mg/dL, although values of <25 mg/dL for prolonged periods have been described. Extensive clinical experience suggests that conjugated hyperbilirubinemia produces no significant adverse consequences, even if prolonged for months at levels of up to 35–40 mg/dL.

Far more common is the defective bilirubin excretion that occurs with a broad spectrum of hepatobiliary diseases. In these conditions, elevations in bilirubin concentration typically occur in association with abnormalities of other hepatic biochemical tests, including elevations in AST, ALT, alkaline phosphatase, and, if severe, reduction in serum albumin and prolongation of clotting times. This broad category of diseases includes hepatocellular and cholestatic liver diseases, benign postoperative jaundice, mechanical intrahepatic or extrahepatic bile duct obstruction, and a rare group of disorders classified under the rubric of familial intrahepatic cholestasis (see below).

Familial hyperbilirubinemias

Familial unconjugated hyperbilirubinemias

The spectrum of familial unconjugated hyperbilirubinemias is indicated in Box 6.1. This review will limit itself to those entities associated with a decrease in hepatic bilirubin clearance: Crigler–Najjar syndrome types I and II and Gilbert syndrome. Important characteristics of these three entities are summarized in Table 6.1. These were once considered distinct genetic and pathophysiologic entities, with Gilbert syndrome reportedly an autosomal dominant and Crigler–Najjar type I an autosomal recessive disorder. However, physiologic observations (see Fig. 6.9) suggested that the three entities might reflect mutations with quantitatively different impact on the functioning of a single gene [130]. Subsequent molecular findings in the specific syndromes and the observation that one *normal* UGT1A1 allele is sufficient to maintain a normal plasma bilirubin concentration [67,70] have established that, in almost all instances, the hereditary unconjugated hyperbilirubinemias are related autosomal recessive disorders.

Crigler–Najjar syndrome type I

Crigler–Najjar syndrome type I is a rare, recessive disorder characterized by profound unconjugated hyperbilirubinemia of 20–45 mg/dL as a result of mutations in UGT1A1 that result in the near total loss of UGT1A1 enzyme activity [67,70,89,131–135]. Mutations most often occur in exons 2–5 of the *UGT1* gene affecting the glucuronidation of a wide spectrum of substrates in addition to bilirubin (type 1a). Less often the mutation occurs in exon 1 and the loss of glucuronidation capacity is largely limited to bilirubin conjugation (type 1b). Crigler–Najjar syndrome type I first appears in the neonatal period and, historically, most patients succumbed from kernicterus in infancy and early childhood. Patients with Crigler–Najjar syndrome type I do not respond to phenobarbital with a reduction in plasma bilirubin concentrations [89,133]. Although survival has been extended with the advent of phototherapy, those who survive beyond early childhood remain at substantial risk for late-onset bilirubin encephalopathy, the onset of which often follows after

Table 6.1 Principal features of the familial unconjugated hyperbilirubinemias.

Feature	Crigler–Najjar syndrome		Gilbert syndrome
	Type I	Type II	
Incidence	Very rare	Uncommon	Up to 12% of population
Total serum bilirubin (mg/dL)	18–45 (usually >20), unconjugated	6–25 (usually ≤20), unconjugated	Typically ≤4 in absence fasting or hemolysis; mostly unconjugated
Defect(s) in bilirubin metabolism	Bilirubin UGT1A1 activity markedly reduced: trace to absent	Bilirubin UGT1A1 activity reduced: ≤10% of normal.	Bilirubin UGT1A1 activity typically reduced to 10–33% of normal; reduced hepatic bilirubin uptake in some cases; mild hemolysis in up to 50% of patients
Routine liver tests	Normal	Normal	Normal
Serum bile acids	Normal	Normal	Normal
Plasma sulfobromophthalein (BSP) removal (% retention of 5 mg/kg dose at 45 minutes)	Normal	Normal	Usually normal (<5%); mildly increased 45-minute retention (<15%) in some patients
Oral cholecystography	Normal	Normal	Normal
Pharmacologic responses/special features	No response to phenobarbital	Phenobarbital reduces bilirubin by ≤75% but not to normal	Phenobarbital reduces bilirubin, often to normal
Major clinical features	Kernicterus in infancy if untreated; may occur later despite therapy	Rare late-onset kernicterus with fasting	None
Hepatic morphology/histology	Normal	Normal	Normal; occasionally increased lipofucin pigment
Bile bilirubin fractions[a]	>90% unconjugated	Largest fraction (mean 57%) monoconjugates	Mainly diconjugates but monoconjugates are increased (mean 23%)
Inheritance (all autosomal)	Recessive	Recessive	Promoter mutation is recessive; missense mutation often dominant
Diagnosis	Clinical and laboratory findings, lack of response to phenobarbital	Clinical and laboratory findings, response to phenobarbital	Clinical and laboratory findings; promoter genotyping may be helpful; liver biopsy rarely necessary
Treatment	Phototherapy or tin protoporphyrin as short-term therapy; liver transplantation definitive	Consider phenobarbital if baseline bilirubin ≥8 mg/dL	None necessary

[a]Bilirubin in normal bile: <5% unconjugated bilirubin, with an average of 7% bilirubin monoconjugates and 90% bilirubin diconjugates.

even mild febrile illnesses (e.g., [89,136]). Although isolated hepatocyte transplantation has been used experimentally in a limited number of cases of Crigler–Najjar syndrome type I [137,138], early liver transplantation remains the best hope to prevent brain injury and death [139–142].

Much of the basis for elucidation of the pathobiology of Crigler–Najjar syndrome type I has arisen from studies that have been performed in the Gunn rat. This mutant Wistar strain of rats was initially described by Gunn in 1938 as having chronic nonhemolytic unconjugated hyperbilirubinemia [143]. As in patients with Crigler–Najjar syndrome type I, jaundice in these animals is inherited as an autosomal recessive trait. Heterozygotes are anicteric, and liver histology in affected rats is normal. Bilirubin glucuronyl transferase activity is undetectable in livers of affected rats [144].

Crigler–Najjar syndrome type II

In contrast, in Crigler–Najjar type II, UGT1A1 activity is maintained, albeit at a minimal level (<10% of normal), and serum bilirubin concentrations typically vary between 6 and 25 mg/dL [133,145,146]. Induction of UGT1A1 levels with exposure to phenobarbital can

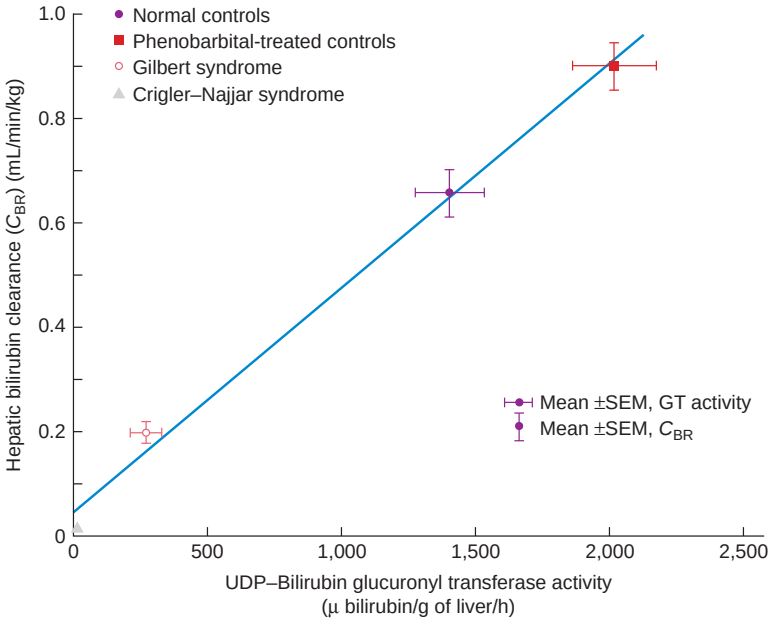

Figure 6.9 Relationship between the mean values for hepatic bilirubin clearance (C_{BR}) and bilirubin–uridine diphosphate (UDP) glucuronsyl-transferase (UDPGT) activity in patients with Crigler–Najjar syndrome type I, Gilbert syndrome, and normal controls. For the control group, data are presented for both untreated and phenobarbital-treated subjects. The line represents a least squares fit to the mean values for the four groups represented. Subsequent data in Crigler–Najjar type II fell on the regression line. Data such as these suggested that Gilbert syndrome and the two Crigler–Najjar syndromes might all reflect mutations with quantitatively differing effects on a single gene, designated at the time bilirubin-UDPGT. (Adapted from Blaschke et al. [130].)

further reduce bilirubin levels by >25% [133,147–150]. Depending on the severity of the molecular defect, either basal or phenobarbital-stimulated enzyme activity is sufficient in most cases to prevent the development of kernicterus. Clinically relevant neurologic sequelae can, however, be precipitated in the setting of intercurrent illnesses, fasting, or any other factor that temporarily raises the serum bilirubin concentration significantly above baseline (e.g., [43]), especially if the resulting bilirubin : albumin molar ratio exceeds 1. Overall, available data in the majority of type II patients indicates that in adolescents and adults with normal serum albumin levels, prolonged exposure to unconjugated bilirubin <16 mg/dL does not result in neurologic injury. Indeed, the majority of patients in the original reports describing the syndrome were healthy adults, many with college-level education [133,145]. To date, a total of 77 different mutations in the *UGT1* gene have been identified in association with either type I or type II Crigler–Najjar syndrome [151]. Chain-terminating mutations have been more commonly associated with a Crigler–Najjar type I phenotype whereas missense mutations have been more frequently observed among less severely affected patients with Crigler–Najjar syndrome type II [151].

Gilbert syndrome

Gilbert syndrome resides at the other end of the spectrum of disorders of bilirubin conjugation. Originally described in 1901 (152), this condition occurs with a phenotypic prevalence of approximately 8% in the general population. It is characterized by a mild, unconjugated hyperbilirubinemia to levels that rarely exceed 4 mg/dL, otherwise normal liver function, and hepatic histology that is also normal other than a modest increase in lipofuscin pigment in some cases. Other than mild icterus in some patients, physical examination is also unremarkable. Bilirubin clearance is reduced to approximately one third of normal (Fig. 6.10) [153], and some patients also exhibit abnormalities in the plasma clearance patterns of other organic anions such as sulfobromophthalein or indocyanine green [53,154], for which the mechanism remains uncertain. By contrast, fasting serum bile acid levels are normal [155]. The most common recognized molecular defect is the addition of an extra dinucleotide sequence, TA, to the transcription initiation sequence (TATAA box) of the promoter for the A1 exon [156]. Thus, compared with the normal $A(TA)_6TAA$ sequence, an $A(TA)_7TAA$ mutation is commonly found in patients with Gilbert syndrome. Much less common $A(TA)_5TAA$ or $A(TA)_8TAA$ mutations are also associated with Gilbert syndrome [157]. In individuals homozygous for one of these variants, enzyme activity is decreased to 10–35% of normal, due to decreased synthesis of a functionally normal enzyme. Homozygosity for the promoter mutation appears to be necessary, but apparently not always sufficient for clinical expression of Gilbert syndrome, as population studies suggest that only about half of $A(TA)_7TAA$ homozygotes have hyperbilirubinemia [158]. It has been suggested that additional variables, such as mild hemolysis (reported in up to 50% of Gilbert patients) or a separate defect in bilirubin uptake [153,156,157,159], might be among the factors enhancing phenotypic expression.

Additional molecular mechanisms result in a phenotype identical to that associated with homozygosity for

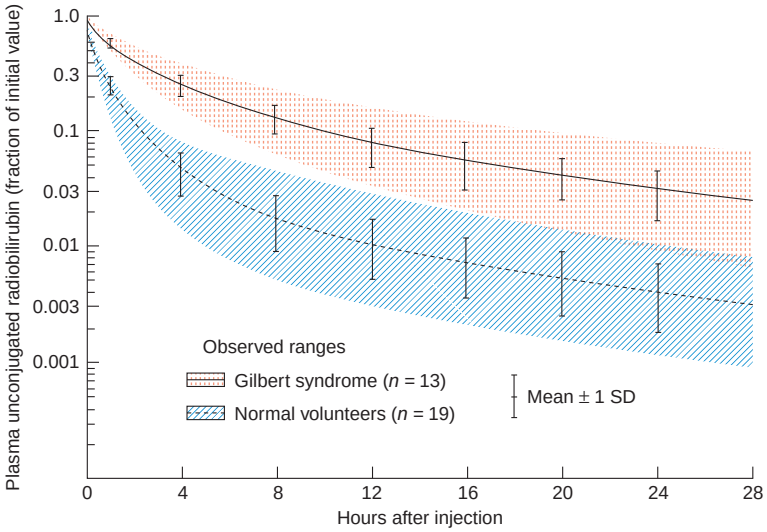

Figure 6.10 Observed ranges of plasma radiobilirubin disappearance curves in patients with Gilbert syndrome and in healthy young adult volunteers. The average curve for each group was calculated by computer from the mean values, for the group, of the intercompartmental rate constants of a compartmental model of bilirubin metabolism. The groups do not overlap for the first 16 hours after injection. Estimates of bilirubin clearance (C_{BR}), calculated from the areas under the curves, were reduced to one third of normal in the Gilbert syndrome patients. (Reproduced from Berk et al. [98] with permission from American College of Physicians.)

the A(TA)$_7$TAA promoter variant (Box 6.2) [156,157]. Consistent with the previously noted observation that one *normal* UGT1A1 allele is sufficient to maintain a normal plasma bilirubin concentration, individuals who are heterozygous for one UGT1A1 allele encoding an enzyme with reduced to absent bilirubin conjugating activity will nevertheless have normal bilirubin concentrations if the second UGT1A1 allele is normal. However, if that second allele has the A(TA)$_7$TAA promoter variant, the patient will have mild unconjugated hyperbilirubinemia with a Gilbert syndrome phenotype. Additionally, a number of instances have been documented in which mutations in the coding regions of the UGT1A1 gene encode proteins with only mildly reduced enzymatic activity. Such missense mutations, which result in a Gilbert syndrome phenotype, have thus far been reported only from Japan [160]. Inheritance has been either recessive or as a dominant negative [156,157]. If a phenotypic reduction in bilirubin clearance is taken as the operational definition of Gilbert syndrome, recognition of these alternative genotypes is important for the appropriate interpretation of mild, nonhemolytic, unconjugated hyperbilirubinemia. While homozygosity for the A(TA)$_7$TAA promoter variant supports a diagnosis of Gilbert syndrome, absence of homozygosity for this variant does not exclude Gilbert syndrome in this setting.

Box 6.2 Alternative molecular bases for the Gilbert syndrome phenotype.

- A(TA)$_7$TAA homozygote
- A(TA)$_7$TAA/structural mutation compound heterozygote
- Structural mutation, for example G71R (homozygous recessive or dominant negative)

The diagnosis of Gilbert syndrome is most often made clinically on the basis of a mild, unconjugated hyperbilirubinemia in the absence of other causes. While a definitive diagnosis can be established by assays of UGT1A1 enzymatic activity or identification of the homozygous A(TA)$_7$TAA promoter mutation, such elaborate studies, like liver biopsies, are rarely necessary [161]. Provocation tests such as a 48-hour fast or the intravenous administration of nicotinic acid augment the bilirubinemia of Gilbert syndrome patients and normal controls by a similar proportion, and are of limited value in establishing a diagnosis of Gilbert syndrome (reviewed in [48]). Bilirubin levels in simple Gilbert syndrome in adults are never sufficiently elevated to pose a risk of neurologic damage. However, neonates with *both* Gilbert syndrome *and* some form of hemolysis are at increased risk of transiently developing dangerous degrees of hyperbilirubinemia [162–165].

Some patients with Gilbert syndrome exhibit abnormalities in the hepatic handling of a variety of xenobiotics metabolized by glucuronidation, including menthol, estradiol benzoate, lamotrigine, tolbutamide, rifamycin SV, acetaminophen [48,166], and HIV protease inhibitors [126]. The HIV protease inhibitors indinavir and atazanavir produce hyperbilirubinemia by specifically inhibiting UGT1A1 [127]. The degree of hyperbilirubinemia is greater with preexisting Gilbert syndrome. Abnormalities in the glucuronidation of other substrates may be attributable to polymorphisms of other UGT isoforms [166]. No significant toxicity has been ascribed to any of these pharmacokinetic abnormalities. Virtually the sole risk from Gilbert syndrome in adults is associated with exposure to the antitumor agent irinotecan (CPT-11), the active metabolite of which is glucuronidated by UGT1A1. Administration of CPT-11 to patients with

Gilbert syndrome has resulted in severe toxicities, including intractable diarrhea and myelosuppression.

Familial conjugated hyperbilirubinemias

Two inherited disorders characterized by conjugated hyperbilirubinemia without cholestasis, the Dubin–Johnson [167] and Rotor [168] syndromes, have been described. Although a third disorder that had been termed hepatic storage disease [169] was also included in this group, more recent evidence indicates that these patients have Rotor syndrome. These disorders are relatively rare. They are clinically benign, but establishment of a precise diagnosis is important to differentiate them from other more serious disorders and to save patients from unnecessary anxiety or surgical intervention. There are several additional familial disorders characterized by conjugated hyperbilirubinemia in association with cholestasis. These include benign recurrent intrahepatic cholestasis, and the progressive familial intrahepatic cholestases, described below.

Dubin–Johnson syndrome

Clinical features

This disorder, independently described in 1954 by Dubin and Johnson [167] and by Sprinz and Nelson [170] is characterized by mild, predominantly conjugated hyperbilirubinemia (Table 6.2). Aside from jaundice, physical examination is normal in most cases, but an occasional patient may be found to have unexplained hepatosplenomegaly [171,172]. Mild constitutional symptoms similar to those observed in Gilbert syndrome (vague abdominal pain, fatigue, weakness) are common [171,172]. However, as in Gilbert syndrome, these symptoms may be related to the anxiety associated with prolonged diagnostic testing. For the most part, newly detected cases are asymptomatic. Hyperbilirubinemia and clinical icterus are typically increased by intercurrent illness, by the administration of drugs that decrease hepatic excretion of organic anions (notably oral contraceptives), and by pregnancy [173]. The condition is rarely observed before the onset of puberty, although occasional cases have been reported in infants [174–176]. Subclinical cases often become manifest during pregnancy or in association with the initiation of oral contraceptive therapy [173]. In contrast to syndromes associated with true cholestasis, pruritus is not seen in Dubin–Johnson syndrome, and serum bile acid levels are characteristically normal [173] as are other routine tests of liver function (e.g., serum alkaline phosphatase) [167,172]. Useful animal models of the Dubin–Johnson syndrome have been described in mutant Corriedale sheep [177–180], golden lion tamarin monkeys [181], and in Tr^{-}/GY [72,182–186], and EHBR [187–189] mutant rat strains. Because of the insights they have provided into the probable pathophysiology of the Dubin–Johnson syndrome, the rat mutants are discussed in detail below.

Frequency

Dubin–Johnson syndrome has been described worldwide in all races, nationalities, and ethnic backgrounds and in both sexes [171,172,190–194]. Uncommon on a worldwide basis, the disorder is highly prevalent (1 : 1300) among Iranian Jews [172]. Its frequent association in this population with a deficiency of clotting factor VII [195,196] appears to represent the coincidental inheritance of two conditions, as factor VII deficiency is not observed as part of the syndrome in other populations, and is caused by a different genetic mutation [197,198].

Table 6.2 Phenotypic features of Dubin–Johnson and Rotor syndromes.

Feature	Dubin–Johnson syndrome	Rotor syndrome
First described	1954	1948
Serum bilirubin	Usually 2–5 mg/dL, predominantly (~60%) direct reacting. Less often ≤25 mg/dL total	Usually 2–5 mg/dL, predominantly (~60%) direct reacting. Less often ≤25 mg/dL total
Other liver function tests	Normal	Normal
Serum bile acids	Normal	Normal
Appearance of liver	Grossly black; coarse, dark centrilobular pigment	Normal
Physical findings	Jaundice ± hepatomegaly	Jaundice
Urine coproporphyrins	Normal total; >80% isomer I	Markedly increased total; isomer I increased, but always <80%
Inheritance	Autosomal recessive	Autosomal recessive

Laboratory findings

Serum bilirubin concentration is typically between 2 and 5 mg/dL, but values as high as 20 or even 25 mg/dL have been reported [171,172]. Fifty percent or more of total serum bilirubin is direct reacting, and, accordingly, bilirubinuria and an increase in the covalently bound δ-bi1irubin fraction in plasma are frequently present. The serum bilirubin concentration often fluctuates and occasional bilirubin determinations may be within normal limits. Other routine tests of liver function are normal, including aminotransferases, alkaline phosphatase, and γ-glutamyl transferase activities; serum albumin concentration; cholesterol level; and (except in the Iranian population) prothrombin time. Hematological studies, including complete blood count, reticulocyte count, and red cell survival studies, are also normal [199], indicating no evidence of hemolysis. Fasting and postprandial levels of the common serum bile acids are normal in the majority of patients with Dubin–Johnson syndrome [173,200] although mild elevations have been described in occasional patients [201].

Imaging studies

Cholecystography, even when carried out with supplemental doses of contrast media, does not visualize the gallbladder in Dubin–Johnson syndrome [171,172] but intravenous administration of iodipamide may permit visualization of the gallbladder at 4–6 hours [202,203]. Biliary scintigraphy with agents such as ^{99m}Tc-lidofenin or ^{99m}TC-disofenin may be helpful in the evaluation of patients with Dubin–Johnson and Rotor syndromes [204–206]. In six patients with Dubin–Johnson syndrome, administration of ^{99m}Tc-lidofenin was followed by rapid, intense, homogeneous accumulation of isotope within the liver without visualization of the intrahepatic biliary tree [204]. In the majority of patients with intact gallbladders, this organ was visualized approximately 90 minutes after injection; in all cases, isotopic activity had reached the intestine within 1 hour of injection. However, in a patient with Rotor syndrome, as well as in jaundiced patients with hepatocellular disease, administration of ^{99m}T-lidofenin resulted in no visualization of the liver, gallbladder, or biliary tract and no accumulation of radioactivity in the intestine over 24 hours of observation. The kidneys visualized intensely in these latter conditions, indicating selective excretion of the radionuclide by this route [204].

Histopathology

Gross examination of the liver from typical patients with Dubin–Johnson syndrome shows it to be intensely pigmented to the point of appearing black in color [170, 171]. Light microscopy reveals no scarring, hepatocellular necrosis, or distortion of zonal architecture. Instead, the characteristic feature is the accumulation of a coarsely granular pigment, most pronounced in the centrilobular zones (Fig. 6.11), with a characteristic appearance of lysosomal distribution [207]. Its nature has been the subject of some debate, with some authors considering it a lipofuscin and others a melanin derivative. The histologically similar pigment observed in mutant Corriedale sheep resembles melanin histochemically and incorporates tritium following infusion of ^{3}H-epinephrine, a finding consistent with a melanin-like origin of the pigment granules [208]. A study of Dubin–Johnson syndrome employing electron spin resonance spectroscopy demonstrated differences in the physicochemical characteristics of the Dubin–Johnson pigment when compared with authentic melanin [209]. Although the nature of the pigment was not clearly defined, the data were consistent with its being composed of polymers of epinephrine metabolites. The degree of hepatic pigmentation may be variable, both within families and in a single individual with the Dubin–Johnson syndrome. Some of the variability may be genetic, but some may be due to the fact that coincidental diseases, such as viral hepatitis, are associated with the complete disappearance of pigment from the liver [210]. Pigment reaccumulates slowly after recovery from the hepatitic episode [211].

Metabolism of organic anions

Following intravenous injection, initial plasma disappearance of organic anions such as bilirubin, sulfobromophthalein (BSP), dibromosulphthalein (DBSP), and indocyanine green (ICG) is normal [212,213]. It should be noted that, with the exception of ICG, these compounds are no longer commercially available for clinical use.

A characteristic feature of Dubin–Johnson syndrome is that the plasma concentration of BSP is higher at 90 minutes as compared with 45 minutes after injection, due to reflux of conjugated BSP back into the circulation from the hepatocyte, where it was conjugated with glutathione (GSH) [172,173,202]. This secondary rise is not seen following the intravenous administration of DBSP or ICG, compounds that are excreted into bile by the hepatocyte without further metabolism [212,213]. A secondary rise, representing reflux of conjugated bilirubin, has been noted following the intravenous administration of unconjugated bilirubin-IXa to patients with this syndrome [209,212]. The defect in the excretion of conjugated BSP has been confirmed by direct studies of the plasma clearance of this metabolite [214], consistent with the presence of a selective abnormality in the bile canalicular excretion of conjugated organic anions with normal excretion of bile salts. Studies of BSP metabolism involving continuous infusion of dye support these findings as they show a marked reduction in the calculated secretory transport maximum with a normal relative storage capacity [172,173]. Even though the secondary rise of BSP levels observed following intravenous administration of a single 5 mg/kg dose is highly suggestive of the syndrome, it is not diagnostic and has occasionally been observed in other hepatobiliary disorders [215].

Urinary coproporphyrin excretion

Patients with Dubin–Johnson syndrome also have a diagnostic abnormality in urinary coproporphyrin excretion [190,216–218]. There are two naturally occurring coproporphyrin isomers, I and III. Normally, approximately 75% of the coproporphyrin in urine is isomer III. In urine from Dubin–Johnson syndrome patients, total coproporphyrin content is normal, but more than 80% is isomer I. Heterozygotes for the syndrome show an intermediate pattern [190,219]. The molecular basis for this phenomenon is not yet known.

Animal models of Dubin–Johnson syndrome

The mutant Corriedale sheep was the first recognized animal model of Dubin–Johnson syndrome [177–180]. These animals have grossly black livers and defects in organic anion and coproporphyrin excretion that are identical to patients with the syndrome. Subsequently two mutant rat models of Dubin–Johnson syndrome were described. These are the TR^-, also known as GY (Groningen yellow), and EHBR rat strains [72,182–189]. These mutant rat strains exhibit many of the characteristic phenotypic features of the Dubin–Johnson syndrome, including: (i) autosomal recessively inherited conjugated hyperbilirubinemia and bilirubinuria; (ii) defective biliary excretion of conjugated organic anions with normal bile acid excretion; and (iii) normal total urinary coproporphyrin excretion with increased percentage of isomer I. Although these animals do not typically have increased hepatic pigmentation, studies in TR^- animals demonstrate accumulation of lysosomal pigment following infusion of epinephrine metabolites, or feeding a diet high in aromatic amino acids [220]. A mutant strain of golden lion tamarins with a Dubin–Johnson phenotype have also been described [181].

Inheritance

The initial descriptions of the Dubin–Johnson syndrome indicated that it was an inheritable disorder [171] and its familial nature has been verified in many subsequent studies [145,191,194,196,202,221,222]. Although it was thought to be inherited as an autosomal recessive trait, there was initially no means to detect heterozygous carriers [223]. This subsequently became available from determination of urinary coproporphyrin excretion [190,219]. As noted above, there is a characteristic abnormality in the pattern of urinary coproporphyrin excretion in patients with Dubin–Johnson syndrome [190,216,217]. Subsequent studies found that in obligate heterozygotes (e.g., phenotypically normal parents and children of Dubin–Johnson syndrome patients), this pattern was intermediate between normal and affected individuals, consistent with autosomal recessive inheritance [190,219]. The pathogenesis of abnormal urinary coproporphyrin excretion in Dubin–Johnson syndrome is not known [224,225].

Genetic defect

The gene responsible for causing Dubin–Johnson syndrome has been identified as *MRP2*, encoding an ATP-dependent canalicular plasma membrane transporter for bilirubin conjugates and a number of other nonbile acid organic anions [226]. Mutations in this gene can result in a Dubin–Johnson syndrome phenotype in rats and humans [194,226–229]. Although it is clear that MRP2 plays a major role in the biliary excretion of conjugated bilirubin, even in its absence bilirubin conjugates are found in bile, implying the existence of other, not yet identified, alternative transport proteins. At least 15 mutations in the *MRP2* gene have been described in patients with the Dubin–Johnson syndrome [228]. These include four splice site mutations, six missense mutations, three nonsense mutations, and one deletion mutation. As noted above, as many as 60% of patients with Dubin–Johnson syndrome in an Israeli series had coexistence of clotting factor VII deficiency. It is now known that the gene for factor VII is located on chromosome 13, in contrast to the localization of *MRP2* to chromosome 10, which has effectively excluded a primary genetic linkage between these two phenotypes.

Treatment

No specific therapy is indicated for Dubin–Johnson syndrome. It is generally considered to be a benign disorder requiring only reassurance of the patient and avoidance of invasive diagnostic procedures. Although phenobarbital has been used in an attempt to reduce the serum bilirubin concentration, the results have been highly variable [230,231]. Although some patients with nonspecific abdominal complaints report amelioration of their vague symptoms during phenobarbital therapy, irrespective of any lowering of the serum bilirubin concentration, chronic phenobarbital administration is not recommended.

Rotor syndrome

This syndrome is characterized by chronic, predominantly conjugated hyperbilirubinemia, phenotypically resembling the Dubin–Johnson syndrome (see Table 6.2), and was initially described in two Philippine families by Rotor et al. in 1948 [168]. Although the incidence of Rotor syndrome remains much less than that of the Dubin–Johnson syndrome, it has a widespread geographic distribution [232–235].

Clinical and laboratory findings

Patients with Rotor syndrome are generally asymptomatic, and their conjugated hyperbilirubinemia is most often discovered incidentally. Some individuals describe mild symptoms such as weakness and vague abdominal pain, but pruritus is not a feature. In contrast to the Dubin–Johnson syndrome, hepatosplenomegaly has not been reported. The serum bilirubin concentration is typically elevated to between 2 and 5 mg/dL but may be as high as 20 mg/dL. More than half of the serum bilirubin is direct-reacting, and bilirubinuria is typically present. Bilirubin levels often fluctuate in a given individual and may be increased by intercurrent illness. Conventional hepatic biochemical tests other than serum bilirubin, such as alkaline phosphatase and aminotransferase activities, serum albumin concentration, and prothrombin time, are typically normal [168,234]. The gallbladder usually visualizes on oral cholecystography, in contrast to findings in the Dubin–Johnson syndrome [232,234]. Liver biopsy also is normal, and there is no increase in hepatic pigmentation.

Organic anion metabolism

Although Rotor syndrome phenotypically resembles the Dubin–Johnson syndrome and both disorders were initially considered to be variants of the same entity, detailed studies of BSP and coproporphyrin metabolism have indicated that they are distinct disorders [232,236]. In addition, while oral cholecystographic agents usually do not visualize the gallbladder in the Dubin–Johnson syndrome, visualization is usual in Rotor syndrome [234,237]. Following the administration of a 5 mg/kg dose of BSP, a compound that is no longer available for clinical use, the initial plasma disappearance rate in Rotor syndrome is markedly reduced and the 45-minute retention is elevated, often to 30–50% [236]. There is no secondary rise in plasma BSP and conjugated BSP does not accumulate in the plasma [236]. Studies of biliary excretion failed to document a defect in the transport of either free BSP or the BSP glutathione conjugate [214]. In contrast to the Dubin–Johnson syndrome, there is marked retention of ICG and unconjugated bilirubin following intravenous infusion [238]. In addition, during constant infusion, the transport maximum T_m for BSP in Rotor syndrome was only minimally to moderately reduced, while the relative storage capacity (S) was reduced by 75–90% [236,238]. These data are in marked contrast to those in the Dubin–Johnson syndrome in which T_m is virtually 0, while S is normal. These results for BSP T_m and S are identical to those that have been described in a phenotypically disorder that had been termed hepatic storage disease [169,239]. It must be concluded that these two disorders are the same. When plasma BSP disappearance studies were conducted in 11 phenotypically normal obligate heterozygotes for Rotor syndrome, mildly elevated retention at 45 minutes, averaging 11%, was intermediate between results in patients and normal controls [236]. Similarly, during constant BSP infusion studies, T_m and S in obligate heterozygotes were also intermediate between those of Rotor syndrome patients and healthy controls [236]. These findings, suggesting an autosomal recessive mode of inheritance for Rotor syndrome, are in contradistinction to similar studies in Dubin–Johnson syndrome, in which the carrier state is not usually detectable by studies of BSP metabolism.

Urinary coproporphyrin excretion

Rotor syndrome is also differentiated from Dubin–Johnson syndrome with respect to patterns of urinary coproporphyrin excretion [218,232,240]. Total urinary coproporphyrin excretion in patients with Rotor syndrome is increased by 2.5–5-fold compared with healthy controls [232,240]. The proportion of coproporphyrin-I is also increased to an average of 65%. These results are similar to those seen in a variety of acquired hepatobiliary disorders and sharply contrast with those observed in the Dubin–Johnson syndrome [241]. Obligate heterozygotes for Rotor syndrome are phenotypically normal and have a coproporphyrin excretion pattern intermediate between that of Rotor syndrome and healthy controls [232]. On the basis of urinary coproporphyrin excretion studies, Rotor syndrome appears to be inherited as an autosomal recessive characteristic and is clearly distinct from Dubin–Johnson syndrome (Fig. 6.12) [232,240].

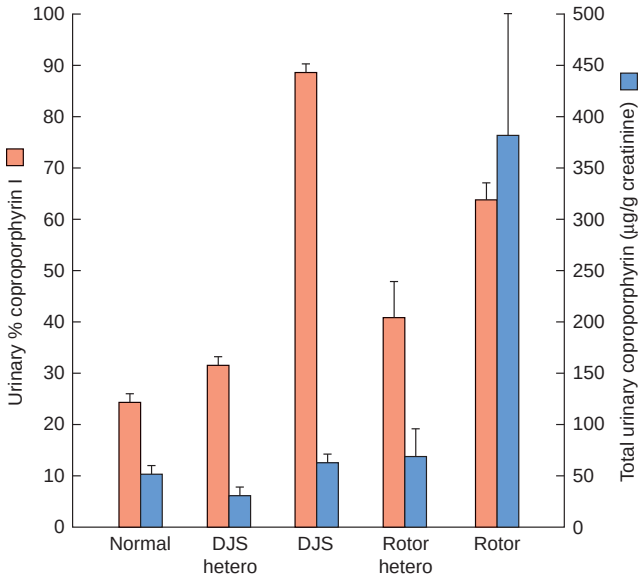

Figure 6.12 Urinary coproporphyrin in Dubin–Johnson and Rotor syndromes. The shaded bars represent the percentage of total urinary coproporphyrin excreted as coproporphyrin I. The open bars represent total urinary coproporphyrin excretion; vertical bars represent ± standard error of the mean. Total urinary coproporphyrin excretion is normal to slightly increased in the Dublin–Johnson syndrome (DJS) with a markedly elevated proportion of coproporphyrin I (approximately 80%). Both variables are markedly elevated in the Rotor syndrome. Thus, with respect to urinary coproporphyrin excretion, the two disorders are distinct. Results in obligate heterozygotes (DJS hetero, Rotor hetero) lie intermediate between results in normal individuals and in individuals manifesting the respective disorder. (Reproduced from Berk et al. [218] with permission from Elsevier.)

Genetic defect

It is clear that Rotor syndrome is an inheritable disorder distinct from the Dubin–Johnson syndrome [232,236,238,240]. However, the genetic defect has not as yet been elucidated.

Treatment

There is no treatment that is required or effective for Rotor syndrome. The majority of patients are, in any case, asymptomatic. In the absence of ill-advised medical or surgical intervention, life expectancy appears to be normal.

Familial cholestasis syndromes

Several rare familial disorders characterized by cholestasis, often in association with conjugated hyperbilirubinemia, have long been recognized, and designated progressive familial intrahepatic cholestasis (PFIC), benign recurrent intrahepatic cholestasis (BRIC), and intrahepatic cholestasis of pregnancy (ICP). In some, notably in PFIC, the cholestasis is associated with the evolution of structural liver damage that may ultimately require liver transplantation. Over the past two decades advances in molecular cloning and the complete sequencing of the human genome have led to the identification of the major components of the hepatocellular bile secretory apparatus [242]. These advances, applied to genetic studies in individuals and kindreds affected by the various familial forms of cholestasis, established that different mutations in just three proteins – familial intrahepatic cholestasis 1 (FIC1), the bile salt export pump (BSEP), and multidrug resistance protein 3 (MDR3) – located in the canalicular plasma membrane and involved in canalicular bile salt and phospholipid transport, were the basis for the multiple different clinical presentations and manifestations of familial cholestasis observed in neonatal, pediatric, and adult – including obstetric – settings. A small number of patients with a PFIC phenotype do not appear to have a mutation in any of these three genes, suggesting that mutations in additional genes also may produce the phenotype.

Progressive familial intrahepatic cholestasis

This name is applied to three phenotypically related syndromes (Table 6.3). PFIC type 1 presents in early infancy as cholestasis that may be initially episodic [243]. However, in contrast to BRIC (see below), PFIC progresses during childhood to malnutrition, growth retardation, and end-stage liver disease often requiring transplantation. The disorder is a consequence of a mutation in the *ATP8B1* gene encoding the protein designated FIC1 [244]. FIC1 is expressed primarily in the small intestine and weakly in the liver. It is a member of a P-type ATPase family that transports aminophospholipids from the outer to the inner leaflet of a variety of cell membranes, and has little similarity to genes that have been shown to play a role in bile canalicular excretion of compounds such as bilirubin conjugates [244–246]. The precise functional relationship of the FIC1 protein to the pathogenesis of cholestasis is not yet entirely clear. However, under normal circumstances, the distribution of phospholipids in the hepatocyte plasma membrane is asymmetric, with phosphatidyl choline being concentrated in the external leaflet and phosphatidyl serine and phosphatidyl ethanolamine in the cytoplasmic leaflet. The asymmetry, which is important to the physical properties of the canalicular membrane, is actively maintained by inwardly directed phospholipid transporters called flippases and outwardly directed ones called floppases. FIC1 is a phosphatidyl serine flippase. In the presence of deficient FIC1 activity, phosphatidyl serine accumulates in the outer membrane leaflet, increasing membrane flexibility. Subsequent phospholipid rearrangement makes the membrane more sensitive to the extraction of cholesterol and certain ectoenzymes by bile salt micelles. This

Resolves after delivery. Increased fetal wastage

leads to impairment of BSEP activity, which is the ultimate cause of cholestasis [247,248]. To date, more than 50 distinct mutations in *ATP8B1* have been reported [249]. Nonsense and frameshift mutations likely to cause severe defects in protein expression or function are typically detected in patients with progressive disease while missense mutations are more common in less clinically severe variants. Homozygosity for the Gly308Val mutation is almost invariably found among old-order Amish in Pennsylvania, where the condition is known as Byler syndrome after the original "founders" of the disease [243]. While other specific mutations are commonly found in several other isolated populations, in the population at large no single mutation is widely detected, so that the entire gene must be sequenced if a diagnosis is to be based on mutational analysis.

Two other types of PFIC (types 2 and 3) have been described. Type 2 is associated with mutations in *ABCB11* [250,251], which encodes BSEP per se. More than 100 mutations have been reported and, as with *ATP8B1* mutations, they produce a clinical spectrum from mild to progressive. The missense mutations Glu297Gly and/or Asp482Gly have been found in more than half of the well-studied European families [249]. PFIC type 3 has been associated with at least 45 different mutations of the *ABCB4* gene encoding MDR3, a protein that is essential for normal hepatocellular excretion of phospholipids across the bile canalicular membrane, where it functions as a phospholipid floppase (i.e., an outwardly directed phospholipid transporter), translocating phosphatidylcholine into the canalicular bile [252–254]. As a result of *ABCB4* mutations, bile phospholipid concentrations in this condition are low. Injury to bile canaliculi and the biliary epithelium in the form of cholangitis is thought to result from their continuous exposure to hydrophobic bile salts, the detergent effects of which are not prevented by the reduced biliary phospholipid levels. Consequently, although all three types of PFIC have similar clinical phenotypes, only type 3 is associated with high serum levels of γ-glutamyltransferase (GGT) activity [249,254]. The activity of this enzyme is normal or only mildly elevated in symptomatic BRIC and PFIC types 1 and 2.

Short of full mutational analysis, distinction among the three forms of PFIC is based on histologic and biochemical differences. All three forms of PFIC exhibit elevated serum bile salt concentrations and abnormalities of standard hepatic biochemical tests. On routine histologic examination, PFIC type 1 tends to show a "bland cholestasis" with little inflammation, whereas PFIC type 2 exhibits features of neonatal hepatitis. Bile ductular proliferation is suggestive of PFIC type 3. Type 3 is distinguishable from types 1 and 2 by having an elevated GGT level. Electron microscopy shows the bile in type 1 to be coarsely granular, while that in type 2 is filamentous.

Overall, most medical therapies are of limited value in PFIC types 1 and 2, especially in patients with progressive disease. Cholestyramine, alone or in combination with rifampicin, may shorten episodes in patients whose cholestasis is intermittent. In contrast, ursodeoxycholic acid (UCDA) therapy may ameliorate symptoms and even normalize hepatic biochemical tests in up to 60% of patients with PFIC type 3 [254,255]. Its mechanism of action in this situation appears to involve the changes it effects in the composition of the bile salt pool with a consequent decrease in hydrophobicity, as well as possible upregulation of the expression of some mutated *MDR3* genes, resulting in some phospholipids being translocated into bile. These two factors may be adequate to protect cell membranes from the toxicity of primary bile salts in some patients [253]. Results with UCDA in PFIC types 1 and 2 are conflicting, varying from no effect to some instances of clear benefit [255].

In many patients with progressive disease who fail medical therapy, partial external biliary diversion may slow disease progression. In those with symptomatically difficult intermittent disease, nasobiliary drainage may bring temporary relief. Ultimately, intolerable pruritus and/or progression to cirrhosis may mandate orthotopic liver transplantation. Although lifelong immunosuppression is often required postoperatively, the procedure usually provides symptomatic relief and correction of the phenotype in type 2 and 3 disease. However, severe recurrence of the phenotype has been reported in type 2 disease due to the formation of autoantibodies against BSEP [256]. In PFIC type 1 disease, diarrhea may appear or worsen after transplantation. Cholestyramine may be of benefit in this situation.

Benign recurrent intrahepatic cholestasis type 1

This rare disorder, also known as Tygstrup or Summerskill and Walshe cholestasis, is characterized by recurrent attacks of pruritus and jaundice. It typically presents with an episode of mild malaise and elevated serum aminotransferases, followed rapidly by rises in alkaline phosphatase and conjugated bilirubin and onset of jaundice, bilirubinuria, and itching [248,257]. Some reports suggest that a fever, even a mild and transient one, is a precipitating event. During the cholestatic episode, hepatic uptake of unconjugated bilirubin has been shown to be normal, but is followed by extensive reflux of conjugated bilirubin to plasma [258]. Initial episodes may be misdiagnosed as acute viral hepatitis. Cholestatic episodes typically begin in childhood or young adulthood, and can last for several weeks to months. In the interval between attacks, lasting from several months to years, there is complete clinical and biochemical resolution. This disorder is familial and has an autosomal recessive pattern of inheritance.

Although BRIC is considered a benign disorder that does not lead to cirrhosis or end-stage liver disease, the prolonged episodes can be highly debilitating, resulting in liver transplantation in some patients. Treatment during the cholestatic episodes is symptomatic and there is no means available to reliably prevent or shorten the occurrence of episodes.

It is now recognized that BRIC type 1 results from mutations in the *ATP8B1* gene encoding FIC1 [244,248,249], the same gene that is mutated in PFIC type 1. There is considerable genetic heterogeneity, and patients with BRIC type 1 may either be heterozygotes for a particular *ATP8B1* gene mutation or homozygotes for a mutation that only partially affects the function of the encoded protein. Interestingly a second phenotypically identical form of BRIC, termed BRIC type 2, has been described resulting from mutations in the bile salt export pump, BSEP [251,259].

Intrahepatic cholestasis of pregnancy

Intrahepatic cholestasis of pregnancy is characterized by the development of pruritus in pregnant women, usually without accompanying clinical jaundice, that most typically presents in the third trimester, becomes more severe as the pregnancy advances, and resolves after delivery [260,261]. Symptoms are typically accompanied by increased serum bile acid, AST, ALT, and alkaline phosphatase concentrations. The syndrome has been associated with heterozygosity for mutations in the genes encoding FIC1 (ICP type 1), BSEP (ICP type 2), and MDR3 (ICP type 3). Serum GGT is typically normal in ICP types 1 and 2, but may be slightly elevated in type 3 [261]. ICP is associated with an increased incidence of fetal distress and prematurity and an unexplained increase in intrauterine deaths, especially after 37 weeks' gestation [24]. Accordingly, the aims of treatment are to reduce maternal symptoms and prevent fetal complications. As the purely obstetric aspects of management are beyond the scope of this chapter, we refer readers to recent reviews of ICP for a detailed overview of management options [24,262].

The most effective medical therapy is UDCA. While not universally approved for use during pregnancy, available data suggest that it is safe and effective in improving both maternal symptoms and biochemical abnormalities [263,264], and may also even diminish fetal complications [265]. A combination of UCDA with *S*-adenosyl-L-methionine is reported to have synergistic benefits [266]. Since intensive fetal monitoring does not prevent intrauterine death, current literature encourages the induction of labor between 37 and 38 weeks of gestation in women with ICP, with the goal of decreasing the incidence of later intrauterine death [262].

After delivery, the serum biochemical abnormalities normally resolve within 2–8 weeks. Follow-up should be maintained at least long enough to ensure normalization of liver tests, and even longer follow-up should be considered as ICP is associated with the development of hepatobiliary disease later in life, for example gallstones, cholecystitis, and cirrhosis [267]. In addition, recurrence of cholestasis is not uncommon in subsequent pregnancies, and may also occur with the use of oral contraceptives.

This outstanding review evaluates the available information on the phenotypic consequences of multiple genotypes, including many mutations in both the UGT1A1 coding regions and in the exon 1 promoter, that have been associated with Gilberts syndrome and Crigler–Najjar syndromes I and II. It leads to a much clearer picture of the complex interactions among these three conditions.

Maisels MJ, McDonagh AF. Phototherapy for neonatal jaundice. *N Engl J Med* 2008;358:920–8.

This review details the biochemistry of bilirubin as it relates to treatment of neonatal jaundice. Current treatment guidelines are reviewed, and rational use of this treatment modality for prevention of kernicterus is clearly presented.

McDonagh AF. The biliverdin–bilirubin antioxidant cycle of cellular protection: missing a wheel? *Free Radic Biol Med* 2010;49:814–20.

Earlier observations led to the proposed existence of a specific intracellular oxidation/reduction cycle in which lipophilic reactive oxygen species (ROS) oxidize bilirubin to biliverdin, which is then re-reduced by biliverdin reductase, thus contributing in a regulated fashion to cellular antioxidant defenses. However, existence of such a cycle appears unlikely on the basis of more recent studies summarized in this review.

Nies AT, Keppler D. The apical conjugate efflux pump ABCC2 (MRP2). *Pflugers Arch* 2007;453:643–59.

This is a review of the pathobiology of the bile canalicular efflux pump, MRP2 (ABCC2) and its relationship to normal liver excretory mechanisms. Mutations that result in Dubin–Johnson syndrome are detailed.

Ostrow JD, Pascolo L, Brites D, Tiribelli C. Molecular basis of bilirubin-induced neurotoxicity. *Trends Molec Med* 2004;10:65–70.

The susceptibility of newborns to bilirubin neurotoxicity is highly variable. Furthermore neurologic damage sometimes occurs at plasma unconjugated bilirubin concentrations well below therapeutic guidelines. This paper reviews current information on mechanisms of cellular bilirubin toxicity, and the transport processes determining its access to and accumulation within the central nervous system.

Multiple choice questions

6.1 **A 36-year-old female nurse presents with a 1-week history of malaise, abdominal discomfort, arthralgias, fatigue, and obvious jaundice. Her past medical history is unremarkable, and she denies any history of a needle-stick. Her family history includes rheumatoid arthritis in her mother and primary biliary cirrhosis in her sister. Her physical examination includes a tachycardia of 120 bpm, icterus, and a spleen that is palpable two finger-breadths below the left costal margin. In the emergency room the hemoglobin (Hgb) is 7.0 g/dL, hematocrit (Hct) 22%, platelets 285,000, and total bilirubin 4.0 mg/dL. During an annual check-up last month her total bilirubin was 0.45 mg/dL and her hemoglobin 12.4 g/dL. The initial differential diagnosis included acute hepatitis, acute biliary obstruction due to gallstones, and chronic liver disease with gastrointestinal bleeding. Which one of the following test results indicates that none of these diagnoses is correct?**

- **a** Stool guaiac: negative.
- **b** Reticulocytes: 12%.
- **c** Urine dipstick for bilirubin: negative.
- **d** Antihepatitis A virus IgM: negative.

6.2 **In the same patient as in question 1, new-onset unconjugated hyperbilirubinemia in the presence of new onset of anemia strongly suggests an acute hemolytic process. Given the positive family history for autoimmune disease an autoimmune hemolytic anemia is now suspected. Direct and indirect Coombs tests are ordered and are positive. The patient is begun on prednisone, 40 mg/day, for an autoimmune hemolytic anemia, and returns to the clinic for follow-up after 1 week. At that time, her Hgb is 8.2 g/dL, Hct 25%, reticulocytes 10%, platelets 225,000, and total serum bilirubin 0.4 mg/dL. Her jaundice has disappeared. However, based on her Hgb, Hct, and reticulocyte count, the resident argues that she must still be hemolyzing, and proposes to increase her prednisone to 60 mg/day. By contrast, the attending declares that the hemolysis has essentially ceased, and orders a continuation of the current prednisone dose. He predicts that the results of a similar group of tests at follow-up in a week will allow them to start reducing her prednisone dose. When the patients returns a week later her Hgb is 11.8 mg/dL, Hct 35%, reticulocytes 2%, and total bilirubin 0.5 mg/dL. The strongest indication that hemolysis had appreciably decreased after 1 week of prednisone was which of the following?**

- **a** An increase in hemoglobin from 7.0 to 8.2 g/dL.
- **b** A fall in reticulocytes from 12% to 10%.
- **c** A decrease in total bilirubin from 4.0 to 0.4 mg/dL.
- **d** A fall in platelet count from 285,000 to 240,000.

6.3 **The following hereditary syndromes may all exhibit both conjugated hyperbilirubinemia and elevated serum bile acids except which of the following?**

- **a** Progressive familial intrahepatic cholestasis type 1.
- **b** Progressive familial intrahepatic cholestasis type 3.
- **c** Benign recurrent intrahepatic cholestasis type 1.
- **d** Dubin–Johnson syndrome.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

CHAPTER 8
Mechanisms of Liver Injury

Harmeet Malhi & Gregory J. Gores
Division of Gastroenterology and Hepatology, Mayo Clinic, College of Medicine, Rochester, MN, USA

Key concepts

- Apoptosis is a prominent feature of acute and chronic liver diseases.
- Injurious stimuli can induce apoptosis in different cellular compartments in the liver.
- Hepatocyte apoptosis is mitochondria dependent.
- Mitochondrial dysfunction in hepatocytes can be secondary to death receptor-mediated extrinsic signals or intrinsic perturbations.
- Apoptosis leads to inflammation and injury in acute liver diseases, and in chronic liver diseases sustained apoptosis begets fibrosis.
- Manipulation of apoptotic pathways has wide therapeutic potential.

The liver is in constant cellular flux with careful removal of senescent or damaged cells and controlled repopulation through a progenitor cell compartment. The unique juxtaposition to the intestine, large resting blood flow, and unfiltered contact with portal blood also provides the liver with a unique sensitivity to various gut-derived, diet-derived, or blood-borne insults. Under basal conditions, removal of hepatocytes occurs mainly through apoptosis without reactive inflammation. Liver injury, on the other hand, is associated with cell death, inflammation, and regeneration.

Cell death in the liver can be apoptotic or necrotic or a combination of the two. Historically, apoptosis, or programmed cell death, has been viewed as a carefully choreographed cascade resulting in protease and endonuclease activation. It has been defined morphologically on the basis of characteristic nuclear appearance, the generation of membrane-bound apoptotic bodies (Councilman bodies), and the absence of an inflammatory reaction. Necrotic cell death has been considered the antithesis of apoptotic cell death. It has been defined on the basis of cellular energy depletion, characteristic morphology of cytoplasmic vacuolation, cell swelling, and the presence of an inflammatory reaction. Cell swelling, a cardinal feature of necrosis, results from an inability to maintain ion gradients, such that the process is in fact called oncotic necrosis. Over the last few years, with better understanding of both pathways of cell death, these arbitrary morphologic definitions have become less important. It is recognized that both apoptosis and necrosis can be triggered by the same stimulus and occur in the same disease process. Furthermore, necroptosis, a form of cell death with necrotic morphology is triggered by apoptotic stimuli in cells deficient in apoptotic signaling, and is a regulated form of cell death. Apoptosis has been shown to be a prominent feature of several liver diseases (Fig. 8.1). The dogma has shifted from apoptosis being a physiologic, bland, noninflammatory process to one that is pathologic, occurs in disease processes, and causes liver inflammation, injury, and fibrosis (Fig. 8.2). This chapter is divided into two sections. The first section provides a general overview of mechanisms of cell death in the liver and the role of the innate immune system in this context. Apoptosis and necrosis are both discussed with emphasis on death receptors and the role of mitochondria in cell fate. The second section focuses on mechanisms of liver injury in some common disorders.

Basic mechanisms

Apoptosis

Apoptosis is a prominent feature of liver injury including drug-induced liver diseases, viral hepatitis, alcoholic liver disease, nonalcoholic fatty liver disease, cholestasis, and vascular liver diseases. Apoptosis of hepatocytes, Kupffer cells, sinusoidal endothelial cells (SECs), hepatic stellate cells (HSCs), and cholangiocytes has been observed in different liver diseases [1]. The initiation of apoptosis occurs via two fundamental pathways: (i) the death receptor or extrinsic pathway; and (ii) the mitochondrial or intrinsic pathway [2]. The extrinsic pathway is triggered by ligation or oligomerization of death receptors. The

mitochondrial pathway is activated by several intracellular perturbations, including DNA damage, lysosomal permeabilization, endoplasmic reticulum stress, chemotherapeutic agents, oxidative stress, toxins, and sustained increases in Ca^{2+} [3]. Cells that die via the extrinsic pathway are classified as type I or type II cells. In type I cells amplification and conduction of death signals occurs exclusive of mitochondrial involvement. In type II cells, death receptor activation is not sufficient to propagate into a lethal signal without mitochondrial involvement. Hepatocytes are type II cells and have an obligate need for mitochondria in cell death [4].

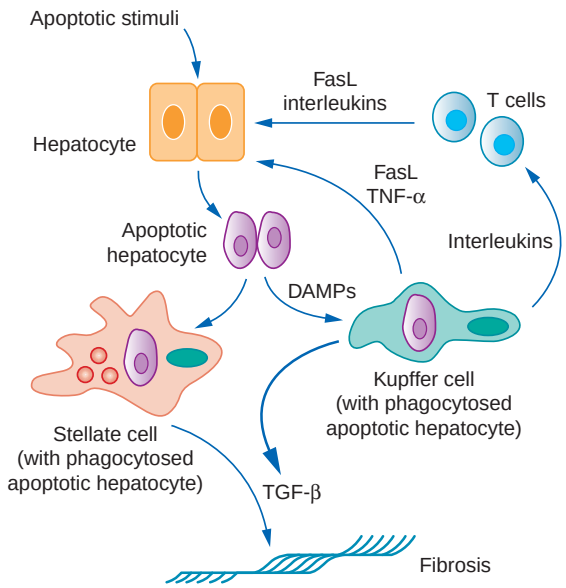

Figure 8.2 Hepatocyte apoptosis is the proximal event in hepatic fibrosis. Apoptotic hepatocytes are engulfed by stellate cells, leading to their activation, and by Kupffer cells, leading to the secretion of several proinflammatory and proapoptotic cytokines. Molecules known as damage-associated molecular patterns (DAMPs) are also released from dead cells and activate cells of the innate immune system, including Kupffer cells. Kupffer cell-derived cytokines promote stellate cell activation and further promote apoptosis. Activated stellate cells play a key role in fibrosis. FasL, Fas ligand; TNF-α, tumor necrosis factor α; TGF-β, transforming growth factor β.

In a homeostatic setting, apoptosis is accompanied by activation of phagocytosis leading to efficient removal of cellular corpses without damage to healthy cells [5]. However, apoptosis, if massive or simultaneous, results in liver injury. For example, in the setting of massive apoptosis, such as fulminant hepatic failure, successful hepatocyte repopulation leads to recovery [6]. In such an environment, if hepatocyte repopulation is protracted or delayed liver injury results. Apoptosis is harmful not just in a passive sense of inadequate repopulation, but also as an active inducer of inflammatory processes. In fact, recent data have established a mechanistic link between liver apoptosis, injury, inflammation, and fibrosis in chronic liver disease [7]. Apoptotic body engulfment by phagocytic cells leads to their activation. This results in chemokine secretion, recruitment of leukocytes and inflammatory cells to the liver, and amplification of liver injury. Hepatic stellate cells are activated by phagocytosis of apoptotic bodies as well, leading to fibrosis (see Fig. 8.2) [8].

Death receptors and the liver

Death receptors, transmembrane proteins that belong to the tumor necrosis factor (TNF)/nerve growth factor superfamily, are essential for death ligand mediated cell death. There are several known death receptors (DRs): Fas (CD95/Apo-1), TNF receptor 1 (TNF-R1), TNF receptor 2 (TNF-R2), TNF-related apoptosis-inducing ligand (TRAIL) receptor 1 (TRAIL-R1/DR4), TRAIL receptor 2 (TRAIL-R2/DR5/Killer/TRICK2), death receptor 3 (DR3/Apo-3/TRAMP/WSL-1/LARD), and death receptor 6 (DR6). Of these receptors, Fas, TNF-R1, and the TRAIL receptors are thought to be of significance in liver injury [4]. Death receptors are activated by engagement with their cognate ligands, Fas ligand (FasL), TNF-α, and TRAIL. Interaction of these ligands with their cognate receptors triggers intracellular signaling pathways. Receptor ligation brings together the intracellular death domains (DDs) that via adaptor proteins (discussed below) lead to the activation of caspase 8 (an initiator caspase). Once activated, caspase 8 cleaves Bid, a cytoplasmic protein. The cleaved protein, tBid, translocates to mitochondria, leading to release of mitochondrial effectors of apoptosis, ultimately activating caspases 3 and 7 (effector caspases).

Fas is expressed by every cell type in the liver, including hepatocytes, cholangiocytes, sinusoidal endothelial cells, stellate cells, and Kupffer cells [1]. Activation of Fas, in

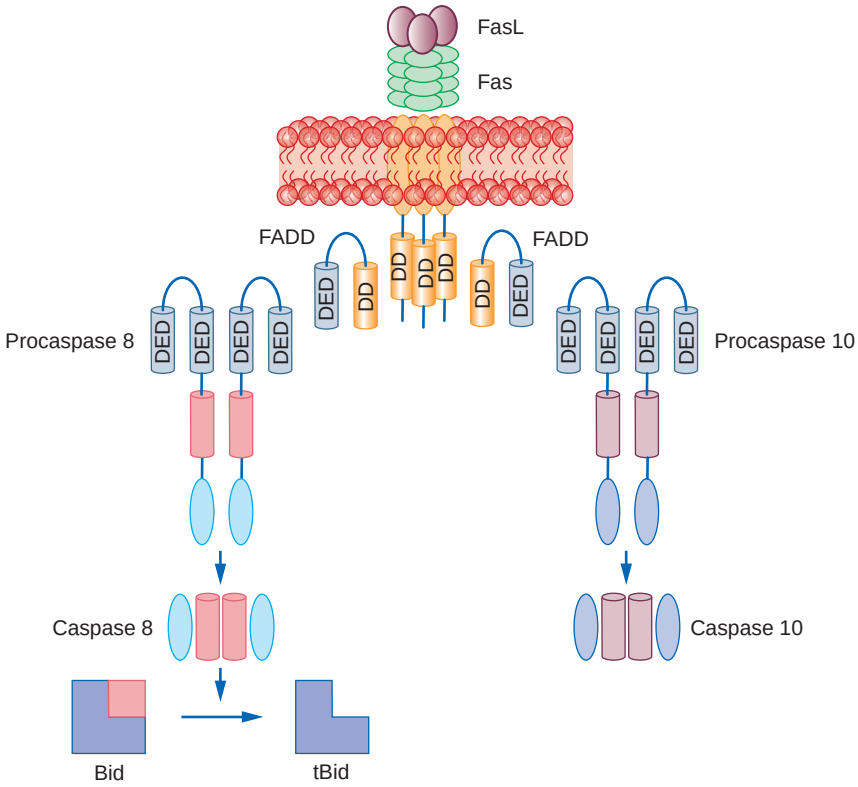

Figure 8.3 Fas receptor and associated signaling. The Fas receptor is activated on ligation with Fas ligand (FasL). The ligated receptor forms homotypic trimers, leading to intracellular signaling initiated by their intracellular death domains (DDs). The DDs of trimerized Fas associate with the protein Fas-associated death domain (FADD) through its DD. FADD in turn possesses death effector domains (DEDs) that bind and activate procaspase 8 by proteolytic cleavage. Caspase 8 leads to the cleavage of Bid to tBid, a form that translocates to the mitochondria and causes mitochondrial dysfunction. Caspase 10 is also activated by FADD, but its intracellular targets remain undefined. This conglomeration of proteins is known as the death-inducing signaling complex (DISC).

most instances, requires binding with membrane-bound FasL-expressing cells or soluble FasL (Fig. 8.3). FasL is expressed in cytotoxic T lymphocytes (CTL) and natural killer (NK) cells. This provides an efficient means of removal of unwanted hepatocytes, such as virus-infected hepatocytes and cancer cells, by T lymphocytes [9]. Mice genetically deficient in Fas exhibit hepatic hyperplasia, proving a role for Fas in hepatic homeostasis in health [10]. Hepatocyte sensitivity to Fas-induced apoptosis is underscored by the fact that the exogenous administration of Fas induces fulminant hepatic failure in mice [11]. Hepatocyte sensitivity to Fas-induced apoptosis is regulated by low cell surface expression levels as well as sequestration by binding with the hepatocyte growth factor (HGF) receptor Met [12]. This inhibitory binding can be overcome by high concentrations of FasL, as well as HGF. Indeed, in diseases such as fatty liver, Fas is dissociated from Met, providing a mechanistic basis for the observed increase in hepatocyte apoptosis [13]. The multifaceted role of Fas in hepatic homeostasis and injury has been introduced in this section, and will be discussed in greater detail in the following sections.

While the significance of Fas in liver disease is undisputed, TNF-α also plays a significant, if somewhat complementary, role. There is clear overlap in the spectrum of liver injury associated with TNF-α and Fas with some features unique to TNF-α receptor-mediated signaling. TNF-R1 and TNF-R2 are both expressed on hepatocytes, although only TNF-R1 expresses a death domain and executes the apoptotic program. TNF-R1 activation leads to both survival and death signals (Fig. 8.4). Immediate recruitment of TNF receptor-associated protein (TRAF2) and receptor interacting protein 1 (RIP1) to ligated TNF-R1 leads to activation of nuclear factor κB (NF-κB) [14]. This transcription factor activates a variety of survival genes (e.g., Bcl-x_L, A1, XIAP, and cFLIP). Apoptosis is initiated subsequently via adaptor protein TRADD (TNF-R-associated protein with death domain)-mediated FADD (Fas-associated protein with death domain) and caspase 8 activation in a receptor initiated, albeit receptor independent, complex [15]. Thus, TNF-R1 signaling is complex and it usually first activates survival signals and an inflammatory response, but in pathophysiologic states can induce apoptosis.

TRAIL and its receptors add further complexity to death receptors and their role in the liver. TRAIL receptors 1 and 2 induce apoptosis via caspase activation, similar to Fas [4,16], where as TRAIL receptors 3 and 4 are thought to function as decoy receptors, interfering with TRAIL-induced death signaling. Traditionally, TRAIL has been thought of as being harmless to normal hepatocytes but efficiently apoptotic in solid tumors [17,18]. However, recent studies have demonstrated a role for TRAIL in murine hepatocyte apoptosis in several models of hepatitis [19,20]. Circulating TRAIL levels are elevated in chronic viral hepatitis, and in ex vivo experiments

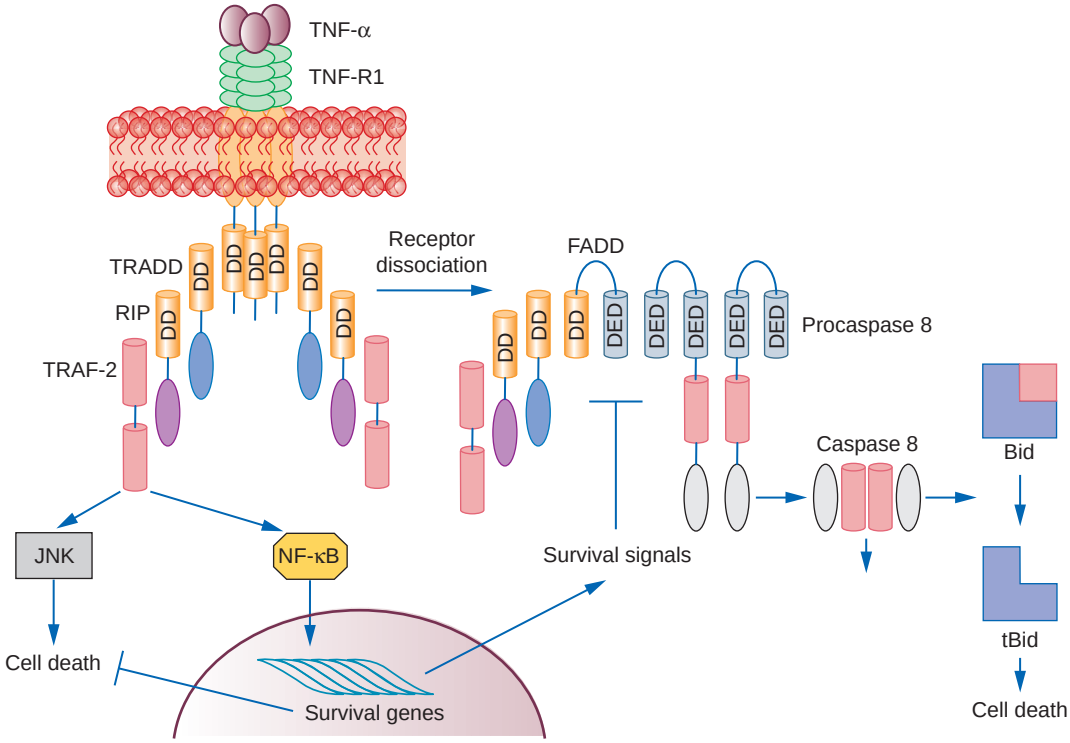

Figure 8.4 Tumor necrosis factor receptor 1 (TNF-R1) and associated signaling. Ligation of tumor necrosis factor α (TNF-α) to its receptor TNF-R1 initiates two distinct set of signals. The initial signaling pathway involves the proteins TRADD (TNF-R-associated protein with death domain), receptor-interacting protein (RIP), and TRAF2 (TNF-associated factor 2), leading to the activation of nuclear factor κB (NF-κB) and c-jun N-terminal kinase (JNK). Following this the receptor undergoes a conformational change, internalization, interaction with FADD, and activation of caspases 8 and 10 with Bid cleavage.

hepatocytes demonstrate enhanced sensitivity to TRAIL-induced apoptosis [21,22]. Steatosis is also associated with enhanced TRAIL receptor expression and ex vivo sensitization to TRAIL-induced apoptosis [22,23]. Thus diseased hepatocytes may be selectively sensitized to TRAIL-induced apoptosis in vivo, and caution should be exercised in using TRAIL-based therapies in patients with underlying liver disease.

Lysosomes

Lysosomes are enzyme-filled, membrane-lined organelles that along with peroxisomes form the acid vesicle system. The intraorganelle pH of lysosomes is acidic, and lysosomal enzymes optimally function at this acidic pH. Abnormal lysosomal morphology is found in acute and chronic liver diseases. The accumulation of phospholipids in lysosomes (phospholipidosis) is associated with drug-induced liver injury by amiodarone, trimethoprin-sulfamethoxazole, alcohol, and ketoconazole. Lipid accumulation in lysosomes is also a feature of hepatocyte steatosis. Iron, copper, and lanthane are also lysomotropic and toxic to lysosomes.

The extent of release of lysosomal contents (permeabilization) leads to either necrotic cell death, if exuberant, or apoptotic cell death, if the release is controlled. Lysosomal permeabilization may simply involve accumulation of lysomotropic agents with subsequent disruption and release of their content into the cytoplasm. Additionally, reactive oxygen species, toxic bile salts, sphingosine, free fatty acids, ceramide, and TNF-α lead to selective lysosomal permeabilization with subsequent apoptotic cell death. Lysosomal permeabilization leads to release of lysosomal enzymes into the cytosol, which triggers the mitochondrial pathway of cell death [24,25].

Endoplasmic reticulum

The endoplasmic reticulum (ER) is a network of intracellular membranes, is the largest membranous organelle in a cell, and is abundant in secretory cells such as hepatocytes. Perturbations that interfere with ER function have been collectively called ER stressors. The ER stress pathway is activated by accumulation of misfolded proteins, glycosylation inhibitors, glucose deprivation, ultraviolet irradiation, oxidative stress, and alterations in intracellular calcium. These stimuli lead to the accumulation of misfolded proteins in the ER lumen, and activate the unfolded protein response, which is a hallmark of ER stress [26]. The three sensors of the unfolded protein response are inositol-requiring enzyme 1α (IRE1α), PKR-like ER-localized eIF2α kinase (PERK), and activating transcription factor 6α (ATF6α). Collectively, they mediate adaptive responses aimed at restoring ER

homeostasis. However, when sustained, ER stress leads to cell death via at least two known mediators. IRE1α can activate c-jun N-terminal kinase (JNK), which in turn can activate many proapoptotic pathways [27]. Another pathway involves the transcription factor CHOP (C/EBP homologous protein). The downstream effectors of CHOP are not well defined, but it regulates apoptosis transcriptionally and nontranscriptionally via protein–protein interactions [28]. ER stress is described in several liver diseases including chronic viral hepatitis C and nonalcoholic fatty liver disease. The exact role of ER stress in liver disease is not well defined, and is an area of active research.

Oxidative stress

Oxygen and oxidative reactions are an essential part of aerobic oxidative phosphorylation, the process that converts nutrient energy into adenosine triphosphate (ATP), the currency of cellular energy. Oxidative stress is a consequence of this aerobic metabolism. The generation of reactive oxygen species (ROS) (O_2^-, H_2O_2, OH) and subsequent formation of the oxidative products of amino acids, proteins, carbohydrates, lipids, and DNA constitutes oxidative stress. The ROS superoxide (O_2^-) also interacts with nitric oxide to form the reactive nitrogen species, peroxynitrite ($ONOO^-$). Peroxynitrite is a potent oxidizing and nitrating agent. It can nitrate tyrosine residues in several cellular proteins and iron residues in metalloproteins. Given the dependence on aerobic metabolism for energy, cells harbor several antioxidant defense systems to protect from oxidative and nitrative stress. When antioxidant defense systems are overwhelmed, oxidative and nitrative damage ensues. In acute injury models, ROS are associated with the mitochondrial permeability transition in both apoptotic and necrotic cell death. Lipid peroxidation, oxidized DNA, and nitrated proteins are seen in several models of chronic oxidative stress-induced liver injury [29–31]. Iron overload, copper overload, chronic ethanol consumption, nonalcoholic steatohepatitis (NASH), and viral hepatitis are all associated with oxidative cellular constituent damage. The importance of oxidative stress is further underscored by the well-established use of the antioxidant *N*-acetylcyteine in acute acetaminophen-induced liver failure.

Mitochondria

Mitochondria are bound by two membranes, the outer and inner mitochondrial membranes. These two membranes enclose the intermembrane space; the inner membrane is folded into cristae and encloses the mitochondrial matrix. Proapoptotic proteins such as cytochrome *c*, SMAC/DIABLO (second mitochondrial activator of caspase/direct IAP-binding protein with low pI), HtrA2/Omi, AIF (apoptosis-inducing factor), and endonuclease G are located within the intermembrane space. The outer mitochondrial membrane is normally impermeable to these proteins, permitting the cell to survive and function. Mitochondrial permeabilization results in release of these proteins into the cytosol with activation of downstream proteases, which in turn culminate in apoptosis (Fig. 8.5) [32].

Mitochondria are essential for apoptosis in hepatocytes. Apoptosis can be divided arbitrarily into three phases: (i) pre-mitochondrial, (ii) mitochondrial, and (iii) post-mitochondrial. The pre-mitochondrial phase has been discussed in detail in the section on death receptors and other perturbations that culminate on mitochondria. The end result of the mitochondrial phase is selective mitochondrial permeabilization. This process is regulated by the pro- and anti-apoptotic proteins of the Bcl-2 family. Of the anti-apoptotic proteins, Bcl-x_L and Mcl-1 are important in the liver. The proapoptotic proteins are further divided into multidomain (Bak and Bax) and BH-3 domain only (Bid, Noxa, Puma, Bim, and Bad). Bax is located in health in the cytosol but undergoes conformational change and insertion into the mitochondrial membrane upon activation. Bak is an integral mitochondrial membrane protein also activated by conformational change. Bak and Bax then form pores in the outer mitochondrial membrane leading to permeabilization. The BH-3-only protein Bid is cytosolic and involved in the pre-mitochondrial phase of apoptosis. Its activation is mediated by death-receptor-activated caspase 8, and thus it serves as a link from the extrinsic to the intrinsic pathway of apoptosis. Bim is activated by release from the cytoskeletal dynein motor complex, and Bad is activated by dephosphorylation. The goal of the proapoptotic members is mitochondrial permeabilization, and the goal of the anti-apoptotic members is to prevent just that. The manner in which this occurs is complex and not fully known, though not just the sum total of the pro- and anti-apoptotic signals

Mitochondrial abnormalities, both structural and functional, are associated with liver disorders. Drugs and xenobiotics can inhibit the electron transport chain, uncouple oxidative phosphorylation, impair fatty acid oxidation, damage mitochondrial DNA, and impair mitochondrial DNA repair. Mitochondrial abnormalities in alcohol-induced liver disease are well described [30]. Ethanol-driven generation of ROS is associated with oxidative damage to lipids, proteins, and DNA. Moreover, high levels of TNF-α expression, driven by ethanol, also leads to an increase in ROS. Ethanol toxicity thus leads to mitochondrial permeability transition (MPT), which may occur either via death-receptor-mediated pathways or via intrinsic cellular stress. Bile acids, characteristically elevated in cholestatic liver diseases, can also trigger mitochondrial dysfunction [33]. Similarly

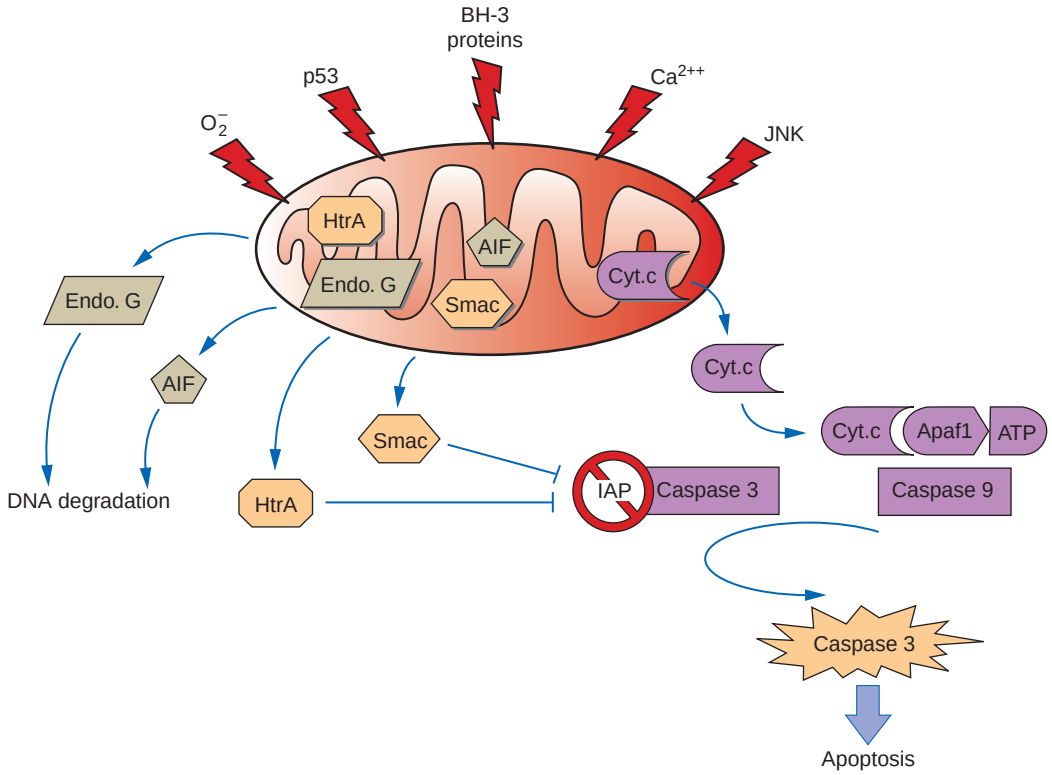

Figure 8.5 The role of mitochondria in cell death. Mitochondrial dysfunction is an obligate event in hepatocellular apoptosis. Intrinsic apoptotic stimuli such as p53, calcium, oxidative stress, and c-jun N-terminal kinase (JNK), as well as extrinsic apoptotic stimuli (BH-3 proteins), converge on mitochondria. Mitochondrial dysfunction leads to the release of several proapoptotic factors. Endonuclease G (Endo. G) and apoptosis-inducing factor (AIF) lead to deoxyribonucleic acid (DNA) degradation. Second mitochondrial activator of apoptosis (Smac) and high temperature requirement A (HtrA) inhibit a set of proteins known as inhibitors of apoptosis (IAP) leading to the release of caspases 3 and 9. Cytochrome c (Cyt. c) complexes with Apaf1 and adenosine-5α-triphosphate (ATP) to form the apoptosome that leads to the activation of caspases 3 and 9 that are released from IAP inhibition.

mitochondrial dysfunction is associated with NASH, though the molecular mediators need to be defined [34].

Necrosis

Necrosis has been defined as an energy-independent process, in which cells swell and lyse, releasing their contents. It has been considered "unprogrammed" compared with apoptosis or programmed cell death. The death signaling in necrosis has been considered absent or disordered, and the cell death equated to a supernova of cellular death phenomenon. Inflammation has been viewed as a consequence of phagocytosis of cellular debris and thought to occur more in necrosis because of the exuberant release of cellular contents. Cellular ATP depletion activates necrotic cell death. During ischemia a lack of oxygen and nutrients leads to a dramatic and absolute inability to generate ATP. This activates processes leading to cellular destruction and necrosis. Exposure to massive ischemia, nitrative/oxidative stress, and xenobiotics can all result in hepatic necrosis [35]. In some instances the magnitude of the noxious stimulus controls the subsequent mode of cell death, apoptosis resulting from a lesser stimulus and necrosis occurring with a greater magnitude of hepatic insult (Fig. 8.6). Although historically viewed as distinct, in the past few years similarities between the two processes have surfaced. Morphologically, hepatocytes with dual characteristics have been observed in vivo in injury models such as ischemia–reperfusion. Regulated, albeit caspase independent and death-receptor-independent, cell death has broadened the definition of necrosis and blurred the erstwhile clear-cut distinction from apoptosis.

The cellular protein kinases of the receptor-interacting protein (RIP) family, specifically RIP1and RIP3, are implicated in necrotic signaling [36]. RIP1 has C-terminal death domains and caspase recruitment domains that allow interaction with adaptor proteins such as TRADD and FADD downstream of death receptors. RIP3 interacts with RIP1 via the RIP homotypic interaction motif. Upon activation, the TNF-R1 signaling complex (or other death receptors) recruits RIP1, which can then promote survival and inflammation when polyubiquitinated or

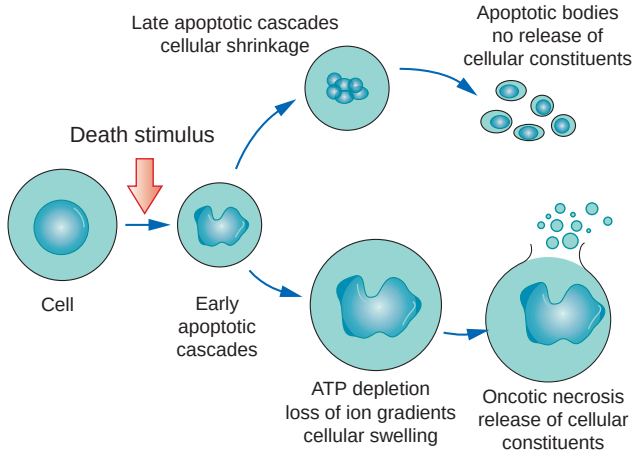

Figure 8.6 Apoptosis and necrosis are divergent end-points of common initiating signals. Death-initiating signals lead to activation of early apoptotic signals. In the milieu of adenosine triphosphate (ATP) depletion, loss of ion gradients, and cellular swelling ensues. This results in mitochondrial and cellular rupture with release of intracellular content. In a controlled and energy-replete environment, the apoptotic cascade proceeds, leading to nuclear condensation and fragmentation of cells into apoptotic bodies. Physiologically, these apoptotic bodies are engulfed and efficiently removed by Kupffer cells.

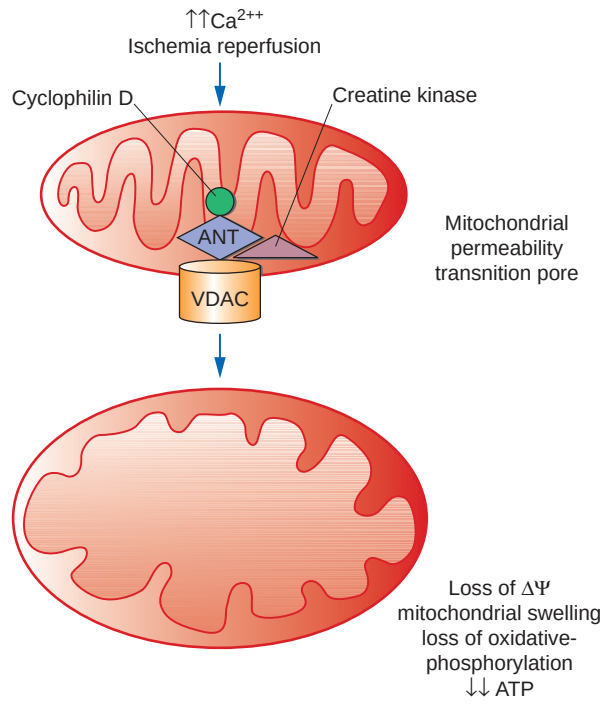

Figure 8.7 The mitochondrial permeability transition pore. Mitochondria mediate necrotic cell death in the liver. The mitochondrial permeability transition pore (PTP) is formed by voltage-dependent anion channel (VDAC) on the outer membrane and adenine nucleotide transporter (ANT) on the inner membrane along with cyclophilin D. Opening of the PTP leads to mitochondrial swelling, rupture, and release of intermembrane proteins. $\Delta\psi$, mitochrondrial membrane potential; ATP, adenosine triphosphate.

programmed necrosis in a deubiquitinated state. Thus, these dichotomous outcomes are determined by the ubiquitination state of RIP1. When apoptosis is inhibited (e.g., by the caspase inhibitor Z-VAD-fmk), RIP1 mediates programmed necrosis or necroptosis downstream of TNF-α. Furthermore, only certain cell lines are susceptible to TNF-α-induced necroptosis; this may be partially explained by RIP3 expression, as it is a downstream mediator of RIP1-induced necropotosis [37]. RIP1 and RIP3 are linked to cellular accumulation of ROS, which correlates with cell death, and reduction of ROS abrogates TNF-α-induced necroptosis. What the role of RIP kinases in hepatocyte cell death and liver injury are, if any, remains to be elucidated, especially given that in a mouse model, TNF-α-induced hepatocyte cell death was caspase 8 dependent [38].

Mitochondria in necrosis

Mitochondria mediate necrotic cell death (Fig. 8.7), in addition to their role in apoptosis. Mitochondrial permeability transition, an abrupt increase in the permeability of the inner and outer mitochondrial membranes, occurs in necrosis. This is mediated by the mitochondrial permeability transition pore (PTP). The PTP is formed by a voltage-dependent anion channel (VDAC) on the outer membrane and adenine nucleotide transporter (ANT) on the inner membrane along with cyclophilin D. The permeability transition leads to dissipation of the electrochemical gradient across the inner mitochondrial membrane, uncoupling of oxidative phosphorylation, and an inability to synthesize new ATP. Calcium and mitochondrial proteins are released as well. Mitochondrial swelling occurs secondary to an increase in membrane permeability leading to mitochondrial rupture and necrotic cell death [39].

Innate immune system in liver injury

The innate immune system in the liver is characterized by tolerance under physiologic conditions, such as gut-derived low-level lipopolysaccharide, and activation in both acute and chronic liver diseases. This activation is manifest as inflammation, which is a vital component of acetaminophen-induced acute liver injury, acute viral hepatitis, chronic viral hepatitis, alcoholic steatohepatitis, and NASH. Immunologic properties have been ascribed to most of the cell types that comprise the liver, including Kupffer cells, NK cells, natural killer T (NKT) cells, dendritic cells, hepatocytes, cholangiocytes, hepatic stellate cells (HSCs), and liver sinusoidal endothelial cells (LSECs) [40]. The liver is enriched in macrophages, known as Kupffer cells, which are liver resident, and can self-renew or be monocyte-derived. They can phagocytose apoptotic hepatocytes, parasites, and bacteria, secrete

pro- and anti-inflammatory cytokines such as TNF-α and interleukin 6 (IL6), and function as antigen-presenting cells. The liver is also enriched in NK cells and NKT cells. These cells produce death ligands such as Fas and TRAIL, and provide antiviral immunity and tumor surveillance. Dendritic cells function as antigen-presenting cells. Hepatocytes mediate acute phase and inflammatory responses; acute phase proteins are synthesized and secreted by hepatocytes, as are several cytokines. LSECs perform a scavenger function and can present antigens to adaptive immune cells. HSCs too can function as antigen-presenting cells. Given the breadth of innate immune functions, there may be redundancies and possibly proinflammatory and anti-inflammatory roles for different cell types, and the exact contribution of each in a given disease process is not well defined.

Activation and signal transduction in cells of the innate immune system is based on molecular pattern recognition. By being responsive to molecular patterns, and not to specific antigens, the innate immune cells can be activated by stimuli that possess these conserved patterns. Receptors that recognize these molecular patterns are termed pattern recognition receptors (PRRs). Microbial pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) can activate PRRs. PRRs can be found within cell cytoplasm or on the cell surface. Toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), and cytoplasmic retinoic acid-inducible gene 1 (RIG-1)-like helicases (RLHs) are examples of PRRs [41]. They can recognize a wide array of molecular patterns derived from microbes or damaged cells such as bacterial lipopolysaccharides, lipoproteins, and peptidoglycans; viral nucleic acids; and uric acid, high mobility group box 1, heat shock protein 70, hyaluronan, cardiolipin, and genomic DNA released from damaged cells [42–44]. The release of DAMPs from apoptotic and necrotic hepatocytes and other target cell death is likely how the innate immune system is activated, and amplifies the subsequent inflammatory response and liver injury. This is exemplified by recent studies using acetaminophen-induced acute liver injury in mice. DAMPs released from dead hepatocytes activate TLR9 with subsequent transcriptional activation of the inflammatory mediators interleukin 1β and interleukin 18 in liver sinusoidal endothelial cells, which are then cleaved to their active forms by the inflammasome [42]. DAMPs from acetaminophen-damaged hepatocytes also activate Kupffer cells [43]. Furthermore, innate immune cells in the liver can distinguish DAMPs released from damaged cells from microbial lipopolysaccharide. Dendritic cells can selectively suppress the inflammatory response to DAMPs released from acetaminophen-damaged hepatocytes while retaining sensitivity to lipopolysaccharide [44]. Thus, existing evidence points to the complex nature of and multilevel interactions between injurious stimuli in the liver and the resultant activation of innate immune cells.

Disease mechanisms

Alcohol-related liver disease

Alcoholic steatohepatitis is characterized by steatosis, hepatocyte apoptosis, and acute inflammation. The cellular mechanisms and cytokine milieu leading to alcohol-induced liver injury are well defined. The factors that impart each individual's susceptibility to liver damage are less well understood. In experimental models ethanol induces changes in mitochondrial and microsomal function with subsequent apoptosis as well as necrosis [45]. Oxidative stress occurs with acute and chronic ethanol ingestion. Mitochondrial permeability transition occurs as a result of oxidative stress, leading to the release of cytochrome *c* and other mitochondrial enzymes, activation of effector caspases, and apoptosis [46]. Neutralization of ROS with antioxidants, inhibition of MPT, or inhibition of caspases prevents acute ethanol-induced apoptosis. Oxidative stress also leads to translocation of Bax from cytosol to mitochondria resulting in mitochondrial dysfunction [47]. Induction of cytochrome P450 2E1 (CYP2E1), a well-known effect of ethanol ingestion, also promotes the generation of ROS and may explain how ethanol induces its own toxicity in a feedback loop [48]. Kupffer cells demonstrate increased expression of CYP2E1, oxidative stress, and, more importantly, they become activated in acute alcohol-mediated liver injury. Once activated, they secrete a number of cytokines, including TNF-α, IL6, and transforming growth factor β1 (TGF-β1) [49,50]. The role of these inflammatory cytokines is underscored by studies using endotoxinemia to promote TNF-α expression and liver injury, and on the other hand, selective gut decontamination (with antibiotics to reduce portal vein endotoxin levels) with attenuation of both TNF-α signaling and liver injury [51]. Furthermore, genetic studies in mice demonstrated that TNF-R1 is essential for alcohol-induced liver injury [52].

Apoptosis occurs in patients with alcoholic steatohepatitis, and correlates with bilirubin, aspartate transaminase (AST), and grade 4 steatohepatitis [53,54]. Hepatic Fas receptor expression is enhanced in alcoholic steatohepatitis, compared with normal livers [53]. Studies on sera of patient with alcoholic steatohepatitis demonstrate increased circulating levels of Fas, FasL, and TNF-α. TNF-α levels correlate with mortality in these patients [55,56]. Hepatocyte apoptosis also correlates with the Maddrey score, a prognostic indicator in acute alcoholic

hepatitis. The characteristic inflammatory response occurs secondary to hepatocyte apoptosis, and also due to the direct effects of ethanol on Kupffer cells leading to cytokine production [49]. In summary, alcohol-induced liver injury occurs in the setting of oxidative stress and a proinflammatory cytokine environment that together induce hepatocyte apoptosis and consequent inflammation. Apoptosis correlates with the severity of liver injury. Inhibition of the apoptotic signaling pathway holds the potential for future therapies of alcoholic liver disease.

Nonalcoholic steatohepatitis

Nonalcoholic fatty liver disease (NAFLD), the hepatic component of the metabolic syndrome, has become the most common liver disorder in the United States. Hepatocyte apoptosis is a prominent feature of NASH and correlates with disease severity, disease progression, and fibrosis [57]. This association underscores the importance of hepatocyte apoptosis and begs the question why only certain steatotic cells die. Recent mechanistic understanding of hepatocyte apoptosis in NASH has elucidated the role of death receptor ligands, circulating and intrahepatic free fatty acids, inflammatory cytokines, mitochondrial abnormalities, and the genes of fat metabolism [34,57,58].

Early pathogenetic studies have described increased Fas and TNF-R1 expression in the livers of patients with NASH [59]. Furthermore, circulating TNF-α levels are also elevated in patients with NASH. This is confirmed by studies in animal models of steatosis, where apoptosis and inflammation are enhanced following administration of death receptor ligands, Fas and TNF-α [60]. These data demonstrate the sensitivity of the steatotic hepatocyte to a secondary insult. Insulin resistance, a feature of obesity and the metabolic syndrome, leads to elevated plasma free fatty acid (FFA) levels. Recent advances have been made in understanding the cellular mechanisms by which apoptosis occurs by FFAs in steatotic hepatocytes, a process termed lipoapoptosis. Lysosomal permeabilization by FFAs in an in vitro model using HepG2 cells has partially elucidated the role of the intrinsic apoptotic pathway. Indeed this has been confirmed in patients with NASH that show evidence of lysosomal permeabilization and release of cathepsin B [61]. Furthermore, TNF-α expression occurs downstream of, and is partially dependent on, lysosomal permeabilization in this model. In a separate in vitro study, sensitivity of steatotic HepG2 cells to FasL, presumably via upregulation of the Fas receptor, provides another piece of the puzzle that integrates the well-characterized death ligand sensitivity of steatotic livers with the primary metabolic abnormality observed in this syndrome [60]. Mitochondria are central to cell death, and FFA-mediated mitochondrial dysfunction in HepG2 cells as well as primary mouse hepatocytes has been described. One way in which mitochondrial dysfunction can be activated is by a family of signaling enzymes, the mitogen-activated protein kinases (MAPKs). FFA-induced activation of JNK, a proapoptotic MAPK, with subsequent JNK-dependent apoptosis in hepatocytes is also an important pathway of FFA-induced lipoapoptosis. Mitochondrial dysfunction in this model results from the upregulation of proapoptotic Bcl-2 family proteins, Bim and Puma, and Bax activation [58,62].

Abnormal mitochondrial structure and function also occur in patients with NASH [34]. Mega-mitochondria with crystalline inclusions, decreased hepatic mitochondrial DNA content, and decreased respiratory chain function occur. CYP2E1 is increased in patients with NASH and there is some evidence for increased oxidative stress, which may be driven by enhanced FFA-driven mitochondrial β-oxidation. Thus, the role of mitochondrial abnormalities and oxidative stress as activators of the intrinsic pathway of apoptosis need to be studied further.

Viral hepatitis

Hepatitis B virus (HBV) and hepatitis C virus (HCV) cause both acute and chronic hepatocellular infection. In acute viral infection, immune-mediated apoptosis leads to elimination of infected cells, and in order for chronic infection to be successful virally infected hepatocytes must evade apoptosis [63]. The cell injury in acute infection occurs in two phases. The first phase in acute HBV and HCV infection involves cytotoxic T lymphocyte (CTL)-induced Fas-mediated hepatocyte apoptosis [64, 65]. The second wave of injury is triggered by apoptosis and occurs as a nonspecific necroinflammatory response that also damages bystander cells that do not express viral antigens [66,67]. Also, the virus has a small direct cytopathic effect.

In chronic infection there is ongoing, low-grade, Fas-mediated apoptosis. Apoptosis correlates with histologic severity of chronic hepatitis [68]. In sera from patients with chronic HBV and HCV infection, soluable Fas levels are increased and correlate with alanine aminotransferase (ALT), histology, and response to therapy [69,70]. Furthermore, at the onset of treatment with interferon, sFas levels increase in parallel with ALT values, suggesting enhanced Fas-mediated immune clearance of infected cells [71]. Active alcohol consumption in hepatitis C leads to a significant increase in hepatocyte apoptosis that correlates with increased Fas levels, pointing towards a convergence of two distinct apoptotic stimuli on the Fas signaling pathway [72]. Not only is there evidence of apoptosis, but also soluble markers of apoptosis hold the promise of surrogacy, decreasing the need for repeated liver biopsies [73]. It is also clear from several experimental models that HCV proteins regulate apoptosis [74]. HCV core protein confers sensitivity to TRAIL-mediated apoptosis in cells previously resistant to its effect [75]. Other HCV

proteins such as NS3 can activate caspase 8-mediated apoptosis, independent of Fas [76]. The inhibition of apoptosis of virally infected hepatocytes possibly provides a mechanism for both viral persistence and the development of hepatocellular carcinoma. Indeed, in a mouse model of hepatic carcinogenesis, the introduction of core, E1, and E2 proteins led to the formation of larger tumors [77]. In complementary in vitro experiments, HCV core protein inhibited Fas and TNF-α-mediated apoptosis in HepG2 cells [78].

Similarly in chronic HBV infection both Fas receptor and TNF-R1 expression are increased in hepatocytes [79]. Levels of circulating Fas and TNF-α are increased as well and correlate with severity of infection [70,80]. HBV X protein has complex biologic functions in the host that remain controversial and has been reported to attenuate and promote cell death [81–83]. Thus, both HCV and HBV infection, though cleared by immune-mediated hepatocyte apoptosis, regulate the apoptotic machinery to establish chronic infections predisposing to hepatocarcinogenesis.

Ischemia–reperfusion injury

Ischemia–reperfusion (IR) injury occurs during liver transplantation, liver surgery, and hypotensive states. Hemodynamic changes are an integral part of liver transplantation surgery, therefore understanding the mechanisms of cold ischemia/warm reperfusion (CI/WR) injury should promote therapeutic strategies to minimize injury and improve allograft function. Warm IR occurs in other forms of liver surgery and hypotensive states. Sinusoidal endothelial cells (SECs) are the immediate target of CI/WR injury with hepatocyte injury occurring after prolonged periods of ischemia. In contrast, hepatocytes are the primary target in warm IR injury. Cold storage alone leads to apoptosis of SECs. Use of caspase inhibitors significantly decreases SEC apoptosis and improves survival after orthotopic liver transplantation [84]. Kupffer cells are activated and secrete numerous cytokines that in turn activate apoptosis and attract inflammatory cells. Depletion of Kupffer cells using gadolinium chloride, decreases SEC apoptosis and liver injury in CI/WR [85].

IR injury involves hepatocyte apoptosis, which also correlates with the duration of ischemia and the presence of preexisting liver damage [86]. Activation of NF-κB, TNF-α, and Fas modulate IR-induced hepatocyte apoptosis [87]. NF-κB has a biphasic activation following IR, the initial phase promotes expression of TNF-α leading to apoptosis and inflammation, and the later phase is protective, such that selective inhibition of activation of the later phase enhanced liver injury and nonspecific inhibition attenuated injury [88]. Historically, necrosis and apoptosis both have been thought to mediate IR injury; recent evidence, however, points towards apoptosis as the principal mode of hepatocyte cell death in IR [35,89]. In experimental models TNF-α-dependent apoptosis, caspase-dependent hepatocyte apoptosis, and an increase in levels of FasL expression were observed [87]. Stress-activated protein kinases, such as JNK, are also activated soon after orthotopic liver transplantation. Use of JNK inhibitors preserves hepatic architecture and attenuates injury [90]. Expression of Bcl-2, an antiapoptotic protein, by several different modalities, protects hepatocytes against ischemic apoptosis and liver injury [91]. The use of small interfering RNA (siRNA) to decrease the expression of caspase 8 and caspase 3 also reduces IR injury. In summary, ischemia reperfusion injury is mediated by apoptosis of both parenchymal and nonparenchymal liver cells. Inhibition of apoptosis in experimental studies has improved the outcomes of orthotopic liver transplantation; this offers promising interventions to maximize allograft function.

Cholestatic injury

Cholestasis, an impairment in bile flow and/or secretion, is characterized by an increase in hepatocellular bile acid concentrations. At a cellular level, the effects of hydrophobic bile acids are well understood. Glycine-conjugated chenodeoxycholic acid (GCDC) is more toxic than taurine-conjugated chenodeoxycholic acid (TCDC) [92]. Toxic bile acids induce hepatocyte apoptosis in vitro and also in animal models of extrahepatic cholestasis (bile duct ligated animal). There is evidence for involvement of the death ligands, Fas, and TRAIL in bile acid-mediated apoptosis [93,94]. The importance of the Fas receptor in this pathway is proved further by studies in mice deficient in Fas receptor (*lpr*). Following bile duct ligation in these *lpr* mice, hepatocyte apoptosis was attenuated [95]. Furthermore, in long-term follow-up in these animals, fibrosis was attenuated as well. This study underscores the importance of the paradigm of hepatocyte apoptosis acting as a fibrogenic stimulus resulting ultimately in liver cirrhosis.

Fas-induced apoptosis is not the only mechanism of hydrophobic bile acid toxicity. In cholestatic *lpr* mice, hepatocyte apoptosis occurs eventually, though delayed and attenuated when compared to wild-type mice. Bax levels and translocation to mitochondria are increased in cholestatic *lpr* mice and explain the onset of apoptosis [96]. Inhibition of apoptosis by inhibiting Bid prevents both Fas-dependent and Fas-independent bile acid-induced hepatocyte apoptosis [97]. Furthermore, in Fas-deficient cells, the role of TRAIL-R2 has been unmasked in bile acid-induced hepatocyte apoptosis. TRAIL activation by GCDC leads to recruitment of the classic TRAIL death-inducing signaling complex with activation of caspase 8 and caspase 10, involvement of mitochondria, release of cytochrome *c*, and apoptosis [98].

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are the two commonest etiologies of adult intrahepatic cholestasis. Immune-mediated apoptosis of biliary epithelial cells (BECs) is well defined in PBC [99]. Pyruvate dehydrogenase complex (PDC), a mitochondrial protein, is expressed on the cell surface membrane of BECs in PBC. Autoantibodies and autoreactive T cells exist against this antigen perpetuating immune-mediated BEC apoptosis. PDC is normally sequestered in the inner mitochondrial membrane. While the perpetuation of autoimmune injury in response to PDC is understood, the initial apoptotic stimulus that leads to mitochondrial dysfunction and expression of PDC on BEC surfaces is unknown. In experimental models it was found that immunoreactive PDC migrated from mitochondria to the plasma membrane of cells after the induction of apoptosis [100]. Thus apoptosis plays a role in bile duct injury, and in the ensuing hepatocellular injury seen in cholestasis.

Wilson disease and hemochromatosis

Wilson disease is characterized by a hepatocellular defect resulting from mutations in a copper transporting P-type ATPase (ATP7B) with an inability to excrete copper in bile. This leads to copper accumulation in hepatocytes, which is cytotoxic [101]. The long evans cinnamon (LEC) rat is a spontaneous mutant that mimics human Wilson disease [102]. These animals show evidence of chronic oxidative damage, such as lipid peroxidation and DNA strand breaks [103,104]. This suggests a role for oxidative stress as copper has redox activity, such as the Fenton and Haber–Weiss reactions, leading to generation of free radicals and oxidative damage to lipids, proteins, and DNA. In vitro data show that copper overload also leads to p53-dependent cell death [105].

The course of Wilson disease in humans runs the gamut from fulminant hepatic failure (FHF) to mild chronic hepatitis. In Wilson disease patients with FHF, high levels of apoptosis, Fas receptor levels, and Fas mRNA levels were detected [106]. Oxidatively damaged DNA and bulky DNA, indicative of damaged DNA with adduct formation, were detected in patients with Wilson disease [29,107]. Thus copper overload causes apoptotic hepatocellular death in patients with Wilson disease.

Oxidative stress is a direct consequence of iron overload, due to the redox activity of iron and the generation of oxygen free radicals. As with copper excess, the generation of ROS occurs via the Fenton and Haber–Weiss reactions. Oxidative damage to all cellular constituents ensues, indeed oxidative DNA adducts are found in patients with hereditary hemochromatosis [108]. Though iron is not a direct carcinogen, iron overload is associated with increased risk for the development of hepatocellular carcinoma [109].

Alpha-1 antitrypsin deficiency

Alpha-1 antitrypsin (A1AT) is normally predominantly secreted by hepatocytes. Patients with A1AT deficiency produce an abnormal variant of the protein, which is aggregation prone, resulting in a failure of hepatocytes to secrete it into serum. This leads to accumulation of the abnormal protein within hepatocytes. This accumulation occurs within the lumen of the ER. The accumulated mutant protein forms aggregates, and a major homeostatic response is to enhance the degradation of the mutant protein via proteasomal degradation and autophagy. Activation of NF-κB occurs secondary to ER accumulation of mutant protein aggregates, and mediates tissue inflammation. Furthermore, mitochondrial dysfunction and caspase 3 activation are associated with ER dysfunction [110]. The exact molecular pathways that mediate A1AT-induced mitochondrial dysfunction and caspase activation are not well defined and are an area for future research.

Fulminant hepatic failure

Several lines of experimental data and human observations point to the importance of death receptor-mediated apoptosis in FHF. In a seminal paper, Lacronique et al. [111] induced massive hepatocyte apoptosis and FHF in mice using an anti-Fas antibody that activates the death signaling cascade, and rescued livers from apoptosis and animals from death by increasing the expression of anti-apoptotic Bcl-2 [11,111]. In patients with FHF, levels of both Fas receptor and FasL expression in hepatocytes are high. FasL levels are elevated in infiltrating lymphocytes, circulating lymphocytes, and sera of patients as well. Hepatocyte apoptosis in addition to enhanced Fas expression has been observed in FHF of different etiologies [112]. In addition to Fas, circulating levels of TNF-α and TNF-α receptors are increased in patients with FHF and correlate with the recovery of native liver function [113]. Besides activation of NF-κB to aid in recovery, the dichotomous role of TNF-α is further developed in FHF, where it increases the expression of FADD protein, perhaps augmenting Fas sensitivity.

In summary, FHF is accompanied by several cytokine changes, of which Fas clearly mediates apoptosis. TNF-α and other cytokines serve dichotomous roles, promoting apoptosis, inflammation, and recovery. Enhancing the milieu in favor of recovery by inhibiting Fas-mediated apoptosis appears to be a promising therapeutic strategy, one that should be developed further with human clinical trials, given the shortage of donor organs.

Therapeutic implications

Understanding apoptotic cascades in liver diseases has unraveled novel therapeutic opportunities (Fig. 8.8). RNA

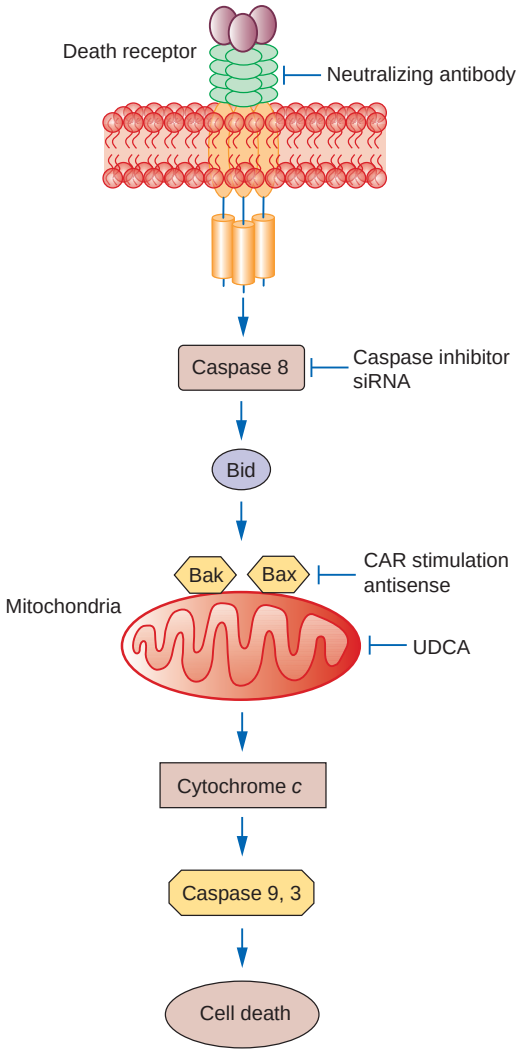

Figure 8.8 Therapeutic targets in apoptosis. Apoptosis can be inhibited at several levels. Death receptor and ligand interaction can be prevented by neutralizing antibodies. Pharmacologic inhibitors, small interfering ribonucleic acid (siRNA), antisense molecules, and modulation of Bcl-2 family pro- and antiapoptotic proteins with nuclear receptor agonists, for example, constitutive androstane receptor (CAR), are all potential therapeutic strategies. Ursodeoxycholic acid (UDCA) has been in clinical use for cholestatic liver disease.

interference (RNAi) therapy selectively manipulates a cell's genetic machinery to reduce expression of the protein of interest. Disruption of Fas and caspase 8 gene expression, using RNAi, ameliorated injury and improved survival in experimental FHF and immune-mediated hepatitis [114,115]. Increased expression of anti-apoptotic Bcl-2 and caspase inhibition protected against FHF [111,116]. Similarly, targeted hepatic delivery of NCX-1,000, a nitric oxide conjugate of urosdeoxycholic acid, which selectively releases nitric oxide in the liver, even after the onset of apoptosis, protects from acetaminophen-induced FHF [117]. In a model of ischemia–reperfusion injury, silencing initiator and effector caspases had a salutary effect on the liver [89]. Urosdeoxycholic acid has a dual effect, not only preventing mitochondrial permeabilization and apoptosis induced by bile acid, ethanol, Fas, and TGF-β1 [118], but also promoting the activation of survival signals in cells. Furthermore, in animal studies an anti-apoptotic molecule, IDN-6556 (a pan-caspase inhibitor), reduced cholestatic hepatocyte apoptosis, stellate cell activation, liver injury, and resultant fibrosis [119]. At a mitochondrial level, the disruption of proapoptotic Bcl-2 family proteins also prevents bile acid-induced apoptosis [97].

The fact that apoptosis can be modulated temporally after cells have been exposed to apoptotic stimuli is appealing in its applicability to the clinical scenario. Indeed, several studies in experimental models of acute and chronic liver diseases have demonstrated amelioration of liver apoptosis and injury and improved survival with inhibition of apoptosis even after exposure to the apoptogenic stimulus. In patients with chronic hepatitis C, short-term administration of IDN-6556 for 14 days was associated with a reduction in transaminases, suggestive of reduced hepatocyte apoptosis [120]. Future studies should be directed toward the development of rational anti-apoptotic therapies, targeted to the liver.

Multiple choice questions

8.1 Fulminant hepatic failure is observed in a mouse upon intravenous administration of a substance. Alanine aminotransferase values are elevated several hundred-fold above normal. Liver tissue is obtained at necropsy and massive hepatocyte apoptosis is observed. Which of the following signaling pathways was activated by the intravenous administration of this substance?

a TNF-R1 and TNF-α.
b NF-κB.
c FasL and Fas.
d TRAIL-R2 and TRAIL.

8.2 Which of the following statements is true?

a Necroptosis is the predominant mode of cell death in hepatocytes.
b Caspase inhibition is associated with increased aminotransferases in patients with hepatitis C.
c The innate immune system is a critical component of pathways that perpetuate liver injury and inflammation.
d Hepatocyte apoptosis can only be initiated by agents that directly damage mitochondria.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 9

Hepatic Manifestations of Systemic Disorders

Stuart C. Gordon & Hemal K. Patel

Division of Hepatology, Henry Ford Hospital, Detroit, MI, USA

Key concepts

- Endotoxin-mediated cytokine release is the likely cause of sepsis-related jaundice, and can occur in the absence of positive blood cultures. High serum bilirubin levels secondary to sepsis is often an unrecognized clinical entity.
- Any infectious organism may involve the liver, and the clinical presentation often mimics other conditions. A disproportionately raised serum alkaline phosphatase level in the presence of fever should raise the possibility of nonviral hepatitis. Sensitive polymerase chain reaction (PCR)-based assays can facilitate a rapid and appropriate diagnosis.
- The porphyria disorders cause liver damage in association with photocutaneous lesions and neurologic dysfunction. Specific causative genetic mutations allow for confident diagnosis.
- Involvement of the liver with lymphoma strongly mimics the various nonviral infectious disorders of the liver, and may cause acute liver failure. A high degree of clinical suspicion is required in order to facilitate the correct histologic diagnosis.
- Diabetes mellitus and celiac disease may independently cause liver disease, or may act to hasten the development of cirrhosis in predisposed individuals. The mechanisms for these recently identified associations remain to be elucidated.

Infectious diseases

Involvement of the liver with various pathogens may be the result of primary infections or represent a component of multisystemic disorders. These conditions, discussed below, often mimic other entities; they therefore mandate a high degree of clinical suspicion in order to establish a potentially life-saving diagnosis.

Independent of infections of the liver itself, jaundice associated with systemic infections is often overlooked among hospitalized patients, and occurs in both pediatric and adult populations [1,2]. A disproportionate increase in serum bilirubin in comparison to aminotransferases and alkaline phosphatase should raise the suspicion of bacteremia, even in the absence of sign/symptoms of infection such as fever, hypotension, tachycardia, or leukocytosis [3].

The mechanism of jaundice in systemic infection remains unclear although endotoxin (i.e., lipopolysaccharide in the outer membrane of Gram-negative bacteria) mediated cytokines, such as tumor necrosis factor α (TNF-α) and interleukin 1 (IL1)-related hyperbilirubinemia have been proposed [3]. Elevated levels of TNF-α and other cytokines are seen in alcoholic hepatitis and total parenteral nutrition (TPN)-associated jaundice [4]. Endotoxemia impairs transport of anions in both sinusoidal and canalicular membranes, resulting in impaired bile flow [5].

Bacterial infections

Salmonella hepatitis (typhoid fever)

According to a 2004 World Health Organization report [6], approximately 26 million new cases and 200,000 deaths from typhoid fever occurred in the year 2000. Both *Salmonella typhi* and *S. paratyphi* can cause typhoid fever. Although clinical hepatitis is unusual (<25%), liver involvement is almost always present in clinical typhoid fever [7]. The term salmonella hepatitis refers to liver injury caused by infection with either *S. typhi* or *S. paratyphi*, and the disease has been documented in both endemic and nonendemic areas. The disease affects people of all ages, and those with immune deficiency are particularly at risk [8].

The clinical presentation of salmonella hepatitis resembles that of viral hepatitis, but certain features help differentiate the two diseases. In particular, high fever (often >40°C) and bradycardia (inappropriate response of heart rate to degree of fever) is more common among patients with salmonella hepatitis. In addition, the biochemical

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

profile in salmonella hepatitis usually suggests the presence of an infiltrative process rather than hepatitis. In a comparison of 27 cases of salmonella hepatitis with acute viral hepatitis, El-Newihi et al. [9] found that patients with salmonella hepatitis were more likely to have a disproportionately increased serum alkaline phosphatase level, and that serum aminotransferase values were far lower than with acute viral hepatitis. Jaundice is unusual, and many cases of salmonella hepatitis are anicteric. In untreated patients, jaundice may be delayed – appearing in the second to the fourth week of the illness. A spectrum of other hepatobiliary disorders secondary to salmonella hepatitis (i.e., acute liver failure, acalculous cholecystitis, spontaneous bacterial peritonitis, liver abscess, etc.) has been reported [10–13].

Establishing a diagnosis of salmonella hepatitis may be difficult because the manifestations are similar to those of other forms of acute hepatitis, including viral hepatitis. One reported series suggested that the alanine aminotransferase (ALT) to lactate dehydrogenase (LDH) ratio is <4 in salmonella hepatitis, >5 in acute viral hepatitis, and <1.5 in central zonal injury, such as hepatic ischemia or acetaminophen injury [9]. Although the diagnosis of typhoid fever is usually established clinically in developing counties, serological tests such as dot enzyme immunoassay (Typhidot-M®) and polymerase chain reaction (PCR)-based tests are widely used; positive blood culture remains the diagnostic standard [14].

The liver histology of salmonella hepatitis is nonspecific. Ballooning degeneration with vacuolation has been reported, as has biliary canalicular injury. Occasionally, *S. typhi* organisms are found in the liver cells, as are lobular aggregates of Kupffer cells, lesions known as typhoid nodules [15].

Prompt diagnosis and early intervention with appropriate antibiotics generally assure a good prognosis. Because of potential resistant strains of *Salmonella*, antibiotic sensitivity testing is advised. A fluoroquinolone is the therapy of choice for fully sensitive or multidrug-resistant strains of *Salmonella*, while azithromycin or ceftriaxone/cefotaxime should be used in quinolone-resistant strains [14].

Tuberculosis

Hepatic tuberculosis (infection with *Mycobacterium tuberculosis*) as a part of miliary disease may occur in up to 80% of all patients dying of pulmonary tuberculosis. The original description of hepatic tuberculosis classified the disease as either: (i) miliary, a part of generalized disease; or (ii) local, with focal involvement of the liver. The portal of entry of *M. tuberculosis* organisms into the biliary tract and the liver is the hematogenous route or, less commonly, the portal vein or lymphatic vessels. The manifestations of tuberculous liver involvement are protean, and terms in the literature used to describe hepatobiliary system involvement with tuberculosis include tuberculous pseudotumor, tuberculous cholangitis, and tuberculous liver abscess [16]. The term hepatobiliary tuberculosis refers to either isolated hepatic, biliary, or hepatobiliary involvement with other organ system involvement [17].

The clinical manifestations of hepatobiliary tuberculosis are those of the extrahepatic disease; hepatic involvement is usually asymptomatic [18]. Nevertheless, cases of acute liver failure, among both immunosuppressed and immunocompetent persons, are reported [19,20]. Right upper quadrant or nonspecific abdominal pain, fever of unknown origin, and weight loss, are common symptoms. The most common physical finding is hepatomegaly, which is present in most cases. A disproportionately increased serum alkaline phosphatase level is a consistent finding suggestive of an infiltrative hepatic process. The presence of jaundice suggests biliary involvement, and the biochemical profile may simulate extrahepatic biliary obstruction [21].

One variant form of hepatic tuberculosis without active pulmonary or miliary disease is the nodular form, which presents as an isolated liver tumor or abscess [22,23]. In most cases, the clinical presentation is that of neoplasm, with solitary liver lesions of variable size and imaging features, raised alkaline phosphatase values and weight loss in the absence of known previous tuberculosis. Classic histologic findings (see below) and/or PCR assay of the liver tissue help in establishing the diagnosis. Prompt treatment with antituberculous agents leads to complete resolution of symptoms, signs, and radiologic findings.

An unusual manifestation of tuberculosis involves the development of portal hypertension caused by the compression of the portal vein by tuberculous lymph nodes, with resultant variceal hemorrhage [24]. Additionally, isolated pancreatic tuberculosis may manifest in a manner very similar to that of a pancreatic neoplasm, including a mass lesion of the pancreatic head [25]. Similarly, gallbladder tuberculosis is reportedly increasing in incidence and may manifest as biliary colic or acute cholecystitis [26].

Yet another unusual but increasingly reported variant of hepatobiliary tuberculosis is obstructive jaundice caused by involvement of the bile duct, pancreas, or gallbladder. Compression of the biliary tree by involved lymph nodes or possibly by direct involvement of the biliary epithelium, or by rupture of a caseating granuloma into the lumen of the bile duct, may cause jaundice and biochemical cholestasis. Intrahepatic bile duct obstruction may result from granulomatous involvement, often as part of miliary tuberculosis. The entity of bile duct tuberculosis [27] may manifest as bile duct dilatation with common hepatic duct strictures (Fig. 9.1). Biliary

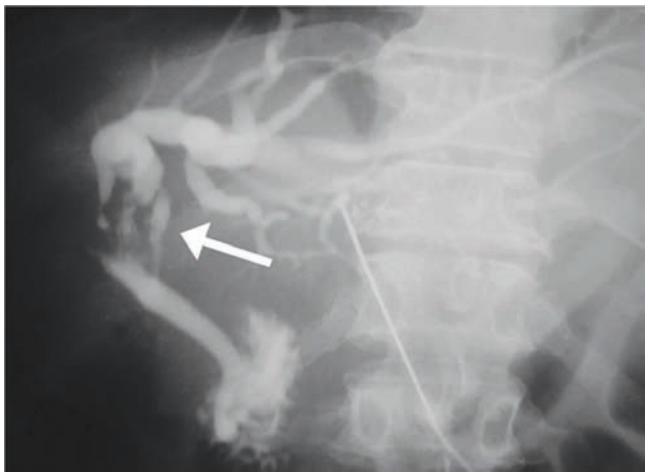

Figure 9.1 A 66-year-old man with abdominal pain and jaundice. Percutaneous transhepatic cholangiogram showing a hilar stricture (arrow) and dilated intrahepatic duct. The diagnosis of tuberculosis was confirmed by fine needle aspiration. (Reproduced from Chong [17] with permission from Wolters Kluwer Health.)

cytologic findings from endoscopic cholangiography may yield the diagnosis. Such patients have painless jaundice and weight loss that mimics pancreatic or cholangiocarcinoma, and dilated bile ducts are found at imaging studies. Experience with therapeutic biliary stenting has been variable, and in unsuccessful cases percutaneous biliary drainage decompresses the obstruction [17,28].

Ultrasonography and computed tomography (CT) may show complex masses, either solitary or multiple. Although the finding of caseating granuloma from a percutaneous biopsy specimen is highly suggestive of tuberculosis (Fig. 9.2), similar pathologic findings occur in brucellosis, coccidioidomycosis, and Hodgkin disease. Giant epitheloid cells and Langhans giant cells are other characteristic histologic findings. The finding of acid-fast bacilli at biopsy occurs infrequently, in <35% of cases. A PCR-based assay on liver tissue has a high sensitivity (overall assay positivity of 88% in one series) with low false negativity among controls [29,30].

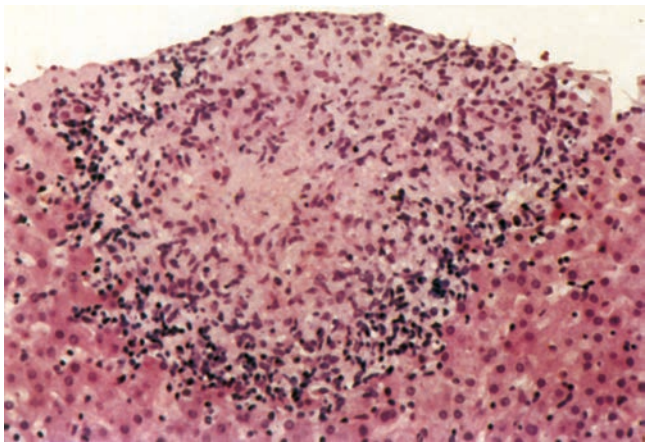

Figure 9.2 Tuberculosis: caseating hepatic granuloma in a patient with fever of unknown origin.

The management of hepatic tuberculosis involves the use of at least four antituberculous drugs, usually including isoniazid, rifampicin, pyrazinamide, and ethambutol. Although therapy traditionally lasts at least 6 months, multidrug-resistant organisms and hepatotoxicity of the agents require alternative regimens. Drug-induced liver injury secondary to antituberculous drugs, especially isoniazid, is idiosyncratic and potentially lethal. The American Thoracic Society recommended more vigilant serum ALT monitoring in patients who consume alcohol, take concomitant hepatotoxic drugs, have viral hepatitis or preexisting liver disease or an abnormal baseline ALT, have human immunodeficiency virus (HIV), have a prior history of isoniazid hepatitis, are pregnant, or are within 3 months postpartum [31]. Careful monitoring for drug-induced hepatitis may obviate fatality, especially in the elderly, and once serum bilirubin rises, the prognosis is guarded.

Legionnaires' disease

Hepatic derangements are observed more frequently in *Legionella pneumophila* pneumonia than in other causes of pneumonia. Elevated aminotransferase levels (up to 15 times the upper limit of normal), alkaline phosphatase levels (up to nine times the upper limit of normal), and hyperbilirubinemia (in up to 15% of patients) have been reported. Therefore, the finding of markedly abnormal liver biochemical values in the presence of obvious pneumonia may be a clue to the appropriate diagnosis. Other hepatic manifestations of *L. pneumophila* include acute liver failure as well as liver abscesses [32]. Antigen detection in the urine may serve as a rapid confirmatory test whenever suspicion for *Legionella* infection is high based upon clinical presentation. Antigen detection in respiratory secretions, as well as serologic testing and PCR-based tests may also facilitate diagnosis. The organism can be found with direct immunofluorescence in liver biopsy. Histologic exam of the liver may show necrotic hepatitis with features similar to other forms of viral hepatitis. Antibiotics of choice include flouroquinolones or the newer macrolides.

Brucellosis

Three species of *Brucella* affect humans: *B. melitensis*, *B. abortus*, and *B. suis*. Brucellosis is an occupational disease that affects food handlers, and organisms enter the body through the skin or oropharynx and spread to regional lymph nodes. The disease can also be airborne and transmitted to personnel in microbiology laboratories.

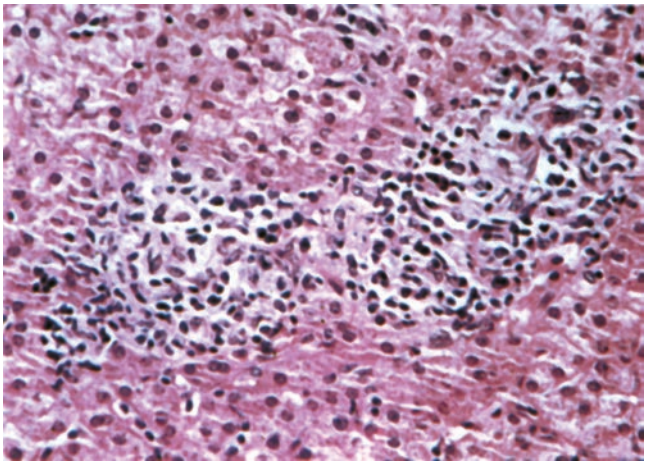

Figure 9.3 *Brucella melitensis*: nonspecific lymphoplasmacytic inflammatory infiltrate in a patient with brucellosis. Hematoxylin and eosin (H&E), original ×510.

The most common clinical manifestation of hepatic involvement by *Brucella* is tender hepatomegaly (20–40%), a modest elevation of aminotransferases (5–40%), and an increase in serum alkaline phosphatase suggesting the presence of an infiltrative process [33]. Spontaneous bacterial peritonitis, acute hepatitis with jaundice, and hepatic abscess have been described [34–36].

Carazo et al. [37] described the imaging features in cases of hepatosplenic brucelloma, and noted that on ultrasound the lesion appears iso- or hypoechogenic with the liver, with focal calcifications. Contrast-enhanced CT scans showed predominantly solid masses with irregular borders, rarely with transdiaphragmatic lung invasion. Histologic examination usually shows granuloma formation with a varying degree of portal and lobular inflammation (Fig. 9.3) [33]. The organism can be isolated from the blood in acute states, but cultures may take 3 weeks to turn positive. Bone marrow aspirate culture is the standard for diagnosis given the very high concentration of the organism in the reticuloendothelial system. Serologic tests are helpful and reliable, and either a titer of 1 : 320 or demonstration of increasing titers establishes the diagnosis. PCR-based tests are reported to be highly sensitive and specific and offer rapid diagnosis [38].

Combination antibiotic therapy rather than use of a single agent is recommended for *Brucella* infection. Doxycycline combined with streptomycin, rifampin, trimethoprim-sulfamethoxazole, gentamicin, or ciprofloxacilin are various options [38]. In cases of hepatic abscess, percutaneous or surgical drainage may be needed [36].

Tularemia

Infection with *Francisella tularensis*, the causative agent of tularemia, occurs after exposure to jackrabbits and hares, the main animal reservoir in North America and Europe. Hunters are at risk and may acquire the disease from tick or deer fly bites in the summer months. In Sweden, the lemming is responsible for this disease ("lemming fever"), whereas in Russia the water rat and muskrat may spread tularemia. The disorder usually affects the lungs, and the usual manifestation is a flu-like syndrome occurring between 1 and 10 days after exposure. Liver involvement occurs in up to 75% of patients, in the form of mild to moderate aminotransferase elevation [39]. Jaundice, marked cholestasis, granulomatous hepatitis, ascites, cholangitis, and liver abscesses have been reported.

Histologic examination of the liver in cases of tularemia shows multiple focal areas of coagulative necrosis with a surrounding chronic inflammatory infiltrate. The diagnosis can be established serologically with demonstration of agglutinating antibodies. Enzyme-linked immunosorbent assay (ELISA) tests are available, but a PCR test for *F. tularensis* should enable rapid confirmation of the clinical diagnosis of tularemia. Treatment consists of streptomycin or gentamicin.

Listeriosis

Listeria monocytogenes, a Gram-positive intracellular bacillus, is widely distributed in nature, including soil and plant material, and was thought to be the only causative organism for human listeriosis until recently when *L. ivanovii*-related gastroenteritis and bacteremia was reported in humans [40]. Human *Listeria* infection usually manifests as meningoencephalitis or pneumonitis, although hepatic involvement is reported. A review of 34 cases of *Listeria*-related liver disease by Scholing et al. [41] showed that the clinical presentation can be of three different types: a solitary liver abscess, multiple abscesses, or diffuse involvement (hepatitis) with or without granulomas. Patients are often immunosuppressed or at extremes of age. The presence of high fever and leukocytosis tends to differentiate this condition from viral hepatitis, and the diagnosis is confirmed by the isolation of the organism from blood. Radiologic imaging and fine needle aspiration, when applicable, helps in establishing the diagnosis. Treatment consists of drainage of the abscess whenever possible along with systemic administration of antibiotics, usually penicillin in combination with aminoglycosides for 3–4 weeks [41].

Melioidosis

Melioidosis, endemic in northern Australia and Southeast Asia, is a potentially fatal infection caused by the bacterium *Burkholderia pseudomallei*. The mortality may be high, averaging 45%, and in cases of acute septicemia, death occurs within the first 3 days after hospital admission. The liver involvement in melioidosis is common

and may manifest as biochemical abnormalities or localized abscesses. Granulomas can be seen on histology. Radiologically, the "honeycomb" appearance has been described as characteristic for large liver abscesses [42]. Immunohistochemistry may play a useful diagnostic role whenever tissue sample is available. Direct immunofluorescence microscopy of the infected material is less sensitive (70%), but highly specific (98%), and confirms diagnosis in 30 minutes [43]. Isolation of the organism from blood remains the most reliable test. Parenteral antibiotics (ceftazidime or amoxicillin-clavulanate) followed by long-term oral antibiotics with a four drug regimen (chloramphanicol, doxycycline, trimethoprim, and sulfamethoxazole) up to 20 weeks may be needed to eradicate the organism [43].

Neisseria and *Chlamydia*

Nonspecific aminotransferase abnormalities may occur in disseminated gonococcal infection. Cervical and pelvic gonorrhea may be associated with violin-string adhesions between the liver capsule and the peritoneal wall, known as Fitz-Hugh–Curtis syndrome (FHCS). However, such adhesions are not pathognomonic for *Neisseria* infection, and may occur after other infections, including hepatic candidiasis (Fig. 9.4) [44]. Liver abscess from *Neisseria sicca* after repeated radiofrequency ablation of hepatocellular cancer was recently reported [45].

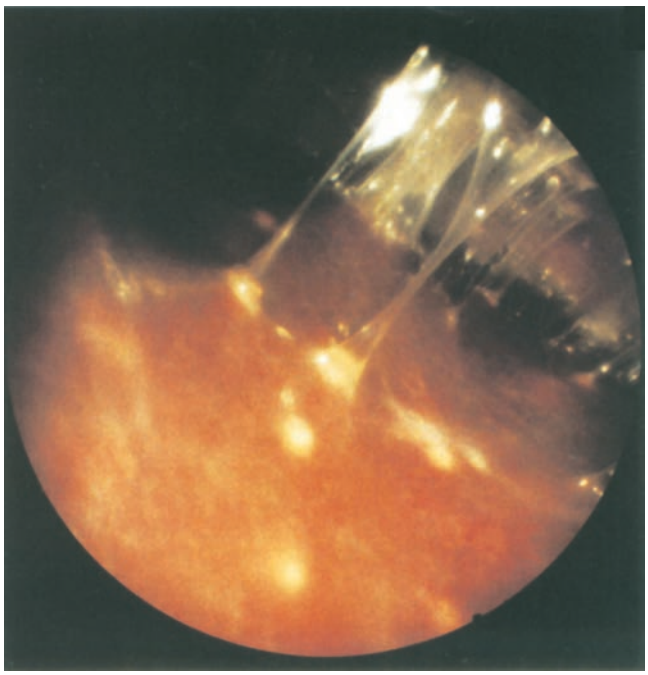

Figure 9.4 Perihepatic adhesion (Fitz-Hugh–Curtis syndrome) may occur in conditions other than gonorrhea. After therapy for hepatic candidiasis, a follow-up laparoscopy showed violin-string adhesions from the focal lesions to the peritoneal wall. Such adhesions may result in marked right upper quadrant pain.

A similar syndrome of perihepatitis occurs with *Chlamydia trachomatis*-related pelvic inflammatory disease (PID) [46]. Various studies have reported the incidence of FHCS to be 4–12% in patients with mild to moderate PID and 20–28% in patients with severe PID [47]. Case reports of Chilaiditi syndrome (colonic or small intestinal interposition between the liver and diaphragm, temporarily or permanently) and right pleural effusion associated with FHCS and *Chlamydia* infection has been reported [48,49]. *Chlamydia pneumoniae* has been purported as a causative agent for primary biliary cirrhosis; however, data on this association are mixed [50].

Campylobacter

Mild liver dysfunction as well as acute biochemical hepatitis may occur after infection with *Campylobacter* organisms. A case of pyogenic liver abscess associated with *Campylobacter curvus* bacteremia was recently reported from Canada [51]. The organism has been isolated from bile during episodes of gallstone-related cholecystitis [52]. Macrolides are the treatment of choice.

Catscratch disease

Hepatosplenic catscratch disease often manifests as fever of unknown origin in children who have had contact with an immature cat. The disease occurs when *Bartonella henselae* causes necrotizing granuloma in the liver or spleen or both. Fleas have also been suggested as vectors for this organism because cat scratches may be absent in some cases. Abdominal pain is common and occasionally is severe. Abdominal ultrasonography shows microabscesses in the liver or spleen. Among HIV-infected patients, a syndrome of peliosis hepatis (bacillary angiomatosis) is caused by *B. henselae* infection. Serologic assays, indirect immunofluorescence, and PCR assays may assist in the diagnosis [53]. Prolonged antibiotic regimens with erythromycin, doxycycline, or macrolides have proved effective in various series [54,55]. In a case report from the United States, *B. henselae*-related liver abscesses developed in a 52-year-old female 3 years following orthotopic liver transplantation [56].

Spirochetal infections

Leptospirosis

Also known as Weil disease, the classic description of leptospirosis – an infection transmitted via exposure to rodent urine – is of febrile headache, jaundice with renal failure, and severe muscle pain. Only a small percentage of patients have these most severe manifestations and most descriptions of liver pathology come from historical autopsy series. Early recognition, with administration of appropriate antibiotics, has resulted in a very low incidence of hepatic manifestations.

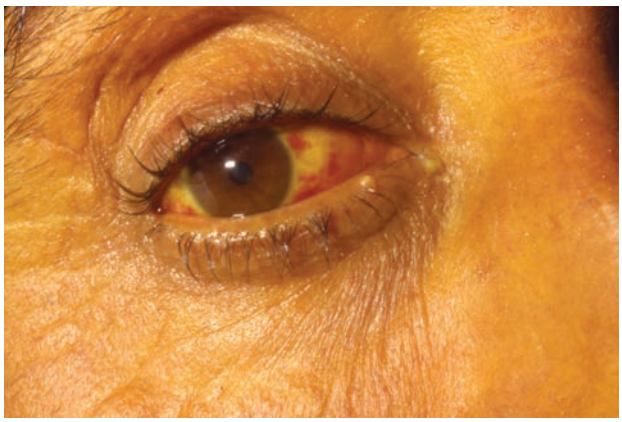

Figure 9.5 Icteric sclera and subconjunctival suffusion in a patient with leptospirosis and liver involvement.

Although often considered a disease of developing nations, cases occur in the United States and may cause a diagnostic dilemma [57]. The initial manifestations are rather nonspecific, i.e., fever, meningism, flu-like illness, abdominal pain, vomiting, and conjunctivitis ("conjunctival suffusion") (Fig. 9.5). The abdominal pain of the acute phase may simulate surgical abdomen and may manifest as biliary colic. During the second phase of illness (usually the second week), severe muscle pain with jaundice and renal failure are common. The serum creatine kinase level may be elevated. The third, or convalescent, stage (third week) shows improvement in mental status and renal function and resolution of jaundice.

When presenting in the late stage of pregnancy, leptospirosis may mimic HELLP syndrome (hemolysis, elevated liver enzymes and low platelets), AFLP (acute fatty liver of pregnancy), or metastatic liver cancer [58–60]. Early intensive care and parenteral antibiotics (penicillin or doxycycline) may be helpful, and therefore early diagnosis is important.

To establish the diagnosis during the first phase, leptospira can be isolated from the cerebrospinal fluid and blood; in the second phase, they are isolated from the urine. Dark-ground microscopic examination of plasma has been found to be a simple and rapid form of early diagnosis of leptospirosis with hepatorenal involvement. PCR based on the *flaB* gene of leptospira has been found to be an efficient tool for rapid detection and identification from clinical specimens. Doxycycline is the treatment of choice. A recent review suggested that the data do not support the practice of doxycycline prophylaxis for all residents of an endemic area, although short-term travelers with a potential for high-risk exposure may be helped [61].

Syphilis

Syphilis is a multisystemic disease caused by the spirochete *Treponema pallidum*. Liver involvement during early syphilis (primary or secondary) presents as biochemical cholestasis with a disproportionate elevation of alkaline phosphatase. An acute cholestatic hepatitis secondary to syphilis occurs among HIV-infected patients – in up to 38% in one series [62].

The gummas of the liver may resemble metastatic disease at autopsy or may resemble cirrhosis because of the nodular configuration of the liver in the later stages. Focal liver lesions with filling defects on CT scans may mimic metastatic disease in a patient with weight loss. Chen et al. [63] reported a case of peliosis hepatis and gummatous syphilis wherein the diagnosis was established by liver biopsy. The pathologic findings generally include lymphocytic and neutrophilic infiltrates in the portal tracts, while pericholangiolar inflammation has also been described (Fig. 9.6). Identification of treponemes in the liver is very uncommon. Additional laboratory studies of the syphilitic hepatitis of secondary stage

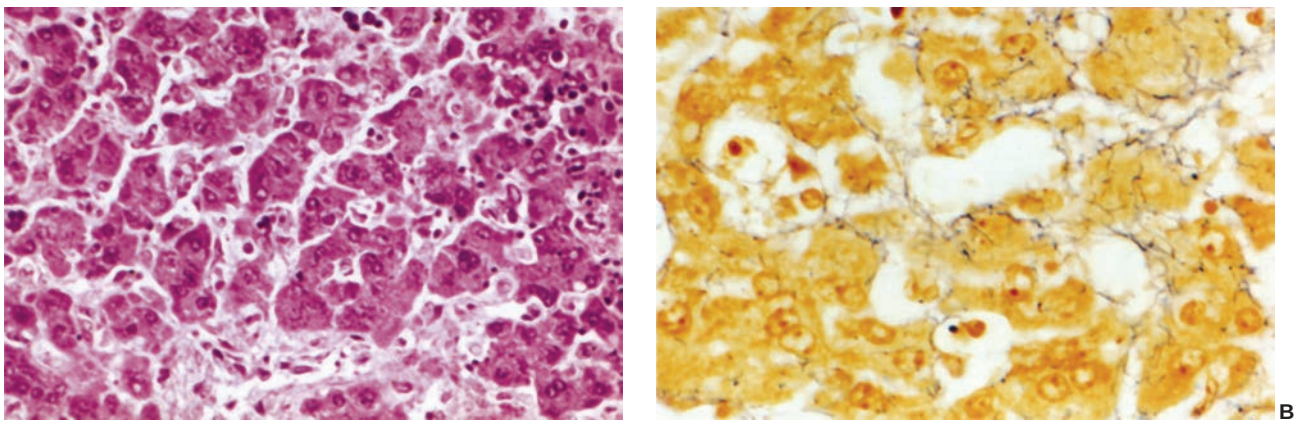

Figure 9.6 Hepar lobatum. (A) Diffuse pericellular sinusoidal fibrosis in congenital syphilis of liver. H&E, original ×485. (B) Numerous spirochetes layered in periphery of sinusoids adjacent to hepatocyte cords. Dieterle stain, original ×1,200. (Courtesy of Dr John Watts.)

disease include a hemagglutination test for *T. pallidum* and a fluorescent treponemal antibody (FTA) absorption (FTA-ABS) test. Treatment with penicillin usually results in symptomatic as well as well biochemical resolution of syphilitic hepatitis.

Lyme disease

Endemic to northeast United States but more recently spreading widely throughout the United States, Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is transmitted to humans by the bite of infected ticks (*Ixodes*). Involvement of the liver is common in the early stage of Lyme disease with a reported incidence of 10–27% [39,64]. The mechanism by which liver injury occurs is not known, but direct toxicity, systemic cytokine release, and immune-mediated damage are proposed theories [65]. Cases of granulomatous hepatitis from Lyme disease have been reported [66].

Histologic examination shows portal inflammation, ballooning of hepatocytes, and sinusoidal mononuclear and neutrophil cell infiltration [65]. Diagnosis is based upon direct tests (microscopy, PCR, and culture) or serological testing. A two-step approach (sensitive enzyme immunoassay or indirect fluorescent antibody assay as the first step, followed by western immunoblots as a confirmatory step) is recommended as *B. burgorferi* shares some antigens with other bacteria and serologic tests can detect nonspecific antibodies. Doxycycline is the treatment drug of choice.

Rickettsial infection

Q fever

The causative rickettsia of Q fever is *Coxiella burnetii*. The organism has been identified in ticks, and the disease has a worldwide distribution. Liver involvement is common. Presentation may vary geographically, as pneumonia is reportedly more common in eastern Canada while hepatitis is more common in southern Spain [67]. A case series of 109 patients reported the prevalence of acute biochemical hepatitis to be as high as 85% [68]. Three main hepatic manifestations of Q fever have been proposed: (i) a clinically acute hepatitis-like illness without respiratory involvement (the most common form of hepatic involvement); (ii) an incidental finding of increased liver biochemical values in a patient with known acute Q fever; or (iii) fever of unknown origin with characteristic hepatic granulomas [69].

The classic "doughnut-like" granuloma of Q fever – a central clear space in the center of the granuloma – is not pathognomonic for the disease and may be seen in Hodgkin disease and infectious mononucleosis (Fig. 9.7). The granuloma is a dense fibrin ring surrounded by a central lipid vacuole and is composed of neutrophils, monocytes, eosinophils, and occasional multinucleated giant cells. Kupffer cells are hypertrophied and there may be a lymphocytic portal inflammation with erosion of the limiting plate.

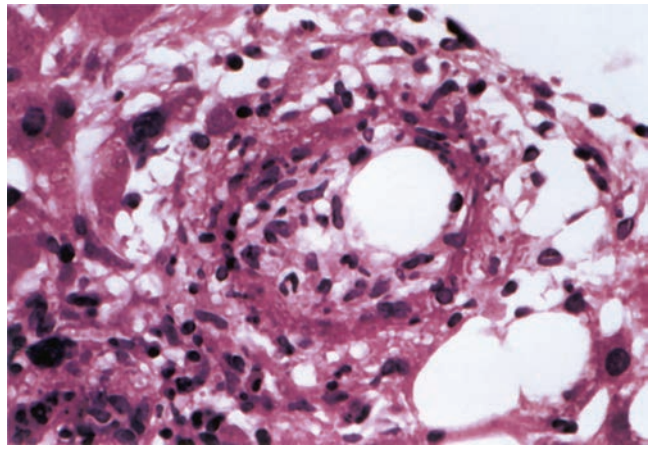

Figure 9.7 Section showing classic doughnut granuloma. The characteristic lesion of Q fever is a doughnut granuloma similar to that shown here. H&E, original ×780. (Courtesy of Dr John Watts.)

The diagnosis is established by a serological test (a microimmunofluorescent antibody titer to *C. burnetii*) to phase I and II antigens [67]. PCR can be used to amplify *C. burnetii* DNA from tissue [70]. Doxycycline is considered the treatment of choice, and a fluoroquinolone such as ofloxacin has been used with success [67]. Although controversial, erythromycin may be an appropriate alternative in the treatment of children. Vaccination can be a safe and efficacious tool in decreasing the incidence and hospitalizations associated with Q fever in endemic areas [71].

Ehrlichiosis

Human infection with *Ehrlichia canis*, a tick-borne infection common among dogs, was first reported in 1987. However, human monocytic ehrlichiosis is mostly caused by *E. chaffeensis*, which is transmitted by the lone star tick, *Amblyomma americanum*.

Involvement of the liver in human ehrlichiosis is common and ranges from mildly elevated aminotransferases to fatal hepatitis [72]. Although rare, marked cholestasis and liver failure has been reported, which responds completely to doxycycline therapy [73]. Liver histology may show lobular lymphohistiocytic foci, diffuse lymphohistiocytic infiltration, various degrees of liver cell injury, and cholestasis with bile duct epithelial injury [74]. The organism may be present within the Kupffer cells. The diagnosis is confirmed by indirect immunofluorescence and PCR [75]. Treatment consists of doxycycline or tetracycline [75].

Rocky mountain spotted fever

Rocky mountain spotted fever, a multisystemic disease caused by *Rickettsia rickettsii*, manifests hepatic involvement by mild to moderate derangements in liver biochemistries. Jaundice is rare but when present could predict a poor prognosis. Rickettsiae mostly infect the endothelial lining of liver sinusoids and portal vasculature while sparing hepatocytes; focal hepatitis and periportal inflammation can be seen on liver biopsy [39]. Vasculitis and significant central nervous system (CNS) and pulmonary manifestations are also the result of rickettsial invasion of the endothelial lining. Leukopenia, thrombocytopenia, mild hyponatremia, and elevated liver enzymes are clues to the diagnosis in patients presenting with rash and CNS manifestations. Serology and PCR-based assays are widely available for aid in diagnosis; doxycycline is the treatment of choice.

Fungal infections

Histoplasmosis

Histoplasmosis has a worldwide distribution, and is the most common cause of fungal infection in the Ohio and Mississippi river valleys of the United States. It is usually transmitted after inhalation of the organism *Histoplasma capsulatum*, which is particularly associated with bird droppings, especially those of chickens.

Among 111 patients with systemic histoplasmosis, fever, respiratory symptoms, weight loss, and bone marrow suppression were the predominant presenting symptoms [76]. Liver involvement mainly included raised serum alkaline phosphatase. Bone marrow suppression and elevated liver enzymes are more common in immunocompromised patients with systemic histoplasmosis than in immunocompetent patients. Liver biopsy may be needed in some cases and hepatic lesions may include widely diffuse granulomas throughout the liver or parenchymal infiltration with macrophages filled with the organism, best seen with fungal staining.

Although liver involvement is common in cases of disseminated histoplasmosis, the disease may also present as an isolated liver mass or as an infiltrative liver disorder. Cases of isolated hepatic histoplasmosis without pulmonary involvement and a solitary right-sided liver lesion invading the diaphragm have been reported [77,78]. A review of the pathologic spectrum of cases of gastrointestinal histoplasmosis showed that 10% of 52 patients had histologic evidence of liver disease, most commonly portal lymphohistiocytic inflammation (Fig. 9.8). Discrete hepatic granulomas were found in fewer than 20% of livers that were involved [79].

Early diagnosis may be life-saving. Fungal culture, histopathology, antibody assays, and histoplasma antigen detection in urine, serum, and other body fluids are the usual modalities to establish the diagnosis. Intravenous itraconazole is recommended for mild to moderate disease, while an amphotericin B formulation is reserved for severe infection [80].

Candidiasis

Caused by infection with fungi of the genus *Candida*, the clinical spectrum of candidal liver disease is varied. The most common species causing human infection is *Candida albicans*, although other species also cause disease. The entity of focal hepatic candidiasis may be part of hepatosplenic candidiasis or chronic disseminated candidiasis [81]. Regular use of antifungal prophylaxis in patients undergoing hematopoietic stem cell transplantation and in neutropenic patients with leukemia undergoing chemotherapy has decreased all-cause mortality from systemic candidiasis [82].

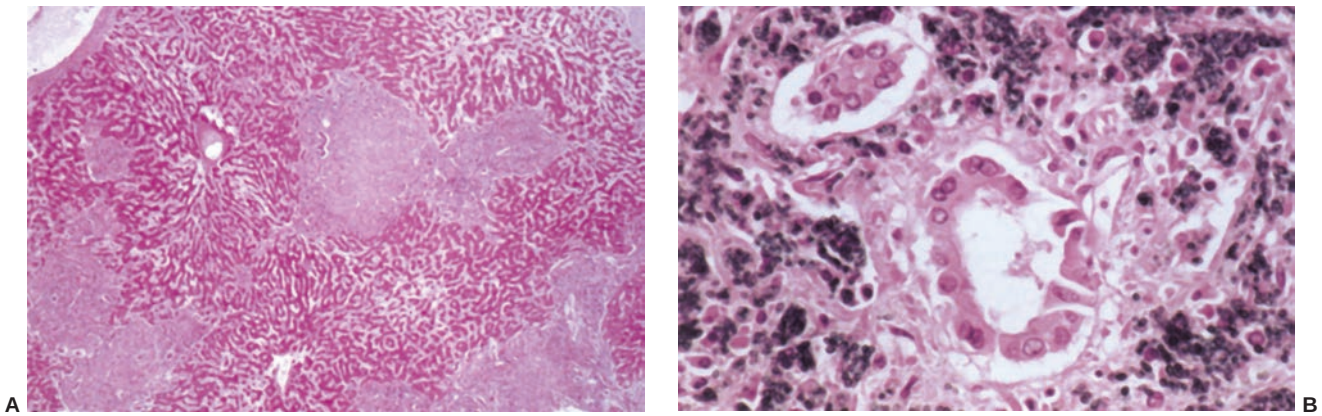

Figure 9.8 An elderly diabetic man living in an area endemic for histoplasmosis with fever and hepatomegaly. (A) Confluent portal granulomas in a patient with hepatic histoplasmosis. H&E. (B) Special stain showing uniform, oval, yeast-like cells morphologically typical of *Histoplasma capsulatum.* H&E, methenamine silver. (Courtesy of Dr Laura Lamps.)

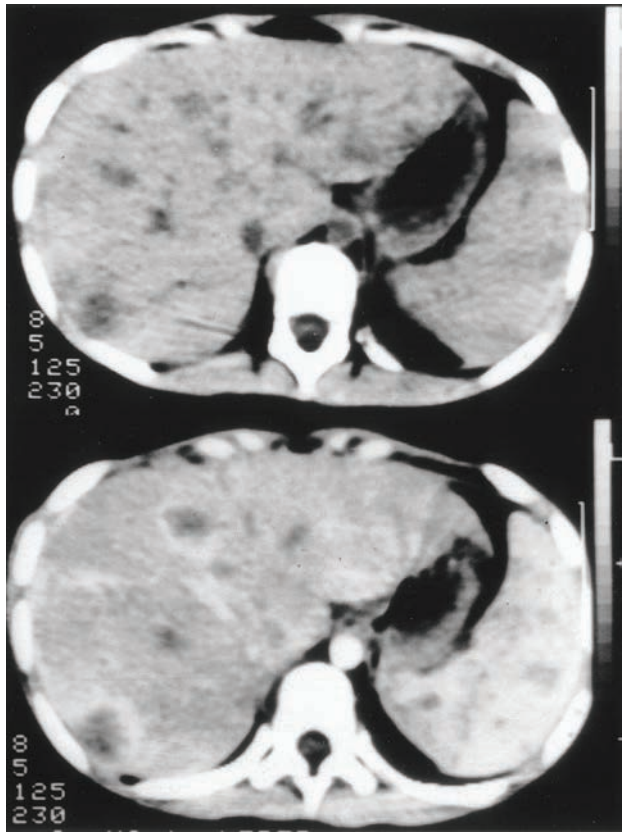

Figure 9.9 Computed tomography scan of a febrile 8-year-old girl with leukemia undergoing chemotherapy. Images before (A) and after (B) administration of contrast material revealing numerous areas of low attenuation throughout the liver and spleen. Rim enhancement of the lesions after injection of contrast material is caused by inflammation. An open biopsy of the hepatic lesion proved the diagnosis of hepatic candidiasis. (Courtesy of Dr Ali Shirkhoda.)

Jaundice and elevated alkaline phosphatase in leukemic patients after chemotherapy is the usual presentation. The pathogen locally invades the colonic mucosa and subsequently enters into the portal circulation [83]. Results from CT and ultrasonography are often normal in the early stage of neutropenic fever, whereas as the neutrophil count returns to normal, imaging studies may show focal liver lesions with a bull's-eye appearance (Fig. 9.9) [83,84]. However, these lesions may be absent on images in some cases even with jaundice. In such cases, diagnostic laparoscopy may show discrete focal yellowish-white punctate lesions scattered throughout the liver surface with direct-guided liver biopsy revealing granuloma with central necrosis (Figs 9.10 and 9.11) [44]. Cholangitis with common bile duct stenosis secondary to *Candida* colonization of the biliary tract was described in a patient on long-time mechanical ventilation [85].

The diagnosis of hepatic candidiasis can be confirmed by culture, immunofluorescence, or PCR-based testing from histologic specimens. Kirby et al. [86] described a

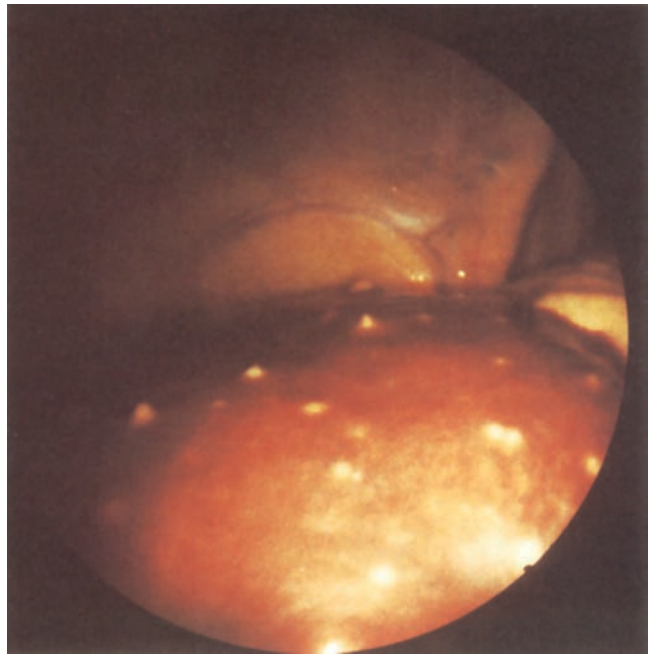

Figure 9.10 A 60-year-old woman with leukemia with fever and jaundice after induction chemotherapy. The computed tomography scan showed no significant pathologic process. At laparoscopy, however, the liver was diffusely infiltrated with small discrete lesions of focal candidiasis.

typical case of hepatosplenic candidiasis in which PCR was positive for *Candida* DNA in both the sera and liver biopsy.

Optimal therapy for hepatic candidiasis has not been established, in part because of the rarity of the condition, the paucity of controlled trials, and the absence of established end-points of treatment. A relapse of the infection may be related to either premature discontinuation of therapy or inadequate antifungal treatment of patients

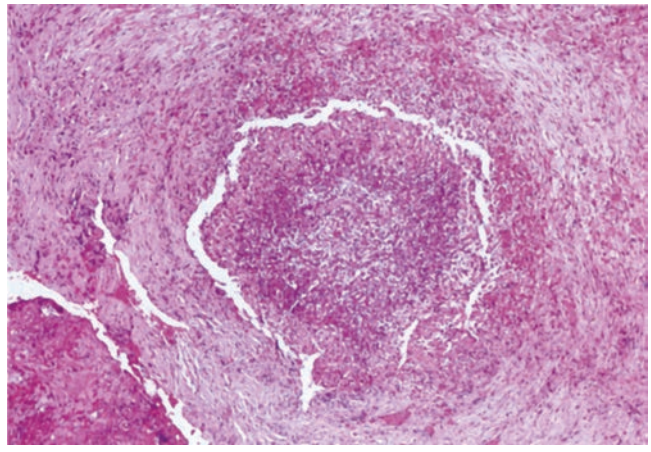

Figure 9.11 Focal hepatic candidiasis (same patient as in Figs 9.4 and 9.10): a centrally necrotic granuloma is surrounded by a thick fibrous capsule. H&E, original ×80. (Courtesy of Dr John Watts.)

with chemotherapy-induced neutropenia [81]. In a review of the treatment of candidiasis [87], it was observed that prior exposure to azoles and the identification of non-*C. albicans* strains can be valuable information, as azole resistance is higher in critically ill patients. Echinocandins are favored for empiric treatment of invasive candidiasis and candidemia [88]. Both fluconazole and caspofungin are as effective as and less toxic than amphotericin B, and can be given orally.

Actinomycosis

Actinomycosis is a chronic, progressive, suppurative disease caused by actinomycetes of the genus *Actinomyces.* The disease occurs worldwide with higher prevalence in areas with low socioeconomic indices and poor dental hygiene. Improved oral hygiene resulted in a decreased incidence of this infection [89]. Involvement of the liver is rare, but primary hepatic actinomycosis may present as hepatocellular carcinoma in endemic areas.

In a recent review of 67 cases of hepatic actinomycosis, the mean age of patients was 44 years (range, 4–85 years) with a male predominance. In 75% of patients, the infection was cryptogenic and 45% of the patients had radiologic findings mimicking liver tumor. Two thirds of the patients had a solitary liver lesion with more than half having right lobe involvement. Elevated serum alkaline phosphatase levels were common. The diagnosis was usually established by microscopic examination of surgical or percutaneous specimens. Antibiotics alone were used in half of the cases, while antibiotics along with surgical/percutaneous drainage were used in the other half. Only two patients required resection as a part of the treatment. The mortality rate was 7.6% in this series [90].

Histologic examination of tissue samples is needed to establish the appropriate diagnosis (Fig. 9.12). The anaerobic *Actinomyces* are difficult to grow in blood culture. Direct fluorescent antibody and immunofluorescence testing can be used but are not readily available in all clinical laboratories [89]. As noted above, most patients respond to prolonged therapy with penicillin (intravenously for 2–6 weeks followed by 6–12 months of oral therapy). Other first-line antibiotics include amoxicillin, tetracycline, erythromycin, and clindamycin. Percutaneous or surgical drainage may be required if an abscess is present [89].

Coccidioidomycosis

The disease known as San Joaquin valley fever is caused by the dimorphic fungus *Coccidioides immitis*. It is endemic in the southwest region of the United States, Central America, and Mexico. The route of infection follows inhalation of the fungus, and the disease may then spread from the primary lung focus to involve the liver. Extrapulmonary disease is rare, but case reports clearly show that both liver and biliary involvement are manifestations of coccidioidomycosis.

The usual clinical features are those of nonspecific anicteric hepatitis, often with biochemical cholestasis, in a person who has recently traveled to Mexico or the American southwest. It commonly presents as a hepatopulmonary syndrome with eosinophilia but may also present as solitary liver mass. Biopsy of the liver shows granulomatous hepatitis. In rare instances, obstructive jaundice may relate to granulomatous involvement of the bile duct epithelium [91].

Among 37 immunosuppressed patients who received liver transplants and later moved to Arizona, the incidence of new coccidioidal infection was 2.7%, suggesting that coccidioidomycosis was not frequent in this population [92]. Nevertheless, among patients with end-stage liver disease listed for transplantation in this same region of Arizona, the incidence of new coccidioidal infection

Table 9.1 Porphyrias: classification and biochemical parameters.

Type of porphyria	Enzyme defect	Site of heme overproduction	Main clinical symptoms	Principal biochemical features
ALA dehydrase deficiency	ALA dehydrase	Liver	Acute attacks and chronic neuropathy	ALA in urine
Acute intermittent porphyria	PBG deaminase	Liver	Acute attacks	ALA and PBG in urine
Congenital erythropoietic porphyria	Uroporphyrinogen III synthase	Erythroid cells	Severe photosensitivity and hemolysis	Uroporphyrin in red cells and urine; coproporphyrin in feces
Porphyria cutanea tarda	Uroporphyrinogen decarboxylase	Liver	Skin fragility and chronic liver disease	Uroporphyrin in urine; isocoproporphyrin in feces
Hepatoerythropoietic porphyria	Uroporphyrinogen decarboxylase	Liver and erythroid cells	Skin fragility and chronic liver disease	Zinc protoporphyrin in red cells; uroporphyrin in urine; isocoproporphyrin in feces
Hereditary coproporphyria	Coproporphyrinogen oxidase	Liver	Acute attacks and skin fragility	ALA, PBG, and coproporphyrin in urine; coproporphyrin in feces
Variegate porphyria	Protoporphyrinogen oxidase	Liver	Acute attacks and skin fragility	ALA, PBG, and coproporphyrin in urine; protoporphyrin in feces
Erythropoietic protoporphyria	Ferrochelatase	Erythroid cells	Photosensitivity and liver damage	Protoporphyrin in red cells and feces

ALA, δ-aminolevulinic acid; PBG, porphobilinogen.

was 4.2%, compared with 0.04% in the same county in the general population [93]. The authors suggested that treatment might alleviate some of the symptoms of coccidioidomycosis originally attributed to disease of the underlying liver disease [93]. Routine surveillance for prior coccidioidal infection and azole prophylaxis (if prior infection is suspected) is advised for patients undergoing solid organ transplantation in endemic areas [94].

Hematology

Porphyrias

Porphyrias represent a group of complex metabolic disorders that result from enzymatic defects in heme biosynthesis. The identification of specific enzyme defects clarified the various subtypes of porphyrias. Subsequently, the identification of specific gene mutations facilitated the screening of relatives and thus early diagnosis and decreased morbidity and mortality. Porphyrias are mostly inherited as autosomal dominants but other patterns (autosomal recessive and complex) are possible. The penetrance of these genes varies and many individuals with genetic defects do not have clinical disease [95].

Heme is synthesized in all human cells, whereas bone marrow (erythroid cells) and liver are the major sites of heme synthesis and therefore porphyrias can be classified as erythropoietic or hepatic, respectively, based on the principal sites of biochemical abnormalities. Porphyrins are excreted mainly through the liver; however, in patients with advanced liver disease from other etiologies, porphyrins appear in the urine because of the liver's inability to exclusively excrete them. This forms the basis of secondary porphyrias. Clinical manifestations of porphyrias can vary, but the principal manifestations are neurovisceral dysfunction, photosensitivity, and structural liver damage. The biochemical and clinical features are described in Table 9.1 [95,96].

Acute porphyrias

Acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria classically present as acute attacks. Acute attacks may also occur in aminolevulinic acid (ALA) dehydrase-deficiency porphyria. Symptoms usually start after puberty and range from mild behavioral changes to autonomic and sensorimotor neuropathies to CNS involvement [95]. The diagnosis is often delayed in patients presenting with acute attacks without a previously established diagnosis of porphyria. Measurement of the urinary excretion of ALA and porphobilinogen (PBG) leads to prompt diagnosis in acutely ill patients, while the diagnosis of a specific type of porphyria can be made later by more specific testing.

Certain medications, alcohol, infection, and fasting can precipitate an acute attack [97]. Specific treatment with

intravenous hematin (3–4 mg/kg daily for 3–4 consecutive days), nutritional support with a high carbohydrate diet or total parenteral nutrition, and symptomatic management are key components of patient care during the acute attack [98]. Liver transplantation can restore normal heme metabolism and has been reported to be curative for acute intermittent porphyria [99,100]. Liver transplantation successfully treated a case of variegate porphyria but cannot be currently recommended for ALA dehydrase-deficiency porphyria [101].

Hepatocellular carcinoma (HCC) has been associated with acute porphyrias and the risk of liver cancer is substantially higher in patients with acute porphyrias compared with the general population [102]. Amongst acute porphyrias, acute intermittent porphyria and porphyria cutanea tarda (PCT) are more commonly associated with HCC. Approximately 5% of patients with porphyria cutanea tarda die of primary liver cancer [102]. The exact pathophysiology remains unexplained, although porphyria-related hepatitis, iron overload, and hepatotoxins are proposed mechanisms [102].

Porphyria cutanea tarda

The most common porphyria worldwide [103], PCT usually manifests after the fourth decade of life although a familial form of PCT may occur early in childhood. PCT is associated with many conditions, including hereditary hemochromatosis, hepatitis C, HIV infection, alcohol consumption, chronic hemodialysis, and estrogen exposure in women.

Patients with symptomatic PCT usually have liver involvement that ranges from mild elevation of aminotransferases to cirrhosis and HCC [104]. If exposed to ultraviolet light, liver biopsy specimens may exhibit red fluorescence. Needle-like cytoplasmic inclusions are found in specimens from untreated patients, which appear to be uroporphyrin crystals. Hemosiderosis is usually demonstrated with iron stains; fatty infiltration is common [105].

The diagnosis is usually made based on clinical presentation and increased urine excretion of uroporphyrin and fecal excretion of isocoproporphyrins. Avoidance of sunlight and fluorescent light, alcohol, contraceptive steroids, and iron supplements should be advised. The mainstay of management are phlebotomies [106]. Urinary excretion of porphyrins usually returns to normal within a year after such therapy, however periodic checks for relapse are required. Patients who continue to have symptoms after phlebotomy, or those who do not tolerate phlebotomies, can be placed on low-dose twice-weekly chloroquine compounds, which enhance porphyrin excretion. Patients with cirrhosis secondary to PCT are at risk for HCC and require screening.

Erythropoietic protoporphyria

Erythropoietic protoporphyria (EPP) is an autosomal dominant condition that usually manifests as acute photosensitivity [103]. Skin symptoms include a burning sensation, edema, and erythema immediately after sun exposure that resolves within a few days. Liver disease is present in 20–30% of symptomatic EPP patients, again ranging from mild disease to cirrhosis [107]. A black pigmentation of the liver results from protoporphyrin deposition in hepatocytes, Kupffer cells, and the biliary system. Birefringence is observed on polarized microscopy as protoporphyrin deposits in the form of crystals [108]. Bile duct destruction (early in the disease), protoporphyrin deposition, portal inflammation, and fibrosis are common findings on liver biopsy. Gallstones are common, again from excessive protoporphyrin accumulation and the resultant excretion that ultimately aggregates – as it is a poorly water-soluble compound – and forms crystalloid deposition.

The biochemical hallmark is an increased level of protoporphyrin in erythroid cells and feces. Excretion of urinary porphyrins is usually normal. No specific therapy is available for patients with liver involvement. Cholestyramine, chenodeoxycholic acid, cysteine, hematin, and blood transfusions have been tried and none has been established as the treatment of choice [107]. A trial of cholestyramine in patients with early liver disease is advised, while monitoring liver chemistries and red cell protoporphyrin levels. Medical treatment followed by bone marrow transplantation was curative in a case of severe cholestatic liver disease [109].

Liver transplantation is well established as a treatment modality for patients with advanced liver disease secondary to EPP [101,110]. Unique complications such as abdominal skin damage from operating room fluorescent lights can be avoided by the use of filters. Perioperative paresis from severe polyneuropathy (a neurotoxic effect of protoporphyrin) can also occur during transplantation. As the ferrochelatase defect in the erythroid cells is not corrected by liver transplantation and because erythroid cells/bone marrow is the major site of biochemical abnormality, protoporphyrin levels remain high after the transplant and can damage the transplanted liver – in up to 65% in a recent series [110]. Bone marrow transplantation after liver transplantation can stabilize recurrent EPP by correcting the biochemical defect [111].

Lymphoma

The neoplastic process of lymphoid tissue commonly involves the liver, as this organ is a part of the reticuloendothelial system. Rarely, however, does lymphoma cause life-threatening hepatic complications. Lymphoma is classified in two broad categories, Hodgkin lymphoma (HL)

and non-Hodgkin lymphoma (NHL), with the latter further subdivided as indolent (35–40%), aggressive (~50%), and highly aggressive (~5%) lymphoma.

Hodgkin lymphoma

Hodgkin disease may actually present as acute liver failure [112] or with hepatomegaly (~9% of patients with stage I–II disease compared to 45% with stage III–IV disease). Jaundice may be multifactorial, more commonly from lymphomatous infiltration causing intrahepatic biliary obstruction, however other etiologies, such as paraneoplastic phenomenon and hepatic microsomal function defect, are possible [113]. Vanishing bile duct syndrome with unexplained jaundice may precede the diagnosis of HL [114].

A liver biopsy is recommended for patients with suspected stage IIIE (extralymphatic) or IV disease as this has implications for prognosis and therapy. Histologic abnormalities in patients with HL are nonspecific. In a series of 308 patients with Hodgkin disease who underwent 459 liver biopsies, 35% had normal histology, only 2.4% had classic Reed–Sternberg cells, and the rest had nonspecific findings [115]. A 25-year-old male presented with hepatomegaly and elevated liver enzymes; a diagnostic laparoscopy and biopsy showed peliosis hepatis, followed by a diagnosis of HL from a biopsy of the mediastinal mass [116]. Successful treatment of HL results in the regression of jaundice in a few patients; persistent jaundice despite remission of HL may signify permanent liver damage [117].

Non-Hodgkin lymphoma

Liver involvement is more common in NHL than in HL – in 15–27% of cases and in more than 50% in autopsy studies [118]. The most characteristic findings include hepatomegaly with raised serum alkaline phosphatase levels. Overt jaundice is rare in patients with NHL, but it may occur secondary to extrahepatic biliary obstruction, most commonly at the porta hepatis.

Primary hepatic NHL is rare and may represent around 1% of extranodal NHL [119]; it can be further subdivided into nodular or diffuse types. Initial presentation may be nonspecific and is usually with "B" symptoms (fever, weight loss, and night sweats). In most cases, liver biochemistries are abnormal. A liver biopsy with immunohistochemistry studies is required for the diagnosis of primary hepatic NHL [118]. Median survival has been estimated to be around 15 months [119]. Management options are not standardized and could include surgery, chemotherapy, radiotherapy, or a combined modality [119]. A small subset of patients with primary hepatic NHL may present with acute liver failure, often with high mortality. Prompt diagnosis with liver biopsy followed by aggressive chemotherapy could be a life-saving measure [120]. Even though generally contraindicated, three patients were treated with orthotopic liver transplantation, with only one out of the three surviving longer than 240 days [119].

Acute liver failure and lymphoma

As noted above, lymphomatous infiltration of the liver may rarely present as acute liver failure. Rowbotham et al. [121] reviewed 4,020 patients with acute liver failure and found only 12 (0.3%) patients (three cases of HL and nine cases of NHL) with lymphoma leading to acute liver failure. NHL appears to be more commonly associated with such presentation than HL. Although a fulminant presentation with acute liver failure (as evidenced by encephalopathy, coagulopathy, and severe lactic acidosis) leading to multisystem organ failure and death is most common, a benign presentation with nonspecific flu-like symptoms and hepatomegaly can also be seen. Replacement of hepatic parenchyma with lymphoid cells, with resultant sinusoidal congestion leading to ischemia and massive hepatocyte necrosis, is the pathophysiology behind such presentation [122]. An antemortem diagnosis is made in less than 50% of cases, attesting to the severity of the presentation [123]. Despite this difficulty, an accurate diagnosis can be established by liver biopsy (transjugular if coagulopathic) and immunohistochemistry and these should therefore be considered in the diagnostic workup of any patient with acute liver failure with negative common etiological evaluation [122]. Histology may show the replacement of hepatic parenchyma with lymphoid cells, sinusoidal congestion, and massive hepatocyte necrosis. In cases with a negative liver biopsy and a high clinical suspicion for lymphoma, a bone marrow biopsy should be pursued [112].

Hepatic lymphoma presenting as acute liver failure carries a grave prognosis, with 83–100% mortality in one series [123]. Systemic lymphoma is a contraindication to liver transplantation as lymphoma frequently recurs [112]. Prompt diagnosis followed by administration of chemotherapy is the only hope for survival in such patients [122].

Sickle cell disease

Sickle cell hepatopathy – liver disorders resulting from the chronic sequelae of sickle cell disease – includes a wide range of clinical syndromes. It is more common in homozygous sickle cell anemia (i.e., sickle cell disease patients) compared with sickle cell trait or hemoglobin sickle cell disease. Hepatic involvement in sickle cell disease can be from the sickling process, which results in acute clinical syndromes (acute sickle hepatic crisis, sickle cell intrahepatic cholestasis, hepatic sequestration crisis, etc.), from multiple transfusions (resulting in iron overload or viral hepatitis), or from chronic hemolysis

(resulting in pigment stone production with consequent cholecystitis, choledocholithiasis, and gallstone pancreatitis) [124].

Abnormal liver tests are common in patients with sickle cell disease, especially unconjugated hyperbilirubinemia from hemolysis, as well as raised LDH levels [124]. Alkaline phosphatase levels can also be elevated; however, the source is mostly osseous rather than liver [125,126].

Acute clinical syndromes often manifest as right upper quadrant pain, fever, and jaundice. Acute sickle hepatic crisis usually presents as elevated aspartate aminotransferase (AST) and ALT (less than 300 U/L), and raised serum bilirubin levels (usually less than 15 mg/dL) [125]. Liver biopsy may show sinusoidal obstruction by sickle cell thrombi, Kupffer cell hypertrophy, and engorgement with sickle-shaped red blood cells, mild centrilobular necrosis, and bile stasis [125]. The syndrome is self-limited and usually resolves within 3–14 days with intravenous hydration and analgesics.

Sickle cell intrahepatic cholestasis is a severe variant of acute sickle hepatic crisis and is the result of widespread sickling within sinusoids resulting in massive hepatic ischemia. Patients initially may present with right upper quadrant pain, jaundice, fever, and leucocytosis, but as widespread sickling continues, renal failure, coagulopathy, and encephalopathy ensue. Serum AST and ALT levels are usually greater than 1,000 U/L, and remarkably high serum bilirubin levels may occur because of a combination of hemolysis, renal failure, and severe intrahepatic cholestasis [127]. Liver biopsy may show sickled red blood cells in hepatic sinusoids and dilated canaliculi with bile stasis [125]. Treatment is mostly supportive with the use of exchange transfusion, although successful liver transplantation has been reported [128]. Sequestration of red blood cells in the liver leads to hepatic sequestration crisis and patients usually present with right upper quadrant pain, hepatomegaly, and a falling hematocrit [129]. Death may occur, so rapid initiation of exchange transfusion may be a life-saving measure and is a recommended management strategy [125]. Budd–Chairi syndrome may develop from sickling within the hepatic vein with resultant thrombosis [130].

Cholelithiasis is common in patients with sickle cell disease and gallstones may be present in up to 58% of patients [131]. Approximately 18% of patients are found to have choledocholithiasis at the time of cholecystectomy. Distinguishing acute cholecystitis from acute sickle hepatic crisis may be difficult because of similar presentations. Biliary scintigraphy is more useful than ultrasound in such cases to confirm the diagnosis of acute cholecystitis [132]. Therefore, elective cholecystectomy is recommended in patients with sickle cell disease and gallstones, although such elective surgery carries the risk of development of acute chest syndrome (up to 10%) [133]. This syndrome is characterized by the presence of new pulmonary infiltrates in a patient with sickle cell disease presenting with chest pain, fever, tachypnea, wheezing, and cough.

Chronic liver disease associated with sickle cell disease is also common. An autopsy series reveal cirrhosis in 16–29% of patients [125]. Chronic liver disease is mostly due to chronic blood transfusion-related iron overload and hepatitis C exposure before 1990 [124]. Reports of sickle cell disease in association with autoimmune liver disease are described in the pediatric literature [134]. Serum ferritin levels are often raised, usually with poor correlation to the degree of hepatic iron overload; Karam et al. [135] recommended liver biopsy in sickle cell patients with high serum ferritin and abnormal liver enzymes to evaluate for fibrosis and other histologic changes.

Endocrinology

Thyroid diseases

The liver is the major site of thyroid hormone metabolism. The conversion of thyroxine (T_4) to tri-iodothyronine (T_3) and reverse T_3 occurs primarily in the liver (85%). In addition, the liver also produces thyroxine-binding globulin, prealbumin, and albumin, the plasma-binding proteins of the thyroid gland. Both hyper- and hypothyroidism can affect the liver in various manners [136].

Hyperthyroidism

It is estimated that most patients with hyperthyroidism will present with one or more abnormalities in liver function tests, including hypoalbuminemia, elevated aspartate/alanine aminotransferases, elevated alkaline phosphatase, or hyperbilirubinemia [136]. Deep jaundice is relatively rare, however it has been reported in patients with thyroid storm [137,138]. Secondary complications such as sepsis, cardiac failure, or intrinsic liver disease must be ruled out in patients with marked jaundice [139].

Even though cardiac output increases in hyperthyroidism, hepatic blood flow remains the same. Hepatic oxygen consumption, however, is increased in patients with hyperthyroidism, resulting in a diminished oxygen supply mainly to the centrizonal area, and rarely leading to necrosis and shock liver [137,139]. Liver histology findings are nonspecific and may be related to heart failure or weight loss associated with hyperthyroidism. Biopsy may show fatty changes, vacuolization of hepatocytes, bile duct proliferation, focal, diffuse, or centrilobular necrosis, and even fibrosis [136].

Antithyroid medications used to treat hyperthyroidism can also cause liver function abnormalities. Methimazole and carbimazole are rare causes of reversible cholestasis [136]. Propylthiouracil is more commonly associated with

mild aminotransferase elevations, which typically normalize with dose adjustment. Clinically significant acute liver failure, resulting in death or transplantation, occurs rarely and is usually seen within the first few months of therapy, often in young women [140,141].

Hypothyroidism

Hypothyroidism can also affect liver function, with a reported decreased hepatic oxygen consumption and decreased bile acid production, flow, and excretion [136]. As a result, elevated bilirubin is common in advanced hypothyroidism. As hypothyroidism also affects lipoprotein synthesis, elevated cholesterol and triglycerides are also common. Hypercholesterolemia along with decreased bile flow may result in an increased risk for gallstone formation. Liver biopsy from patients with longstanding hypothyroidism-related hepatic dysfunction reveals central congestive fibrosis and scarring, likely related to right-sided heart failure [139].

Many of the signs and symptoms of hypothyroidism mimic liver disease, including myalgias, fatigue, elevated liver chemistries, encephalopathy from myxedema coma, and myxedema ascites. Two theories for ascites in myxedema have been proposed: (i) it is secondary to right sided heart failure resulting in central venular scarring; or (ii) it is due to increased permeability of the peritoneal membrane to proteins and mucopolysaccarides along with decreased lymphatic drainage, thus yielding a low serum to ascites albumin gradient. Hypothyroidism mimicking acute liver failure in a patient with known cirrhosis has been described [142]. Differentiating clinical hypothyroidism from the encephalopathy of advanced liver disease is crucial because this form of encephalopathy usually resolves with thyroid replacement therapy.

Diabetes mellitus

The notion that diabetes mellitus is an independent risk factor for the development of liver disease, distinguishable from the recognized risk for nonalcoholic fatty liver disease (NAFLD) associated with obesity or metabolic syndrome, is a relatively new concept. Since 2000 there have been a few small studies [143–146] exploring the association between diabetes and liver disease in US populations that suggest a higher prevalence of type 2 diabetes mellitus in patients with cirrhosis. Such epidemiologic studies were, however, potentially biased because patients with cirrhosis have impaired glucose metabolism.

In 2004, El-Serag et al. [147] from the US Department of Veterans Affairs showed that diabetes doubles the risk not only of liver disease, but also of hepatocellular carcinoma. By excluding patients with any prior history of liver disease and by excluding all patients with chronic viral hepatitis and alcoholism, the authors only examined cases wherein the diagnosis of diabetes mellitus clearly preceded the development of liver disease or liver cancer. The report provided strong evidence that diabetes acts independently as a liver disease risk factor, but did not shed light on the underlying mechanisms. In a recent study from Canada that complements the El-Serag report, Porepa et al. [148] examined administrative health databases over the last decade in the province of Ontario and performed a population-based matched cohort study. Similar to previous reports, these investigators found that adults with newly diagnosed diabetes had a significantly greater risk (adjusted hazard ratio, 1.77; 95% CI, 1.68–1.86) of "serious liver disease," as defined by cirrhosis, liver failure, or need for liver transplantation. This so-called "diabetic hepatopathy" suggests causality, but it remains uncertain whether the liver disease associated with diabetes is distinct from that associated with the other manifestations of the metabolic syndrome, which exists in the majority of diabetic patients [149].

Insofar as diabetes as an independent risk for the development of liver neoplasm, Chen et al. [150] from Taiwan confirmed in a population-based study the association of diabetes and liver neoplasm, adding that diabetic patients with clinical risk factors (especially those with viral hepatitis and cirrhosis) are at especially high risk for hepatocellular carcinoma, and should be screened appropriately. Longer duration of diabetes may likewise increase liver cancer risk [151].

Gastroenterology

Celiac disease

Celiac disease (celiac sprue or gluten-sensitive enteropathy), once thought to be a primary gastrointestinal malabsorption syndrome, is now recognized as a multisystem disorder involving skin, bones, heart, nervous system, and liver [152]. The liver involvement in celiac disease has a wide spectrum that ranges from mild aminotransferase elevations (less than five times the upper limit of normal) to severe liver injury [152]. Conversely, celiac disease was reported to be present in 9% of patients with unexplained chronic liver chemistry abnormalities [153]. The mechanism of liver injury is poorly understood, however an increased permeability of the small intestinal mucosa secondary to inflammation and the resultant accumulation of toxins, antigens, and inflammatory substances in the portal circulation may play a role [153]. Liver biopsy typically reveals nonspecific findings such as periportal inflammation, increased Kupffer cells and mononuclear infiltrates in portal triads, steatosis, fibrosis, and/or cirrhosis [152]. Such patients may be misdiagnosed with NAFLD, thus mandating a heightened clinical suspicion for underlying celiac disease. A gluten-free diet resulted in the normalization of

so-called "celiac hepatitis" in 75–95% patients, often with a reversal of histologic changes [152].

In addition to liver dysfunction directly attributable to celiac disease, the condition has also been associated with many other liver disorders, such as primary biliary cirrhosis (PBC), autoimmune hepatitis, primary sclerosing cholangitis (PSC), hemochromatosis, NAFLD, cryptogenic cirrhosis, nodular regenerative hyperplasia, and hepatocellular carcinoma [153]. Celiac disease is not common in patients with inflammatory bowel disease (IBD) compared with the general population, but IBD is in fact more prevalent in patients with celiac disease [154,155]. In contrast to the nonspecific hepatitis associated with celiac disease, the disease courses of PBC, PSC, and autoimmune hepatitis are not changed by the initiation of a gluten-free diet [153].

Inflammatory bowel disease

Hepatobiliary involvement is one of the common extraintestinal manifestations of IBD. Navaneethan and Shen [156] categorized such manifestations into three subtypes: (i) diseases from similar pathogenesis (i.e., PSC, small duct PSC, autoimmune hepatitis, and idiopathic acute or chronic pancreatitis); (ii) diseases from IBD-related damages, (i.e., cholelithiasis and portal vein thrombosis); and (iii) diseases resulting from the medications used to treat IBD, such as drug-induced hepatitis, pancreatitis, cirrhosis, reactivation of hepatitis B, and biologic agent associated hepatosplenic lymphoma. Other less common associated disorders are immunoglobulin G4 (IgG4)-associated cholangitis, PBC, fatty liver, granulomatous hepatitis, and amyloidosis [156]. PSC is the most common hepatobiliary manifestation associated with IBD, and is discussed in detail elsewhere in this text (Chapter 20).

The prevalence of abnormal liver biochemistries varies from 3% to 50% in patients with IBD [157]. Such abnormalities persist even after colectomy and ileal pouch–anal anastomosis, albeit to a lesser degree, and could be related to coexisting liver disease [157]. Gisbert et al. [158] reported the prevalence of abnormal liver function tests at 20% in their 786 IBD patients, wherein use of azathioprine/6-mercaptopurine and fatty liver were the most common explanations (42.3% and 40.8%, respectively). At least seven cases of hepatocellular carcinoma arising in patients with Crohn disease – without associated viral hepatitis and/or cirrhosis – have been described to date, predominantly among those with early-onset IBD [159].

Rheumatology

Most rheumatologic diseases affect the liver, and various medications used to treat such diseases are potentially hepatotoxic. Distinguishing drug-induced liver disease from liver disease associated with the underlying systemic rheumatic disease may be difficult.

Systemic lupus erythematosus

Liver involvement in patients with systemic lupus erythematosus (SLE) is common, with a spectrum of clinical and biochemical derangements, such as hepatomegaly, splenomegaly, and jaundice [160,161]. Kaw et al. [162] differentiated SLE-associated hepatitis from autoimmune hepatitis (Table 9.2) [162]. Such differentiation is

Table 9.2 Systemic lupus erythematosus hepatitis versus autoimmune hepatitis (AIH).

	Systemic lupus erythematosus hepatitis	Autoimmune hepatitis
Histology	Lobular, rarely periportal	Periportal, piecemeal necrosis
ACR criteria	100%	20%
Hypergammaglobulinemia	Common	Common, IgG elevated
ANA positivity	>99%	80% in type 1 AIH
SMA	30%	60–80%
Serology		
Anti-dsDNA ELISA	Positive	34–64%
Anti-LSP antibody	Negative	Often present
Anti-LKM-1	Negative	Present in type 2 AIH
Response to steroids	Favorable	Favorable

ACR, American College of Rheumatology; ANA, antinuclear antibody; dsDNA, double-stranded deoxyribonucleic antibody lipoprotein; ELISA, enzyme-linked immunoadsorbent assay; LKM, liver kidney microsome; LSP, liver-specific lipoprotein; SMA, smooth muscle antibody.
Reproduced from Kaw et al. [162] with permission from Springer.

important, as autoimmune hepatitis has a more aggressive histologic pattern, low survival without treatment, and increased progression to advanced liver disease as compared with SLE-associated hepatitis. This finding is further corroborated by a recent retrospective review showing favorable liver disease-free survival at 5 years in patients with lupus-associated hepatitis [163].

Nodular regenerative hyperplasia, granulomatous hepatitis, idiopathic portal hypertension, features of PBC, Budd–Chiari syndrome, and hepatic infarction have all been reported in association with SLE [164]. Hemophagocytic syndrome (systemic proliferation of hemophagocytic cells), clinically manifested as fever, cytopenias, lymphadenopathy, and liver dysfunction, may occur in up to 10% of patients with SLE [165].

Treatment of the underlying SLE or cessation of offending medications usually leads to improvement in the biochemical and histologic liver markers [166]. Corticosteroid treatment also improves biochemical abnormalities [161]. Aspirin use may contribute to the abnormal biochemical parameters and is a well-described reversible cause of liver involvement in patients with SLE [166].

Rheumatoid arthritis and Felty syndrome

Abnormal liver biochemistries may occur in anywhere between 6% and 50% of patients with rheumatoid arthritis [164,166,167], but a raised alkaline phosphatase level of bone origin may often be the explanation. Liver biopsy findings are nonspecific [167]. Nodular regenerative hyperplasia may accompany rheumatoid arthritis or Felty syndrome [167]. Felty syndrome is characterized by rheumatoid arthritis in the setting of leukopenia and splenomegaly, often with abnormal liver function tests. This form of noncirrhotic portal hypertension is discussed elsewhere (Chapter 14).

Medications used in the treatment of rheumatoid arthritis, such as methotrexate, gold salts, diclofenac sodium, and immune-modulating agents, have potential drug hepatotoxicity. A case of primary hepatic lymphoma was reported in a 70-year-old male with difficult to control rheumatoid arthritis presenting with elevated liver tests and multiple hypoechoic lesions on liver ultrasound [168].

Sjögren syndrome

The most common liver disease associated with primary Sjögren syndrome (keratoconjunctivitis sicca) is primary biliary cirrhosis in the setting of positive antimitochondrial antibody (AMA) (6.6% of 300 patients with Sjögren syndrome [169]). Patients with primary Sjögren syndrome and abnormal liver tests should undergo AMA testing [164,167]. An association between hepatitis C virus (HCV) infection and Sjögren syndrome is thought to be related to sialotropic properties of HCV and is associated with lymphocytic sialadenitis [164]. In one recent series from Israel, Sjögren syndrome was proved to be the cause of a previously deemed idiopathic granulomatous hepatitis [170].

Scleroderma

Scleroderma is a chronic systemic disease characterized by tissue fibrosis and small vessel vasculopathy. The disease can present as part of the CREST (calcinosis, Raynaud phenomenon, esophageal dysfunction, and sclerodactyly, telangiectasia) syndrome or in a diffuse (systemic scleroderma) form. Although rare, liver involvement has long been described in scleroderma patients, usually in the form of PBC [164]. A positive AMA may be present in >25% of patients with scleroderma; similarly, the anticentromere antibody (a specific antibody of the CREST syndrome) may be positive in approximately 25% of patients with PBC [164]. Powell et al. [171] coined the acronym PACK to describe the association between PBC, anticentromere antibody positivity, CREST syndrome, and keratoconjunctivitis sicca. AMA testing is a sensitive marker for the detection of PBC in patients with scleroderma [172].

Adult Still disease

Adult Still disease (fever, rash, seronegative polyarthritis, lymphadenopathy, and splenomegaly) may involve the liver (hepatomegaly or raised liver enzymes) in up to half of affected individuals [162]. Elevated serum aminotransferase levels occur in up to 92% of patients, and increased serum alkaline phosphatase and bilirubin levels have been described in up to 65% of patients. All biochemical abnormalities resolve either spontaneously or with the treatment of the underlying Still disease. Rare cases of acute liver failure, with death or requiring liver transplantation, have been described [173,174].

Polyarteritis nodosa

Polyarteritis nodosa (PAN) is a focal, segmental, necrotizing vasculitis primarily involving medium-sized arteries. It has been classically associated in hepatitis B virus (HBV) infection, with hepatitis B surface antigen (HBsAg) positivity in about 7% of cases [175]. Anecdotal reports associating chronic HCV infection with PAN are noted, but HCV is primarily associated with mixed cryoglobulinemia [176]. Mild biochemical abnormalities may be noted in 16–55% of patients with PAN, but advanced liver disease is rare [175]. PAN manifesting as acute gastrointestinal hemorrhage in a post-transplant patient has been reported [177]. Liver biopsy in patients with PAN rarely reveals the characteristic lymphocytic infiltration of the intima and media of the hepatic arteries [175] – a finding that can be observed on autopsy specimens (Fig. 9.13). Treatment of HBV-associated PAN

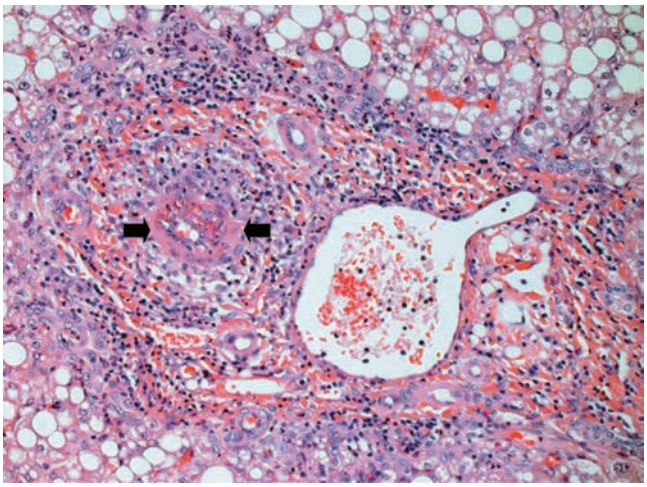

Figure 9.13 Liver biopsy specimen from a patient with hepatic involvement in polyarteritis nodosa revealing a lymphocytic infiltrate in the intima and media of the hepatic artery (arrows). H&E. (Courtesy of Dr John Hart.)

consists of a short course of corticosteroids to decrease the inflammation, along with an oral antiviral agent for HBV treatment [176].

Multiple choice questions

9.1 Which of the following clinical presentations represent hepatic manifestations of tuberculosis?

- **a** Acute liver failure.
- **b** Isolated hepatic lesion.
- **c** Signs and symptoms of portal hypertension.
- **d** Biliary dilatation with strictures.
- **e** All of the above.
- **f** None of the above.

9.2 All of the following are true regarding leptospirosis except which one?

- **a** Presentation as acute abdominal pain simulating a surgical abdomen.
- **b** Current guidelines advise antibiotic prophylaxis for exposed individuals in endemic regions.
- **c** The treatment of choice is doxycycline.
- **d** Headache, myalgia, jaundice, and renal failure are typical findings.

9.3 Which of the following statements is true regarding erythropoietic protoporphyria?

- **a** Hepatic involvement is present in more than 75% of cases.
- **b** Liver transplantation results in a cure of the underlying ferrochelatase defect.
- **c** Increased levels of protoporphyrin in erythroid cells and feces helps establish the diagnosis.
- **d** The mainstay of management is periodic phlebotomies.
- **e** Alcoholic beverages may precipitate acute disease flares.

9.4 All of the following are true regarding liver involvement in celiac disease except which one?

- **a** Celiac disease includes a spectrum of liver disease that may evolve into cirrhosis.
- **b** A gluten-free diet improves liver histopathologic changes.
- **c** A gluten-free diet may improve the disease course of primary biliary cirrhosis when underlying celiac disease is present.
- **d** Celiac disease should be considered in cases of unexplained liver enzyme elevation.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 10

Hepatobiliary Complications of Hematopoietic Cell Transplantation

Josh Levitsky[1] *& Natasha Walzer*[2]

[1]Division of Hepatology and Comprehensive Transplant Center, Northwestern University Feinberg School of Medicine, Chicago, IL, USA
[2]Division of Hepatology, University of Illinois at Chicago, Chicago, IL, USA

Key concepts

- An early rise in bilirubin after hematopoietic cell transplantation (HCT) is a negative prognostic indicator for liver-related morbidity and mortality.
- Liver test abnormalities soon after HCT are most commonly caused by acute graft-versus-host disease (GVHD), drug toxicity, and infection.
- Distinguishing sinusoidal obstruction syndrome (SOS) and GVHD may be difficult and require liver biopsy with hepatic venous pressure gradient measurement.
- Liver disease late after HCT is most commonly due to chronic GVHD, hepatitis B virus (HBV), hepatitis C virus (HCV), and iron overload.
- Anti-HBV prophylaxis should be administered before HCT to all HBV surface antigen positive and possibly core positive patients. Donors should be screened for HBV and other transmissible pathogens.
- Life-threatening opportunistic infections (fungus, herpesvirus) typically occur within weeks after HCT and require urgent diagnosis and treatment.

Hematopoietic cell transplantation (HCT) is now a standard procedure to treat patients with malignant and nonmalignant hematologic disorders. Most patients who remain free of their original disease 2 years after HCT are expected to be long-term survivors [1]. Advances in preparative regimens as well as graft-versus-host disease (GVHD) and anti-infective prophylaxis and treatment have brought significant advances in long-term disease-free survival. However, hepatic complications remain a considerable challenge after HCT and are responsible for significant morbidity and mortality after transplantation. Fortunately, they have become far less frequent and detrimental over time with improvements in diagnosis and treatment algorithms. Pretransplant evaluation of donors and recipients and close monitoring of recipients after HCT appears to reduce the incidence of hepatic complications. This chapter will focus on the causes of liver dysfunction following HCT, and the related morbidity, diagnosis and treatment of these conditions.

Prevalence and prognosis

Chronic liver disease in patients being evaluated for HCT is primarily due to viral hepatitis and iron overload. The presence of hepatic fibrosis and cirrhosis can significantly increase the risk of severe liver injury soon after HCT, regardless of the etiology. Long-term survivors of HCT with chronic liver disease may progress to cirrhosis given the interplay of cancer therapy, immunosuppression, and liver disease etiologies [2]. The cumulative incidence of cirrhosis 10 and 20 years after HCT is approximately 0.6% and 3.8%, respectively. Cirrhosis related to chronic hepatitis C virus (HCV) infection is rising in frequency among patients who were transplanted more than 20 years ago [3]. Serum transaminase elevations in the range of 2–10 times normal are fairly common during the first year after HCT [2]. Sinusoidal obstruction syndrome (SOS), GVHD, cholestasis of sepsis, viral hepatitis, drug- and parenteral nutrition-induced liver injury, and biliary complications are the most common causes of early liver dysfunction after HCT (Fig. 10.1). In autologous transplants, hematologic disease recurrence rather than GVHD and sepsis are the main culprits. Liver disease may be responsible for up to 30% of deaths in HCT recipients, and this risk is increased when the donor or recipient have abnormal liver function or are older or unrelated [4]. A bilirubin rise of >3 mg/dL within the first 6 months is associated with a greater than six-fold increase in mortality [5].

Donor evaluation

Prospective donors should undergo liver function testing and serologic testing for infections that are potentially transmissible (Table 10.1). Assessment of previous exposure to hepatitis B virus (HBV), HCV, and cytomegalovirus (CMV) provides an important estimate of the risk of transmission and the need for closer monitoring or prophylaxis. Ideally, a donor that has not been infected by a hepatitis virus should be selected.

Table 10.1 Donor and recipient assessment prior to hematopoietic cell transplantation.

Donor	Recipient
Liver function tests	Liver function tests
Hepatitis B virus	Hepatitis B virus
Surface antibody and antigen	Surface antibody and antigen
Core IgG	Core IgG
DNA	DNA
Hepatitis C antibody	Hepatitis C antibody
Cytomegalovirus IgG	Cytomegalovirus IgG
Epstein–Barr virus IgG	Epstein–Barr virus IgG
	Varicella zoster virus IgG
	Iron studies
	Iron, TIBC, ferritin
	Hepatobiliary ultrasonography with Doppler

DNA, deoxyribonucleic acid; IgG, immunoglobulin G; TIBC, total iron-binding capacity.

Recipient diagnosis and evaluation

Before HCT, recipients should also be evaluated with liver function tests, viral hepatitis serologies, and for CMV and Epstein–Barr (EBV) antibodies. Consumption of alcohol and potentially hepatotoxic medications should be avoided. The patient should be monitored clinically for any signs of liver dysfunction (right upper quadrant pain, jaundice, ascites, and weight gain). Any suggestion of liver disease should prompt an immediate diagnostic evaluation that is focused on the specific time period after HCT (Fig. 10.1). Early diagnosis and treatment results in improved prognosis for most etiologies of liver disease post HCT. Infectious causes, including viral hepatitis, should be initially ruled out, preferably with nucleic acid testing, due to the immunosuppressed state. In addition, a thorough medication review should be performed. Imaging tests are primarily useful when there is concern that there may be SOS, complications from gallstones, or the development of portal hypertension. Liver biopsy as a diagnostic tool for abnormal liver function tests in HCT recipients is controversial, although decision making is often altered as a result of liver biopsy findings [6]. Transvenous biopsy is typically required to reduce bleeding complications in patients with coagulopathy or thrombocytopenia [7]. Furthermore, this approach allows an assessment of the hepatic venous pressure gradient (HVPG), which may provide additional support for the diagnosis of SOS or other etiologies [6].

Common complications

Acute graft-versus-host disease

Acute GVHD occurs in up to 70% of allograft recipients, depending on the degree of donor/recipient human leucocyte antigen (HLA) mismatch and the intensity of GVHD prophylaxis [8–10]. Risk factors for the development of acute GVHD include age of over 40 years, degree of HLA disparity, donor/recipient gender disparity, and high-intensity transplant conditioning regimen [11]. Organ involvement is typically less than that of chronic GVHD and is mainly limited to the skin, gastrointestinal tract, and liver. The liver is usually the last organ affected and is characterized by a cholestatic pattern (raised alkaline phosphatase and γ-glutamyltransferase) of liver function tests.

Liver biopsy confirmation of GVHD is almost always justifiable, even in HCT recipients with skin or gastrointestinal GVHD who develop cholestatic parameters.

One study reported that when GVHD was suspected clinically, only 43% of biopsies were confirmatory [12]. In addition, acute GVHD was established on biopsy in 17% of unsuspected cases. Histologic findings of acute GVHD include lymphocytic involvement of intralobular bile ducts, bile duct epithelial cell dropout, and minimal inflammation due to post HCT immunosuppression [13]. A recent review of 48 biopsy specimens demonstrated that bile duct injury was the most common finding [14]. Treatment of acute GVHD can be difficult, and the mortality of steroid-refractory GVHD can exceed 70%. As a result, the development and use of effective prophylaxis is extremely important. Significant risk factors for mortality are a non-HLA-matched sibling donor, absence of methotrexate (MTX) in GVHD prophylaxis, initial liver involvement (versus other organ first), and steroid-refractory GVHD [15].

Prophylactic agents have had varied success in preventing acute GVHD after HCT. Immunosuppression with tacrolimus ± MTX has been found to be superior to cyclosporine + MTX in both sibling and unrelated transplants [16]. Although this regimen has become the standard of care in most transplant centers, it is ineffective in a significant percentage of patients. In addition, MTX is associated with a number of adverse events, including renal, hepatic, and gastrointestinal toxicity [17–19]. One reasonable alternative is to use lower doses of MTX to reduce toxicity, although this may compromise efficacy in preventing acute GVHD. An alternative regimen, using tacrolimus and mycophenolate mofetil (MMF) may have less early toxicity but does not appear to be as effective in preventing severe acute GVHD [20]. Ursodeoxycholic acid (12 mg/kg/day) given up to 90 days post HCT lowers the incidence of severe acute GVHD and is associated with an improved 1-year survival compared with placebo [21].

Prophylaxis for acute GVHD often leads to reduced rates of chronic GVHD. In addition, early-onset (<30 days) acute GVHD portends a worse prognosis in terms of the development and severity of chronic GVHD [22]. Tacrolimus and cyclosporine prophylaxis may reduce the incidence of chronic GVHD to 25–50% [19,23]. While most studies have not shown a survival benefit with prophylaxis, tacrolimus plus MTX has been associated with a 2-year disease-free survival of 50% in one study [24]. A recent study compared tacrolimus plus MTX with tacrolimus plus MMF, and found there were no significant differences between the arms in terms of mortality or overall survival in both acute and chronic GVHD. Ursodeoxycholic acid does not reduce the incidence of chronic GVHD, but 1-year survival is improved mainly due to a reduction in acute GVHD [21].

Corticosteroids are the initial treatment of choice for acute GVHD. Response rates in the range of 24–55% are seen with grade II or greater acute GVHD, with the remaining patients being unresponsive or steroid resistant [25]. Corticosteroids are more effective in treating dermatologic and gastrointestinal manifestations of GVHD than liver involvement [26]. For steroid-refractory acute GVHD, options including MMF, tacrolimus, cyclosporine, interleukin 2 receptor inhibitors (daclizumab), anti-CD54 antibodies (alemtuzumab), and rapamycin [27,28]. In severe, refractory cases, orthotopic liver transplantation (OLT) may be an acceptable treatment option, although recent malignancy may be an absolute contraindication unless the risk of relapse is low. Data from a national database demonstrated reasonable post-OLT 1- and 5-year actuarial survival rates (72.4% and 62.9%, respectively) [29].

Chronic graft-versus-host disease

Chronic GVHD develops in ~50% of long-term survivors of allogeneic HCT. Risk factors include older donor/recipient age, busulfan conditioning, previous acute GVHD, CMV seropositivity, granulocyte colony-stimulating factor use, and receiving an unrelated donor HCT [30–32]. Clinical characteristics differentiating chronic from acute GVHD are as follows: timing (chronic >100 days after HCT), more extensive organ injury, and involvement of other systems (exocrine glands, genitourinary tract, lungs). Portal involvement with lymphocytes and bile duct dropout, periportal fibrosis, piecemeal necrosis, and cholestasis are the predominant histologic features of chronic GVHD (Fig. 10.2). The inflammatory mononuclear cells reacting to mismatched histocompatibility antigens on host biliary epithelial cells lead

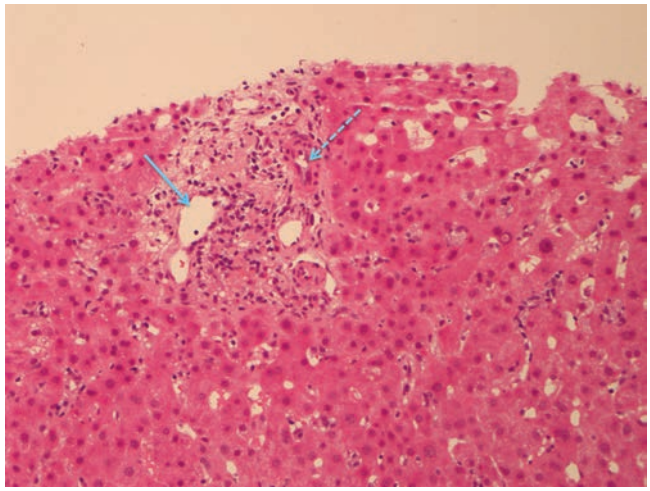

Figure 10.2 Chronic graft-versus-host disease. The portal triad shows the presence of a branch of the hepatic artery (dashed arrow) and portal vein (solid arrow) but no accompanying bile duct. Original ×200. (Courtesy of Simbasiva Rao, Northwestern University Department of Pathology.)

to subsequent obliteration and loss of intrahepatic bile ducts [33].

The liver function tests are predominantly cholestatic, with elevations in the serum alkaline phosphatase, bilirubin, and γ-glutamyltransferase. Rarely, chronic GVHD (>100 days) can present with liver transaminases more than 10 times normal, similar to that of acute viral or drug-induced hepatitis. This classically occurs with recent reduction or cessation of anti-graft-versus-host immunosuppressant therapy. On liver biopsy, lobular hepatitis with hepatocyte necrosis and acidophil bodies are seen in comparison to the characteristic biliary injury features of chronic GVHD [34]. Rapid reinstitution of immunosuppressive therapy and ursodeoxycholic acid generally results in resolution [35]. Interestingly, patients with chronic GVHD may have a clinical and histologic presentation similar to patients with primary biliary cirrhosis (PBC) [36,37]. There is a high frequency of antimitochondrial antibodies in chronic GVHD, although they are often falsely positive. In addition, a bile duct lesion of GVHD can resemble that seen in PBC, without the granulomas [35,38]. Therapy for chronic GVHD is not always indicated, especially when there is stable, mild elevation of liver function tests. Patients with a more severe, cholestatic presentation, are initially treated with corticosteroids ± a calcineurin inhibitor and ursodeoxycholic acid [38]. Most patients require systemic treatment for at least 2 years, but only 50% are able to discontinue therapy after 5 years and 30% are refractory [39]. Salvage treatments result in response rates varying between 19% and 77% [40,41]. MMF has the highest efficacy in refractory cases but may be associated with gastrointestinal side effects and opportunistic infections. Tacrolimus improves and normalizes liver tests in 60% and 33%, respectively [42]. Ursodeoxycholic acid is the only liver specific therapy, and it improves liver tests and long-term hepatic complications [43]. Liver transplantation, including living donor transplantation, for either acute or chronic GVHD appears to be a feasible option in severe, refractory cases [44]. The 5-year survival after OLT for refractory chronic GVHD is reasonable (62.9%) and the rate of retransplantation and recurrent GVHD is fortunately low [29].

Sinusoidal obstruction syndrome

Sinusoidal obstruction syndrome, previously referred to as venocclusive disease, typically occurs within 30 days of HCT and carries a mortality rate of up to 50% in severe cases [45]. The incidence varies widely with the intensity of the conditioning regimen, from <10% with the majority of regimens to as high as 50% after cyclophosphamide 120 mg/kg plus total body irradiation (TBI) >14 Gy [46]. Most series report an incidence of around 20% in HCT recipients [47,48]. The incidence may also be affected by the use of drugs that alter the metabolism of the myeloablative drugs or cause concomitant liver injury. Recently, the frequency and severity of SOS have fallen significantly for a variety of reasons. The doses of TBI >14 Gy are rarely used anymore, cyclophosphamide has been largely replaced by fludarabine, and the use and efficacy of prophylactic medications have increased. The prognosis depends on the extent of hepatic injury, underlying liver dysfunction, and the presence of multiorgan failure [49]. Multiorgan failure, including fulminant hepatic failure, occurs in about 20–25% of patients and is associated with a near 100% fatality rate [50,51]. Patients typically present with tender hepatomegaly, elevated serum bilirubin (>2 mg/dL), and weight gain (>5%) due to fluid retention and ascites. A continuous increase in bilirubin within 3 weeks after HCT is significantly associated with developing SOS [52]. The diagnosis is secure in patients who meet these clinical criteria, although those with two or less criteria are less likely to have SOS and may need liver biopsy and HVPG measurement for confirmation [53].

Risk factors for SOS are listed in Table 10.2. Busulfan induces oxidative stress by reducing glutathione levels in hepatocytes and sinusoidal endothelial cells [54]. Additional risk factors are female gender, elevated serum ferritin, advanced disease status and high Karnofsky score, total body irradiation, treatment with gemtuzumab ozogamicin, and allogeneic transplantation [55]. Preexisting liver disease significantly increases the risk of developing SOS [56,57]. Patients with chronic hepatitis C can have abnormal sinusoidal endothelium, which could make them more susceptible to the cytoreductive regimen injury.

Table 10.2 Risk factors for sinusoidal obstruction syndrome.

Definite	Suspected
High-dose conditioning	Glutathione-*S*-transferase M1 polymorphism
Busulfan	Intravenous immunoglobulin
Cyclophosphamide	Unrelated or allogeneic transplant
Hepatitis C virus	Norethisterone
Advanced disease status and Karnofsky score	Previous abdominal irradiation
Abnormal liver aminotransferases (any cause)	
Gemtuzumab-ozogamicin	
T-cell depletion	
Low protein C activity	

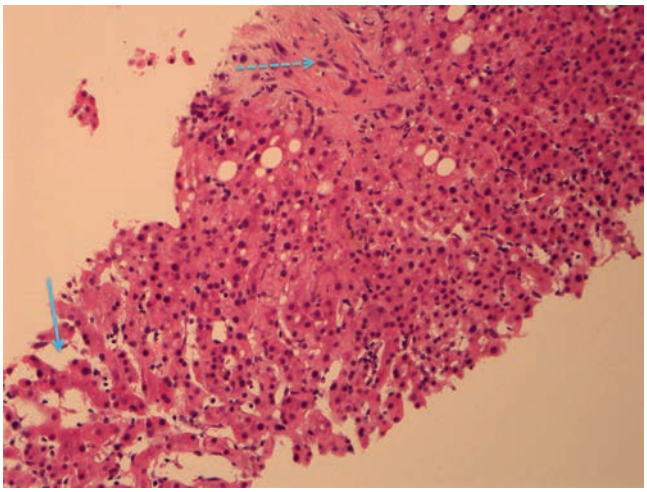

Figure 10.3 Sinusoidal obstruction syndrome showing central vein sclerosis (dashed arrow) and sinusoidal dilatation (solid arrow). Original ×200. (Courtesy of Simbasiva Rao, Northwestern University Department of Pathology.)

Local activation of the coagulation cascade and collagen deposition in the perivenular and subendothelial region results in a reduction in blood flow from the sinusoids to the central veins [58]. Histologically, findings include central vein subendothelial thickening, sinusoidal dilatation, red blood cell extravasation outside the sinusoids, and pericentral hepatocyte necrosis. Activated stellate cells, identified by immunohistochemical staining for alpha smooth muscle actin antibodies, play an important role in the development of luminal narrowing and sinusoidal fibrosis [59]. With ongoing obstruction and necrosis, the fibrosis can extend from these obliterated central veins. Later histologic findings include sclerosis of venular walls (Fig. 10.3) and occlusion of terminal hepatic venules. As such, the term venous occlusive disease has been replaced by sinusoidal obstruction syndrome as not all cases have terminal hepatic venule occlusion. The number and degree of perivenular changes is associated with the clinical severity of SOS and not solely with the presence of occlusion of terminal hepatic venules [60,61].

Rapid diagnosis and intervention are important in the management of SOS. Ultrasonographic findings, such as hepatomegaly, splenomegaly, ascites, an abnormal portal vein waveform, attenuated hepatic venous flow, and an elevated hepatic artery resistive index correlate with the clinical and histologic diagnosis of SOS [62,63]. An HVPG of >10 correlates highly with the histologic diagnosis of SOS and may be useful when the biopsy or clinical features are inconclusive [6].

Because of the absence of specific, effective therapy, prevention of the initial damage to the hepatic sinusoidal endothelial cells is critical. This can be ameliorated via prophylactic strategies or an alteration to the myeloablative conditioning regimen. The latter strategy, however, may result in either a decrease in the rates of engraftment or an increase in malignancy relapse rates. Once an assessment of the risk of a particular patient has been performed (see Table 10.2), a prophylactic agent should be used in those patients deemed to be at increased risk for the development of SOS. The most promising agents are ursodeoxycholic acid, heparin, and defibrotide [64]. Two of three randomized trials have shown a significant reduction in the incidence of SOS with the use of ursodeoxycholic acid compared with placebo [21,65,66]. Heparin, either unfractionated or low molecular weight or in combination with defibrotide, is also effective in preventing SOS compared with placebo, with a low rate of bleeding complications [67–70]. Based on findings that antithrombin III (ATIII) confers a protective effect on vascular endothelium and ATIII levels are decreased in patients with SOS, a number of trials have tested whether ATIII has activity in SOS. A recent large pediatric trial in which 91 children received preemptive ATIII replacement demonstrated that ATIII administration did not reduce the incidence of SOS compared with the control group who received no SOS prophylaxis [71].

Response rates depend on early diagnosis and severity of the disease. Early intervention has been associated with a complete response in 76% and 50% of all and severe cases of SOS, respectively [63,72]. Those who are deemed to have a mild disease and are likely to recover (>70% of patients) can be treated conservatively with management of fluid balance with sodium restriction, diuretics, and paracentesis as needed for ascites. Those with a poor prognosis can be recognized by rapid rises in serum bilirubin levels, significant weight gain, portal pressures >20 mmHg, and serum alanine aminotransferase (ALT) values >750 U/L [73,74]. Defibrotide is a mixture of porcine oligodeoxyribonucleotides that has local antithrombotic, anti-ischemic, and anti-inflammatory activity. It is able to protect the hepatic sinusoidal endothelium without compromising the antitumor effects of cytotoxic therapy [75]. Previous studies have demonstrated an overall response rate of 55–76% with a severe disease response rate of 36–50% [72,76]. Although not available in the United States, defibrotide is preferred over other thrombolytic agents, such as recombinant tissue plasminogen activator (TPA), that have a significantly higher rate of bleeding complications [77,78]. For refractory cases, transjugular intrahepatic portosystemic shunt (TIPS) improves abdominal pain and ascites but does not result in improved survival [79,80]. In selected cases with a low risk of disease recurrence, liver transplantation may be performed with a potential for long-term survival. A recent review of the literature identified 15 patients with severe SOS who underwent OLT as a life-saving measure [81]. Only 33% of the patients

survived more than 2 years, with the remaining dying of overwhelming infections. In the same paper, however, a review of the United Network for Organ Sharing (UNOS) database revealed an additional five cases of SOS where the patients had undergone transplantation with only one death [81].

Hepatitis B virus (de novo and reactivation)

Hepatitis B virus reactivation after HCT is a well-recognized complication in patients who either retain hepatitis B surface antigen (HBsAg) or have resolved infection (hepatitis B core (HBc) antibody) [82]. In addition, HBV can be transmitted from donor to recipient and cause acute hepatitis soon after HCT. For HBV-negative recipients, donors not previously exposed to HBV infection are preferred [83]. The pathophysiology of reactivation is related to impaired cellular immunity because of the underlying hematologic disease and treatment, allowing for viral replication. In addition, subsequent to the withdrawal of the immunosuppressive agents, there is a restoration of immune function that results in the T-cell immune-mediated destruction of the infected hepatocytes.

Donor evaluation

There is a high incidence of HBV-related hepatitis after HCT when HBsAg-positive donors are used, with a mortality rate of up to 17% [84]. Overall, de novo HBV has been reported to occur in 3.2% of recipients [85]. The presence of donor HBsAg and a high viral load predisposes recipients to developing HBV-related hepatitis [86]. HBV carriers (HBsAg without detectable HBV DNA) rarely transmit HBV to the recipient and can be donors if their serum and peripheral stem cells are HBV DNA negative [85,87]. In addition, recipient surface antibody positivity seems to confer protection against HBV [88]. HBsAg-positive donors have been used safely in an HBV endemic area when the donor and recipient are treated with lamivudine, in addition to the recipient being given HBV vaccination before transplantation [89]. Interestingly, adoptive transfer of surface antibody from donor to recipient may result in recipient loss of surface antigen and acquisition of surface antibody [90,91].

Risk of reactivation and acute flare

The degree of immunosuppression and donor/recipient viremia immediately prior to HCT are the most significant risk factors for severe HBV infection or reactivation. Recipients with surface antigen and undetectable HBV DNA have a significantly lower risk of reactivation than those with detectable DNA [92]. Patients with a precore mutant are prone to more severe reactivation episodes and decompensation after HCT [87]. The presence of recipient core antibody also poses a risk, particularly in the setting of detectable DNA and chronic GVHD [93,94]. Reverse seroconversion, that is HBV reactivation in patients with antibodies to HBsAg and/or hepatitis B core antigen, has been reported to occur [86,95,96]. One study demonstrated a 35% risk of HBV reactivation in patients with isolated anti-HBc antibodies [97]. The availability of potent immunosuppressive drugs, like anti-CD20 and anti-CD52 monoclonal antibodies, has further increased the risk of HBV reactivation. It has been reported that patients with surface antibody who have presumed immunity from prior infection can develop acute hepatitis after HCT, potentially related to low surface antibody titers and the presence of viral DNA either in blood or tissues [98,99]. Fulminant hepatic failure can occur if the diagnosis is detected late and therapy is not instituted in timely fashion [100].

Treatment

Acute reactivations of HBV in the setting of immunosuppression tapering or withdrawal are becoming less common with advances in the treatment and prophylaxis of HBV before and after HCT. Lamivudine is typically the first agent selected for HBV flares after HCT, unless the patient has a known lamivudine-resistant strain. Adefovir used in addition to lamivudine or alone is also effective in this situation [101]. In addition, there are multiple new antiviral agents (tenofovir, entecavir) with lower rates of resistance that may be utilized particularly if the patient has cirrhosis or is likely to be on long-term therapy. The length of treatment in all cases is also unknown. Those with reactivation during immunosuppression withdrawal should be treated until immunosuppressive agents are tapered or discontinued and for a time period (~6–12 months) thereafter.

Prevention

Antiviral therapy can prevent most cases of acute hepatitis B after transplant if initiated prior to the start of conditioning therapy in those who are viremic. Patients with known chronic HBV should be treated with antiviral therapy prior to HCT with the goal of undetectable virus at the time of HCT, time permitting. Therapy should continue until long after engraftment and immunosuppression withdrawal. Patients who cannot wait for viral clearance should be given antiviral prophylaxis as soon as possible prior to conditioning. HBsAg-positive recipients who are given lamivudine prophylaxis have a significantly higher 1-year survival (94% versus 54%) and lower incidence of hepatitis flares (5% versus 45%) and acute liver failure (0% versus 15%) compared with those given no prophylaxis [102]. Despite the previously described risk of reactivation, controversy still exists about antiviral prophylaxis in recipients who are anti-HBc positive. In one series, among 25 patients with anti-HBc

antibodies, reverse seroconversion and acute hepatitis were not observed in those treated with lamivudine, whereas HBV reactivation developed in three of the untreated patients [103]. The impact of lamivudine resistance in this setting does not appear to be of great concern, as only short-term therapy is needed. Newer antiviral therapies can be used but are probably only required in those requiring long-term therapy.

Hepatitis C virus

Although the risk of acquiring HCV from HCT is relatively low, many patients come to HCT already chronically infected. A large prospective study demonstrated a prevalence of about 6%, although this percentage varies widely in the literature [85]. Prior to the institution of blood product screening, one study demonstrated that a third of patients who had undergone HCT from 1987 to 1988 acquired HCV [104]. Transmission of HCV is currently low due to adequate blood product screening, newer generation HCV antibody testing, and treatment of donors and recipients [105]. Despite this, HCV is the main etiology of chronic liver disease long after HCT [106]. Moreover, a more rapid rate of liver fibrosis has been observed in patients with HCV who received HCT [3].

Risk of acute flare

Although a significant contributor to long-term morbidity, unlike HBV, HCV does not cause severe acute hepatitis or flare upon the withdrawal of immunosuppression after HCT. Mild elevation in liver aminotransferases, limited to a 5–10-fold increase, are not uncommon. The presence of HCV alone is not an independent predictor of liver failure in HCT recipients [107], although the risk of SOS itself is increased with underlying HCV unless the conditioning regimen has little or no liver toxicity. There is no prophylactic agent or antibody for HCV prior to the institution of chemotherapy or HCT to prevent complications.

Long-term prognosis

The influence of chronic HCV on the outcomes for HCT recipients is not fully clear. Some patients can develop progressive fibrosis and clinical decompensation, while other HCV infections lie dormant for years. Studies with long follow-up confirm that HCV leads to a cumulative incidence of cirrhosis of 24% at 20 years, ranking HCV third behind infection and GVHD as a cause of late death after HCT [108]. In addition, iron deposition is thought to be a major cofactor in fibrosis progression. Other potential risk factors for progression are HCV genotype (1a and 1b), hepatic steatosis, insulin resistance, obesity, and the presence of extrahepatic manifestations of HCV.

Treatment

Data regarding HCV treatment after HCT are sparse. One study involved 11 patients 24–65 months post HCT who were treated with interferon for 6–12 months [109]. Ten completed the protocol, 40% had a sustained virological response and 50% had improved liver histology. A more recent evaluation of 22 HCV-infected HCT recipients demonstrated that combined therapy (pegylated or standard interferon with ribavirin) led to a sustained virological response in 4/18 (20%) patients compared with 2/20 (10%) in patients who received interferon alone [110]. Combination therapy led to an increased risk in hematologic toxicity, but only led to drug discontinuation or dose modification in a small percentage.

Iron overload

Iron overload is associated with organ toxicity and can be a cause of significant morbidity in patients with hematologic malignancies [111]. Patients undergoing HCT have ineffective erythropoiesis, increased iron absorption, and often have a need for multiple red blood cell transfusions [112]. Progressive fibrosis due to hepatic iron deposition in HCT recipients is most commonly seen in patients with a pre-HCT history of iron overload from multiple blood transfusions. Pretransplant red blood cell transfusion dependence and/or elevated serum ferritin levels are associated with diminished post-transplant survival among patients with myelodysplastic syndrome and acute leukemia [113]. The presence of severe iron overload significantly impacts survival and transplant-related mortality. As such, those who have hepatomegaly and fibrosis prior to HCT will typically develop progressive iron overload and fibrosis years after HCT [114].

The diagnosis of iron overload is suspected in patients with elevated ferritin and transferrin saturation in association with abnormal liver aminotransferases. A liver biopsy may not be necessary, although other causes of abnormal liver enzymes should be excluded. In addition, biopsy may be of prognostic value, as hepatic iron stores often reflect total body iron stores accurately and may give prognostic information. Iron overload suggested on magnetic resonance imaging is common after HCT and may correlate with the number of previous blood transfusions [115]. Early iron reduction with phlebotomy or iron chelation therapy is safe and may be effective in reducing ferritin levels immediately after HCT, although this is better tolerated when adequate return of red cell production by the bone marrow occurs later after HCT. Studies have shown significant improvements in ferritin, transferrin saturation, liver enzymes, hepatic iron concentration, and fibrosis scores in patients undergoing phelobotomy years following HCT [116].

Causes of cholestasis

Sepsis

Sepsis of any cause, particularly in the setting of neutropenia or high levels of immunosuppression, may lead to biochemical liver abnormalities and cholestasis. The pathophysiologic features of cholestasis due to sepsis are similar in general and transplant populations. Canalicular cholestasis is the most common histologic finding, typically with dilated periportal ductules and occasionally inspissated bile in cholangioles. Other nonspecific findings include steatosis and pericentral ischemic necrosis, the latter related to poor perfusion from sepsis. The serum bilirubin can become quite elevated in severe septic shock. It is thought that the cytokine release that occurs during sepsis downregulates bile acid transport and bile secretion [117]. Ultrasonography can help differentiate cholestasis of sepsis from ductal obstruction. Resolution of sepsis invariably results in slow normalization of bilirubin and cholestasis.

Total parenteral nutrition

Total parenteral nutrition (TPN) as a primary cause of cholestasis after HCT can be a challenging diagnosis to make in the setting of other concurrent factors, including medications, infection, and GVHD. Increases in serum transaminases, alkaline phosphatase, and γ-glutamyltransferase are often seen within 3 weeks of TPN initiation and return to normal in over 75% of patients after withdrawal. The most common histologic abnormalities include intrahepatic cholestasis, portal/periportal fibrosis, and periportal macrovesicular steatosis [118]. Progression to cirrhosis and the development of clinically significant liver disease is uncommon in adults. Reduction of dextrose in the TPN solution with conversion to more lipid-based calories can improve cholestasis. Additionally, cycling infusions to allow "TPN-free" periods can improve biliary flow. TPN should be discontinued, if possible, if cholestasis progresses despite these measures.

Drug hepatotoxicity

Drug-induced liver injury is a cause of liver dysfunction in many patients post HCT, although isolating the culprit drug can often be difficult. Numerous medications can lead to intrahepatic cholestasis and liver test abnormalities. Many chemotherapeutic agents and corticosteroids cause steatosis, SOS, cholestasis, and/or hepatocellular injury. Prophylactic and therapeutic anti-infective agents such as the sulfonamides, macrolides, cephalosporins, penicillins, and azole antifungals can lead to cholestasis, vanishing bile duct syndrome, or phospholipidosis. A recent retrospective review demonstrated a 34% rate of hepatotoxicity with voriconazole therapy, although this is rarely severe [119]. Agents used for GVHD (e.g., cyclosporine and less commonly tacrolimus) can cause cholestasis in the setting of high serum and tissue levels. Cyclosporine inhibits bile transport and can often raise the serum bilirubin without affecting the serum ALT or alkaline phosphatase. Histologic changes consist of bile duct epithelial hypertrophy with cytoplasmic vacuoles and foamy deposition within the hepatic sinusoids.

Uncommon complications

Herpesvirus infections

Herpes simplex virus 1 and 2

With the routine prophylactic use of aciclovir or valaciclovir, acute hepatitis due to herpesvirus infections is uncommon [120]. Fulminant hepatitis due to herpes simplex virus (HSV) early after HCT has been reported, although incidence data in this population are not available [121]. Risk factors for reactivation include pretransplant conditioning, HSV seropositivity, and a history of leukemia. Antiviral drug prophylaxis should be given primarily to HSV-seropositive patients. Herpes hepatitis typically causes massive coagulative necrosis with purple nuclear inclusions surrounding the regions of necrosis. HSV DNA detected in peripheral leukocytes is more specific for disseminated infection (esophagitis, hepatitis) and may have predictive value when rapidly rising [122]. When herpesvirus hepatitis is suspected, immediate treatment with intravenous aciclovir is warranted [123]. Prophylactic strategies after HCT, including use of aciclovir and its derivatives, have been shown to lower the incidence of HSV infections in general. Aciclovir- and foscarnet-resistant HSV strains have been reported, but are uncommon in HCT recipients [124].

Varicella-zoster virus

The incidence of varicella-zoster virus (VZV) infections has also been declining, likely due to antiviral prophylaxis and less intensive immunosuppression regimens [125]. Up to one third of patients can have reactivation of VZV after transplantation. Fortunately, the majority of cases are confined to the skin. Visceral presentation has been reported to occur in 1–7% of HCT recipients [126]. Infections typically occur within the first year after transplantation and usually in the setting of GVHD, pretransplant VZV seropositivity, and tapering of antiviral prophylaxis [127]. Immunosuppressed patients may fail to develop a skin rash, especially in the early phase of the infection [128]. Clinically, patients with VZV hepatitis classically present with severe abdominal pain and significant liver aminotransferase elevation. Fulminant hepatic failure from varicella hepatitis has been reported after HCT [129]. Hepatic lesions appear

similar to those of HSV with necrosis and minimal inflammation. Electron microscopy, immunocytochemistry, and polymerase chain reaction analysis may help differentiate VZV from other herpesviruses. Prompt antiviral treatment with aciclovir can significantly decrease the high morbidity and mortality associated with the illness. For prophylaxis, aciclovir reduces VZV reactivation significantly, although VZV can occur soon after prophylaxis is discontinued. Longer term prophylaxis may be considered in patients at high risk for VZV (previous zoster infection, GVHD). Varicella vaccination given before HCT has been shown to significantly reduce the incidence of zoster and the potential for viral dissemination [130].

Epstein–Barr virus

Proliferation of EBV occurs in the setting of high immunosuppression, antilymphocyte therapy, and T-cell depletion. Subsequently, this may lead to B-cell proliferation and the potential for post-transplant lymphoproliferative disorder (PTLD). Clinical signs, such as fever, lymphadenopathy, splenomegaly, weight loss, abnormal liver aminotransferases, and bone marrow suppression are common. Histopathology shows a diffuse lymphocytic infiltrate in the sinusoids and focal apoptotic cells [131]. Routine antiviral prophylaxis for EBV has little impact on the development of EBV PTLD. As a serum EBV DNA level of $>10^4$ associated with the development of PTLD after HCT, prospective monitoring of EBV viremia may be recommended in high-risk or pediatric patients [132,133]. In addition, rapid reduction in viremia predicts a successful response [134]. Studies have shown that early intervention with anti-CD20 antibody (rituximab) when EBV DNA is $>10^3$ or CD8+ responses to EBV are detected may prevent the subsequent development of PTLD [135]. Polyclonal EBV infections typically respond to a reduction in immunosuppression. However, rituximab appears to be safe and efficacious for monoclonal or more aggressive EBV PTLD [136].

Cytomegalovirus

There are few reports on the incidence of CMV hepatitis following stem cell transplantation. It is known that recipients of CD34+ peripheral blood stem cell transplants, alemtuzumab infusions, and transfusions without leukocyte depletion or CMV screening have a higher rate of CMV infection [137]. Presenting signs and symptoms include fever, cytopenia, colitis, pneumonitis, and abnormal aminotransferases. The pathognomonic finding is a hepatocyte, bile duct epithelium, or endothelial cell containing cytoplasmic basophilic granules and an intranuclear inclusion surrounded by a clear halo (Fig. 10.4). This is typically positive on CMV immunohistochemical staining (Fig. 10.5). Blood CMV DNA testing is more sensitive than culture or antigen testing and may predict the development of CMV end organ disease. Antiviral prophylaxis after HCT, including aciclovir, valaciclovir, ganciclovir, and valganciclovir, are all successful in reducing the incidence of CMV infection. However, prevention of late infections continues to be a challenge in high-risk (donor-positive, recipient-negative) populations [138]. Intravenous ganciclovir is the treatment of choice for confirmed disease, with foscarnet reserved for ganciclovir-resistant strains (<10%). Another preemptive approach is to closely monitor for CMV infection using pp65 antigen or DNA and only treat once CMV is detected before the onset of symptoms

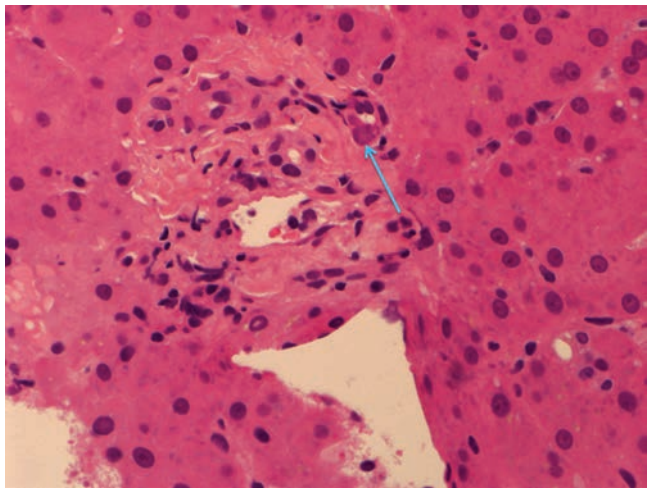

Figure 10.4 Cytomegalovirus hepatitis showing a viral inclusion present in a bile duct epithelial cell (arrow). Original ×600. (Courtesy of Simbasiva Rao, Northwestern University Department of Pathology.)

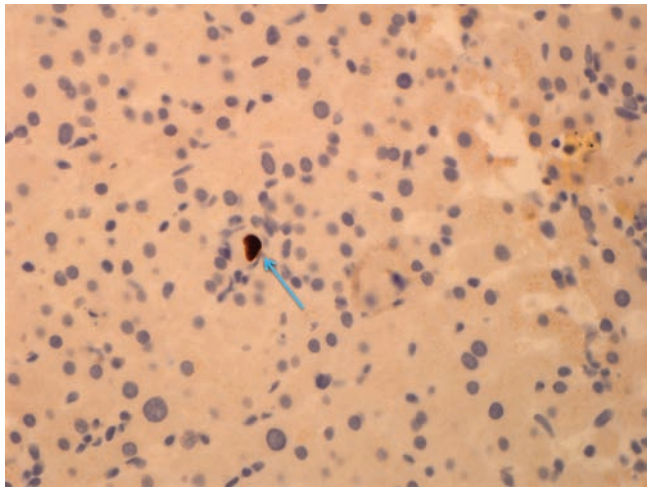

Figure 10.5 Cytomegalovirus hepatitis. Immunostaining for a cytomegalovirus-positive cell (arrow). Original ×600. (Courtesy of Simbasiva Rao, Northwestern University Department of Pathology.)

[139]. Isolation and donor transfer of T cells with specific activity against CMV antigens may reconstitute cellular immunity against CMV and might represent a novel approach [140].

Human herpesvirus 6

Infection with human herpesvirus 6 (HHV6) in transplant recipients, often transmitted from donor to recipient, may result in a lobular, nonspecific hepatitis, marrow suppression, and gastrointestinal symptoms [141]. The detection of HHV6 early after HCT may also be associated with delayed engraftment [142]. A high percentage of HCT recipients have HHV6 viremia, but symptoms and disease specifically related to HHV6 are uncommon. Cidofovir and foscarnet have the highest antiviral activity against HHV6 but are rarely needed.

Adenovirus

Adenovirus infection causing acute hepatitis after HCT is rare and is typically only seen in the setting of induction chemotherapy, high levels of immunosuppression, and GVHD [143]. The clinical presentation is similar to CMV, with pneumonia, gastroenteritis, hepatitis, and occasionally encephalitis and hemorrhagic cystitis. Fulminant hepatic necrosis with intranuclear inclusions appears similar to HSV and VZV. Thus, electron microscopy, immunohistochemical staining, or polymerase chain reaction are often needed to distinguish these etiologies. Treatment with antiviral agents, such as cidofovir and ribavirin, have had limited success.

Fungal infections

In the early days of HCT, fungal organisms were found in up to 10% of liver autopsy specimens. Risk factors after HCT include pre-HCT fungal infection, superficial and deep fungal infections, and severe liver dysfunction either from SOS or GVHD. The most common fungal infections involving the liver are candidiasis, aspergillosis, and zygomycosis, but other mycoses, such as cryptococcosis, histoplasmosis, blastomycocis, and coccidiomycosis can be seen with regional or travel exposures. Hepatosplenic candidiasis can present with multiple portal and periportal abscesses and granulomas, as well as sinusoidal hyphae. Prior to HCT, patients can be treated aggressively with amphotericin to eradicate candidiasis and can still successfully undergo HCT. Aspergilli (*Aspergillus fumigates* and *A. flavus*) and zygomycosis (*Rhizopus*, *Mucor*, and *Absidia*) can cause hemorrhagic hepatic necrosis and local infarction due to blood vessel invasion. Assessing the size, morphology, and special staining on histology typically confirms the specific diagnosis. Specific culture of liver tissue may be necessary. Imaging tests such as ultrasonography and computed tomography scan, particularly for hepatosplenic candidiasis, may provide additional evidence for fungus, although the sensitivity is low as resolution of neutropenia is required to visualize lesions. The treatment of invasive hepatic infections is usually with amphotericin B or azole agents. Post-HCT prophylaxis with itraconazole, fluconazole, or low-dose amphotericin can significantly reduce the incidence, morbidity, and mortality associated with invasive fungal infections [144,145].

Biliary complications

While gallbladder sludge and stones are typical in HCT recipients, complications such as cholecystitis and cholangitis are uncommon. Gallbladder sludge containing nonspecific residue, calcium-binding protein, and calcium bilirubinate crystals forms early after HCT and often progress to true stone formation [146]. Cholecystitis is treated with either cholecystectomy or nonsurgical measures (antibiotics, percutaneous drainage) in poor surgical candidates. Acalculous cholecystitis is less common and is associated with prolonged fasting, SOS, transfusions, and the use of TPN. This entity usually requires cholecystectomy, as gallbladder wall necrosis and perforation are often present. The incidence of biliary obstruction after HCT was reported to be 0.1% in one large study [147]. The causes were mainly biliary sludge/stones and strictures from recurrent malignancy, EBV PTLD, and GVHD. Endoscopic or percutaneous treatment is usually sufficient to treat and relieve obstruction.

Tumor infiltration

New secondary malignancies can occur in up to 20% of recipients within 10–15 years after HCT. Leukemia and lymphoma can infiltrate the liver, leading to hepatomegaly and high levels of alkaline phosphatase. Secondary solid cancers occur almost twice as frequently in HCT recipients as in the healthy population [1]. In addition, due to exposure to hepatitis B and C before the 1990s, recipients can develop chronic liver disease and hepatocellular carcinoma. Biopsy is the gold standard to differentiate malignancy from infection and other causes of liver dysfunction.

Nodular regenerative hyperplasia

In rare cases, HCT recipients can develop idiopathic nonneoplastic hepatic nodules (nodular regenerative hyperplasia) without fibrosis or liver dysfunction. The etiology is unknown but does not appear to be related to age, underlying disease, or cytoreductive regimen [148]. Even though nodules are less than 1.0 cm in size, they can significantly distort the hepatic architecture enough to cause sinusoidal and presinusoidal portal hypertension (ascites, variceal hemorrhage). The diagnosis can be difficult to determine and is not always apparent on standard liver biopsy, unless a laparoscopic wedge biopsy is taken

[149]. The HVPG may or may not be elevated depending on the region (sinusoidal or presinusoidal) of portal hypertension. Nodular regenerative hyperplasia may resolve spontaneously months after HCT and does not appear to contribute significantly to mortality. Management includes standard therapies for managing portal hypertension (salt restriction, diuretics, primary or secondary prophylaxis of gastrointestinal varices).

Multiple choice questions

10.1 All of the following are considered risk factors for liver dysfunction following hematopoietic cell transplantation (HCT) except which one?

a Donor HbsAg positivity.
b Recipient HCV antibody positivity.
c Abnormal donor or recipient liver aminotransferases.
d Matched donor/recipient HCT.
e High recipient ferritin level.

10.2 All of the following are important presenting features of sinusoidal obstruction syndrome (SOS) except which one?

a Presence of weight gain and ascites.
b Terminal hepatic venule occlusion on biopsy.
c Elevated hepatic venous pressure gradient.
d Hyperbilirubinemia.
e Time period <21 days of HCT.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 11
The Liver in Pregnancy

Yannick Bacq
Department of Hepatogastroenterology, Centre Hospitalier de Tours, Hôpital Trousseau, Tours, France

Key concepts

- During normal pregnancy, except for alkaline phosphatase, most values of serum liver tests remain below the upper normal limits established in nonpregnant women. Consequently, increased levels of aminotransferases, bilirubin, or serum bile acids usually indicate the presence of liver disease. By contrast, an increase in serum alkaline phosphatase in pregnancy is not specific for liver disease because it may be of placental origin.
- The liver disorders that occur in pregnancy can be divided into three groups: (i) liver diseases that are specifically pregnancy related; (ii) intercurrent liver diseases in pregnancy, i.e., acute liver disease occurring during pregnancy; and (iii) chronic liver diseases that may be revealed by pregnancy, or more often diagnosed fortuitously during pregnancy.
- It is essential that liver disease in pregnancy is recognized and understood because certain disorders can threaten the lives of both mother and infant.
- Liver disorders unique to pregnancy include the exceptional primary hepatic pregnancy, liver dysfunction associated with hyperemesis gravidarum, intrahepatic cholestasis of pregnancy (ICP), liver disorders of preeclampsia including HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets), and acute fatty liver of pregnancy (AFLP).
- ICP is a benign disease for the mother, but carries a risk for the baby because of the possibility of premature delivery and sudden fetal death. Generalized pruritus is the main symptom. Serum bile acid and aminotransferase levels are increased, although the γ-glutamyl transpeptidase levels may be normal or only slightly increased.
- AFLP is a form of hepatic failure associated with coagulopathy and occasionally encephalopathy and hypoglycemia. An association has been found between AFLP and a defect of long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD) in the fetus. Women in whom AFLP develops and their offspring should undergo DNA testing for the main associated genetic mutation (c.1528G>C) in the gene coding for LCHAD.
- Certain liver diseases that can occur in anyone, pregnant or not, are more severe during pregnancy, for example, viral hepatitis E and herpes simplex hepatitis. Other disorders can be precipitated by pregnancy or during postpartum, such as cholelithiasis and Budd–Chiari syndrome.
- Pregnancy in patients with advanced chronic liver disease is rare, although patients with treatable liver diseases, such as autoimmune hepatitis and Wilson disease, may regain fertility and should be maintained on their treatment during gestation. By contrast, successful pregnancy in patients with mild chronic liver disease, such as viral hepatitis B or C, is common. Pregnancy after liver transplantation may be associated with prematurity and increased maternal complications, but not with teratogenicity.

Liver disease in a pregnant woman can make the consulting physician uneasy. Most gastroenterologists and hepatologists are unfamiliar with the pregnant state and the liver diseases associated with it, and pregnancy is rarely seen in patients with severe chronic liver disease. Also, the stakes are higher for these patients, given the presence of a second life in the form of the fetus. The distress on the part of the consultant is well founded because pregnancy is a state of altered, albeit normal, physiology. Certain disorders of the liver are unique to pregnancy and are not comparable with liver diseases in nonpregnant patients. Furthermore, some conditions that can affect anyone, pregnant or not, may follow an unusually severe course in the pregnant woman. Despite these problems, the care of these otherwise young and healthy women is gratifying, and most return to good health simply by being delivered. Recent advances in our understanding of liver diseases during pregnancy have rationalized the approach to these patients.

The liver in normal pregnancy

The changes involving the liver during normal pregnancy have been discussed in a review of the literature [1].

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.
© 2012 John Wiley & Sons, Ltd. Published 2012 by John Wiley & Sons, Ltd.

Physical examination
Spider angiomata and palmar erythema are common during pregnancy and usually disappear after delivery. In late pregnancy, physical examination of the liver is difficult because of the expanding uterus.

Ultrasonographic examination
Ultrasonographic examination reveals no dilatation of the biliary tract, but increases in fasting gallbladder volume and residual volume after contraction are noted.

Pathology
Standard and ultrastructural examination of the liver during normal pregnancy reveals no or minimal abnormalities.

Hemodynamics
The plasma volume increases steadily between weeks 6 and 36 of gestation (by about 50%). The red cell volume also increases, but the increase is moderate (about 20%) and delayed. Consequently, the total blood volume increases with hemodilution reflected by a decrease in the hematocrit. It is necessary to bear this phenomenon of hemodilution in mind during an interpretation of serum concentrations during pregnancy. The plasma volume and red cell volume decrease rapidly after the termination of pregnancy, aided by the loss of blood at delivery. Cardiac output increases until the second trimester, then decreases and normalizes near term. Absolute hepatic blood flow remains unchanged, but the percentage of cardiac output to the liver decreases.

Serum protein and lipids
The serum albumin levels decrease during the first trimester, and this decrease becomes more accentuated as the pregnancy advances. However, the serum concentrations of some proteins increase, such as α_2-macroglobulin, ceruloplasmin, and fibrinogen. The serum cholesterol and triglyceride concentrations increase markedly during pregnancy, and measurement of these serum lipid concentrations is rarely useful during pregnancy. The prothrombin time is unchanged during pregnancy, and the fibrinogen level increases in late pregnancy.

Liver tests
A knowledge of the changes associated with normal pregnancies is necessary for the interpretation of liver test values and the management of liver diseases during pregnancy [2]. The serum alkaline phosphatase levels increase late in pregnancy, mainly during the third trimester, as a result of production of the placental isoenzyme and an increase in the bone isoenzyme. In the majority of published studies, the serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) remain within normal limits during pregnancy. Serum γ-glutamyltransferase (GGT) activity decreases slightly during late pregnancy. The total and free bilirubin concentrations are lower than in nonpregnant controls during all three trimesters, as are the concentrations of conjugated bilirubin during the second and third trimesters. The serum 5′-nucleotidase activity is normal or slightly higher during the second and third trimesters than in nonpregnant women. Fasting serum total bile acid concentrations usually remain within normal limits, and their routine measurement remains useful for the diagnosis of cholestasis during pregnancy, especially when routine liver tests are still within normal limits. Thus, increased values of serum ALT and AST activity, serum bilirubin, and fasting total bile acid concentrations should be considered pathologic, as they are in nonpregnant women, and prompt further evaluation. The main changes in liver function tests during normal pregnancy compared to nonpregnant women are summarized in Box 11.1.

Liver diseases unique to pregnancy

The liver diseases unique to pregnancy include primary hepatic pregnancy, hyperemesis gravidarum, intrahepatic cholestasis of pregnancy (ICP), the liver disorders of preeclampsia with HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets), and acute fatty liver of pregnancy (AFLP). The main factors of diagnosis

Box 11.1 Liver tests in normal pregnancy.

Tests not affected by pregnancy
- Serum aminotransferase levels (aspartate aminotransferase, alanine aminotransferase)
- Prothrombin time
- Serum concentration of total bile acids (fasting state)

Tests affected by pregnancy[a]
- Serum albumin levels (decreased from the first trimester)
- Alkaline phophatase levels (increased in the second and above all in the third trimester)
- Serum bilirubin levels (slightly decreased from the first trimester)
- 5′ nucleotidase levels (slightly increased)
- γ-Glutamyltransferase levels (slightly decreased in late pregnancy)

[a]Increased or decreased in relation to values in nonpregnant women.

Box 11.2 Main signs and symptoms of liver diseases occurring during pregnancy.

- Jaundice
- Generalized pruritus
- Nausea or vomiting
- Pain in epigastrium or right hypochondrium
- Arterial hypertension and proteinuria
- Polyuria and polydipsia without diabetes mellitus

of liver disease in pregnancy are given in Box 11.2. Gestational age at the time of the onset of signs and symptoms can be helpful in the differential diagnosis. Hyperemesis gravidarum begins in the early part of the first trimester. ICP usually does not present until the second or third trimester. Preeclampsia is a disorder of the second half of pregnancy, and patients with HELLP syndrome usually present in the third trimester. Similarly, AFLP, which can be associated with preeclampsia, is usually a disorder of the third trimester of pregnancy. The main signs and symptoms of these liver diseases are given in Box 11.3.

Box 11.3 Main diagnostic features of liver diseases in pregnancy.

Questioning

- Term of pregnancy
- Past medical history with emphasis of history of pruritus during previous pregnancy or oral contraception use
- Pruritus during current pregnancy
- Abdominal pain, nausea, or vomiting
- Polyuria and polydipsia
- Drug treatment

Clinical examination

- Temperature
- Blood pressure
- Liver examination (difficult during late pregnancy)
- Herpetic vesicles on skin or mucosa

Blood tests

- Routine liver function tests (see Box 11.1)
- Glycemia, creatininemia, electrolytes, and uricemia
- Full blood count including platelets
- Prothrombin time
- Viral hepatitis and cytomegalovirus serology
- Possible measurement of serum total bile acids when cholestasis is suspected (not a routine test)

Urine tests

- Proteinuria and bacteriuria

Ultrasonography of the liver and bile ducts

Evolution of symptoms and liver function tests after delivery

Primary hepatic pregnancy

On exceedingly rare occasions, the inferior surface of the right lobe of the liver is the site of ectopic implantation. Such patients may present early in gestation with hemoperitoneum resulting from hepatic hemorrhage. If the pregnancy progresses toward term, the patient presents with a mass in the liver. Primary hepatic pregnancy can be diagnosed by ultrasound examination or computed tomography (CT) scan (Fig. 11.1) and termination of pregnancy by laparotomy is recommended in view of the risk of rupture.

Hyperemesis gravidarum

Nausea and vomiting are common symptoms of early pregnancy, occurring in up to 50% of all pregnancies and corresponding to "morning sickness." By contrast hyperemesis gravidarum occurs much less frequently, complicating about 0.5–1.5% of pregnancies [3,4]. There is no clear demarcation between common symptoms and severe forms, and thus there is no universally accepted definition. Hyperemesis gravidarum can be defined as persistent vomiting associated with weight loss greater than 5% of prepregnancy body weight, and large ketonuria [4]. Hyperemesis gravidarum leads to dehydration, and hospitalization is usually required. Liver involvement as described below is common in this condition [5].

Pathology

Liver biopsy is rarely needed to confirm this diagnosis, given its typical clinical presentation. When performed, it shows surprisingly little. There is no inflammation, but centrilobular vacuolization, necrosis with cell dropout, and rare bile plugs may be seen [6].

Clinical and biochemical findings

This disorder presents early in the first trimester of pregnancy, during weeks 4–10 of gestation, with intractable nausea and vomiting. As a rule, it resolves by the 20th week, regardless of therapy. It is more common during a first pregnancy than in multiparous women. In the modern era, liver disease is inconspicuous and jaundice is rare. This was not the case before the widespread use of intravenous fluids; for example, Charlotte Brontë, the author of *Jane Eyre*, died in 1855 with nausea, vomiting, and jaundice during the fourth month of her first pregnancy.

When the liver is involved, the most striking abnormality is the elevation of aminotransferase levels, with ALT levels exceeding AST levels as usual in nonalcoholic and noncirrhotic liver diseases. ALT levels are greatly variable and may be as high as 1,000 IU/L. Increases in bilirubin can occur. When the patient is treated with gut rest and

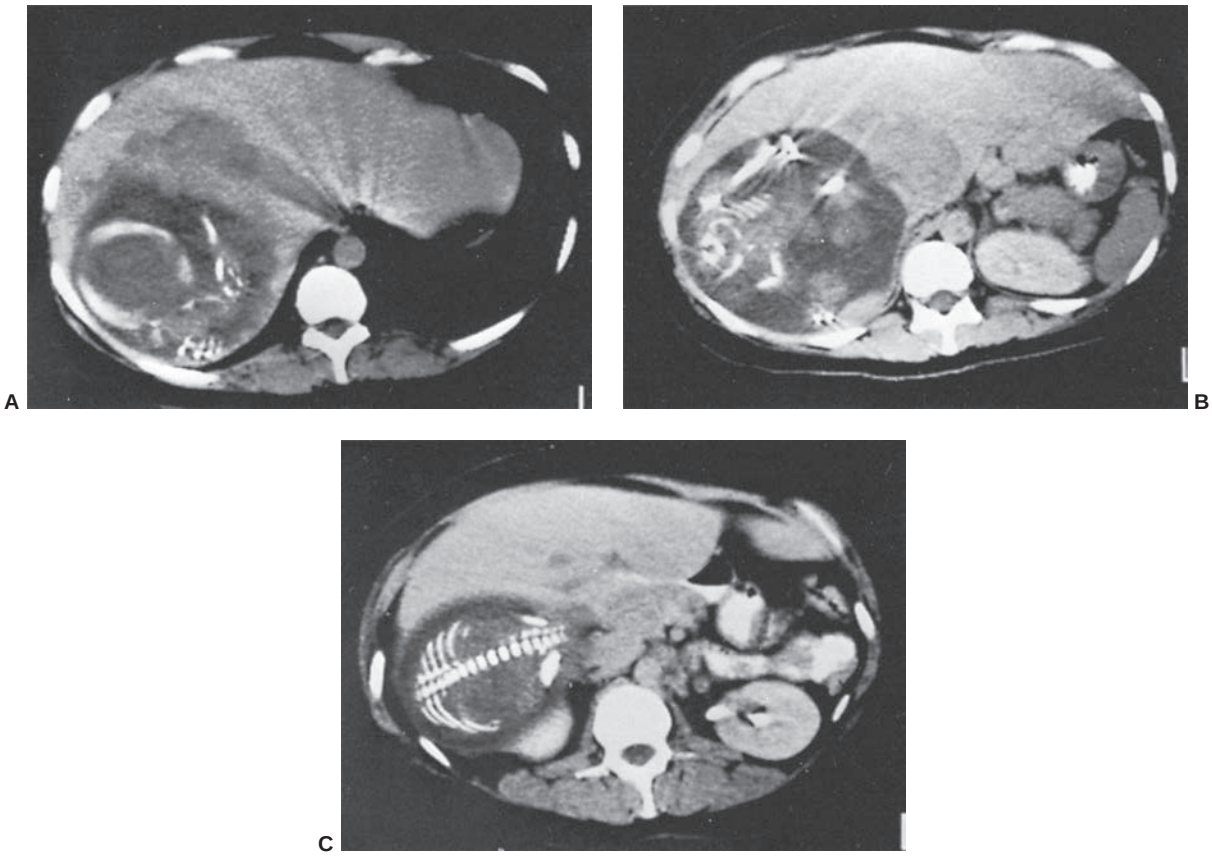

Figure 11.1 Intrahepatic pregnancy demonstrated by computed tomography. (A) A cut from below the dome of the liver showing skull bones of the fetus and the placenta invading the hepatic substance. (B, C) Lower cuts demonstrating fetal position with the spine protruding from the inferior surface of the liver. (Courtesy of Professor Caroline A. Riely.)

intravenous fluids, the abnormalities resolve. Pregnancies complicated by hyperemesis gravidarum have been associated with transient hyperthyroidism [7].

Affected patients may be thought to have hepatitis or gastric outlet obstruction resulting from peptic ulcer disease. Hepatitis serologies are always useful in the differential diagnosis. Abdominal pain is not a typical complaint.

Maternal and fetal outcome

Many affected patients respond to rehydration and a short period of gut rest followed by reintroduction of a diet rich in carbohydrates and low in fat. Thiamine supplementation is recommended especially for women who have vomited for several weeks to prevent Wernicke encephalopathy. Antiemetics including antihistamines (H1 receptor antagonists such as promethazine, cyclizine, doxylamine, and dimenhydrinate) and metoclopramide have a good safety during pregnancy and may be useful [8]. Ondesantron has also been proposed in this condition [9]. Intravenous corticosteroid treatment for hyperemesis gravidarum remains controversial and should be reserved for more severe refractory cases [8]. Enteral nutrition via gastric or duodenal intubation is effective and preferable to the parenteral route [10]. Despite the severity of the illness and attendant weight loss, infants born following affected pregnancies usually do not differ in regard to birth weight, gestational age, and birth defects from infants born following pregnancies unaffected by hyperemesis gravidarum [3,11].

Pathophysiology

Hyperemesis gravidarum is a complex disease and the exact cause is unknown. Various associations, including infection with *Helicobacter pylori* and anatomic and hormonal factors, have been reported with this condition [8]. The pathogenesis of hyperemesis gravidarum is also unclear, but the liver involvement, like the thyroid involvement noted above, appears to be secondary to the disorder itself and not a causative factor.

Intrahepatic cholestasis of pregnancy

Intrahepatic cholestasis of pregnancy usually occurs during the second or third trimester and disappears

spontaneously after delivery. The prevalence of ICP varies widely by country [12,13]. The highest frequencies have been reported in Bolivia and Chile. In Chile, the prevalence in 1974–1975 was reported to be 15.6%, ranging from 11.8% to 27.7% according to ethnic origin [14]. For unknown reasons, the prevalence has more recently appeared to decrease (to between 4.0% and 6.5%) [15,16]. In the United States, the prevalence has been estimated from 0.3% to 5.6% according to ethnic origin [17,18]. The prevalence is Europe is about 0.5–1.5% [13]. Generally, ICP is more common in twin pregnancies [19].

Pathology

Liver biopsy is rarely necessary for the diagnosis. Histopathology is characterized by pure cholestasis, sometimes with bile plugs in the hepatocytes and canaliculi, predominantly in zone 3. Inflammation and necrosis are not usually observed, and the portal tracts are unaffected [20].

Clinical and biochemical findings

Pruritus, which is the main symptom, is very uncomfortable and difficult to tolerate. It is often generalized but predominates on the palms and soles. It is more severe at night and disturbs sleep. Pruritus usually disappears within the first few days following delivery. The clinical examination findings are normal except for evidence of scratching. Fever, if present, is usually caused by an associated urinary tract infection. About 10% of patients have jaundice. The greater frequency of jaundice in some studies may be a consequence of concomitant urinary tract infection [21]. ICP with jaundice but without pruritus is rare [22]. Patients do not experience abdominal pain or encephalopathy. Ultrasonographic examination reveals no dilatation of the biliary tract, but may show gallstones.

Measurement of serum ALT activity is a sensitive test for the diagnosis of ICP. Patients with ICP frequently exhibit very significant increases in serum ALT activity that suggests acute viral hepatitis, which should be ruled out with suitable serologic tests [22]. Liver histology does not reveal necrotic lesions, and the ALT elevations may be secondary to an increase in membrane permeability. The serum GGT activity is normal or only slightly increased [22]. The serum bile acid concentrations are increased, and may be the first or only laboratory abnormality [22,23]. A relationship between maternal serum bile acid levels and fetal distress has been found [24], and evaluation of the serum bile acid concentration has been suggested as a mean of fetal assessment in patients with ICP [25]. At the present time, however, no consensus has been reached concerning the usefulness of evaluating the serum bile acid concentrations in the obstetric management of patients with ICP [26]. Little or no correlation has been found between the serum total bile acid concentration and other liver test values [22]. The serum bile acid concentration and serum ALT activity decrease rapidly after delivery and, as a rule, normalize in a few weeks. Recently the measurement of serum glutathione-*S*-transferase, a maker of hepatocellular integrity, has been proposed to distinguish ICP from "benign pruritus gravidarum" [27]. The prothrombin time is usually normal. It may become abnormal in severe cholestasis with jaundice or in patients who have been treated with cholestyramine. The abnormality is caused by vitamin K deficiency, which should be anticipated and treated before delivery to prevent hemorrhage. Such therapy contributes to a good maternal prognosis.

Maternal and fetal outcome

Cholestasis frequently recurs in subsequent pregnancies. As a rule, the long-term maternal prognosis is good. However, a recent longitudinal retrospective population-based cohort study, from Finland, suggests reconsidering the long-term follow-up of patients suffering from ICP [28]. Patients with a history of ICP (10,504 women during the years 1972–2000) and 10,504 women with normal pregnancies (controls) were matched for age, time of delivery, and place of delivery. The results show an association of ICP with several liver diseases: hepatitis C, gallstones and cholecystitis, nonalcoholic pancreatitis, and nonalcoholic liver cirrhosis including cases of primary biliary cirrhosis [28].This large study questions the diagnosis of "true" ICP and confirms the importance of determining whether normalization of liver tests occurs after delivery in any woman suffering from cholestasis during pregnancy. This study confirms also the association between hepatitis C and ICP previously reported [29,30], and the importance of checking viral hepatitis serologies (especially hepatitis C) in any pregnant woman with elevated serum ALT.

ICP does carry a risk for the fetus [31]. The main complication of ICP is prematurity, which is more frequent in patients with ICP than in the general population [16]. The rate of prematurity varies greatly according to the study and may be increased because of the high rate of multiple pregnancies in patients with ICP [22]. The other complication of ICP is the risk of sudden fetal death. The prevalence is about 1% but varies according to studies. Sudden fetal death rarely occurs before the last month of pregnancy.

The administration of oral contraceptives to women with a history of ICP may rarely result in cholestasis, but ICP is not a contraindication for their use [22]. Oral contraception (either combined contraceptives with a low dose of estrogen, or progestin-only contraceptives) can be started after the liver test values have normalized. The patient should be informed of the possibility of

cholestasis (abnormal liver tests with or without pruritus) during subsequent use of contraception.

Pathophysiology

The cause of ICP is unknown. The results of previous epidemiologic and clinical studies suggest that genetic, hormonal, and exogenous factors all play a role [32]. Genomic variants (mutations or polymorphisms) in genes coding for several hepatobiliary transporters were found in patients with ICP. The *ABCB4* gene encodes the multidrug resistance 3 P-glycoprotein (MDR3 P-glycoprotein) or ABCB4, which is the translocator of phosphatidylcholine across the canalicular membrane into bile. In the absence of phospholipids in bile, bile acids can injure the canalicular membrane, leading to cholestasis [33]. A non-sense mutation of the *ABCB4* gene has been found in a child with progressive familial intrahepatic cholestasis type 3 (PFIC3) and in three mothers suffering from cholestasis during pregnancy [34]. In this familial study, the infant with PFIC3 was homozygous for the ABCB4 mutations, whereas the mothers with ICP were heterozygous. Non-sense mutations in the *ABCB4* gene were then found in patients with ICP in a number of studies [35–38]. The prevalence of such mutations in Caucasian patients with a clearly defined phenotype of ICP was estimated to 16% [39]. Mutations in the *ABCB11* gene, which encodes the bile salt export pump (BSEP), have been found in only 1% of European patients with ICP [40]. However, one particular polymorphism in *ABCB11* (c.1331C>T, V444A) has been identified as a risk factor for ICP, suggesting a role for this gene in the pathogenesis of ICP [40]. Defects in the *ATP8B1* gene, which is associated with progressive familial intrahepatic cholestasis type 1 (PFIC1) and benign recurrent intrahepatic cholestasis (BRIC), have also been found in patients with ICP but it seems that this gene is not a major contributor to ICP [41].

A role of estrogens in ICP has been clearly established. Animal studies have shown that estrogens, in particular ethynyl estradiol, are cholestatic. Genetically determined abnormalities may lead to unique hepatic reactions to estrogens or to dysfunction of estrogen metabolism [32]. Progesterone metabolism is also involved in the pathophysiology. Abnormalities of progesterone metabolism, especially elevated levels of serum sulfated metabolites, have been found in women with ICP [42]. The formation of large amounts of sulfated progesterone metabolites, possibly related to greater 5α and 3α reduction, may in some genetically predisposed women result in a saturation of the hepatic transport system(s) involved in the biliary excretion of these compounds [43]. One study has shown that oral natural progesterone prescribed for threatened premature delivery can trigger ICP in predisposed women [22]. The intake of progesterone may place an additional load on the transport system of the sulfated metabolites. Progesterone treatment should therefore be avoided in pregnant women, especially late in pregnancy or when the patient has a history of ICP.

Some characteristics of ICP suggest that exogenous factors may be associated with an underlying genetic predisposition: (i) ICP recurs in only 60–70% of pregnancies in multiparous women; (ii) seasonal variability has been observed in several countries; and (iii) the prevalence of ICP has decreased in Chile. For example, a deficiency in selenium may be a factor involved in the pathophysiology of ICP [44].

Medical and obstetric Management

Hydroxyzine (25–50 mg/day) may alleviate the discomfort of pruritus. Cholestyramine (8–16 g/day) decreases the ileal absorption and increases the fecal excretion of bile salts. Its effect on pruritus is limited in patients with ICP. The efficacy of *S*-adenosyl-L-methionine is a matter of debate [15,45,46]. Currently, the most effective medical treatment is ursodeoxycholic acid [46–54]. Ursodeoxycholic acid relieves pruritus and improves liver function test values (Fig. 11.2). Ursodeoxycholic acid may also prevent prematurity. No side effects have been reported for mothers or babies [55]. Thus, ursodeoxycholic acid (usually 500 mg twice a day or 15 mg/kg/day) appears to be safe during late pregnancy and may be useful in improving liver tests and relieving cholestasis. The mechanism of the beneficial effect of ursodeoxycholic acid for the mother and the baby in ICP remains speculative. As in chronic liver diseases, ursodeoxycholic acid, which is a hydrophilic bile acid, may decrease signs of cholestasis in the mother by providing cytoprotection against the hepatotoxic effects of the hydrophobic bile acids, and by improving the hepatobiliary bile acid transport. In ICP, ursodeoxycholic acid may also have a specific effect by improving the transport of bile acid across the placenta.

It is often difficult to decide the best time for delivery and no consensus has been clearly established [56,57]; there are no randomized clinical trials to try and establish best obstetric management [58]. When cholestasis is severe (e.g., if the patient has clinical jaundice), delivery has been recommended at 36 weeks of gestation if the fetal lungs have matured, or as soon thereafter as possible [16].

Preeclampsia liver disorders

Liver disorders associated with preeclampsia are certainly the most frequent causes of liver abnormalities occurring during pregnancy [59]. Preeclampsia is a common complication of pregnancy (2–7% in healthy nulliparous women) and is a major cause of maternal and perinatal morbidities [60]. A variety of genetic and/or immunologic factors are suspected of playing a role in

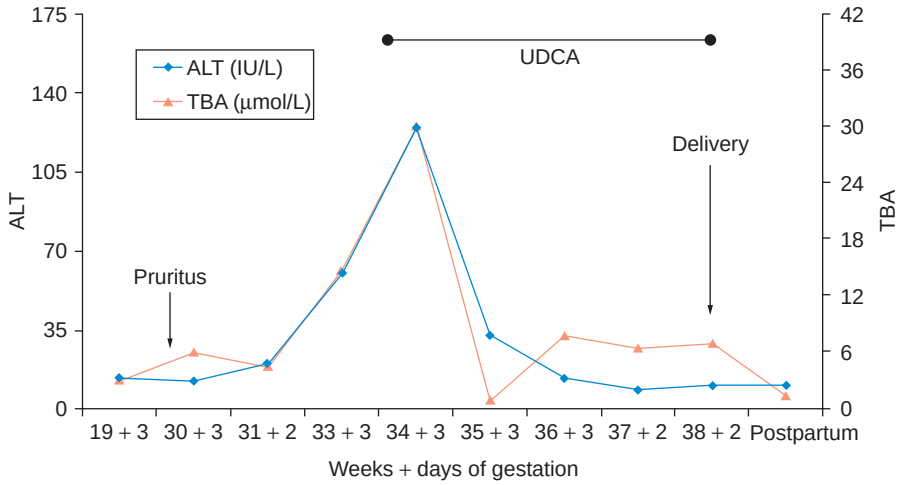

Figure 11.2 Treatment of intrahepatic cholestasis of pregnancy (ICP) with ursodeoxycholic acid (UDCA). This patient had experienced ICP during a previous pregnancy. Regular surveillance during the current pregnancy was proposed and once the diagnosis of recurrent ICP had been confirmed, treatment with UDCA was initiated. Serum total bile acid concentration (TBA, upper normal limit: 6 μmol/L) and serum alanine aminotransferase activity (ALT, upper normal limit: 35 IU/L) improved and the patient delivered at 38 weeks of gestation.

the mechanisms of this enigmatic disease [60–62]. The disease is thought to start early in pregnancy, with abnormal implantation of the trophoblast, which leads to restricted perfusion of the placenta. The fall in systemic vascular resistance typical of normal pregnancy does not occur in patients with preeclampsia; their sensitivity to vasospasm is enhanced, with resultant poor perfusion of and injury to a variety of organs, including the liver. Some risk factors for developing preeclampsia have been identified. In a systematic review of controlled studies, the most significant risk factors are a history of preeclampsia and the presence of antiphospholipid antibodies [63]. In the same study, the following factors clearly also increase the risk of preeclampsia: preexisting diabetes and prepregnancy body mass index (BMI) $>35\,kg/m^2$, nulliparity, a family history of preeclampsia, a twin pregnancy, maternal age $\geq$40 years, booking BMI $\geq 35\,kg/m^2$, and hypertension (systolic blood pressure $\geq$130 mmHg) at the booking visit.

The typical presentation of preeclampsia is hypertension with proteinuria, presenting in the latter half of pregnancy. However, both conditions are not found in all patients with this multisystem disease. Patients may also have renal failure, seizures (eclampsia), pancreatitis, or pulmonary edema. Preeclampsia has long been known to affect the liver in a variety of ways including HELLP syndrome [64].

HELLP syndrome

The HELLP syndrome is defined as hemolysis (usually subclinical, with characteristic schistocytes and burr cells on a smear test), elevated liver enzymes (usually elevated aminotransferases), and low platelets [65]. Affected women are less likely to be primiparous and tend to be older than the average woman with preeclampsia [64]. The hepatic histology is that of preeclamptic liver disease, with periportal hemorrhage and fibrin deposition. Little correlation is found between the degree of histologic aberration and the severity of the clinical findings. Fat may be seen, but as macrovesicular fat distributed in modest quantities throughout the liver lobule, not as the microvesicular centrizonal fat typical of AFLP [66]. Despite similar settings and occasional clinical overlap, these two conditions are histologically distinct [67].

The clinical presentation of HELLP varies markedly, with no symptom other than abdominal pain recorded in more than 50% of patients [68]. The pain is usually located in the midepigastric, right upper quadrant, or substernal regions. Many patients have nausea, vomiting, and malaise, which suggest a diagnosis of viral hepatitis. Jaundice is present in about 5% of patients [68]. The majority of cases are diagnosed during the third trimester, although the condition may present postpartum. In a large series of 437 patients who had 442 pregnancies with HELLP syndrome, 70% of cases occurred before delivery and 30% after delivery; 11% developed before 27 weeks' gestation and 18% after 37 weeks [68]. Most, but not all, patients have the hypertension and proteinuria typical of preeclampsia. The diagnosis usually rests on clinical grounds, although imaging studies, particularly CT (Fig. 11.3) and magnetic resonance imaging (MRI), are useful in detecting the complications of hepatic infarct, hematoma, and rupture [69]. The outcome for mothers is generally good, but serious complications are relatively common. The maternal mortality rate was 1.1% in a large

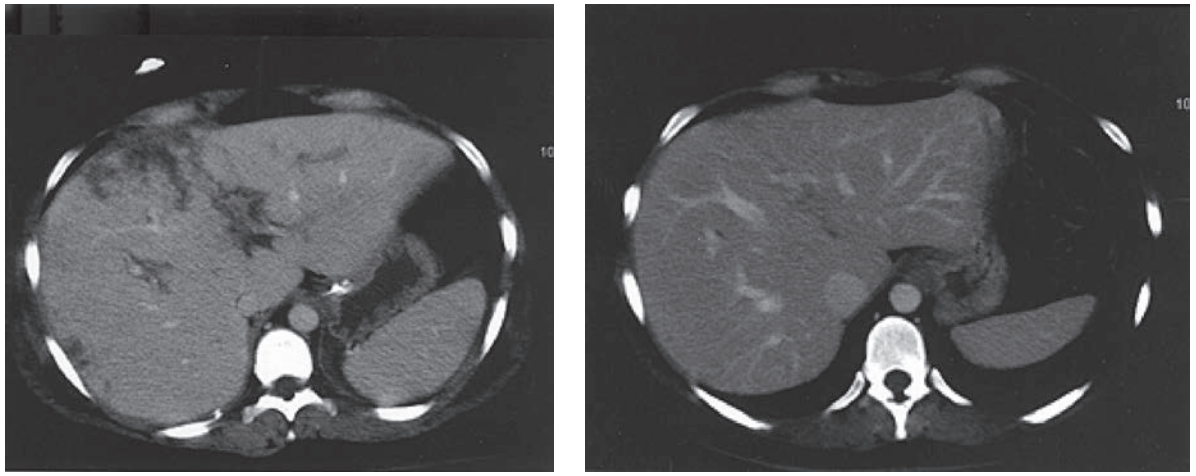

Figure 11.3 Hepatic involvement in a 24-year-old primipara with severe preeclampsia. (Courtesy of Dr Béatrice Scotto.)

series [68]. Rarely, patients may require liver transplantation [70]. The main risk for the fetus is prematurity.

Management is supportive and may include transfer to a medical intensive care unit, with ventilatory support and dialysis provided in severe cases. The cornerstone of therapy is early delivery, which is generally indicated, although temporizing management (24–48 hours) with intensive monitoring may be discussed before 34 weeks' gestation for some patients without fetal or maternal distress [64]. The condition starts to reverse with delivery. Long-term follow-up has shown an increased risk of obstetric complications in subsequent pregnancies, but no tendency for a repetition of the HELLP syndrome [71].

Hepatic hematoma and rupture

In rare pregnant patients, a hematoma develops beneath the Glisson capsule. This may remain contained, or rupture of the liver capsule may result in hemorrhage into the peritoneal cavity from multiple lacerations where the capsule has been lifted from the surface. Rupture usually occurs in the setting of the HELLP syndrome. Some patients do not have thrombocytopenia or typical preeclampsia [72]. Clinically, affected patients have abdominal pain and, when the liver has ruptured, swelling of the belly from hemoperitoneum, along with shock. The aminotransferase levels are usually slightly raised, but values in the range of 4,000–5,000 IU are seen occasionally [64]. CT or MRI of the body is more dependable than ultrasonography for detecting these lesions [69]. The management of a contained hematoma is supportive. If a rupture of hematoma is confirmed, transfusions, and radiological hemostatic measures or laparotomy are indicated. Liver transplantation has been used when the hemorrhage could not be contained [64]. Such patients are thus best managed by a team experienced in liver surgery including liver transplantation [73]. Patients who survive have no hepatic sequelae and have been documented to have normal subsequent pregnancies [71].

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy was distinguished as a specific clinical entity unique to pregnancy in 1940 [74]. Early diagnosis and prompt delivery have dramatically improved both maternal and fetal prognosis [75]. AFLP is a rare disease, and incidence has been evaluated at between 1 per 7,000 and 1 per 20,000 deliveries. The incidence was initially estimated to be 1 per 13,328 deliveries at the Los Angeles County University of Southern California Medical Center [76], and more recently to be 1 in 6,659 births in the same center [77]. The incidence was estimated to be 1 per 15,900 deliveries in Santiago, Chile [78]. In the United Kingdom, a large population-based study that included 1,132,964 pregnancies between 2005 and 2006 diagnosed 57 women with AFLP, i.e., about 1 case per 20,000 pregnancies [79].

Pathology

Liver biopsy is the best way to confirm the diagnosis of AFLP, but because it is invasive it is not always performed. Also, we can now take advantage of noninvasive procedures to demonstrate fat in the liver and exclude other liver diseases, such as viral hepatitis. Nevertheless, liver biopsy may be useful in atypical cases, especially if the appropriate treatment (delivery) is being delayed.

The overall architecture of the liver is not altered. The characteristic picture is a microvesicular fatty infiltration of the hepatocytes, which are swollen. The droplets are minute and surround centrally located nuclei, so that

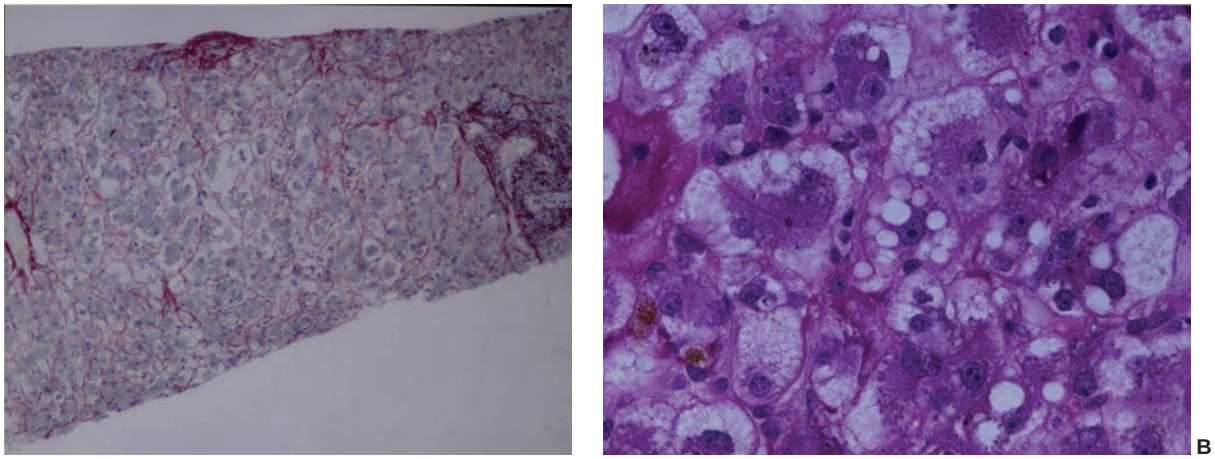

Figure 11.4 Acute fatty liver of pregnancy in a 24-year-old primipara. This woman had experienced nausea and vomiting, abdominal pains, and jaundice in late pregnancy. A transvenous liver biopsy was performed postpartum showing: (A) intact lobular architecture (hematoxylin and eosin, original ×200), and (B) typical microvesicular fatty infiltration in hepatocytes and features of cholestasis (original ×400). (Courtesy of Dr Anne de Muret.)

the cytoplasm has a foamy appearance (Fig. 11.4). In a few cases, rare, large fat vacuoles are associated with the microvesicular steatosis. The microvesicular fatty infiltration is most prominent in the pericentral zones and midzones (zones 2 and 3) and usually spares a rim of periportal cells. The droplets stain with oil red O, which is specific for fat. The histologic features of cholestasis (i.e., bile thrombi or bile deposits within hepatocytes) are common. Inflammation is not prominent but is also common [80]. The histologic features are not always evident, and cases of AFLP have been misdiagnosed as hepatitis. Necrosis with acidophilic bodies is inconspicuous, and massive panlobular hepatocellular necrosis, as in fulminant viral hepatitis, is not seen. Electron microscopy confirms the presence of fat droplets and has shown nonspecific changes in mitochondrial size and shape [81]. A stain specific for fat or electron microscopy is useful for pathologic confirmation of the diagnosis in patients with ballooning of the cytoplasm but no evident vacuolization. Therefore, whenever AFLP is suspected, a piece of the liver biopsy specimen should be reserved before paraffin embedding and processed appropriately with special stains to confirm the presence of fat in the hepatocytes. The pathologic changes normally reverse rapidly after delivery, and AFLP is not associated with progression to cirrhosis [82].

Clinical and biochemical findings

As a rule, AFLP is a disease of the third trimester that may occur during any gestation. However, some reports have detailed cases presenting at 22 weeks [83] or 26 weeks [84] of gestation. The onset of disease is never after delivery, but the diagnosis may be made after delivery. The frequency of twin gestations is increased among patients with AFLP (14–19%, vsersus ~1% in the general population) [79], and 7% of triplet pregnancies have been reported to be complicated by AFLP [85]. The most frequent initial symptoms are nausea or vomiting, abdominal pain (especially epigastric), anorexia, and jaundice. In the past, jaundice was almost always seen during the course of the disease, but because of earlier diagnosis, prompt delivery, and the diagnosis of milder cases, we now see affected patients without jaundice. The size of the liver is usually normal or small. Patients with AFLP rarely have pruritus but may have concurrent ICP [86]. About half of affected patients have high blood pressure or proteinuria, which are the main symptoms of preeclampsia [80]. On the other hand, some affected patients do not have any of these signs. Patients may demonstrate asterixis and encephalopathy, with or without coma, and some have pancreatitis. Esophagitis and Mallory–Weiss syndrome related to severe vomiting have been reported. Gastrointestinal bleeding secondary to the esophageal lesions, in addition to gastric ulceration related to shock, have been reported. Genital bleeding is frequent. These hemorrhages are exacerbated by associated coagulation disorders. Ascites may be present and is partially related to portal hypertension. Polyuria and polydipsia have been noted in about 5% of patients with AFLP [80], and an association between transient diabetes insipidus and AFLP has been reported [87]. Pancreatitis is a rare but potentially severe complication [88].

The serum aminotransferase levels are raised, but usually the level is not as high as in acute viral hepatitis. The bilirubin level is almost always increased. Patients may demonstrate hypoglycemia. In severe cases, the prothrombin time is increased and the fibrinogen level decreased. These coagulation disorders are caused by hepatic insufficiency, disseminated intravascular coagulation, or both. A low platelet count is usual in AFLP and is not always associated with other signs of

disseminated intravascular coagulation. Thrombocytopenia may be the most striking laboratory feature and normalizes spontaneously after delivery. The diagnosis of AFLP should always be considered when thrombocytopenia occurs during late pregnancy and should always prompt the performance of liver function tests, particularly determination of the aminotransferase levels. Renal failure (mainly functional) and hyperuricemia are usual. Ultrasonography of the liver may show increased echogenicity [89]. CT may be useful for the diagnosis, and a liver density that is lower than usual may be demonstrated by Hounsfield unit values in the liver that are equal to or lower than those in the spleen [90]. The findings on imaging studies may be normal, however; a study showed that the findings on CT, which is more sensitive than ultrasonography, were normal in half of patients with AFLP [91]. In clinical practice, these complementary examinations should not delay delivery, particularly in severe cases, which can usually be diagnosed on clinical grounds with routine biologic data.

Maternal and fetal outcome

The maternal mortality rate of AFLP was very high before 1970 (about 90%) [80]. The maternal prognosis is currently greatly improved, and maternal mortality is about 10% or less worldwide [92,93]. This improvement is related principally to early delivery, to advances in intensive care support for patients with severe forms, and also to the detection of patients with less severe forms. Most patients recover completely after delivery without sequelae. However, one patient remained in a prolonged coma after hemorrhagic shock [94], and cases of neurohypophyseal insufficiency have been reported associated in one case with definitive diabetes insipidus [95]. In a recent population-based study in the United Kingdom that included 57 women with AFLP, one patient died and one patient required liver transplantation [79].

AFLP may recur during subsequent pregnancies, although recurrence is not the rule. At least 25 cases without recurrence have been reported; 17 patients had a normal pregnancy, and four had two normal pregnancies following a pregnancy with AFLP. However, at least eight cases of recurrence have been reported since 1990 [96]. Mothers who have experienced AFLP should be informed of the risk for recurrence and closely followed during subsequent pregnancies. Follow-up should be both clinical and biologic (liver function tests, tests for uricemia, and platelet counts twice monthly during the third trimester).

Until 1985, fetal mortality was reported to be as high as 50% [82]. Early delivery has also resulted in an improved fetal prognosis, and the final outcome for infants delivered alive is usually considered to be good. However, in view of the possibility of congenital enzyme deficiency involving intramitochondrial β-oxidation of fatty acids, these infants should be closely followed from birth (see below).

Pathophysiology

The cause of AFLP remains unknown, although good progress toward a better understanding of this disorder has recently been made. An association of inherited defects in the β-oxidation of fatty acids with AFLP was first suggested by Schoeman et al. [97] and Wilcken et al. [98] in 1991–1993. A case of long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD) deficiency in a 4-month-old baby born to a mother who had had AFLP and HELLP syndrome at 36 weeks of pregnancy was then reported in 1994 [94]. Both parents were heterozygous for LCHAD deficiency. Since these initial reports, the association between AFLP and LCHAD deficiency has been confirmed by several studies. β-Oxidation of fatty acids, measured by the activity of LCHAD in skin fibroblast culture, was studied in 12 women who had had AFLP [99]. LCHAD activity was reduced in eight of them, consistent with heterozygosity for LCHAD deficiency. Four women had no deficiency. The eight heterozygous women had a total of nine pregnancies complicated by AFLP. Of the nine offspring delivered from these pregnancies, four were confirmed to be homozygous for LCHAD deficiency. Three other infants died with a clinical picture compatible with this diagnosis. The two other infants were healthy at 18 and 24 months of age and had LCHAD activity in the intermediate range. The five fathers tested were heterozygous [99]. These findings show that a deficiency in the β-oxidation enzyme in the fetus may lead to maternal hepatic steatosis in late pregnancy, if the mother is in the intermediate range for the deficiency.

Several mutations have been observed in the gene coding for LCHAD in three families with a child with LCHAD deficiency whose mothers had had AFLP or HELLP syndrome [100]. The mutation c.1528G>C (or p. E474Q, Glu474Gln) in the gene *HADHA* coding the α-subunit of LCHAD is the most common mutation in families with AFLP [101]. In the reported cases of AFLP where genetic screening was performed on the LCHAD-deficient offspring, all the fetuses were either homozygous for the c.1528G>C mutation or compound heterozygous with one c.1528G>C allele in combination with another mutation [102]. In other words, when a woman is heterozygous for a *HADHA* mutation, AFLP may occur regardless of her genotype if her fetus is deficient in LCHAD and carries at least one allele with the c.1528G>C mutation. It seems prudent, therefore, to screen all the offspring born to mothers suffering from AFLP for the mutation c.1528G>C [102]. Such screening can be life saving. Infants with a LCHAD deficiency can present with a metabolic crisis, or suffer a sudden unexpected death at a

few months of age [102]. Therefore, screening in infants born to mothers with AFLP should be sought as soon as possible after delivery. In affected families, a prenatal diagnosis based on sampling of chorionic villi has proved both feasible and accurate [103]. These forms of AFLP associated with a genetic deficiency of β-oxidation have not been observed in all countries; the common mutation (c.1528G>C) was not found in 14 women with AFLP observed consecutively in a French hospital [104].

A deficiency of carnitine palmitoyltransferase I has also been associated with AFLP [105]. No familial cases (i.e., AFLP in mother and daughter) have been reported.

Medical and obstetric management

Acute fatty liver of pregnancy must be considered an obstetric emergency. AFLP does not usually resolve before delivery, and if delivery is delayed complications such as hemorrhage and intrauterine death may develop. Consequently, the primary therapy for AFLP is early delivery. The choice of the route of delivery remains the decision of the obstetrician and must be appropriate for the individual clinical situation. Generally speaking, if the patient is in labor and in good general condition and no sign of fetal distress is detected, then vaginal delivery may be attempted with careful monitoring of the mother and baby [106]. For patients with severe disease, urgent delivery must be considered, usually by cesarean section, after correction of the coagulation disorders, especially those related to the thrombocytopenia.

The etiology of AFLP is not known, and no specific medical treatment is available. Esophagitis should be treated with appropriate drugs to prevent bleeding. The blood sugar levels should be monitored and hypoglycemia treated by a continuous intravenous infusion of glucose. Patients with fulminant hepatic failure are best managed in an intensive care unit before and after delivery. Some patients with serious disease that continued after delivery were treated successfully by liver transplantation [79,107,108], and auxiliary transplantation has been used successfully in this setting [109]. Nevertheless, the role of liver transplantation in AFLP is probably limited. Early diagnosis and prompt delivery of a patient with AFLP should avoid the difficult decision about later liver transplantation.

Intercurrent liver disease in pregnancy

In addition to the disorders unique to pregnancy, pregnant women are susceptible to diseases that can affect anyone. Some common disorders can take a fulminant course in pregnant women, hepatitis E being the most frequently cited example. Furthermore, pregnancy predisposes a woman to the development of the usual liver diseases, such as cholelithiasis.

Acute viral hepatitis

The response of a pregnant woman to acute infection with the viruses that cause hepatitis varies depending on the type of virus.

Hepatitis A

Pregnant women who contract hepatitis A are not at increased risk of severe disease from this infection [110], although the risk for premature labor may be increased in women who are seriously ill during the third trimester [111,112].

Hepatitis B

In patients with documented acute hepatitis B, pregnancy is not associated with increased mortality or teratogenicity. Infection during gestation should not prompt termination of the pregnancy. Perinatal transmission of hepatitis B virus can occur, especially in women with acute infection during the third trimester. Such transmission should be prevented by immunoprophylaxis at birth. Women exposed to hepatitis B during gestation may be vaccinated without any reported increase in congenital anomalies.

Hepatitis E

Hepatitis E, caused by infection with hepatitis E virus, occurs both in epidemics and sporadically in endemic regions, e.g., India, Pakistan, northern Africa, and Mexico [113]. In nonendemic regions, until recently, autochthonous cases of hepatitis E were extremely uncommon. However, in the last few years, an increasing number of cases have been reported in nonendemic regions [113]. These cases appear related to zoonotic transmission from pigs or numerous wild species [113]. Women in the third trimester are more likely to have more severe disease than are other persons. The fatality rate in this group may be as high as 25% [114–116]. It is important to differentiate between acute hepatitis E and pregnancy-related acute liver disease to consider early delivery in AFLP or the HELLP syndrome. This differentiation may be difficult [115]; in this setting, the presence of ascites and hypertension is suggestive of pregnancy-related acute liver disease [117]. Women in the third trimester of pregnancy should carefully consider the risks associated with travel to areas where this disease is endemic. Hepatitis E virus can cause acute hepatitis in the newborn, and can be transmitted in utero to the fetus [114,116,118].

Hepatitis caused by herpes simplex virus

When it occurs in the third trimester of pregnancy, hepatitis resulting from a primary systemic infection with

herpes simplex virus is likely to be severe. Most reported cases of fulminant herpetic hepatitis have occurred in pregnant women [119]. Affected patients may have a "viral" syndrome that includes fever and upper respiratory tract symptoms. Despite marked abnormalities in their aminotransferase levels (several thousands units per liter) and prothrombin time, these patients may be anicteric at presentation. A vesicular eruption is diagnostically useful but may not yet be visible at presentation. Cultures and histology of liver biopsy specimens are helpful in the differential diagnosis, which should include severe liver disorders associated with pregnancy, such as AFLP and the HELLP syndrome. Therapy with aciclovir is successful, and affected women need not be delivered early [119–121]. Why herpes simplex hepatitis is more severe and is associated with such increased hepatic injury in the third trimester of pregnancy is unclear. Herpes simplex hepatitis is known to be also more severe in certain immunocompromised states, such as chronic immunosuppression following transplantation [122].

Biliary tract disease and pancreatitis

Pregnancy decreases gallbladder motility and increases the lithogenicity of bile. Pregnancy has long been considered a risk factor for the development of gallstones; epidemiologic studies confirm an association with an increased risk for gallstones, but only for a 5-year period after pregnancy. Thereafter, the risk drops back to that of the never-pregnant population [123]. Ultrasonographic studies show that gallstones and biliary sludge may accumulate throughout gestation and then resolve with a return to nonpregnant physiology [124,125]. In a prospective study of 3,254 women, the cumulative incidence of new sludge, new stones, or progression of baseline sludge to stones was 10.2% by 4–6 weeks postpartum (versus 5.1% by the first trimester). In the same study, 28 women (0.8%) underwent cholecystectomy within the first year postpartum [126]. Higher BMI and serum leptin levels were independent risk factors for gallstones.

Acute cholecystitis may occur in pregnancy, and in many cases can be managed conservatively until delivery. Laparoscopic cholecystectomy by a skilled laparoscopic surgeon may be safely performed during pregnancy [127,128].

Acute pancreatitis may complicate pregnancy [129]. The serum amylase and lipase levels are normal during pregnancy, so abnormal values warrant attention [130]. Pancreatitis usually occurs in the setting of cholelithiasis [129], and gallstones should be sought in any affected patient. Patients with pancreatitis or symptomatic cholelithiasis during pregnancy may be managed by endoscopic retrograde cholangiopancreatography with sphincterotomy [131,132]. Pancreatitis complicating pregnancy may be associated etiologically with AFLP or preeclampsia. In rare cases, pancreatitis may occur in association with severe hyperemesis gravidarum, with familial hypertriglyceridemia, exacerbated by the physiologic hypertriglyceridemia of pregnancy [133], or with hyperparathyroidism [134,135].

A choledochal cyst may present during pregnancy, with abdominal pain, a mass, and jaundice [136]. Such presentations may represent cases of congenital choledochal cyst exacerbated by the effects of pregnancy on biliary motility. Spontaneous rupture of a choledochal cyst has been reported in pregnancy [137].

Budd–Chiari syndrome (hepatic vein thrombosis)

Reports from India suggest that Budd–Chiari syndrome is more common in pregnant women, usually occurring immediately after delivery [138,139]. The prognosis of such pregnant women has been considered as ominous. In a recent series of 43 women with Budd–Chiari syndrome, seven women (16%) presented with either liver disease during pregnancy (three women) or puerperium (four women), and all seven patients were alive after a median follow-up of 39 months (range 8 to 121 months) [140]. Two patients underwent transjugular intrahepatic portosystemic shunt (TIPS) and one orthotopic liver transplantation (OLT) within 2 months of delivery. Anticoagulation should be administered as soon as the diagnosis of Budd–Chiari syndrome is established. During pregnancy, oral anticoagulants are contraindicated, and low molecular weight heparin is preferred to unfractionated heparin [141]. Recurrence has been reported in a patient whose anticoagulants were stopped when she again became pregnant [142]. Several reports have linked acute Budd–Chiari syndrome during pregnancy in western women with an underlying procoagulant state, such as primary antiphospholipid [143], factor V Leiden mutation [144], thrombotic thrombocytopenic purpura [145], or myeloproliferative disease [140]. Among seven women with Budd–Chiari syndrome presenting during pregnancy or puerpuerium, at least one risk factor for hepatic vein obstruction (not including pregnancy) was found in six women, and several thrombotic risk factors were associated in some of the women [140]. So it is unlikely that pregnancy alone causes Budd–Chiari syndrome in the absence of other thrombotic risk factors [140].

Drug-induced hepatic injury

Because of concern about fetal teratogenicity, pregnant women in general take fewer drugs than those who are not pregnant. When they do take drugs, however, they run the same risks for adverse drug reactions as others. Drug-induced liver disease may occur during any trimester as well as during the postpartum period. Potentially fatal hepatotoxicity has been reported in

pregnant women undergoing antiretroviral therapy for human immunodeficiency virus (HIV) infection [146]. Acetaminophen overdose leading to death has been reported [147]. α-Methyldopa, which is commonly used in the treatment of hypertension in pregnancy, rarely may induce acute severe hepatitis [148,149].

Malignant tumors of the liver

The liver is not palpable in normal pregnant women and thus hepatomegaly detected on physical examination requires immediate evaluation. Patients with extensive tumor invasion of the liver may present with abdominal or back pain, rupture of the liver, or hepatic failure. The usual source of metastasis is from a common tumor, such as carcinoma of the colon or pancreas. Gestational trophoblastic neoplasm (hydatidiform mole) can be a source of tumor spread to the liver. Breast cancer may also present with hepatomegaly during pregnancy. A patient presenting at 26 weeks' gestation with hypertension and thrombocytopenia, imitating HELLP syndrome, was found to have cholangiocarcinoma [150]. Severe epigastric pain may reveal ruptured hepatocellular carcinoma during pregnancy [151]. It is possible that the modest immunosuppressive state associated with pregnancy promotes extensive tumor spread and growth.

Other complicating illnesses

Sepsis, particularly urinary tract infections, may lead to cholestasis with or without jaundice in pregnant women as it can do in the nonpregnant state [152]. Echinococcal cysts of the liver have been reported during pregnancy [153]. While leptospirosis rarely occurs during pregnancy, a case without fever may mimic AFLP or HELLP syndrome in late pregnancy [154].

Pregnancy in women with chronic liver disease

Monitoring of liver disease is necessary when its presence is known before pregnancy, and this requires cooperation between the obstetric team and hepatologists. Most patients with severe liver disease are not women of childbearing age or they are infertile because of the associated anovulatory state. Nevertheless some of these women can become pregnant, and when they do some special problems arise. On the other hand, most young women with chronic but nonsevere liver disease can have full-term pregnancies without any particular risk. However, there is the question of the effect of liver disease or its treatment on the fetus. Certain drugs should not be stopped during pregnancy because of the risk of relapse of the liver disease due to withdrawal of treatment. This is the case, for example, with immunosuppressive treatment for chronic autoimmune hepatitis and with penicillamine used as a copper chelator in Wilson disease (see below). Other drugs, such as ribavirin used in the treatment of hepatitis C, are strictly contraindicated in pregnancy. In the case of ribavirin, the patient should be clearly informed of the need for effective contraception throughout treatment and during 6 months thereafter.

Cirrhosis and portal hypertension

Worsening jaundice with progressive liver failure, ascites, and hepatic coma have been reported during the course of pregnancy in women with cirrhosis. Whether the exacerbation of hepatic dysfunction is caused by gestation or is merely coincident with it is unclear. By contrast some women with cirrhosis can sustain pregnancy without any worsening of hepatic function. Published reports document an increased incidence of stillbirths, premature delivery, hypertension, and peripartum infection in women with cirrhosis, especially when ascites is present [155]. The fertility of women with noncirrhotic portal hypertension, as seen in congenital hepatic fibrosis or portal vein thrombosis, is not diminished; thus, pregnancy is encountered in this setting with some frequency [156,157]. A worsening of preexisting portal hypertension may be anticipated because of the marked increase in blood volume and azygos flow that occurs during normal pregnancy. Variceal hemorrhage during pregnancy or labor has been reported. It is not clear that the incidence of variceal hemorrhage in pregnant patients is higher than the incidence in nonpregnant patients with known varices. Sclerotherapy or endoscopic band ligation have been reported to be successful in pregnant women with variceal hemorrhage [156,158]. Prevention of hemorrhage due to esophageal varices in a woman with known cirrhosis who desires pregnancy is based on classic treatment with β-blockers and/or endoscopic ligature. In these patients, an upper endoscopy is therefore usually performed before pregnancy. Prophylaxis with β-blockers may be continued during pregnancy, but newborns should be monitored during the first days of life because of risks of hypoglycemia and bradycardia. Generally, vaginal delivery with early analgesics for the mother assisted by an extraction device is preferred to caesarean section, which must be reserved for obstetric indications [155].

Specific liver diseases

Alcoholic liver disease

Alcoholic liver disease is often associated with infertility. Most alcoholics do not have significant liver disease, however. Pregnancy in a fertile alcoholic woman can result in fetal alcohol syndrome in the infant, which includes typical facies, malformations, and developmental delay. For

the most part, liver disease or its treatment is not teratogenic. The risk of prematurity is increased.

Chronic hepatitis B

In general, pregnancy is well tolerated by women who are chronic carriers of the hepatitis B virus (HBV) [159]; reactivation of the virus with exacerbation of disease during or after gestation is the exception rather than the rule [160]. The placenta forms an excellent barrier against transmission of this virus, and intrauterine infection with HBV is rare. The major problem for women who are chronic carriers of HBV is the risk of maternal-to-infant (vertical) transmission of infection at delivery. Transmission at birth is more likely if the mother is positive for hepatitis B e antigen (HBeAg) or has high circulating levels of HBV DNA [161]. The rate of transmission may be lower if the delivery is by cesarean section [162]. This is not indicated, however, because appropriate immunoprophylaxis for the newborn with both hepatitis B immunoglobulin (HBIg) and vaccine is very efficient in interrupting transmission. Routine prenatal screening of all pregnant women for hepatitis B surface antigen (HBsAg) is now the standard of care. A test for HBsAg screening should be ordered with other recommended screening tests, regardless of previous hepatitis B vaccination or previous negative HBsAg test results [163]. Infants born to infected mothers should be protected by the recommended combination of vaccine and HBIg at birth [164]. Infants born to carriers of the HBV precore mutant who are positive for antibody to HBeAg with high levels of HBV DNA in their serum are at risk for fulminant hepatitis B during the first 2–4 months following birth [165]. HBIg and vaccine should therefore be given to the infants of all mothers who are HBsAg-positive, regardless of their HBe status. In women with very high HBV DNA levels (as high as 9 $\log_{10}$ copies/mL), vertical transmission of HBV may occur despite vaccination of the child. In such women, treatment with lamivudine (100 or 150 mg/day) during the last months of pregnancy has been given to decrease the HBV DNA level and was associated with a reduction of the risk of HBV transmission [166–168]. Hepatitis D (delta) virus can also be transmitted from mother to infant at birth [169]. Breastfeeding is not contraindicated for infants born to HBsAg-positive mothers [170].

Chronic hepatitis C

Uneventful pregnancy without worsening disease or fetal complications has been reported in women with hepatitis C [171]. Several studies have demonstrated that aminotransferase levels decrease as the pregnancy progresses, whereas the hepatitis C virus (HCV) load increases during the course of gestation [172–174]. Early evidence suggests that the hepatic histopathology may worsen during gestation [175]. Whether or not pregnancy has any effect on the progression of this disease remains to be proved [176].

Transmission from mothers who are chronic carriers to their offspring may occur but appears to be much less efficient than the vertical transmission of hepatitis B. There are currently no interventions available to prevent vertical transmission of HCV [177], except successful antiviral treatment before the onset of pregnancy. Indeed, transmission of HCV occurs only when HCV RNA is detectable. Transmission may be related to higher levels, ranging from 4% to 7% per pregnancy [178]. No association with breastfeeding has been shown, and breastfeeding is not contraindicated [177–179]. It may be prudent for mothers who are HCV infected and who choose to breastfeed to consider abstaining from breastfeeding if their nipples are cracked and bleeding [179]. The rate of transmission is not lower in infants delivered by cesarean section and cesarean section is not recommended for women with chronic HCV infection alone [177,178]. Coinfection with HIV increases the rate of transmission [180]. HCV/HIV coinfected mothers should follow exiting HIV guidelines [177].

Testing a newborn can be misleading. Early after birth, antibodies acquired from the mother usually result in positivity for HCV, and transient viremia can be seen in infants who later test negative. Cord blood can be negative for HCV RNA, while the infant is subsequently shown to be HCV RNA-positive [172]. To reduce the number of tests, the minimum requirement to confirm or exclude infection would be an antibody test at 18 months of age, with a positive result confirming the presence of infection and a negative result confirming the absence of infection [177].

Autoimmune hepatitis

A distinctive clinical characteristic of autoimmune hepatitis is the rapid and complete (or nearly complete) remission that occurs in response to immunosuppression with corticosteroids, given either alone or in combination with azathioprine. The disorder presents frequently in young women, who become anovulatory in response to the active and severe hepatitis, which has sometimes progressed to cirrhosis by the time of diagnosis. Women appropriately treated for this disease with corticosteroids and azathioprine regain their fertility, and successful pregnancies without any increase in fatality have been reported [181]. The aminotransferase levels may decrease during the second and third trimesters of pregnancy, and some have advocated lowering doses of immunosuppressive drugs during gestation [182]. The conventional therapy should be reinstituted immediately before delivery [183]. Untreated patients may go into remission during pregnancy [184]. Worsening of the underlying disease or even initial presentation of autoimmune hepatitis have

been reported during pregnancy [181]. The underlying disease may flare up after delivery, and women should be followed carefully for 3 months postpartum, particularly if the immunosuppressive dose has been decreased [181,185]. Azathioprine has been associated with congenital malformations in pregnant mice; however, it has not been reported to be teratogenic in humans in this setting of low-dose therapy, and seems to be safe for the mother and the baby [181,185,186]. Consequently, it is not usually recommended to stop azathioprine, either for conception or for the duration of pregnancy [187]. However, because the data concerning the safety of azathioprine in pregnant women remain limited, and because this drug is not essential in the management of autoimmune hepatitis, it may be prudent to substitute prednisone for azathioprine [183]. Successful treatment of infertility in these patients, with in vitro fertilization/embryo transfer, has been reported [188].

Primary biliary cirrhosis

The effects of pregnancy on women with this disease have been reported to be variable although studies are scarce. Pregnancy may be associated with an increase in cholestasis that resolves after delivery, regression of cholestasis, or progression of disease including the complications of portal hypertension [189–192]. Ursodeoxycholic acid has been used for ICP with no reports of adverse effects and can be used in patients with primary biliary cirrhosis at the very least during the second and third trimester. In a report of nine pregnancies in six women with ursodeoxycholic acid-treated primary biliary cirrhosis, pregnancy was associated with improvement of liver function tests [193].

Wilson disease

Women with ovulatory failure secondary to Wilson disease regain their fertility, often quite rapidly, when treated. Either they or their physicians may be tempted to discontinue therapy during gestation, but, as in nonpregnant patients with Wilson disease, cessation of therapy can have devastating effects and should not be attempted [194,195]. Successful pregnancies without teratogenicity have been reported in patients taking penicillamine or trientine [196–198]. Zinc treatment has also been successful during pregnancy [199]. Clearly, the major risk to the mother created by stopping therapy greatly outweighs the potential risk to the fetus, and therapy should be continued because successful pregnancy in treated women is the rule [195,196]. Doses of penicillamine or trientine may be reduced during the last trimester [195,196]. Women taking D-penicillamine should not breastfeed [195].

Benign liver tumors (hepatocellular adenoma, focal nodular hyperplasia, hemangioma)

Hepatocellular adenomas associated with the previous use of oral contraceptive agents have been reported to enlarge or rupture during subsequent pregnancy [200–203], and rupture is associated with high mortality [200]. Successful surgical resection of a large (7×9 cm) hepatocellular adenoma performed at 13 weeks' gestation has been reported; the patient complained of increasing epigastric pain and the tumor was in the left hepatic lobe [204].

A study of 216 women with focal nodular hyperplasia showed no association between oral contraceptive use and change in lesion size. Twelve women in this group became pregnant, with no change in lesion size or problems with pregnancy [205]. An enlargement of a focal nodular hyperplasia associated with the previous use of oral contraceptive was, however, reported in one pregnant woman [206].

The results of a prospective study of 94 women (with 181 hemangiomas) suggests that endogenous and exogenous female sex hormones may play a role in the pathogenesis of liver hemangiomas, although significant enlargement occurs only in a minority of patients [207]. These liver hemangiomas are rarely symptomatic and complications are exceptional.

Familial hyperbilirubinemia

The unconjugated hyperbilirubinemia of Gilbert syndrome is not exacerbated by pregnancy [208]. In Dubin–Johnson syndrome, however, the conjugated hyperbilirubinemia may worsen during gestation, but returns to prepregnancy levels after delivery [209]. Women with type II Crigler–Najjar syndrome have been reported to have uncomplicated pregnancies with or without phenobarbital therapy [210,211].

Porphyrias

These genetic disorders of heme metabolism, which may be exacerbated by estrogenic hormones, occasionally cause problems for affected women and their fetuses during pregnancy. Porphyria cutanea tarda has rarely been reported to present initially during pregnancy [212]. Acute attacks often complicate the course of pregnancy in patients with acute intermittent porphyria, variegate porphyria, or hereditary coproporphyria [213,214], and they may result in intrauterine growth retardation or, rarely, maternal death. On the other hand, many women with acute porphyria, particularly those with little clinical expression of the defect, weather pregnancy with no problems. Precipitation of an initial attack of acute intermittent porphyria by the nausea and vomiting of

hyperemesis gravidarum, coupled with antiemetic therapy, has been reported [215].

Budd–Chiari syndrome

Women with Budd–Chiari syndrome have become pregnant after the syndrome has been treated and well controlled [216]. By contrast with a good maternal outcome, the fetal outcome remains relatively poor, possibly because of the underlying prothrombotic disorders. Patients should be fully informed of the persistent risk of such pregnancies [216].

Liver transplantation

Liver transplantation is now accepted as a treatment of both acute liver failure and end-stage chronic liver disease, with a 1-year survival exceeding 85%. Patients who have undergone transplantation regain their fertility promptly – within weeks or months of surgery [217]. Young women should be counseled about the risks of becoming pregnant and encouraged to use effective contraception, preferably barrier methods or intrauterine contraceptive devices, until their immunosuppressive regimen has been stabilized [218,219]. A review of 136 pregnancies after liver transplantation reported to the US National Transplantation Pregnancy Registry has shown that most are successful, with no birth defects in the offspring [220]. The number of premature infants was increased, and women whose renal function was compromised did not do as well. Ten episodes of acute rejection occurred during pregnancy in this study, and three women lost their grafts as a result. Seven of the women died, three within a year of the pregnancy [220]. The effects of prior transplantation on maternal and fetal outcomes were also analyzed in a US nationwide study [221]. Between 1993 and 2005, 146 deliveries among liver transplant recipients were identified and compared with a control group. There was no maternal mortality, but there was an increased fetal mortality and maternal and fetal complications, especially gestational hypertension and postpartum hemorrhage. The infants have an increased risk of prematurity, fetal distress, and growth restriction but not congenital anomalies [221]. The risk of teratogenicity with standard immunosuppressive agents, including prednisone, azathioprine, cyclosporine, and tacrolimus, is low [222,223]. It is preferable to delay pregnancy until the immunosuppressive regimen has been stabilized, i.e., 1 year after grafting [224]. Surveillance for infection, such as with cytomegalovirus, should be increased during gestation. If the results of liver tests become abnormal, then a liver biopsy should be performed to establish the nature of the dysfunction. Increased monitoring of the blood levels of cyclosporine and other immunosuppressive agents is necessary, both before and for several months after delivery [225]. Such pregnancies should be considered high risk and managed together with transplant hepatologists and experts in maternal–fetal medicine, and neonatologists when necessary [221]. Breastfeeding has been discouraged because of concerns about potential immunosuppression of the newborn, but many examples of successful breastfeeding without adverse effects have been reported [220].

Liver transplantation has been accomplished during pregnancy, with and without fetal wastage [220,226–228]. Livers from living related donors have also been transplanted during pregnancy [229]. Obviously, such heroic surgery must be considered with extreme care in this setting. If the condition prompting transplantation is caused by pregnancy (e.g., AFLP or HELLP syndrome), then prompt diagnosis, followed by termination of the pregnancy with maximum support for the mother, is the treatment of choice.

Armenti VT, Herrine SK, Radomski JS, et al. Pregnancy after liver transplantation. *Liver Transpl* 2000;6:671–85.
A review of the complications and outcomes of 136 pregnancies after liver transplantation. Three stillbirths but no birth defects were recorded. Prematurity and low birth weight were common, as were preeclampsia and infection in the mothers. Such pregnancies should be considered high risk.

Arrese M, Macias RI, Briz O, et al. Molecular pathogenesis of intrahepatic cholestasis of pregnancy. *Expert Rev Mol Med* 2008;10:e9.
A comprehensive review that summarizes current knowledge on the potential mechanisms involved in intrahepatic cholestasis of pregnancy. Hormonal and genetic factors are important. Hormonal factors are well known and a genetic hypersensitivity to female hormones (estrogens and/or progesterone) is thought to impair bile secretary function. More recently data suggest that mutations of genes coding hepatobiliary transport proteins may predispose to intrahepatic cholestasis of pregnancy. Environmental factors may also influence the expression of this disease, but these factors have not been clearly identified

Bacq Y, Zarka O, Bréchot J-F, et al. Liver function tests in normal pregnancy: a prospective study of 103 pregnant women and 103 matched controls. *Hepatology* 1996;23:1030–4.
A prospective study of pregnant patients and matched controls. The results of standard liver tests in all three trimesters were considered. Levels of alkaline phosphatase rose in the third trimester. The total bile acid levels did not differ between the pregnant women and the controls. The levels of bilirubin and GGT were lower in the pregnant women than in the controls. AST and ALT values remained in normal limits.

Barton JR, Sibai BM. Gastrointestinal complications of pre-eclampsia. *Semin Perinatol* 2009;33:179–88.
A recent and comprehensive review on the hepatic and pancreatic complications of preeclampsia/eclampsia, with an emphasis on the HELLP syndrome. Clinical presentation, initial management, and management of hepatic complications of the HELLP syndrome are discussed.

Bottomley C, Bourne T. Management strategies for hyperemesis. *Best Pract Res Clin Obstet Gynaecol* 2009;23:549–64.
A comprehensive review on the pathogenesis, diagnosis, and management of this complex disorder unique to pregnancy. Treatment is supportive with intravenous rehydration, antiemetics, and correction of vitamin deficiency. This review discusses also the prevention, recognition, and treatment of serious complications associated with hyperemesis gravidarum such Wernicke encephalopathy, osmotic demyelinization syndrome (central pontine myelinolysis), and thromboembolism.

A review of a large case series. The authors emphasize the high incidence of renal compromise and significant hypoglycemia, and plead that liver transplantation be avoided in those patients whose liver disease is reversible.

Gambarin-Gelwan M. Hepatitis B in pregnancy. *Clin Liver Dis* 2007; 11:945–63.

This article reviews in depth the consequences of HBV infection in pregnant women and discusses its management. Perinatal transmission of HBV from mother to infant is important and should be prevented by the administration of hepatitis B immunoglobulin and hepatitis B vaccine at birth. Even with such prevention, mother to infant transmission has been observed in some women with very high serum HBV DNA levels (>8 log_{10} IU/mL). In these women, antiviral therapy at the end of pregnancy (usually with lamivudine), in addition to immunoprophylaxis, has been proposed to decrease the risk of transmission. Breastfeeding is not contraindicated for infants born to HBsAg-positive mothers.

Heneghan MA, Norris SM, O'Grady JG, et al. Management and outcome of pregnancy in autoimmune hepatitis. *Gut* 2001;48:97–102.

A review of the King's College experience of 35 pregnancies in 18 women with autoimmune hepatitis. Two patients presented during pregnancy, and four had flares. No birth defects were noted despite azathioprine therapy in some.

Heneghan MA, Selzner M, Yoshida EM, Mullhaupt B. Pregnancy and sexual function in liver transplantation. *J Hepatol* 2008;49:507–19.

This article combines the opinion of several expert reviews on some relevant clinical questions related to the indications of transplantation during pregnancy and sexual function, contraception, and pregnancy after liver transplantation.

Ibdah JA, Bennett MH, Rinaldo P, et al. A fetal fatty acid oxidation disorder as a cause of liver disease in pregnant women. *N Engl J Med* 1999;340:1723–31.

A study of families affected by long-chain 3-hydroxyacyl coenzyme A dehydrogenase deficiency. The pregnancies of mothers of deficient fetuses carrying the Glu474Gln mutation were complicated by AFLP or HELLP, a unique example of maternal illness caused by deficiency in the fetus.

Ko CW, Beresford SA, Schulte SJ, Matsumoto AM, Lee SP. Incidence, natural history, and risk factors for biliary sludge and stones during pregnancy. *Hepatology* 2005;41:359–65.

A prospective study on biliary sludge and stones during pregnancy and postpartum in 3,254 women. Sludge or stones were found on at least one ultrasound study in 5.1% by the second trimester, 7.9% by the second trimester, and 10.2% by 4–6 weeks postpartum. Twenty-eight women (0.8%) underwent cholecystectomy within the first year postpartum. Prepregnancy body mass index and serum leptin were risk factors for gallbladder disease.

Kumar A, Beniwal M, Kar P, Sharma JB, Murthy NS. Hepatitis E in pregnancy. *Int J Gynaecol Obstet* 2004;85:240–4.

A prospective study of 62 pregnant women in India having jaundice in the third trimester. Twenty-eight patients (45.2%) had hepatitis E and 26.9% of these patients with hepatitis E infection died with fulminant hepatic failure (five patients died undelivered). Vertical transmission of hepatitis E virus was observed in 33.3% of cases. This study confirms the poor prognosis of hepatitis E during the third trimester of pregnancy.

Pembrey L, Newell ML, Tovo PA. The management of HCV infected pregnant women and their children. European Paediatric HCV Network. *J Hepatol* 2005;43:515–25.

A review with guidelines for the clinical management of HCV-infected pregnant women and their children. HCV infection is not a contraindication for pregnancy. The estimated risk of vertical transmission is 5%, ranging from 3% to 7%. There are currently no interventions available to prevent vertical transmission of HCV (except antiviral treatment with sustained virologic response before the pregnancy). Neither elective caesarean section nor avoidance of breastfeeding should be recommended to prevent mother-to-child transmission of HCV. The minimum requirement to confirm or exclude infection in children born from HCV-infected mothers is an antibody test at 18 months of age, with a positive result confirming presence of infection and a negative result confirming absence of infection.

Rautou PE, Angermayr B, Garcia-Pagan JC, et al. Pregnancy in women with known and treated Budd–Chiari syndrome: maternal and fetal outcomes. *J Hepatol* 2009;51:47–54.

A retrospective study of 24 pregnancies in 16 women with Budd–Chiari syndrome that was known and treated before pregnancy. Anticoagulation was administered during 17 pregnancies. In two patients, symptomatic thrombosis recurred during pregnancy or postpartum. All patients were alive after a median follow-up of 34 months after the last delivery. By contrast, the prognosis of the babies was not so good. Seven fetuses were lost before gestation week 20 and there was one stillbirth. The prognosis of the 16 infants born alive was good although there was a high level of prematurity (12/16 cases). In the absence of obstetric indication for a caesarean, vaginal delivery should be encouraged in such patients.

Ropponen A, Sund R, Riikonen S, Ylikorkala O, Aittomaki K. Intrahepatic cholestasis of pregnancy as an indicator of liver and biliary diseases: a population-based study. *Hepatology* 2006;43:723–8.

This longitudinal retrospective population-based cohort study was designed to analyze the occurrence of liver and biliary diseases in women suffering from ICP in Finland. Patients with a history of ICP (10,504 women during the years 1972–2000) and 10,504 women with normal pregnancies (controls) were matched for age, time of delivery, and place of delivery. The results show an association of ICP with several liver diseases: hepatitis C (rate ratio (RR), 3.5; 95% CI, 1.6–7.6, P <0.001), gallstones and cholecystitis (RR, 3.7; 95% CI, 3.2–4.2;P <0.001), and nonalcoholic pancreatitis (RR, 3.2; 95% CI, 1.7–5.7; P <0.001). An association was also found with nonalcoholic liver cirrhosis including cases of primary biliary cirrhosis (RR, 8.2; 95% CI, 1.9–35.5; P <0.05). This last result suggests that the long-term follow-up of patient suffering from ICP may be reconsidered.

Multiple choice questions

11.1 Which of the following items is not associated with intrahepatic cholestasis of pregnancy (ICP)?

a ICP is usually revealed by a generalized pruritus during the second or third trimester.
b ICP recurs frequently during subsequent pregnancies (more than 50% of cases).
c Ursodesoxycholic acid may be used in the treatment of ICP.
d ICP is a cause of acute liver failure.
e ICP may be responsible for intrauterine fetal death.

11.2 Which of the following items is not associated with acute fatty liver of pregnancy (AFLP)?

a AFLP is the most frequent cause of liver disease unique to pregnancy.
b AFLP is a cause of acute liver failure during the third trimester.
c AFLP is an indication of prompt delivery.
d AFLP may be associated with long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency.
e AFLP may recur during subsequent pregnancies.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

PART III

Consequences of Liver Disease

CHAPTER 12
Hepatic Fibrosis

Scott L. Friedman
Mount Sinai School of Medicine, New York, NY, USA

Key concepts

- Hepatic fibrosis is a reversible wound-healing response characterized by the accumulation of extracellular matrix (ECM) or "scar;" it follows chronic, but not self-limited, liver disease. The ECM components in fibrotic liver are similar, regardless of the underlying cause.
- Activation of hepatic stellate cells is the central event in hepatic fibrosis. These perisinusoidal cells and related myofibroblasts from intra- and extrahepatic origins orchestrate an array of changes including degradation of the normal ECM of liver, deposition of scar molecules, vascular and organ contraction, and release of cytokines.
- Not only is hepatic fibrosis reversible, but it is also increasingly clear that cirrhosis may be reversible as well. The exact stage at which fibrosis/cirrhosis becomes truly irreversible, and its biologic determinants, are not known.
- Antifibrotic therapies have entered clinical trials. Emerging therapies will be targeted to those patients with reversible disease. The paradigm of stellate cell activation provides an important framework for defining therapeutic targets. Currently, the most significant impediment to drug development is the lack of robust noninvasive markers of fibrosis to accurately assess response to therapy.

Fibrosis is a reversible scarring response that occurs in almost all patients with chronic liver injury. Ultimately, hepatic fibrosis leads to cirrhosis, characterized by nodule formation and organ contraction. The causes of cirrhosis are multiple and include congenital, metabolic, inflammatory, and toxic liver diseases (Box 12.1).

It is essential to understand the molecular underpinnings of fibrosis because the fibrotic response underlies all the complications of end-stage liver disease, including portal hypertension, ascites, encephalopathy, synthetic dysfunction, and impaired metabolic capacity. Therefore, fibrosis is deleterious both by its direct effects on cellular function and by its mechanical contribution to increased portal resistance.

This chapter reviews the significant progress made toward elucidating the cellular basis of hepatic fibrosis and how these insights are leading to advances in the diagnosis and treatment of chronic liver disease.

Biologic basis of hepatic fibrosis

General principles

1 *Hepatic fibrosis is a wound-healing response* in which the damaged regions are encapsulated by extracellular matrix (ECM), or scar. In all circumstances, the composition of the hepatic scar is similar. The cells and soluble factors participating in this response in the liver are also similar to those involved in parenchymal injury to the kidney, lung, or skin. This understanding has helped to identify underlying mechanisms and will likely lead to new therapies for fibrotic diseases of many organs including the liver.

2 *Myofibroblast-like cells produce hepatic fibrosis regardless of the underlying cause*. As discussed in the subsequent text, the activated hepatic stellate cell is the key cellular source of these myofibroblasts, but additional origins of fibrogenic cells may include peribiliary fibroblasts, bone marrow, and even epithelial–mesenchymal transition (EMT) from epithelial cells. How stellate cells and related cells are activated in response to so large a variety of hepatic insults – from inborn metabolic defects to chronic viral hepatitis – is being increasingly revealed.

3 *Hepatic fibrosis follows chronic, not self-limited, injury*. For example, patients surviving fulminant hepatitis do not develop scarring despite an abundance of fibrogenic stimuli, unless chronic injury follows. Moreover, even fibrosis associated with sustained injury is often reversible. The reason for fibrosis reversibility, even in chronic liver disease, is not certain, but may be related to the relative activity of matrix-degrading enzymes and their inhibitors, as well as the relative extent of collagen cross-linking.

Box 12.1 Causes of fibrosis and cirrhosis.

Presinusoidal fibrosis
- Schistosomiasis
- Idiopathic portal fibrosis

Parenchymal fibrosis
- Drugs and toxins:
  - Alcohol
  - Methotrexate
  - Isoniazid
  - Vitamin A
  - Amiodarone
  - Perhexiline maleate
  - α-Methyldopa
  - Oxyphenisatin
- Infections:
  - Chronic hepatitis B and C
  - Brucellosis
  - Echinococcosis
  - Congenital or tertiary syphilis
- Autoimmune disease:
  - Autoimmune hepatitis
- Vascular abnormalities:
  - Chronic passive congestion
  - Hereditary hemorrhagic telangiectasia
- Metabolic/genetic diseases:
  - Wilson disease
  - Genetic hemochromatosis
  - α_1-Antitrypsin deficiency
  - Carbohydrate metabolism disorders
  - Lipid metabolism disorders
  - Urea cycle defects
  - Porphyria
  - Amino acid metabolism disorders
  - Bile acid disorders
- Biliary obstruction:
  - Primary biliary cirrhosis
  - Secondary biliary cirrhosis
  - Cystic fibrosis
  - Biliary atresia/neonatal hepatitis
  - Congenital biliary cysts
- Idiopathic/miscellaneous:
  - Nonalcoholic steatohepatitis
  - Indian childhood cirrhosis
  - Granulomatous liver disease
  - Polycystic liver disease

Postsinusoidal fibrosis
- Sinusoidal obstruction syndrome (venoocclusive disease)

4 *Fibrosis occurs earliest in regions in which injury is most severe*. This is especially true in chronic inflammatory liver disease due to alcohol or viral infection. For example, pericentral injury is a hallmark of alcoholic hepatitis, and the development of pericentral fibrosis (also known as sclerosing hyaline necrosis or perivenular fibrosis) is an early marker of likely progression to panlobular cirrhosis.

Extracellular matrix composition of the normal liver and hepatic scars

Extracellular matrix refers to the array of macromolecules comprising the scaffolding of normal and fibrotic liver. The components of hepatic ECM include several families of structural and supporting molecules: collagens, noncollagen glycoproteins, matrix-bound growth factors, glycosaminoglycans, proteoglycans, and matricellular proteins. Of the 20 types of collagens characterized thus far, ten have been identified in the liver.

In the normal liver, so-called fibril-forming collagens (types I, III, V, and XI) are largely confined to the capsule, around large vessels, and in the portal triad, with only scattered fibrils containing types I and III collagen in the subendothelial space. Smaller amounts of other collagens, including types VI, XIV, and XVIII, can be found. Glycoproteins and matricellular proteins are also present, including subendothelial deposits of fibronectin, laminin, tenascin, secreted protein that is acidic and rich in cysteine (SPARC), and von Willebrand factor. Proteoglycans primarily consist of heparan sulfate proteoglycans including perlecan, as well as small amounts of decorin, biglycan, fibromodulin, aggrecan, glypican, syndecan, and lumican.

The fibrotic liver is characterized by both quantitative and qualitative differences in the matrix composition compared with the normal liver; as noted, these changes are similar regardless of the type of liver injury. Total collagen content increases 3–10-fold, although the collagen is not "abnormal" in sequence or structure. Overall, there is a marked increase in "interstitial matrix" that is typical of the healing wound, which includes fibril-forming collagens (types I, III, and V) and some nonfibril-forming collagens (types IV and VI), several glycoproteins (e.g., cellular fibronectin, laminin, SPARC, osteonectin, tenascin, and von Willebrand factor), a large number of proteoglycans and glycosaminoglycans (e.g., perlecan, decorin, aggrecan, lumican, and fibromodulin), and related receptors, including dystroglycan [1].

Biologic activity of extracellular matrix in the liver

Extracellular matrix is a dynamic regulator of cell function and not an inert "ground substance." Early, subendothelial matrix accumulation leading to "capillarization" of the subendothelial space of Disse is a key event and may be more important than overall increases in matrix content (Fig. 12.1). The basement membrane constituents within the subendothelial space may be essential for preserving the differentiated functions of hepatocytes,

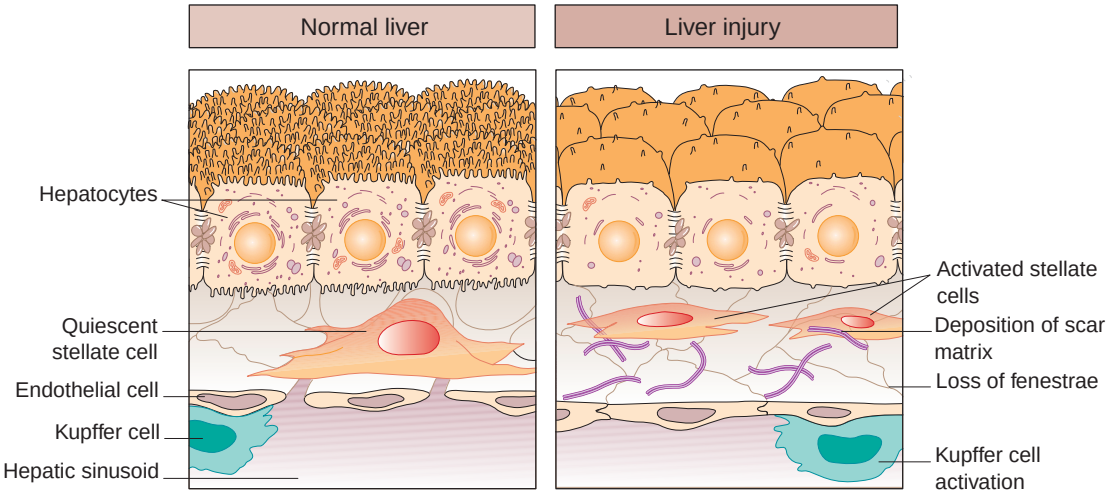

Figure 12.1 Matrix and cellular alterations in hepatic fibrosis. Changes in the subendothelial space of Disse as fibrosis develops in response to liver injury include alterations in both cellular responses and extracellular matrix composition. Stellate cell activation leads to an accumulation of scar (fibril-forming) matrix. This in turn contributes to the loss of hepatocyte microvilli and sinusoidal endothelial fenestrae, which results in the deterioration of hepatic function. Kupffer cell (macrophage) activation accompanies liver injury and contributes to the paracrine activation of stellate cells. (Reproduced from Friedman [168] with permission from American Society for Biochemistry and Molecular Biology.)

hepatic stellate cells, and endothelial cells. Replacement of the normally low-density matrix by interstitial matrix directly perturbs hepatocyte function and could explain the synthetic and metabolic dysfunction that is characteristic of more advanced fibrosis and cirrhosis. This high-density matrix also activates stellate cells and leads to a decrease in fenestrations of sinusoidal endothelial cells, which could impair the transport of solutes from the sinusoid to hepatocytes.

In liver injury, an increase in cellular fibronectin levels is among the first matrix alterations seen within this region. A consequence of this change is the activation of hepatic stellate cells and acceleration of fibrosis (see section below).

Altered cellular behavior induced by matrix alterations is typically mediated by cell membrane receptors. *Integrins*, a large family of homologous membrane linker proteins, are the best characterized type of ECM receptor. Integrins are noncovalent αβ-heterodimers that consist of a large extracellular domain, a membrane-spanning domain, and a cytoplasmic tail [2,3].

In addition to integrins, a growing number of other adhesion proteins and cell matrix receptors have been characterized, including cadherins and selectins, which mediate interactions between inflammatory cells and the endothelial wall. For example, upregulation of a tyrosine kinase receptor, discoidin domain receptor 2 (DDR2), has been identified during stellate cell activation, which signals in response to fibrillar collagens, leading to enhanced matrix metalloproteinase (MMP) expression and cell growth [4]. The DDR family is the only family of receptor tyrosine kinases whose ligands are ECM molecules rather than peptide ligands, and their upregulation could be a critical requirement to perpetuate liver fibrosis.

ECM can also indirectly affect cell function through the release of soluble growth factors (cytokines), which is in turn controlled by local metalloproteinases. These include platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), connective tissue growth factor (CTGF), tumor necrosis factor α (TNF-α), basic fibroblast growth factor (bFGF), and vascular endothelial cell growth factor (VEGF). Controlled release from ECM is a key mechanism for regulating cytokine activity because it provides a local, accessible source that is tightly regulatable through the actions of proteases and their inhibitors. In addition, ECM can regulate the activity of proteases through specific binding to collagens or fibronectins [1].

Cellular sources of extracellular matrix in normal and fibrotic liver

The identification of the cellular sources of ECM in hepatic fibrosis has been a significant advance that laid the groundwork for defining mechanisms of fibrosis and potential therapies. The *hepatic stellate cell* (previously called the lipocyte, Ito, fat-storing, or perisinusoidal cell) is the primary source of ECM in the normal and fibrotic liver. In addition, related mesenchymal cell types from a variety of sources may also make measurable contributions to total matrix accumulation, including classic portal fibroblasts (especially in biliary fibrosis) [5], bone marrow-derived cells [6], and fibroblast-derived EMT involving hedgehog signaling [7].

Hepatic stellate cells are resident perisinusoidal cells in the subendothelial space between hepatocytes and

sinusoidal endothelial cells [8]. They are the primary sites for storing retinoids within the body. Stellate cells can be recognized by their vitamin A autofluorescence, perisinusoidal orientation, and expression of the cytoskeletal proteins desmin and glial acidic fibrillary protein. In strict terms, "stellate cells" may represent a heterogeneous population of mesenchymal cells with respect to cytoskeletal phenotype, vitamin A content, and localization, but collectively they are the key fibrogenic cell type in the liver. Moreover, the remarkable plasticity of the stellate cell phenotype has been documented in vivo and in culture, precluding a strict definition based only on the cytoskeletal phenotype.

Studies in situ in both animals and humans with progressive injury have defined a gradient of changes within stellate cells that are collectively termed *activation* (see subsequent text) [9]. Stellate cell activation refers to the transition from a quiescent vitamin A-rich cell to a highly fibrogenic cell characterized morphologically by the enlargement of rough endoplasmic reticulum, diminution of vitamin A droplets, ruffled nuclear membrane, appearance of contractile filaments, and proliferation. As noted in the preceding text, the proliferation of stellate cells occurs in regions of greatest injury, which is typically preceded by an influx of inflammatory cells and is associated with subsequent ECM accumulation.

Stellate cells have now been characterized in many human liver diseases. Alcoholic liver disease is the best studied example, with numerous reports documenting features of activation in situ; activation may occur even in the presence of steatosis alone without inflammation [10]. Activated stellate cells have also been observed in viral hepatitis [11]. In hepatocellular carcinoma, activated stellate cells contribute to the deposition of tumor stroma.

Remarkably, very few studies have defined the cellular or matrix composition of congenital hepatic fibrosis, an entity whose pathogenesis is not clear. Current theories suggest that as in adults, congenital hepatic fibrosis represents a final common pathway of fetal hepatic injury, whether from biliary malformations, viral infections (especially cytomegalovirus), or other insults, with the stellate cell playing a significant role. Very few studies have examined specific mediators, but stellate cells contribute to fibrosis in this disease as well [12]. It is unclear, however, why fibrosis develops in weeks to months in utero, whereas it requires months to years in adults (see "Fibrosis progression and reversibility" below).

ECM production by sinusoidal endothelial cells, although less than that by stellate cells, is nonetheless an important component of early fibrosis. After acute liver injury, increased expression of cellular isoforms of fibronectin by these cells is a key early event because their appearance creates a microenvironment that activates stellate cells [13].

Degradation of extracellular matrix

Degradation of extracellular matrix represents a key component of hepatic fibrosis for at least two reasons: (i) early disruption of the normal hepatic matrix by matrix proteases ("pathologic" matrix degradation) hastens its replacement by scar matrix, which in turn has deleterious effects on cell function (See "Biologic activity of extracellular matrix in the liver" above); and (ii) in established fibrosis in patients with chronic liver disease there is an urgent need to resorb the excess wound matrix ("therapeutic" matrix degradation) in the hope of arresting or reversing hepatic dysfunction and portal hypertension. Because fibrosis reflects a balance between matrix production and degradation, this balance must be shifted in favor of degradation for any antifibrotic therapy to succeed.

There has been significant progress in elucidating the fundamental mechanisms of matrix remodeling and how these apply to hepatic fibrosis. An enlarging family of MMPs (also known as matrixins) has been identified; they are calcium-dependent enzymes that specifically degrade collagens and noncollagenous substrates [14]. Broadly, these fall into five categories based on substrate specificity: (i) interstitial collagenases (MMP-1, -8, -13); (ii) gelatinases (MMP-2, -9) and fibroblast activation protein; (iii) stromelysins (MMP-3, -7, -10, -11); (iv) membrane-type MMPs (MMP-14, -15, -16, -17, -24, -25); and (v) a metalloelastase (MMP-12). Metalloproteinases are regulated at many levels to restrict their activity to discrete regions within the pericellular milieu. Inactive metalloproteinases can be activated through proteolytic cleavage by either membrane-type 1 matrix metalloproteinase (MT1-MMP) or plasmin, and inhibited by binding to specific inhibitors known as *tissue inhibitors of metalloproteinases* (TIMPs). The stoichiometry and molecular basis for these interactions has been greatly clarified. For example, MT1-MMP (MMP-14) and TIMP-2 form a ternary complex with MMP-2, possibly including $\alpha v\beta 3$ integrin, which is essential for optimal MMP-2 activity [15]. Similarly, plasmin activity is controlled by its activating enzyme, uroplasminogen activator, and a specific inhibitor, plasminogen activator inhibitor 1, and can be stimulated by active transforming growth factor β1 (TGF-β1). Therefore, net collagenase activity reflects the relative amounts of activated metalloproteinases and their inhibitors, especially TIMPs. In addition to TIMPs, other protease inhibitors may affect the net degradative activity, including α_2-macroglobulin.

In the liver, "pathologic" matrix degradation refers to the early disruption of the normal subendothelial matrix, which occurs through the actions of at least four enzymes: *MMP*-2 (also called gelatinase A or 72 kDa type IV collagenase) and *MMP-9* (gelatinase B or 92 kDa type IV collagenase), which degrade type IV collagen;

membrane-type MMP-1 or -2, which activates latent MMP-2; and *stromelysin 1* (MMP-3), which degrades proteoglycans and also activates latent collagenases. Stellate cells are a key source of MMP-2, MMP-13 in rodents, and stromelysin 1 [15]. Markedly increased expression of MMP-2 is characteristic of cirrhosis; yet, in experimental animals that lack MMP-2, fibrosis is worse than in normal animals after toxic liver injury [16], which suggests that MMP-2 may normally limit liver injury. These findings suggest that simple inhibition of metalloproteinases may not be an efficacious strategy to limit fibrosis.

Failure to degrade the increased interstitial or scar matrix is a major determinant of progressive fibrosis. MMP-1 is the main protease that can degrade type I collagen, the principal collagen in the fibrotic liver. However, the sources of this enzyme are not as clearly established as for the type IV collagenases. Progressive fibrosis is associated with marked increases in TIMP-1 and TIMP-2 [17], leading to a net decrease in protease activity and, therefore, more unopposed matrix accumulation. Stellate cells are the major source of these inhibitors [17]. Sustained TIMP-1 expression is emerging as a key reason for progressive fibrosis, and its diminution is an important prerequisite to allow for reversal of fibrosis (see below).

Stellate cell activation, the central event in hepatic fibrosis

It is useful to frame the pathophysiology of hepatic fibrosis around the mechanisms of hepatic stellate cell activation because this cell type is the major source of ECM. Activation consists of two major phases: *initiation* (also called a preinflammatory stage) and *perpetuation* (Fig. 12.2) [18]. Initiation refers to early changes in gene expression and phenotype, which render the cells responsive to other cytokines and stimuli, while perpetuation results from the effects of these stimuli on maintaining the activated phenotype and generating fibrosis. Initiation is largely due to paracrine stimulation, whereas perpetuation involves autocrine and paracrine loops.

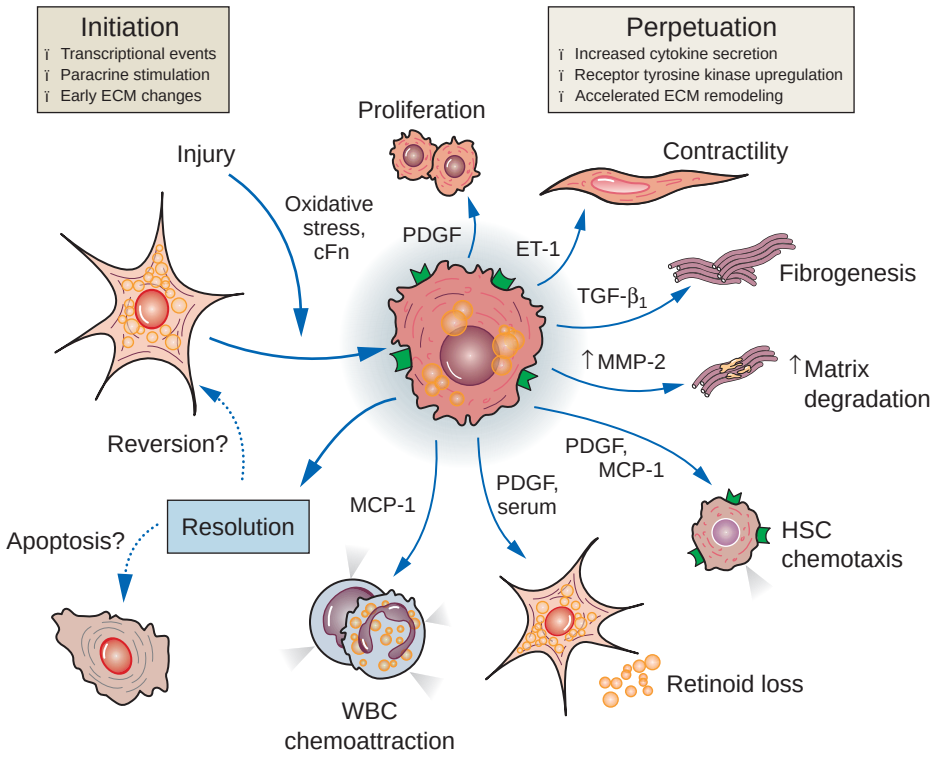

Figure 12.2 Phenotypic features of hepatic stellate cell activation during liver injury and resolution. Following liver injury, hepatic stellate cells undergo "activation," during which they are transformed from quiescent vitamin A-rich cells into proliferative, fibrogenic, and contractile myofibroblasts. The major phenotypic changes after activation include proliferation, contractility, fibrogenesis, matrix degradation, chemotaxis, retinoid loss, and white blood cell (WBC) chemoattraction. The key mediators underlying these effects are shown. The fate of activated stellate cells during the resolution of liver injury is uncertain but may include reversion to a quiescent phenotype or selective clearance by apoptosis. cFn, cellular fibronectin; ECM, extracellular matrix; ET-1, endothelin-1; HSC, hepatic stellate cell; MCP-1, monocyte chemoattractant protein 1; MMP-2, matrix metalloproteinase 2; PDGF, platelet-derived growth factor; TGF-β1, transforming growth factor β1. Initiation of stellate cell activation

The earliest changes in stellate cells are likely to result from paracrine stimulation by all neighboring cell types, including sinusoidal endothelium, Kupffer cells, hepatocytes, and platelets. As noted in the preceding text, early injury to endothelial cells stimulates the production of cellular fibronectin, which has an activating effect on stellate cells [13]. On the other hand, resting endothelial cells may preserve stellate cell quiescence [19]. Sinusoidal endothelial cells, normally fenestrated to allow rapid bidirectional transport of solutes between sinusoidal blood and parenchymal cells, may rapidly lose their fenestrations following injury and express proinflammatory molecules including intercellular adhesion molecule 1 (ICAM-1), VEGF, and adhesion molecules. Together with stellate cells, they activate angiogenic pathways in response to hypoxia associated with local injury or malignancy [20].

Hepatic inflammation and Kupffer cell infiltration and activation also play prominent roles. An influx of Kupffer cells coincides with the appearance of stellate cell activation markers. Kupffer cells can stimulate matrix synthesis, cell proliferation, and the release of retinoids by stellate cells through the actions of cytokines (especially TGF-β1) and reactive oxygen intermediates/lipid peroxides; they also secrete MMP-9, a type IV collagenase.

Early stimulation of stellate cells by oxidant stress in vivo may be important in many forms of liver fibrosis, particularly hepatitis C, nonalcoholic steatohepatitis (NASH), and iron overload [21]. Fibrosis is more likely among patients with NASH who are obese, which correlates with increased hepatic steatosis [22]. Because antioxidant levels are typically depleted in cirrhotic liver as fibrosis advances, their loss could further amplify the injurious effects of lipid peroxides.

Hepatocytes, as the most abundant cells in the liver, are a potent source of these fibrogenic lipid peroxides [21]. Steatosis in NASH and hepatitis C virus (HCV) correlates with increased stellate cell activation and fibrogenesis [23], possibly because fat represents an enhanced source of lipid peroxides. Whereas hepatocyte necrosis associated with lipid peroxidation is considered a classic inflammatory and fibrogenic stimulus, apoptosis, or programmed cell death, also stimulates the fibrogenic response associated with enhanced cell survival and upregulation of nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH) oxidase, which further generates oxidant stress [24,25].

Platelets are often overlooked as a paracrine stimulus, but, in fact, they are a potent source of growth factors and are present within the injured liver. Potentially important platelet mediators include PDGF, TGF-β1, epidermal growth factor (EGF), and the chemokine ligand CXCL4 [26].

Perpetuation of stellate cell activation

Perpetuation of stellate cell activation involves at least seven discrete changes in cell behavior: (i) proliferation; (ii) chemotaxis; (iii) fibrogenesis; (iv) contractility; (v) matrix degradation; (vi) retinoid loss; (vii) chemokine, adipokine, and neuroendocrine signaling; and (viii) inflammatory and immune signaling. Either directly or indirectly, the net effect of these changes is to increase the accumulation of ECM. For example, proliferation and chemotaxis lead to increased numbers of collagen-producing cells, but there is also more matrix production per cell. Cytokine release by stellate cells can amplify the inflammatory and fibrogenic tissue responses, and matrix proteases may hasten the replacement of normal matrix with a matrix typical of the wound "scar."

Proliferation

Platelet-derived growth factor is the most potent stellate cell mitogen identified [27]. Induction of PDGF receptors early in stellate cell activation increases responsiveness to this mitogen. Downstream pathways of PDGF signaling have been carefully characterized in stellate cells and include PI3 kinase [28], and convergence with ephrin signaling [29], among others. Transgenic expression of PDGF-C in mice leads to both hepatic fibrosis and carcinoma [30]. Other mitogenic stimuli in stellate cells include VEGF [31], thrombin and its receptor EGF, TGF-α, and keratinocyte growth factor, among others [32].

Chemotaxis

Stellate cells can migrate towards cytokine chemoattractants, leading to their accumulation in zones of injury. Potent stellate cell chemoattractants include PDGF [33], MCP-1 [34], and CXCR3 [35]. PDGF-stimulated chemotaxis is associated with cell spreading at the tip, movement of the cell body towards the stimulant, and retraction of trailing protrusions associated with transient myosin phosphorylation [36]. In contrast, adenosine blunts chemotaxis and may immobilize cells once they reach the site of injury through reduced contractility [37].

Fibrogenesis

Stellate cells generate fibrosis not only by increased cell numbers, but also by increasing matrix production per cell. The best studied component of hepatic scar is collagen type I, the expression of which is regulated both transcriptionally and post-transcriptionally [38] in hepatic stellate cells by a growing number of stimuli and pathways.

The most potent stimulus for production of collagen I and other matrix constituents by stellate cells is TGF-β1, which is derived from both paracrine and autocrine sources [39]. Signals downstream of TGF-β1 include a family of bifunctional molecules known as Smads, upon

which many extracellular and intracellular signals converge to fine-tune and enhance TGF-β's effects during fibrogenesis [39]. TGF-β1 also stimulates the production of other matrix components including cellular fibronectin and proteoglycans.

Connective tissue growth factor (CTGF/CCN2) is also a potent fibrogenic signal towards stellate cells [40] and may be upregulated by hyperglycemia and hyperinsulinemia [41]. While stimulation of CTGF production has traditionally been considered TGF-β dependent (42), there is also TGF-β-independent regulation [43].

Contractility

The collagenous bands typical of end-stage cirrhosis contain large numbers of activated stellate cells that contribute to contractility of both cells and the entire organ [44]. These bands impede portal blood flow by constricting individual sinusoids and by contracting the cirrhotic liver. Endothelin 1 and nitric oxide are major counterregulators controlling stellate cell contractility, in addition to a growing list of other mediators including angiotensinogen II, eicosanoids, atrial natriueretic peptide, somatostatin, and carbon monoxide, among others [44]. As stellate cells activate, the expression of the cytoskeletal protein α-smooth muscle actin (α-SMA) is increased, which confers increased contractile potential.

Another key contractile mediator in activated stellate cells is angiotensin II, which is synthesized by activated stellate cells in a NADPH-dependent pathway [45]. These findings are particularly relevant to human disease because antagonism of this pathway is an attractive antifibrotic therapy using a variety of safe, well-tolerated medications that are already available (see therapy section below) [46].

Matrix degradation

Quantitative and qualitative changes in matrix protease activity play an important role in the ECM remodeling that accompanies fibrosing liver injury (see "Degradation of extracellular matrix" above). Stellate cells express virtually all the key components required for pathologic matrix degradation and, therefore, play a key role not only in matrix production but also in matrix degradation.

Retinoid loss and nuclear receptor signaling

Activation of stellate cells is accompanied by the loss of the characteristic perinuclear retinoid (vitamin A) droplets. In culture, retinoid is stored as retinyl esters, whereas the form of retinoid released outside the cell during activation is retinol, suggesting that there is intracellular hydrolysis of esters prior to export [47]. Retinoid content and cellular activation may be linked through adipose differentiation-related protein (ADRP), which is increased as retinoids accumulate in stellate cells; its knockdown by siRNA increases fibrogenesis in cultured stellate cells [48]. Interestingly, mice genetically deficient in lecithin:retinol acyltransferase (LRAT) lack lipid droplets in their stellate cells, but it is unknown what impact this has on their fibrogenic potential [49]. Thus, whether retinoid loss is required for the activation of stellate cells, or which retinoids might accelerate or prevent activation are not clarified.

Chemokine, adipokine, and neuroendocrine signaling

Chemokine signaling has been strongly implicated in the pathogenesis of hepatic fibrosis [50,51]. In particular, CCR1 and CCR5 are both fibrogenic, but they arise from distinct cellular sources [50]: CCR5 is derived from resident liver cells, whereas CCR1 is derived from bone marrow cells. Interestingly, sources of CCR2 evolve with progressive liver injury, and are initially derived from bone marrow cells but later derive from resident liver cells [51]. In contrast, activity of CXCL9 through its cognate receptor, CXCR3, is antifibrotic, and polymorphisms in CXCL9 may contribute to fibrosis progression risk in patients with chronic liver disease [52].

Pathways stimulated by adipokines, or polypeptides derived from adipose, are increasingly implicated in hepatic disease [53]. Whereas some adipokines are strictly derived from fat, others are also produced by resident liver cells. For example, leptin and adiponectin are both derived from hepatic stellate cells, among other sources, and their reciprocal dysregulation may drive fibrogenesis primarily through local paracrine signaling [54].

Neuroendocrine activity also contributes to hepatic fibrogenesis [55], especially cannabinoid signaling. Interruption of cannabinoid activity is an appealing therapeutic target, because CB1 receptor signaling is profibrogenic, and thus efforts to antagonize this molecule have met with significant success in animal models [56] and are being evaluated in human trials. Conversely, CB2 receptor signaling is antifibrogenic, and thus a strategy to agonize this receptor also shows promise [57]. On the other hand, CB2 agonists may amplify inflammation [58], suggesting that CB1 antagonism may be a more rational target than CB2. Similar to cannabinoids, data now also implicate neurotrophins [59,60], serotonin, and opioids in local fibrogenic signaling, and, like cannabinoids, divergent effects of these compounds in stellate cells may be elicited by different subtypes of their receptors [55].

Inflammatory and immune signaling

There has been tremendous progress in establishing a central role of stellate cells in inflammatory and immune signaling. Stellate cells are not only targets of immune mediators, but orchestrate immune responses as well. Recents studies have defined interactions not only with macrophages and traditional lymphocyte subsets (e.g., T

and B cells), but also with natural killer (NK) cells, NK T cells [61,62], B cells [63], dendritic cells [64], and mast cells, as well as newly uncovered contributions by Toll-like receptors [65–68], nuclear factor κB (NF-κB) signaling [69], and the inflammasome [70]. Moreover, bidirectional interactions between stellate cells/myofibroblasts and immune cell subsets elicit specific cellular responses that modulate the composition of inflammatory infiltrates and the vigor of fibrogenesis [71,72]. In aggregate, these studies point to the liver as a major immunoregulatory organ, and underscore the critical contribution of immune cell subsets in modulating fibrosis as well as liver injury.

Gene regulation in hepatic stellate cells and myofibroblasts

The many advances in understanding gene regulation have benefited the study of hepatic stellate cell biology, including transcription factor activity, localization, and modification [73], as well as epigenetic regulation of gene expression by methylation [74,75], mRNA stabilization [76], and microRNA interactions [75,77,78]. Elucidating the precise molecular events underlying stellate cell activation and fibrogenesis is translating into fruitful new therapeutic approaches [69]. A growing repertoire of transcription factors cooperatively regulate gene expression through post-translational modification of regulatory proteins, particularly through phosphorylation. For example, stellate cell activation provokes phosphorylation of the RelA subunit of NF-κB at a specific serine residue (Ser^{536}) that leads to its nuclear import, resulting in increased NF-κB transcriptional activity [45], which increases survival of activated stellate cells. Treatment of either rodents with experimental fibrosis using an angiotensin-converting enzyme inhibitor, or humans with hepatitis C using an angiotensin receptor blocker, leads to reduced survival of activated stellate cells/myofibroblasts and regression of fibrosis by inhibiting this phosphorylation [45]. In an example of epigenetic regulation, myofibroblast activity can also be controlled by a microRNA, miR132, that releases a translational block on the methyl-CpG-binding protein, which in turn leads to repression of the peroxisome proliferator-activated receptor γ (PPARγ) transcription factor [75]. In a final example, phosphorylation of the transcription factor C/EBPb by the ribosomal S-6 kinase (RSK) is critical for stellate cell activation; this phosphorylation can be inhibited by cell-permeable peptides that block RSK and lead to cellular apoptosis [79].

Clinical aspects

Fibrosis progression and reversibility

There has been significant progress in our ability to predict the rate progression of fibrosis in an individual patient. Several general principles apply.

1. *Fibrosis usually requires at least several months to years of ongoing insult*. Three exceptions in adults are sinusoidal obstruction syndrome (SOS) (previously referred to as venoocclusive disease), subfulminant drug-induced liver injury, and mechanical biliary obstruction, in which fibrosis can progress more rapidly. In SOS, a dramatic deposition of ECM in pericentral zones associated with activated stellate cells can follow within weeks of myeloablative therapy, leading to rapid onset of ascites and possibly death [80]. In infants with neonatal obstruction, fibrosis can also develop in utero or within weeks of birth. Mechanisms underlying these examples of "fulminant fibrosis" remain obscure, but stellate cell activation and upregulation of fibrogenic cytokines accompany these fibrotic states as they do in more common forms of hepatic fibrosis.
2. *The severity of inflammation, necrosis, and injury usually correlate with the rate of progression*, as documented in studies of alcoholic liver disease and hepatitis C [81]. Indeed, patients with persistently normal alanine aminotransferase and HCV are less likely to progress [82], indicating decreased overall necroinflammation during the course of their disease.
3. *Concurrent hepatic insult by more than one agent is synergistic for the progression of fibrosis*. This has been especially well documented in patients with HCV infection who abuse large amounts of alcohol but is also true for those with viral coinfection, including hepatitis B virus (HBV) with either HCV or hepatitis delta virus (HDV) [83], as well as HCV with human immunodeficiency virus (HIV) [84]. In patients with HIV/HCV coinfection, direct effects of HIV proteins on stellate cells probably contribute to accelerated fibrosis [85].

   Iron overload, whether primary or secondary, is also a risk factor for fibrosis progression [86]. In genetic hemochromatosis and rodent models of iron overload, a threshold iron concentration of 22,000 μg/g of dry weight has been identified. Higher iron content also correlates with increased inflammation and fibrosis, and synergizes inflammation. Increased steatosis is associated with increased fibrosis in patients infected with HCV or in those who have NASH. Other risk factors for fibrosis in patients with NASH include older age, obesity, and the presence of diabetes mellitus.
4. *Genetic risk is an important predictor of fibrosis progression, independent of other factors.* Fibrosis progression is strongly driven by genetic factors that can be identified by simple tests already available for clinicians. A large number of genetic markers have been uncovered that reportedly correlate with fibrosis progression rate, primarily in hepatitis C [52,87–89]. Among these, a seven-gene *cirrhosis risk score* (CRS), comprised of seven single nucleotide polymorphisms (SNPs) combined into a scoring system, is strongly

associated with fibrosis progression [90], and has been validated in two separate large prospective cohorts [91,92].

In addition to testing genetic markers in multiple populations, a key to establishing their relevance is to link these DNA sequence changes to altered pathways of disease pathogenesis, thereby providing a mechanism to explain the impact of the SNPs on fibrosis. At least two of the SNPs within the CRS have been linked to altered stellate cell activity [67,93], as well as several other SNPs [52,94,95].

5 *Environment and behavioral factors contribute to fibrosis risk*. In addition to genetic determinants, associations between environmental or behavioral risk factors and fibrosis progression have also been strengthened. For example, recent studies have demonstrated a protective effect of both coffee [96,97] and caffeine [98]. The profibrotic effect may be due to antagonism of adenosine receptor activity, which in animal models reduces the fibrogenic activity of stellate cells [99]. Moreover, while until recently there were no data linking specific viral factors with fibrosis progression, two recent studies have demonstrated that hepatitis B genotype C [100], and hepatitis C genotype 3 [101] are both associated with more rapid fibrosis progression. The findings complement the well-known impact of HIV on accelerating fibrosis progression due to hepatitis C coinfection, as underscored by a recent study based on repeated liver biopsies in coinfected patients [84].

6 *The exact moment when fibrosis becomes irreversible is not known*, in terms of either a histologic marker or a specific change in the matrix composition or content. Dense cirrhosis, with nodule formation and portal hypertension, is generally considered irreversible, but more intermediate lesions can show remarkable reversibility. It is important to consider the possibility that even advanced stages of fibrosis/cirrhosis might be reversible as clinical trials of antifibrotics emerge. Moreover, just as fibrosis may progress over decades, the reversal of fibrosis may also require many years, a fact that will influence the design of antifibrotic trials. Irreversibility may be conferred by the density and acellularity of the septal scars, leading to the loss of sources of interstitial collagenases.

Reversibility of cirrhosis has now been well documented in a number of diseases including HCV, HBV, HDV, and alcoholic liver disease [102,103]. More importantly, regression of fibrosis following clearance of HCV leads to improved clinical outcomes and reduced portal pressure in some patients [104–106].

Animal studies have also yielded significant insight into the mechanisms of fibrosis regression. Sustained experimental liver injury by carbon tetrachloride (CCl_4) leads to delayed reversibility because of thick collagen bands, high levels of TIMP-1, and significant collagen cross-linking by tissue transglutaminase [107] or lysl oxidase 2, whose expression is increased in activated stellate cells. A major activity of TIMP-1 is to inhibit the apoptosis of activated stellate cells, thereby allowing these fibrogenic cells to persist in the injured liver [108], associated with sustained NF-κB signaling that provides an intracellular signal to preserve this activated state [109]. Mice that overexpress TIMP-1 in the liver indeed have a delayed regression of experimental fibrosis [110], reinforcing its role in preventing reversibility. In addition, extracellular survival signals, some of which are bound to surrounding ECM, may further prevent apoptosis.

7 *Cirrhosis is more than a single stage, with a variable risk of decompensation*. Not all patients with cirrhosis have a comparable prognosis, as some will remain stable for up to 10 years while others may decompensate in a short interval [111]. These variable outcomes are not accurately predicted by either histologic staging systems or standard clinical parameters in patients with either a low model for end-stage liver disease (MELD) or Child–Pugh score. However, a recent large-scale analysis from the HALT-C low-dose interferon trial indicated that common clinical and laboratory features may be predictive in patients with more advanced disease [112]. Moreover, some, but not all studies suggest that transient elastography (see below) may identify patients with a higher likelihood of esophageal varices [113], or hepatocellular carcinoma [114].

Among the candidate modalities for predictive tests, hepatic venous pressure gradient (HVPG), while an invasive test requiring technical expertise, is remarkably accurate in addressing this need. For example, a long-term study of patients enrolled in a trial for β-blockers to prevent variceal hemorrhage demonstrated that patients with a baseline HVPG of $\leq$10 mmHg had only a ~15% chance of decompensation during a follow-up of 8 years, whereas those patients with a baseline HVPG of >10 mmHg had a ~70% risk of decompensation over the same interval [115]. Remarkably, simple pathologic features on liver biopsy may provide surrogates for these divergent outcomes, in that smaller nodule size and thicker septae both indicate a higher risk of decompensation, presumably because they reflect a higher HVPG [116]. Interestingly, these same features are also characteristic of more advanced experimental cirrhosis, and when fibrosis regresses in these models the smaller nodules begin to expand and thickened septae become thinner [117].

As underscored in a recent review [111], the increasingly refined view of cirrhosis as more than one stage demands a reassessment of staging systems to create better ways of predicting prognosis and anticipating complications.

Diagnosis and assessment

Accurate assessment of the extent of fibrosis is essential to guide management and predict prognosis in patients with chronic liver injury. Histologic assessment of a liver biopsy specimen remains the "gold standard" for quantifying fibrosis, with increasing interest in the use of noninvasive markers to allow more frequent sampling and avoid the risks of percutaneous biopsy.

Histologic and morphometric methods

Three methods of assessment of histologic fibrosis are in widest use: the Ishak score, the Metavir score, and the Desmet/Scheuer staging system [118]. Each relies on a progressive development of periportal fibrosis, then septal fibrosis, and finally nodule formation. The key distinguishing feature is the presence of two cirrhotic stages (5 and 6) in the Ishak system, and only one (F4) in the Metavir system. Interobserver variation is low in both systems, especially if pathologists have been "trained" before the use of these systems. However, sampling error may exceed 30%, as demonstrated by a study in which laparoscopic biopsies were obtained from both lobes of patients with HCV, yet 33% of the 124 patients had differences of at least one stage between the two lobes [119]. Two key features determining the accuracy of liver biopsy are length and width, with a minimum of 2.5 cm generally required to achieve reproducible sampling. In a study from Paris using the Metavir scoring system, 65% of biopsies 15 mm in length were categorized correctly, which increased to 75% for a 25 mm liver biopsy specimen [120]. This same study estimated, using "virtual" biopsy lengths, that only biopsy specimens 4 cm or greater in length would reliably avoid sampling error. This is not possible, of course, but it emphasizes that liver biopsy is unlikely to completely overcome the inherent problem of an uneven distribution of fibrosis in the liver. This, combined with inadequate sample size, is a problem amplified by increasing reliance on the use of radiologists to obtain liver biopsies using automated devices that are especially narrow. At best, a biopsy captures only 1/50,000th of the liver, and, therefore, some sampling error would seem inevitable. Morphometric and computerized systems may yield data that are continuous rather than discontinuous, but if the tissue sample is not adequate, or there is uneven distribution of fibrosis, then these quantitative methods will not enhance the quality of the data obtained.

Immunohistochemical and in situ mRNA hybridization methods to identify specific matrix components or α-smooth muscle actin (to reflect the extent of stellate cell activation), can be employed for experimental studies. These methods may have some clinical utility in assessing fibrosis progression [121]. Semiquantitative or real-time polymerase chain reaction can be used to measure mRNA transcripts for several cytokines and matrix components, for example PDGF and TGF-β1. This method has potential use for the analysis of liver biopsies because it may be more sensitive in assessing fibrogenesis than the evaluation of tissue sections stained for ECM. However, even when accurate, this method reflects mRNA levels and not protein levels, and the two may not always correlate.

Noninvasive methods

There is an urgent need for a noninvasive diagnostic procedure for liver fibrosis because this is currently the main limitation of drug testing in clinical trials. Assessment of fibrosis progression can be valuable in hepatitis C disease for at least four reasons:

1. The actual stage of fibrosis will indicate the likelihood of response to interferon-α or interferon-α/ribavirin because patients with advanced stages of fibrosis (Metavir F3 or F4) generally have a lower response rate to antiviral therapy.
2. If little fibrosis progression has occurred over a long interval, then treatment with antiviral therapy may be deemed as less urgent, and it may be safe to await more effective and/or better tolerated therapy.
3. The approximate time to the development of cirrhosis can be estimated.
4. As antiviral and antifibrotic therapies are refined, they will be most appropriately tested in "proof of principle" trials in patients who are at highest risk for progression in the absence of any treatment. This would not, however, indicate if/when clinical liver failure would eventuate, which may be delayed for up to a decade or more after the establishment of cirrhosis [115]. Accurate prediction of fibrosis progression will help identify those patients in whom the efficacy of an antifibrotic drug will be more easily uncovered in a controlled trial compared with placebo-treated control patients who have similar risk factors.

There has been a considerable effort to identify serum markers as noninvasive measures for the diagnosis of hepatic fibrosis. Although their accuracy and predictive value are improving, they have not yet supplanted direct analysis of the liver. The *ideal fibrosis marker* is one that is specific, biologically based, noninvasive, easily repeated in all patients, well correlated with disease severity and outcome, and not confounded by co-morbidities or drugs. Although this ideal has not yet been reached, progress can be anticipated on the basis of the advances to date and the intense interest in this area.

Serum markers of matrix molecules or modifying enzymes

There has been a major effort to identify serum markers as noninvasive measures of hepatic fibrosis. Although their

accuracy and predictive value are improving, they cannot fully supplant direct analysis of liver. Thus far, no serum test has emerged as the perfect marker of fibrosis.

Serum markers have some limitations:

1 They typically reflect the rate of matrix turnover, not deposition, and therefore tend to be more elevated when there is high inflammatory activity. In contrast, extensive matrix deposition can go undetected if there is minimal inflammation.
2 None of the molecules are liver-specific, so extrahepatic sites of inflammation may contribute to elevated serum levels.
3 Serum levels are affected by clearance rates, which may be impaired because of either sinusoidal endothelial cell dysfunction or impaired biliary excretion.
4 They are surrogates, not biomarkers, of fibrosis.

Currently, two commercial serum marker systems have been extensively validated, the FibroTest® (marketed in the United States by Labcorp) [122,123] and the enhanced liver fibrosis (ELF) markers, utilizing a diagnostic algorithm and assays by Siemens Diagnostics [124]. In addition, a growing list of other noninvasive tests have been developed using a variety of standard serum hematologic or chemistry parameters in varying combinations [122,125].

To date there are only modest differences among the major serum assays, depending on the distribution of fibrosis severity and other factors [126,127], and their overall value can be summarized as follows:

1 The tests are extremely accurate (>95%) in determining the near absence (F0 or F1) of fibrosis in hepatitis C or the presence of cirrhosis, but are less accurate in intermediate stages of fibrosis. Therefore, in select clinical circumstances, the findings from these tests may obviate the need for biopsy, or may help guide decisions about treatment with antiviral combinations. Less is known about their value in patients with other forms of liver disease apart from hepatitis C, but data are beginning to emerge.
2 They suffer from a variable but significant number of indeterminate outcomes (up to 50% with the FibroTest).
3 There is no evidence yet that any test can discern changes in fibrosis content over time in an individual patient.
4 These tests are, however, proving valuable in cohort studies, in which mean changes in serum values among a group of patients correlate with changes in fibrosis.

Moreover, they are more accurate than biopsy in predicting clinical outcomes [128,129], and show improvement when underlying HCV is cleared [130].

Overall, the serum assay approach is gaining value and appeal, in part because these tests may represent an "integrated" readout of liver activity rather than a minute sampling of the type obtained by conventional liver biopsy. Continued refinements are likely, and serum assays already have established an important niche, especially in patients who have a high risk of complications from liver biopsy or in those with liver disease not under the care of a hepatologist/gastroenterologist (e.g., patients coinfected with HCV/HIV). Their appeal also lies in the diminishing fraction of gastroenterologists and hepatologists who remain skilled in performing percutaneous liver biopsy.

Proteomics and glycomics

A different approach is the analysis of patterns of either protein or glycoprotein peaks, as assessed by mass spectroscopy of serum samples. These methods clearly represent "surrogate" markers and, in fact, the identities of the peaks are generally not known. None of these methods have yet reached the stage of widespread clinical testing and validation, however.

In summary, there remains for a need for improved noninvasive markers that accurately reflect the matrix content of the tissue and have better prognostic accuracy than standard clinical and laboratory indices such as the Child–Pugh or MELD classifications, which are only applicable to patients with cirrhosis.

Therapy

General considerations

The improved understanding of mechanisms underlying hepatic fibrosis makes effective antifibrotic therapy an emerging reality. However, treatment will remain a challenging task, and thus far no drugs have been approved as antifibrotic agents in humans. Therapies will have to be well tolerated over decades, with good targeting to the liver, and few adverse effects on other tissues. Combination therapies may prove synergistic rather than additive, but agents must first be tested individually to establish safety and "proof of principle." It is uncertain whether antifibrotic therapies will require intermittent or continuous administration. For putative agents, evidence of a direct antifibrotic effect must be established in experimental models rather than only an indirect effect by abrogating the injury. Candidate therapies must be effective in a liver that is already damaged – as in clinical liver disease – rather than only before the onset of injury. Antifibrotic therapies also carry the theoretical concern that inhibiting the scarring response will prevent the encapsulation of injured regions, leading to extension of tissue damage. In reality, however, antifibrotic therapies only need to downregulate the scar response to be effective, and in patients with cirrhosis it is the scarring, not injury, that usually leads to liver failure.

Antifibrotic therapies: rationale and specific agents

The paradigm of stellate cell activation provides an important framework to define sites of antifibrotic therapy (Box 12.2) [131,132]. The rationale is as follows: (i) cure the primary disease to prevent injury; (ii) reduce inflammation or the host response to avoid stimulating stellate cell activation; (iii) directly downregulate stellate cell activation; (iv) neutralize proliferative, fibrogenic, contractile, and/or proinflammatory responses of stellate cells; (v) stimulate apoptosis of stellate cells; and (vi) increase the degradation of scar matrix, either by stimulating cells that produce matrix proteases, downregulating their inhibitors, or by direct administration of matrix proteases.

We are still lacking a "proof of principle" trial that establishes the value of targeting fibrosis directly in the presence of ongoing liver disease. Despite this obstacle, the number of potential therapies is expanding rapidly, and the potential for antifibrotic therapies has been embraced by the pharmaceutical and biotech sectors, and by the public (reviewed in [131,133,134]). Moreover, exciting prospects for targeting either diagnostic agents or therapies directly to stellate cells may enhance efforts to improve both the diagnosis and treatment of hepatic fibrosis [135,136].

Primary disease cure

The most effective way to eliminate hepatic fibrosis is to clear the primary cause of liver disease. This includes abstinence in alcoholic liver disease, removal of excess iron or copper in precirrhotic genetic hemochromatosis or Wilson disease, clearance of HBV or HCV in chronic viral hepatitis, eradication of organisms in schistosomiasis, or decompression in mechanical bile duct obstruction. Not to be overlooked, weight loss through either diet and exercise, or bariatric surgery in patients with NASH [137], or even those with HCV who are overweight, may improve histology and is a simple recommendation. Eventual identification of the pathogenetic mechanisms underlying primary biliary cirrhosis and sclerosing cholangitis could lead to the elimination of bile duct injury and periductular fibrosis.

Reduction of inflammation and the immune response

Reduced fibrosis and improved clinical outcomes have been reported in patients with HCV successfully treated with pegylated interferon-α and ribavirin [105], presumably through its effect on viral replication and liver injury. Unfortunately, there was no long-term benefit on fibrosis or outcomes of low-dose maintenance interferon in the large multicenter HALT-C trial [138].

Box 12.2 Therapeutic strategies for hepatic fibrosis.

Reducing injury and inflammation

- Antiviral therapy for viral hepatitis
- Antihelminthic therapy for schistosomiasis
- Chelation/venesection, treatment of metabolic disease
- Angiotensin II type I receptor antagonists, ACE inhibitors
- Hepatoprotectants, e.g., HGF/HGF mimetics
- Corticosteroids for autoimmune disease
- Ursodeoxycholic acid for primary biliary cirrhosis

Attenuating stellate cell activation

- Antioxidants
- Vitamin E, PDTC
- Angiotensin II type I receptor antagonists
- Cytokine-directed therapy
- TGF-β antagonists
- Endothelin receptor antagonists
- HGF
- FXR agonists
- Aldosterone antagonists
- Pentoxyphylline

Inhibiting properties of activated stellate cells

- Antiproliferative
- PDGF and tyrosine kinase receptor antagonists
- Sodium exchange inhibitors
- Plasmin/thrombin receptor antagonists
- Anticontractile
- Endothelin/endothelin receptor antagonists
- Nitric oxide donors
- Antifibrogenic
- Collagen synthesis inhibitors
- TGF-β inhibitors (soluble receptors, neutralizing antibodies)
- HGF/HGF mimetics
- Angiotensin II type I receptor antagonists
- ACE inhibitors
- Integrin antagonists
- Smad 7 agonists
- Cannabinoid receptor 2 antagonists

Promoting specific apoptosis of hepatic stellate cells

- Gliotoxin
- Sulfasalazine
- Nerve growth factor agonists
- TIMP antagonists

Degrading scar matrix

- Direct collagenase administration
- Inhibitors of transglutaminase or collagen cross-linking
- TIMP antagonists
- TGF-β inhibitors

ACE, angiotensin-converting enzyme; FXR, farnesyl X receptor; HGF, hepatocyte growth factor; PDGF, platelet-derived growth factor; PDTC, pyrrolidine dithiocarbamate; TGF-β, transforming growth factor β; TIMP, tissue inhibitor of metalloproteinase.

A number of other agents have anti-inflammatory activity in vitro and in vivo, which may eliminate the stimuli for stellate cell activation. Corticosteroids have been used for decades to treat several types of liver disease, in particular autoimmune hepatitis. Their activity is solely as anti-inflammatory agents, with no direct antifibrotic effect on stellate cells. Antagonists to TNF-α or NF-κB modulators have some rationale, as do a growing number of biologically active agents currently used in other chronic inflammatory diseases, in particular inflammatory liver disease. Pentoxyphylline may exert its antifibrotic activity by downregulating TNF-α signaling, although an effect on renal blood flow seems more likely in patients with cirrhosis [139]. Other efforts to neutralize inflammatory cytokines include the use of integrin antagonists, which may limit injury and/or fibrogenesis [140].

The renin–angiotensin system may also amplify inflammation through the generation of oxidant stress, and therefore either angiotensin-converting enzyme antagonists and/or angiotensinogen II type I receptor antagonists may have anti-inflammatory and antifibrogenic activity [141,142].

A new class of drugs, broadly referred to as *hepatoprotectants*, are showing considerable promise in preclinical and clinical studies, including HGF, HGF deletion variants, and HGF synthetic mimetics [143]. HGF's antifibrotic activity is mediated at least in part through suppression of fibrogenic signaling [144]. Trials in large animals and humans are anticipated, with careful monitoring planned to screen for potential hepatocarcinogenesis because HGF is a hepatocyte mitogen.

Inhibition of stellate cell activation

Reducing the transformation of quiescent stellate cells to activated myofibroblasts is a particularly attractive target, given its central role in the fibrotic response. The most practical approach is to reduce oxidant stress, which is an important stimulus to activation. Antioxidants, including α-tocopherol (vitamin E), have recently shown benefit in a large multicenter trial among patients with NASH [145]. Other antioxidants can also reduce stellate cell activation in culture, which provides a rationale for antioxidant trials in humans, although more potent formulations than those currently available may be required.

Silymarin, a natural flavonoid component of the milk thistle *Silybum marianum*, has sparked interest as a potential antifibrotic therapy. The compound functions as an antioxidant and may decrease hepatic injury and fibrosis [146]. However, there is no conclusive evidence of antifibrotic efficacy from human clinical trials.

The cytokine interferon-γ has inhibitory effects on stellate cell activation in animal models of fibrosis. However, a clinical trial of interferon-γ did not show any antifibrotic benefit in patients with HCV [147].

PPARγ nuclear receptors are expressed in stellate cells, and synthetic PPARγ ligands (thiazolidinediones) downregulate stellate cell activation. Disappointingly, a recent clinical trial showed no antifibrotic benefit in patients with HCV [121]. Farnesoid X receptor (FXR) ligands appear to have similar effects and small molecule agonists are under study in preclinical models, with evidence of antifibrotic activity [148].

Leptin, produced by activated stellate cells, not only affects lipid metabolism but also directly stimulates wound healing. In fact, animals deficient in leptin have reduced hepatic injury and fibrosis [54]. On the basis of this finding, the discovery of adiponectin, a natural counterregulator to leptin, may lead to its use as an antifibrotic, particularly in patients with NASH [53].

Cannabinoid (CB1) receptor antagonists have consistently shown antifibrotic activity in animal models, and a human trial showed equal promise in patients with NASH [149,150]. However, the drug Rimonabant®, a CB1 receptor antagonist, was associated with high rates of depression that led to discontinuation of clinical trials. However, efforts are now underway to develop CB1 antagonists that do not cross the blood–brain barrier, which may prove highly effective in liver disease and will be better tolerated.

Progress in understanding transcriptional regulation has offered the opportunity to block stellate cell activation by inhibiting the activity of histone deacetylases (HDACs), enzymes critical for modifying chromatin during gene transcription. Highly specific HDAC inhibitors offer the potential for selectively blocking stellate cell activation with tolerable safety and good efficacy [151], but none has reached clinical use. Similarly, modulation of intracellular proteins including transcription factors remains an interesting but elusive target of antifibrotic therapy.

Herbal therapies and products derived from natural compounds that are commonly used in the Far East are increasingly being tested under controlled, scientifically rigorous conditions [152]. Some show promise of efficacy, in particular Sho-saiko-to, *Salvia miltiorrhiza*, and a green tea polyphenol.

Neutralization of proliferative, fibrogenic, contractile, and/or proinflammatory responses of stellate cells

Significant advances in growth factor biology will benefit the treatment of hepatic fibrosis through the development of antagonists to cytokines and their receptors. In particular, many proliferative cytokines including PDGF, FGF, and TGF-α signal through tyrosine kinase receptors, inhibitors of which are already undergoing clinical trials in other tissues [153,154].

Inhibition of matrix production has been the primary target of most antifibrotic therapies to date. This has been attempted directly by blocking matrix synthesis and processing, or indirectly by inhibiting the activity of TGF-β1, the major fibrogenic cytokine. Inhibitors of collagen synthesis such as HOE 077, which blocks the enzyme prolyl hydroxylase, were among the first antifibrotic compounds tested in liver diseases, but success with this agent has been modest. The emerging importance of translational regulation of collagen gene expression could lead to specific translational inhibitors with therapeutic value. Colchicine generated excitement at one time because of its apparent efficacy in a small group of patients; however, a more recent study of its use in alcoholic cirrhosis showed no benefit [155].

TGF-β antagonists are being extensively tested because neutralizing this potent cytokine would have the dual effect of inhibiting matrix production and accelerating its degradation Animal and culture studies using soluble TGF-β receptors or other means of neutralizing the cytokine, including monoclonal antibodies and protease inhibitors to block TGF-β activation, have established proof of principle [156]. There are concerns that inhibiting TGF-β may stimulate hepatocellular growth and enhance the risk of cancer, which could limit their utility. A number of even newer TGF-β antagonists are also being developed and may undergo testing soon. These could include recombinant Smad 7 [157], which antagonizes TGF-β activity in stellate cells, and integrin antagonists that block cell surface TGF-β activation [140].

Relaxin, a natural peptide hormone that mediates parturition, has been developed as an agent that decreases collagen synthesis by stellate cells and increases matrix degradation in vitro and in vivo. Stellate cells also express relaxin receptors which might represent an attractive target for antagonism [158,159].

Because endothelin-1 is an important regulator of wound contraction and blood flow regulation mediated by stellate cells, antagonists have been tested as both antifibrotic and portal hypotensive agents [160]. Bosentan, a mixed endothelin A and B receptor antagonist, has antifibrotic activity and reduces stellate cell activation in experimental hepatic fibrosis. This and other endothelin antagonists remain attractive drug development targets although some hepatotoxicity has been observed in clinical trials in patients with pulmonary disease.

Halofuginone, an anticoccidial compound, has antifibrotic activity by blocking collagen expression, and has been used in a number of models of tissue fibrosis, including the liver [161].

The potential utility of retinoids (vitamin A) as antifibrotic therapy has been limited by inadequate knowledge about their regulatory role in stellate cell activation, and by toxicity concerns. Although stellate cells export retinoid as they activate, it does not follow that restoration of cellular retinoid will prevent activation. In fact, some retinoids may accelerate fibrosis by augmenting membrane injury, for example in patients with hypervitaminosis A.

Stimulation of stellate cell apoptosis or senescence

Attention is increasingly focused on how liver fibrosis regresses, and in particular the fate of activated stellate cells as fibrosis recedes. Mounting evidence indicates that either reversal of the activated stellate cell phenotype or stellate cell senescence and apoptosis all occur in vivo [162,163]. In particular, as liver fibrosis is decreased, there is selective cell death of activated stellate cells. This exciting observation has led to animal studies using either gliotoxin or sulfasalazine, which provoke selective apoptosis of stellate cells in culture and in vivo, leading to reduced fibrosis [162,164]. A TIMP-1 neutralizing antibody has antifibrotic activity in experimental liver fibrosis [165], which also accelerates stellate cell apoptosis.

Degradation of scar matrix

This component of treatment is very important because antifibrotic therapy in human liver disease will need to provoke resorption of existing matrix, in addition to preventing the deposition of new scar. As noted in the preceding text, TGF-β antagonists have the advantage of stimulating matrix degradation by downregulating TIMPs and increasing net activity of interstitial collagenase. Retinoids may also stimulate matrix degradation but concerns over toxicity limit their utility. Relaxin can directly increase matrix degradation.

Direct expression of metalloproteinases in animal models of hepatic fibrosis has begun to confirm that matrix can be resorbed through the expression of exogenous enzymes [166]. Although this may seem impractical in humans, data have established the important proof of principle that hepatic ECM is responsive to degradation. Moreover, an experimental study has affirmed the importance of matrix degradation in the regression of hepatic fibrosis by demonstrating that a genetically altered mouse expressing mutant collagen resistant to degradation displayed delayed regression of fibrosis after liver injury [167].

Future prospects

Continued progress can be anticipated in unraveling the molecular regulation of fibrosis and its treatment. Rapid advances in gene therapy, tissue-specific targeting, and high-throughput small molecule screening of cytokine inhibitors are likely to benefit the diagnosis and therapy

of hepatic fibrosis. New insights into the regulation of growth, apoptosis, and intracellular signaling by cytokines, adipokines, and hormones could have direct implications for stellate cell behavior in liver injury. Additionally, there is tremendous interest in herbal and natural antifibrotic remedies, particularly in the Far East, where many such compounds are undergoing clinical trials. Accelerating progress is certain once methods of noninvasive diagnosis are established that enable rapid assessment of fibrosis in clinical trials, and ultimately in clinical practice.

CHAPTER 13

Preoperative Evaluation of the Patient with Liver Disease

Lawrence S. Friedman

Department of Medicine, Newton-Wellesley Hospital, Newton, MA, USA

Key concepts

- The diseased liver is particularly susceptible to the hemodynamic and hypoxic insults that may accompany anesthesia and surgery.
- Anesthesia, including spinal and epidural anesthesia, reduces hepatic blood flow and can precipitate hepatic decompensation in persons with liver disease. Certain anesthetic agents, particularly those that undergo little hepatic metabolism, are preferable in patients with liver disease.
- In general, elective surgery is contraindicated in patients with acute hepatitis, acute liver failure, or alcoholic hepatitis.
- In patients with cirrhosis, surgical risk has traditionally been predicted by the Child–Pugh class. The model for end-stage liver disease (MELD) score appears to provide a more precise estimate of surgical risk.
- Certain operations, particularly biliary tract surgery, cardiac surgery, and hepatic resection, as well as emergency surgery, pose particular risk in patients with cirrhosis.
- Careful preoperative preparation, including management of ascites, renal dysfunction, encephalopathy, coagulopathy, and malnutrition, and close postoperative monitoring are critical to successful outcomes in patients with liver disease who undergo surgery.

Surgery is performed in patients with liver disease more frequently now than in the past, in part because of the long-term survival of patients with cirrhosis since the advent of liver transplantation and new measures to treat the complications of portal hypertension. Hemodynamic instability in the perioperative period can worsen liver function in patients with liver disease, who are at risk of hepatic decompensation. Considerable progress has been made in estimating perioperative risk in patients with liver disease. Operative risk correlates with the severity of the underlying liver disease and the nature of the surgical procedure. Thorough preoperative evaluation is necessary prior to elective surgery to estimate the risk of surgery and attempt to reduce it. Surgery is contraindicated in patients with acute hepatitis, acute liver failure, and alcoholic hepatitis. The Child–Pugh classification (Child–Turcotte–Pugh score) and particularly the model for end-stage liver disease (MELD) score (see Chapter 14) provide reasonable estimations of perioperative mortality in patients with cirrhosis. However, they do not replace the need for clinical judgment as well as careful preoperative preparation and postoperative monitoring; early detection of complications is essential for improving outcomes. Medical therapy for specific manifestations of hepatic disease, including ascites, renal dysfunction, and encephalopathy, should be optimized preoperatively and, if necessary, administered in the postoperative period.

Consequences of reduced hepatic blood flow, hypoxemia, and altered drug metabolism

Liver disease, especially cirrhosis, causes a hyperdynamic circulation with increased cardiac output and decreased systemic vascular resistance. At baseline, hepatic arterial and portal-venous perfusion of the cirrhotic liver may be decreased: arterial blood flow can be decreased because of impaired autoregulation, and portal blood flow is reduced as a result of portal hypertension. Moreover, patients with liver disease may have alterations in the systemic circulation, including arteriovenous shunting and reduced splanchnic inflow to the liver. The decreased hepatic perfusion at baseline makes the diseased liver more susceptible to the consequences of hypotension and hypoxemia in the operating room [1]. Anesthetic agents,

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

including spinal and epidural anesthesia, may reduce hepatic blood flow by 30–50% following induction and frequently lead to transient minor elevations in serum liver biochemical test levels in persons without liver disease [2]. Agents such as isoflurane, desflurane, and sevoflurane that cause less perturbation in hepatic arterial blood flow than other inhaled anesthetic agents are preferred in patients with liver disease. Propofol is another acceptable anesthetic agent in patients with liver disease; the elimination kinetic profile of propofol is similar in persons with and without cirrhosis, although recovery times are longer in those with cirrhosis [1].

Additional factors that may contribute to decreased hepatic blood flow perioperatively include hypotension, hemorrhage, and vasoactive drugs. Intermittent positive pressure ventilation and pneumoperitoneum during laparoscopic surgery mechanically decrease hepatic blood flow [3]. In addition, laparotomy with traction on the abdominal viscera may cause reflex dilatation of the splanchnic veins and thereby lower hepatic blood flow.

Risk factors for acute intraoperative hypoxemia in patients with liver disease include ascites, hepatic hydrothorax, hepatopulmonary syndrome (the triad of liver disease, an increased alveolar–arterial gradient, and intrapulmonary shunting), which is found in 5–32% of cirrhotic patients followed at transplant centers, and portopulmonary hypertension. Portopulmonary hypertension is found in up to 6% of patients with advanced liver disease and increases postoperative mortality after noncardiac surgery [4] (see Chapter 16). In general, ascites and hepatic hydrothorax should be treated preoperatively, and elective surgery should be avoided in patients with either hepatopulmonary syndrome or portopulmonary hypertension. During surgery, hypercarbia should be avoided in patients with liver disease because it initiates sympathetic stimulation of the splanchnic vasculature and thereby decreases portal blood flow.

The volume of distribution of nondepolarizing muscle relaxants is increased in patients with liver disease, and larger doses may therefore be required to achieve adequate neuromuscular blockade (see Chapter 28). Atracurium and cisatracurium are considered the preferred muscle relaxants in patients with liver disease because neither the liver nor the kidney are required for their elimination [1]. Vecuronium, rocuronium, and mivacurium are metabolized by the liver and must be used with caution in patients with liver disease. Doxacurium, which is metabolized by the kidney, is the preferred muscle relaxant for longer procedures such as liver transplantation. Sedatives and narcotics are generally tolerated in patients with compensated liver disease but must be used with caution in patients with hepatic dysfunction, because they may cause a prolonged depression of consciousness and precipitate hepatic encephalopathy. In general, narcotics and benzodiazepines should be avoided in these patients; however, when necessary, remifentanil (and possibly sufentanil and fentanyl) and oxazepam are the preferred narcotic and sedative, respectively, because the metabolism of these agents is unaffected by liver disease. Morphine, meperidine, alfentanil, and dexmedetomidine (an α_2-adrenergic agonist with sedative and analgesic properties) should be used with caution in patients with advanced cirrhosis [1,2].

Operative risk in patients with liver disease

In a patient with liver disease, surgical risk depends on the severity of liver disease, nature of the surgical procedure, and presence of co-morbid conditions. A number of conditions related to liver disease are contraindications to elective surgery (Box 13.1). When these contraindications are absent, patients should undergo a thorough preoperative evaluation, and their conditions should be optimized prior to elective surgery. Patients found to have advanced liver disease may benefit from alternative nonsurgical therapies when available and appropriate.

Once liver disease is identified in a patient in need of surgery, an assessment of the severity of liver disease should be undertaken, as should an evaluation for other known risk factors for perioperative mortality (Box 13.2). Data from studies of patients with cirrhosis suggest that the severity of liver disease can best be assessed by the Child–Turcotte–Pugh (CTP) score (Child–Pugh, or Child, class) and MELD score (see later). The majority of published studies describing operative risk in patients with liver disease derive from single-center, retrospective cohorts and involve patients with cirrhosis. These data are susceptible to limitations, including small cohort size, selection bias, and lack of external validation. Despite these limitations, the results of studies describing operative risk in patients with liver disease have been remarkably consistent. As one might expect, operative morbidity and mortality increase with increasing severity of liver disease, whether measured

by the Child–Pugh class or MELD score. In general, patients with compensated cirrhosis who have normal synthetic function have a low overall risk, and those with decompensated cirrhosis have a higher risk, which may be prohibitive in patients with severe hepatic decompensation.

Conditions for which elective surgery is generally contraindicated

Acute hepatitis

Patients with acute hepatitis of any cause have an increased operative risk [2] (see Chapters 23–25). This conclusion is based on data from older studies, in which operative mortality rates of 10–13% were reported among patients who underwent laparotomy to distinguish intrahepatic from extrahepatic causes of jaundice [5]. Although diagnostic and surgical techniques have improved since these studies were published, elective surgery is still considered contraindicated in patients with acute hepatitis. In most cases, acute hepatitis is either self-limited or treatable, and elective surgery can be undertaken after the patient improves clinically and biochemically.

Alcoholic hepatitis

Alcoholic hepatitis is a contraindication to elective surgery and greatly increases perioperative mortality after surgery [6] (see Chapter 26). In one retrospective series of patients with alcoholic hepatitis, the mortality rate was 58% among the 12 patients who underwent open liver biopsy, compared with 10% among the 39 who underwent percutaneous liver biopsy. Because only one death in the former group was secondary to intra-abdominal hemorrhage, open abdominal surgery, rather than liver biopsy, is likely to have been responsible for the high mortality rate.

Acute liver failure

Patients with acute liver failure (defined as the development of jaundice, coagulopathy, and hepatic encephalopathy within 26 weeks in a patient with acute liver injury and without preexisting liver disease) are critically ill (see Chapter 19). All surgery other than liver transplantation is contraindicated in these patients.

Operative risk assessment in patients with cirrhosis

Surgical risk is increased in patients with cirrhosis. The magnitude of perioperative risk correlates with the degree of hepatic decompensation. Additional factors may affect surgical risk and perioperative management depending on the underlying cause of chronic liver disease (Box 13.3).

Stratification by Child–Pugh class

Since the 1970s, the standard for assessing perioperative morbidity and mortality in patients with cirrhosis has been the CTP scoring system, which is based on the patient's serum bilirubin and albumin levels, prothrombin time, and severity of encephalopathy and ascites [2] (see Chapter 14). The studies that led to this standard have all been retrospective and limited to a small number of highly selected patients, but the results have been remarkably consistent. Two of the most important studies, separated by 13 years, reported nearly identical results: mortality rates for patients undergoing surgery were 10% for those with Child–Pugh class A, 30% for those with Child–Pugh class B, and 76–82% for those with Child–Pugh class C cirrhosis [7,8]. In a third study of patients with cirrhosis undergoing abdominal operations published in 2010, mortality rates for patients with Child–Pugh class A, B, and C cirrhosis were 2%, 12%, and 12%, respectively, suggesting that mortality has declined with improvements in the overall care of critically ill patients in the past decade [9]. In addition to predicting perioperative mortality, the Child–Pugh class correlates with the frequency of postoperative complications, which include liver failure, worsening encephalopathy, bleeding, infection, renal failure, hypoxia, and intractable ascites.

Box 13.3 Perioperative considerations in patients with various causes of chronic liver disease.

Chronic viral hepatitis
- HBV and HCV carrier states per se do not affect surgical risk; risk correlates with biochemical and histologic severity of hepatitis
- Interruptions in antiviral therapy should be avoided, if possible

Autoimmune hepatitis
- Surgical risk correlates with biochemical and histologic severity of hepatitis
- "Stress" doses of glucocorticoids may be required in the perioperative period

Nonalcoholic fatty liver disease
- Mortality rate is increased (7–14%) following hepatic resection in patients with moderate to severe hepatic steatosis; whether steatohepatitis increases the risk further is unclear
- Additional surgical risk is associated with obesity and diabetes mellitus

Alcoholic liver disease
- Alcoholic hepatitis is a contraindication to elective surgery
- Alcoholic fatty liver per se is not associated with increased operative risk, but abstinence for 6–12 weeks before surgery is advised because of adverse effects of alcohol on drug metabolism (e.g., acetaminophen, halothane) and the risk of alcohol withdrawal in the postoperative period

Hemochromatosis
- Cardiomyopathy associated with hemochromatosis increases surgical risk
- Associated diabetes mellitus may increase surgical risk

Wilson disease
- Informed consent may be challenging in patients with neuropsychiatric disease
- Surgery may precipitate or aggravate neurologic disease
- The dose of D-penicillamine should be decreased in the perioperative period to reduce the risk of poor wound healing

Alpha-1 antitrypsin deficiency
- Associated pulmonary disease may increase surgical risk

Cirrhosis
- Surgical risk correlates with Child–Pugh class and MELD score (see text)

HBV, hepatitis B virus; HCV, hepatitis C virus; MELD, model for end-stage liver disease.

In patients with Child–Pugh class A cirrhosis, the risk of perioperative morbidity is increased when there is associated portal hypertension. Postoperative morbidity in patients with portal hypertension and Child–Pugh class A cirrhosis, and possibly with Child–Pugh class B and C cirrhosis, has been reported to be reduced by preoperative placement of a transjugular intrahepatic portosystemic shunt (TIPS) [10–12].

Several other factors can increase the perioperative risk above and beyond the Child–Pugh class. Emergency surgery is associated with a higher mortality rate than that associated with nonemergency surgery, with comparative rates of 22% versus 10% for patients in Child–Pugh class A, 38% versus 30% for those in Child–Pugh class B, and 100% versus 82% for those in Child–Pugh class C in one study [8]. A diagnosis of chronic obstructive lung disease and surgery on the respiratory tract are also independent risk factors for perioperative mortality in patients with cirrhosis [13].

A general consensus is that elective surgery is well tolerated in patients with Child–Pugh class A cirrhosis, permissible with preoperative preparation in patients with Child–Pugh class B cirrhosis (except those undergoing cardiac surgery or extensive hepatic resection, see later), and contraindicated in patients with Child–Pugh class C cirrhosis.

Stratification by model for end-stage liver disease score

The MELD score was created to predict mortality after TIPS, then implemented to risk stratify patients awaiting liver transplantation, and more recently utilized to predict perioperative mortality [14]. The MELD score, a linear regression model based on a patient's serum bilirubin and creatinine levels and international normalized ratio (INR), has several distinct advantages over the Child–Pugh classification: it is objective, weights the variables, and does not rely on arbitrary cutoff values. Each 1-point increase in the MELD score makes an incremental contribution to operative risk, thereby suggesting that the MELD score increases precision in predicting postoperative mortality [15].

A number of studies have examined the MELD score as a predictor of surgical mortality in patients with cirrhosis. In a retrospective study of 140 patients with cirrhosis who underwent surgery, a 1% increase in mortality for each 1-point increase in the MELD score from 5 to 20 and a 2% increase in mortality for each 1-point increase in the MELD score above 20 was observed [16]. The largest study of the MELD score as a predictor of perioperative mortality (also retrospective), by Teh and colleagues [17], evaluated 772 patients with cirrhosis who underwent abdominal (other than laparoscopic cholecystectomy), orthopedic, and cardiovascular surgery. The patients' median preoperative MELD score was 8, and few had a MELD score greater than 15. In addition, most patients had a platelet count greater than 60,000 mm^3/L and an INR of less than 1.5. In this selected cohort, patients with a MELD score of 7 or less had a mortality

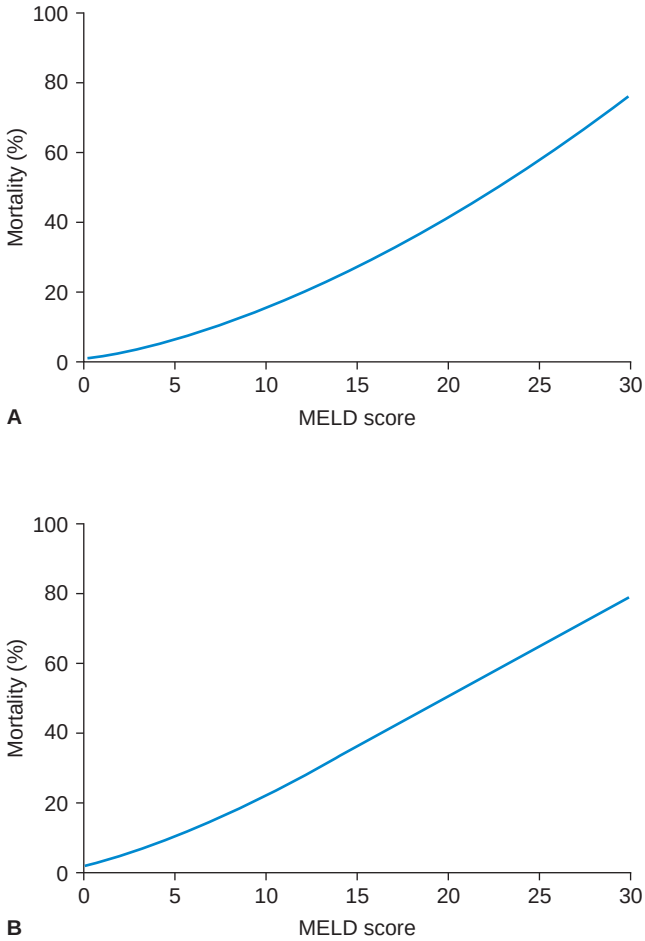

Figure 13.1 Relationship between operative mortality and model for end-stage liver disease (MELD) score in 772 patients with cirrhosis who underwent surgery in 1980–1990 and 1994–2004: (A) 30-day mortality; (B) 90-day mortality. For patients with a MELD score of >8, each 1-point increase in the MELD score was associated with a 14% increase in both 30-day and 90-day mortality rates. (Reproduced from Teh et al. [17] with permission from Elsevier.)

rate of 5.7%; patients with a MELD score of 8 to 11 had a mortality rate of 10.3%; and patients with a MELD score of 12 to 15 had a mortality rate of 25.4%. The increase in relative risk of death was nearly linear for MELD scores greater than 8 (Fig. 13.1).

In addition to the MELD score, an increasing American Society of Anesthesiologists (ASA) class (on a scale of I to V) and the age of the patient were shown by Teh et al. to contribute to the postoperative mortality risk (Box 13.4) [17]. Telem et al. [9] also found that an ASA class of more than III was a risk factor for morbidity and mortality. In the study by Teh et al. [17], an ASA class of IV added the equivalent of 5.5 MELD points to the mortality rate, whereas an ASA class of V was associated with a 100% mortality rate. The influence of the ASA class was greatest in the first 7 days after surgery, after which the MELD score became the principal determinant of risk. In this study [17], no patient under 30 years old died, and an age greater than 70 years added the equivalent of 3 MELD points to the mortality rate. Unlike studies that evaluated the ability of the Child–Pugh class to predict surgical mortality, emergency surgery was not an independent predictor of mortality when the MELD score was considered, because patients who underwent emergency surgery had higher MELD scores than those who underwent elective surgery.

Based on the study of Teh et al. [17], a website (http://www.mayoclinic.org/meld/mayomodel9.html) was developed that can be used to calculate estimated 7-day, 30-day, 90-day, 1-year, and 5-year perioperative mortality rates based on a patient's age, ASA class, INR, and serum bilirubin and creatinine levels (the last three items constitute the MELD score). Use of the MELD score and Child–Pugh class are not mutually exclusive, however, and the two scoring systems appear to complement one another. The MELD score is probably the more precise predictor of perioperative mortality. The study by Telem et al. [9] has further suggested that in patients with a MELD score of 15 or more, a low serum albumin level (≤2.5 mg/dL) is associated with a particularly high mortality rate (60%) compared with the rate in patients with a serum albumin level of >2.5 mg/dL (14%).

Box 13.4 American Society of Anesthesiologists (ASA) classification.

Class I	Healthy patient
Class II	Patient with mild systemic disease without functional limitation
Class III	Patient with severe systemic disease with functional limitation
Class IV	Patient with severe systemic disease that is a constant threat to life
Class V	Moribund patient not expected to survive >24 hours with or without surgery
Class E	Emergent nature of surgery (added to class I–V above)

Operative risk associated with specific types of surgery

In patients with cirrhosis, operative mortality is highest for biliary tract, cardiac, and hepatic resection surgery. The mortality rate is increased further when surgery is performed emergently. In patients with portal hypertension in particular, colectomy and gastric resection are also associated with a high operative risk.

Biliary tract surgery

Patients with cirrhosis are at increased risk of gallstone formation and associated complications when compared with noncirrhotic persons [18–21]. In a case–control study of patients who underwent laparoscopic cholecystectomy, a MELD score of ≥8 had a sensitivity of 91% and a specificity of 77% for predicting 90-day postoperative morbidity. In general, laparoscopic cholecystectomy is permissible for patients with Child-Pugh class A cirrhosis and selected patients with Child-Pugh class B cirrhosis without portal hypertension and is associated with lower rates of morbidity and blood transfusion and a reduced length of hospital stay compared with open cholecystectomy [20]. In contrast, in patients with Child–Pugh class C cirrhosis, cholecystostomy, rather than cholecystectomy, is recommended; when surgery is deemed the only option, an open rather than laparoscopic approach is recommended.

In patients with benign etiologies of obstructive jaundice or malignant causes that are not amenable to curative surgery, nonsurgical approaches to decompression via endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography are preferred. Before ERCP was widely used, a study of patients with obstructive jaundice indentified three predictors of perioperative mortality: a hematocrit value less than 30%, an initial serum bilirubin level greater than 11 mg/dL (200 μmol/L), and a malignant cause of obstruction [22]. When all three factors were present, the mortality rate approached 60%; when none was present, the mortality rate was only 5%. Not surprisingly, malignant biliary obstruction carried a dramatically higher operative mortality rate (26.1%) than benign biliary obstruction (3.7%). In addition, patients with obstructive jaundice are at increased risk of infection, disseminated intravascular coagulation, gastrointestinal bleeding, delayed wound healing, wound dehiscence, incisional hernias, and renal failure. In patients undergoing surgery for cancer of the pancreatic head, routine preoperative decompression of an obstructed biliary tract (at least with plastic stents) does not appear to reduce subsequent operative mortality and may increase the rate of complications [23]. Preoperative relief of biliary obstruction is indicated, however, in patients with acute cholangitis and in those with severe pruritus in whom surgery is delayed.

Although endoscopic sphincterotomy is associated with an increased risk of bleeding in patients with cirrhosis, morbidity and mortality rates for this procedure are low even in patients with Child–Pugh class C cirrhosis. In patients with coagulopathy or thrombocytopenia, endoscopic papillary balloon dilation is associated with a lower risk of bleeding than standard sphincterotomy and is preferred despite a possibly higher risk of acute pancreatitis [24].

Cardiac surgery

Cardiac surgery and other procedures that require the use of cardiopulmonary bypass are associated with greater mortality in patients with cirrhosis than are most other surgical procedures. Risk factors for hepatic decompensation following cardiac surgery include the use of cardiac bypass, total time on bypass, use of nonpulsatile as opposed to pulsatile bypass flow, and need for perioperative vasopressor support. In retrospective series of patients who underwent surgery requiring cardiopulmonary bypass, relatively low mortality rates were observed in those with Child–Pugh class A cirrhosis (0–11%), but rates were markedly increased in those with Child–Pugh class B (18–50%) and C (67–100%) cirrhosis. In addition, more than 75% of Child–Pugh class B and C patients experienced hepatic decompensation following surgery [25–27]. Increased mortality following cardiac surgery is also predicted by an increased MELD score. A MELD score greater than 13 predicts a poor prognosis, although no "safe" cutoff score has been established. In general, a CTP score of 7 or less (Child–Pugh class A) or a low MELD score suggests that cardiopulmonary bypass can probably be accomplished safely in patients with cirrhosis.

In addition to an elevated CTP or MELD score, clinically significant portal hypertension is a contraindication to cardiothoracic surgery. Portal decompression with TIPS placement may make the risk acceptable if the CTP and MELD scores remain low [28]. However, elevated right-sided cardiac pressures from cardiac dysfunction and pulmonary hypertension are absolute contraindications to TIPS placement. Several centers have reported successful outcomes of combined liver transplantation and cardiac surgery (including heart transplantation) in selected patients with advanced liver disease and severe heart disease [29].

Hepatic resection

Mortality rates as high as 25% are reported following hepatic resection in patients with cirrhosis [30] (see Chapter 37). Risk stratification based on the Child–Pugh class and MELD score has allowed more appropriate selection of patients, thus leading to lower mortality rates. In an analysis of 82 cirrhotic patients who underwent hepatic resection for hepatocellular carcinoma, the perioperative mortality rate was 29% in patients with a MELD score ≥9 but 0% in those with a MELD score ≤8 [31]. Another study of 94 cirrhotic patients who underwent hepatic resection for hepatocellular carcinoma reported mortality rates of 15.3% and 0% in those with a MELD score ≥10 and ≤9, respectively [32]. On the other hand, one study [33] identified Child–Pugh class and ASA class, but not MELD score, as significant predictors of outcome following liver resection. In this study [33], the mean MELD

score (6.5) was low, which likely limited the ability of the MELD score to discriminate between risk groups. In addition to predicting mortality, the MELD score can predict morbidity after liver resection. In one study [34], the frequency of post-liver resection liver failure was 0%, 3.6%, and 37.5% in patients with MELD scores of <9, 9–10, and >10, respectively. Additional predictors of mortality are the extent of hepatectomy and a low serum sodium concentration [35].

Post-resectional liver failure has been defined as a prothrombin time index (control prothrombin time divided by the patient's prothrombin time) of less than 50% (INR >1.7) and a serum bilirubin greater than 50 μmol/L (2.9 mg/dL), the so-called "50-50" criteria. When these criteria are met the postoperative mortality rate is 59%, compared with 1.2% in patients not meeting these criteria [36].

Endoscopic procedures

Endoscopy with moderate sedation is not contraindicated in patients with advanced cirrhosis, although coagulopathy may influence the approach to certain procedures such as polypectomy and sphincterotomy (see earlier). Variceal band ligation can be performed in patients with a high INR or thrombocytopenia. Gastrostomy tube placement should be avoided in patients with ascites, because of a high risk of leakage and infection, and in patients with visible abdominal wall collateral veins or enlarged intra-abdominal veins on imaging studies, because of the risk of bleeding.

Perioperative preparation

Every effort should be made to optimize the condition of a patient with liver disease prior to surgery. Ascites should be treated medically to avoid respiratory compromise, wound dehiscence, and abdominal wall herniation (see Chapter 17). In some cases, preoperative placement of a TIPS may be necessary. If abdominal surgery is undertaken, the ascites can be drained at surgery. The patient's volume status and renal function should be optimized to attempt to reduce the risk of hepatorenal syndrome in the postoperative period (see Chapter 15). Hepatic encephalopathy should be treated, but there is no evidence that prophylactic therapy in cirrhotic patients without encephalopathy in useful (see Chapter 18). In patients with cirrhosis, the INR correlates with impaired liver function but not with bleeding risk (see Chapters 12 and 14). Nevertheless, an attempt to improve coagulopathy with the administration of vitamin K, fresh frozen plasma, or both is often made. The use of recombinant factor VIIa in this setting is limited because of its high cost, transient effect, absence of data showing improved outcomes, and associated risk of thromboembolism. Maintenance of a low central venous pressure during surgery may reduce intraoperative blood loss [37]. Finally, patients with advanced liver disease are likely to have protein–energy malnutrition, which contributes to mortality and morbidity, and may benefit from nutritional supplementation, preferably via the enteral route, before surgery.

Postoperative monitoring

Postoperatively, patients with cirrhosis need to be monitored for the development of signs of hepatic decompensation, including ascites, renal dysfunction, encephalopathy, coagulopathy, and worsening jaundice. The prothrombin time is the single best indicator of hepatic synthetic function. An elevated serum bilirubin can indicate worsening hepatic function but can be elevated for other reasons, including blood transfusions, resorption of extravasated blood, or infection. Renal function must be monitored closely. Hypoglycemia may occur in patients with decompensated cirrhosis or acute liver failure as a result of depleted hepatic glycogen stores and impaired gluconeogenesis. Serum glucose levels should be monitored closely when postoperative liver failure is suspected. Careful attention should be paid to the patient's intravascular volume, which is often difficult to assess in the setting of extravascular volume overload. Maintenance of intravascular volume minimizes the risk of hepatic and renal underperfusion. On the other hand, infusion of too much crystalloid may lead to acute hepatic congestion, increased venous oozing, and pulmonary edema and to postoperative ascites, peripheral edema, and wound dehiscence.

Multiple choice questions

13.1 A 45-year-old man sees his primary care physician (PCP) prior to an elective left inguinal hernia repair. He has no other medical problems but drinks two or three cocktails a day and more on weekends. Other than the hernia and a body mass index of 28 kg/m^2, the physical examination is unremarkable. Routine laboratory studies show a serum alanine aminotransferase level of 25 U/L and aspartate aminotransferase level of 142 U/L. The serum alkaline phosphatase level is 101 U/L, total bilirubin level 1.3 mg/dL, and albumin level 3.7 g/dL. The international normalized ratio (INR) is 1.3. Which of the following would you advise the PCP regarding the planned inguinal hernia repair?

- **a** Proceed with surgery if serologic markers for viral hepatitis are negative.
- **b** Proceed with surgery if a repeat INR is 1.0 after administration of vitamin K.
- **c** Proceed with surgery after excluding diabetes mellitus and hypertriglyceridemia.
- **d** Repeat the laboratory studies in 2 weeks; proceed with surgery if the results are stable.
- **e** Cancel the surgery.

13.2 In a patient with cirrhosis who undergoes hepatic resection for hepatocellular carcinoma, postoperative liver failure and mortality are predicted by the "50–50" rule. Which of the following defines the rule?

- **a** Resection of 50% of the liver.
- **b** Resection of 50% of the liver plus a serum bilirubin level of >50 μmol/L.
- **c** A serum bilirubin level of >50 μmol/L plus a prothrombin time index of <50%.
- **d** An increase in the serum bilirubin level of 50 μmol/L and a decrease in the serum albumin level by 50% after surgery.
- **e** An increase in either the Child–Turcotte–Pugh score or the model for end-stage liver disease (MELD) score after surgery of 50%.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 14

Portal Hypertension: Nonsurgical and Surgical Management

Hitoshi Maruyama[1] *& Arun J. Sanyal*[2]

[1]Department of Medicine and Clinical Oncology, Chiba University Graduate School of Medicine, Chiba, Japan
[2]Division of Gastroenterology and Hepatology, Virginia Commonwealth University, Richmond, VA, USA

Key concepts

- Portal hypertension is the most common and lethal complication of chronic liver diseases. It is responsible for the development of gastroesophageal varices, variceal hemorrhage, ascites, renal dysfunction, portosystemic encephalopathy, hypersplenism, and hepatopulmonary syndrome.
- Portal hypertension is defined by a pathologic increase in portal pressure, in which the pressure gradient between the portal vein and inferior vena cava (the portal pressure gradient (PPG)) is increased above the upper normal limit of 5 mmHg. Portal hypertension becomes clinically significant when the PPG increases above the threshold value of 10 mmHg (e.g., formation of varices) or 12 mmHg (e.g., variceal bleeding, ascites). PPG values between 6 and 10 mmHg represent subclinical portal hypertension.
- PPG is determined by the product of blood flow and vascular resistance within the portal-venous system. Portal hypertension is initiated by an increased resistance to portal blood flow and aggravated by an increased portal-venous inflow. The site of increased resistance to portal blood flow is the basis for the classification of portal hypertension: prehepatic (e.g., portal vein thrombosis), intrahepatic (e.g., cirrhosis), and posthepatic (e.g., hepatic vein thrombosis, heart disease).
- Increased resistance in cirrhosis represents not only disruption of the liver's vascular architecture by liver disease but also a dynamic component resulting from the active contraction of vascular smooth muscle cells, myofibroblasts, and hepatic stellate cells. Active contraction is caused by decreased production of vasodilators such as nitric oxide (NO) and by increased release of endogenous vasoconstrictors. Increased hepatic vascular tone is the basis for the use of vasodilators to treat portal hypertension in cirrhosis.
- Portal inflow is increased by splanchnic vasodilatation, which is caused by an increased release of local endothelial factors and humoral vasodilators. Splanchnic vasodilatation can be counteracted with vasoconstrictors and β-blockers, which is why these drugs are used to treat portal hypertension.
- Portal pressure is most commonly assessed clinically by measuring the hepatic venous pressure gradient (HVPG), which is the difference between the wedged hepatic venous pressure (WHVP) and free hepatic venous pressure (FHVP), at hepatic vein catheterization. The HVPG accurately reflects the portal pressure in both alcoholic and viral cirrhosis. HVPG has to be above 10 mmHg for varices to develop and above 12 mmHg for variceal bleeding. The threshold values define "clinically significant portal hypertension."
- Bleeding from ruptured esophageal or gastric varices is a major complication of portal hypertension and a frequent cause of death. Approximately 40% of patients with compensated cirrhosis have varices at the time of diagnosis. The rate of formation of varices is approximately 8% per year, so varices develop in most patients during long-term follow-up. The risk of bleeding increases as the pressure and size of the varices increase and as the thickness of the variceal wall decreases. These parameters determine the tension of the variceal wall; rupture and bleeding occur when wall tension increases above the elastic limit of the varices.
- Most drugs used to treat portal hypertension are splanchnic vasoconstrictors, which act primarily by reducing portal and collateral blood flow. This group includes vasopressin, terlipressin, the somatostatins, propranolol, nadolol, and other β-blockers.
- Vasodilators that decrease the portal pressure include isosorbide-5-mononitrate (IMN), which acts as an NO donor, and adrenergic antagonists, such as clonidine, prazosin, and carvedilol. A common problem with vasodilators is that they cause arterial hypotension, which in turn may enhance sodium retention and aggravate renal dysfunction in patients with cirrhosis and ascites.
- In combination therapy, a vasoconstrictor and a vasodilator are administered together. The combination prevents most of the adverse effects of the vasodilator and enhances the fall in portal pressure caused by the reduction in blood flow induced by the vasoconstrictor. Drug combinations with proven clinical efficacy are vasopressin plus nitroglycerin and propranolol or nadolol plus IMN.

- Either nonselective β-blockers or endoscopic variceal ligation are the treatments of choice for the primary prevention of variceal bleeding. They should be given to all patients with medium or high variceal bleeding risk (patients with medium or large varices or those with small varices and red color signs or with poor liver function – Child–Pugh class B and C) who have no contraindications to β-blockers. Therapy should be maintained indefinitely and is relatively well tolerated; the rate of discontinuation because of side effects or poor tolerance is 15%. Patients with high-risk varices and contraindications to β-blockers should be treated with endoscopic band ligation.
- During acute variceal hemorrhage, general supportive therapy including antibiotic prophylaxis of bacterial infections and a very conservative use of blood transfusion should be instituted. The prognosis is worse in patients with advanced liver failure or with early (first week) rebleeding. Terlipressin and somatostatin are drugs that have proved effective as a first-line treatment in arresting variceal bleeding and reducing mortality from variceal hemorrhage. Drug therapy has been shown to be as effective as and safer than emergency endoscopic therapy. Drug therapy should be started early on arrival at the emergency room or even during transfer to the hospital. Endoscopic band ligation is the endoscopic treatment of choice for acute esophageal variceal bleeding; however, endoscopic injection sclerotherapy can be used in the acute setting if endoscopic band ligation is technically difficult. Drug therapy is usually continued for 3–5 days even if the bleeding is apparently controlled by endoscopic therapy. Endoscopic variceal obturation with tissue adhesives is recommended for acute fundal gastric variceal bleeding.
- Failures of medical treatment should be managed aggressively with emergency surgery or a transjugular intrahepatic portosystemic shunt (TIPS), preferably using expanded polytetrafluoroethylene (ePTFE) covered stents. Because of higher rates of morbidity and mortality, rescue derivative surgery should only be considered in low-risk patients (Child–Pugh score <8).
- A combination of β-blockers and band ligation is probably the best treatment option, especially in patients who have bleeding while under either therapy alone. Patients who rebleed despite combined endoscopic and pharmacologic treatment may be treated by transjugular intraheptic or surgical portosystemic shunting; TIPS is the only option in nonsurgical candidates. All Child–Pugh class C patients should be considered for liver transplantation.
- Patients who survive an episode of variceal bleeding are at high risk for rebleeding. Medical treatment with β-blockers ± isosorbide mononitrate is as effective as endoscopic band ligation in preventing rebleeding. The best results are obtained when the HVPG is reduced by at least 20% of the baseline value or below 12 mmHg. The combination of IMN and propranolol or nadolol significantly increases the number of patients in whom the target reduction in portal pressure is achieved.
- Variceal decompression is indicated for patients who fail primary therapy or who cannot undergo primary therapy. Decompression is performed with a transjugular intrahepatic portosystemic or surgical shunt.
- The occurrence of encephalopathy and liver failure after insertion of a shunt depends on the extent of liver disease and loss of portal perfusion.
- Devascularization procedures are a surgical alternative in the management of variceal bleeding in patients who cannot undergo shunting.
- Liver transplantation has significantly improved outcome among Child–Pugh class C patients with variceal bleeding, and is the only treatment that reliably prolongs life.

Anatomy and classification

The portal vein normally drains blood from the stomach, intestines, spleen, and pancreatic bed via the superior mesenteric, splenic, and left gastric veins (Fig. 14.1). The tributaries of the portal vein also communicate with veins draining into the systemic venous circulation with the following five portosystemic communications: (i) at the cardia via the intrinsic and extrinsic veins of the region; (ii) in the anal canal via anastomoses between the superior and middle hemorrhoidal veins; (iii) in the falciform ligament via recanalization of the paraumbilical veins and direction of flow to the veins draining the abdominal wall; (iv) in the splenic venous bed and the left renal vein; and (v) in the retroperitoneum. Among these communications, the gastroesophageal collaterals are of great clinical significance because they are associated with the development of gastroesophageal varices [1].

The veins draining the esophagus may be classified as intrinsic, extrinsic, and venae comitantes of the vagus nerve. The intrinsic veins include a subepithelial and submucosal plexus running along the length of the

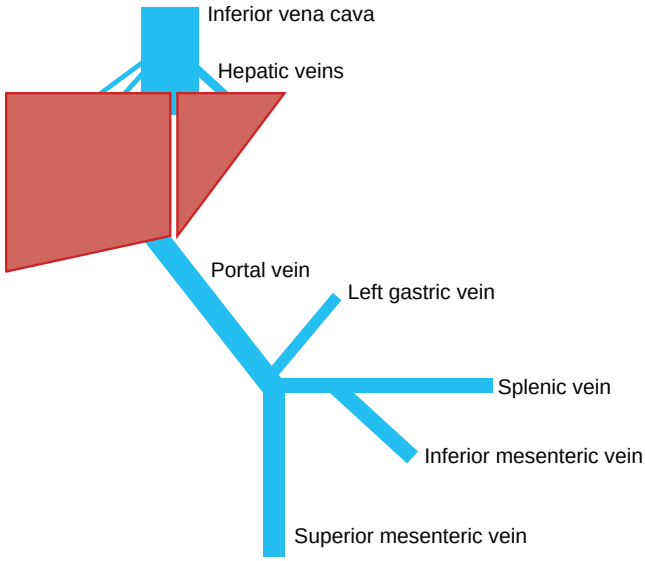

Figure 14.1 Anatomy of the portal-venous system. Although the flow direction of the portal vein, splenic vein, superior mesenteric vein, and inferior mesenteric vein is hepatopetal in normal subjects, it may change in cases of portal hypertension.

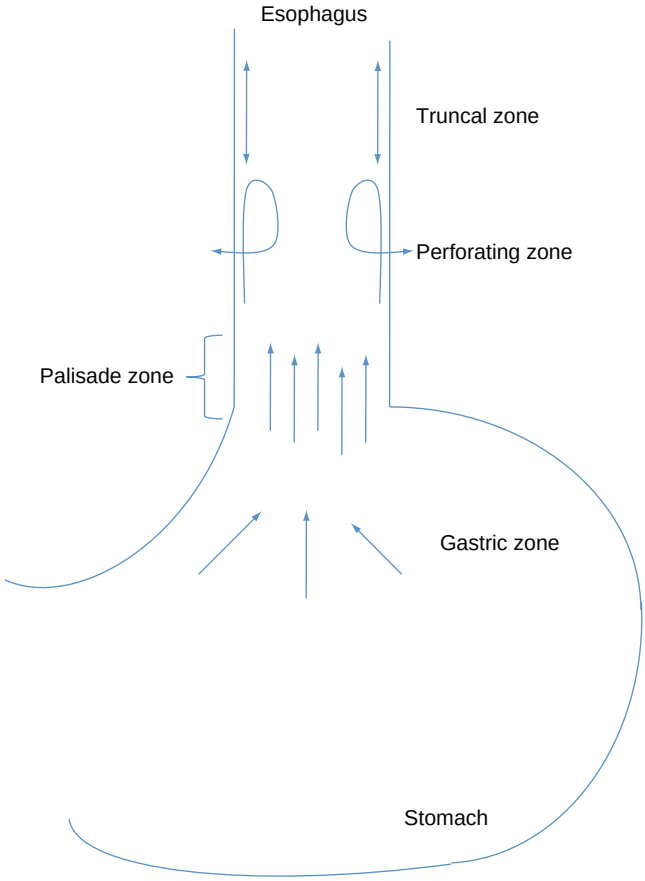

Figure 14.2 Venous anatomy of the gastroesophageal junction. There are four zones identified in this area: the gastric zone, palisade zone, perforating zone, and truncal zone. Increased venous blood flow in the palisade region causes varices.

esophagus. These drain via perforating veins into an extrinsic plexus of veins, which drain into the inferior thyroid and brachiocephalic veins in the neck, azygous veins in the thorax, and left gastric vein in the abdominal part of the esophagus.

The intrinsic veins of the gastroesophageal junction are divided into four well-defined zones (Fig. 14.2):

1 Gastric zone: this is a 2–3 cm zone with its upper border at the gastroesophageal junction and is composed of a radial band of veins in the submucosa and lamina propria.
2 Palisade zone: this commences at the gastroesophageal junction and extends cranially for 2–3 cm and is a direct extension of the veins of the gastric zone, which run in "palisades" or packs of longitudinally arrayed veins in the lamina propria. These veins are the primary site of communication between the portal bed and azygous bed.
3 Perforating zone: the intrinsic veins drain into the extrinsic veins primarily in this region via valved perforating veins, which only allow unidirectional flow normally. It extends 2–3 cm cranially from the palisade zone.
4 Truncal zone: an 8–10 cm zone extending upward from the perforating zone. The intrinsic veins are composed of three or four large venous trunks in the submucosa, which communicate with an irregular polygonal venous plexus in the submucosa. Flow direction in these veins is from a cranial to caudal direction and drains via the perforating veins into the extrinsic veins. In cases of portal hypertension, an adaptive increase in flow through the portasystemic communications occurs to return blood to the heart. The vessels involved, especially the intrinsic veins around the gastroesophageal (GE) junction dilate and become tortuous forming varicose veins.

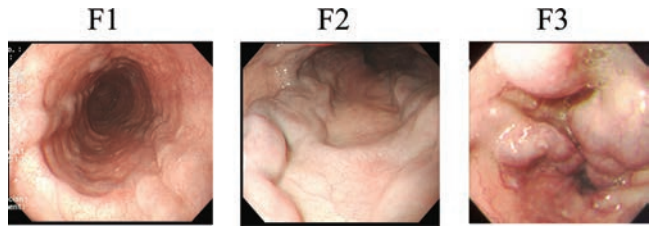

Figure 14.3 Endoscopic grade of esophageal varices, which are often graded by size, from F1 to F3. For details, see text.

Gastroesophageal varices show four basic patterns: (i) varices in the fundus of the stomach; (ii) gastric and palisade-zone varices; (iii) varices in the perforating zones; and (iv) paraesophageal varices, which involve the extrinsic esophageal veins. In contrast to normal individuals, the valves in the perforating veins become incompetent, thereby permitting reverse flow into the intrinsic plexus from the extrinsic veins. Clinically, GE varices are classified by location into esophageal and gastric varices.

Esophageal varices are often graded by size (Fig. 14.3). A common system is as follows:

- F1: small, straight varices.
- F2: enlarged, tortuous varices, occupying less than one third of the lumen.
- F3: large, coil-shaped varices, occupying more than one third of the lumen.

Gastric varices are classified primary by location. As agreed upon at the Baveno Consensus Conference, they are described as follows:

- Gastroesophageal varices (GOVs): gastric varices in continuity with esophageal varices:
  - type 1 (GOV1): along the lesser curve (usually 2–5 cm in length);
  - type 2 (GOV2): along the greater curve extending towards the fundus of the stomach.
- Isolated gastric varices (IGVs):
  - type 1 (IGV1): isolated cluster of varices in the fundus of the stomach;

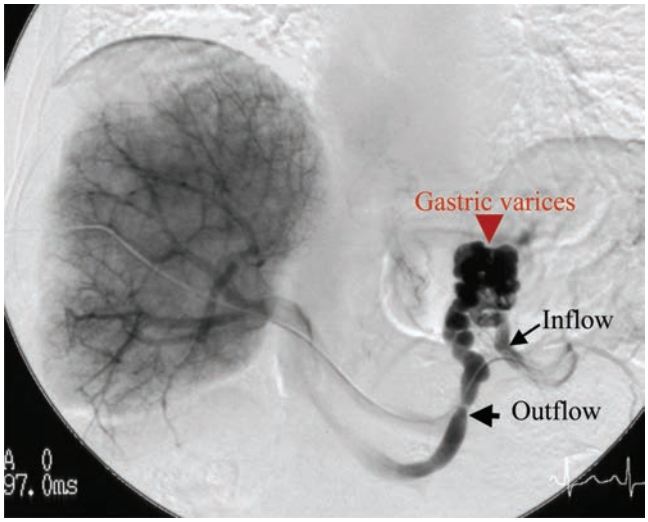

Figure 14.4 Angiographic feature of gastric varices. The portogram shows spontaneous collaterals from the splenic vein to the renal vein, feeding gastric varices. Thin arrow, inflow vessel; thick arrow, outflow route; arrow head, gastric varices.

- type 2 (IGV2): isolated gastric varices in other parts of the stomach.

GOV1 varices form when a branch of the left gastric vein penetrates the gastric wall (cardiac vein) and join the deep submucosal veins in the gastric zone; they are in direct continuity with those in the palisade zone and are usually associated with large esophageal varices. In contrast, large esophageal varices are present in only 50% of GOV2 varices. IGV1 are often associated with either segmental portal hypertension (splenic vein thrombosis) or the presence of spontaneous collaterals from the splenic vein to the renal vein, which feed these varices (Fig. 14.4). Almost half of cases with ectopic varices including IGV2 are associated with portal vein thrombosis.

Pathophysiology

The portal pressure is directly related to portal inflow and outflow resistance, expressed by the following formula:

$$\text{Portal pressure} = \text{portal-venous inflow} \times \text{outflow resistance}$$

Sites and common causes of portal hypertension are presented in Box 14.1. Free hepatic venous pressure (FHVP) and wedged hepatic venous pressure (WHVP) are measured by hepatic venous catheterization, and the hepatic venous pressure gradient (HVPG) is calculated by folloing formula:

$$\text{HVPG} = \text{WHVP} - \text{FHVP}.$$

Box 14.1 Etiology of portal hypertension.

Prehepatic

- Splenic vein thrombosis
- Portal vein thrombosis
- Congenital stenosis of the portal vein
- Extrinsic compression of the portal vein
- Arteriovenous fistulae (splenic, aortomesenteric, aortoportal, and hepatic artery–portal vein)

Intrahepatic

- Partial nodular transformation
- Nodular regenerative hyperplasia
- Congenital hepatic fibrosis
- Peliosis hepatis
- Polycystic disease
- Idiopathic portal hypertension
- Hypervitaminosis A
- Arsenic, copper sulfate, and vinyl chloride monomer poisoning
- Sarcoidosis
- Tuberculosis
- Primary biliary cirrhosis
- Schistosomiasis
- Amyloidosis
- Mastocytosis
- Rendu–Osler–Weber syndrome
- Liver infiltration in hematologic diseases
- Acute fatty liver of pregnancy
- Severe acute viral hepatitis
- Chronic active hepatitis
- Hepatocellular carcinoma
- Hemochromatosis
- Wilson disease
- Hepatic porphyrias
- α_1-Antitrypsin deficiency
- Cyanamide toxicity
- Chronic biliary obstruction
- Cirrhosis from hepatitis B and C virus infection
- Alcoholic cirrhosis
- Alcoholic hepatitis
- Venoocclusive disease

Posthepatic

- Budd–Chiari syndrome
- Congenital malformations and thrombosis of the inferior vena cava
- Constrictive pericarditis
- Tricuspid valve diseases

WHVP reflects sinusoidal pressures, while FHVP corrects for the effects of intra-abdominal pressures.

Portal hypertension is initiated by an increase in outflow resistance from the portal-venous bed, and it is further worsened by splanchnic arterial dilatation, which increases portal-venous inflow in cirrhosis. Once portal hypertension occurs, a collateral circulation develops to return blood to the systemic circulation. For a given

varice, the transmural pressure gradient is the product of flow and resistance: $P1 - P2 = Q \times R$, where $P1$ and $P2$ are the pressures within and outside the varices respectively, Q means the blood flow per unit time, and R means the resistance to flow through the varices.

Poiseuille's formula states that resistance to flow may be expressed as:

$$R = nl/\pi r^4,$$

where n is blood viscosity, and r and l are the length and radius of the vessel. The formula

$$\text{Wall tension} = [Q \times (nl/\pi r^4)] \times r/w$$

indicates variceal wall tension, which is determined by the transmural pressure, radius, and wall thickness (w) (Laplace's law). Variceal wall tension determines the probability of rupture. Based on this equation, long, large varices with high flow rates and thin walls are most likely to rupture and bleed. Conversely, by decreasing collateral flow, resistance to flow, or increasing wall thickness, the risk of variceal rupture should also be decreased. Most pharmacologic treatments are directed at decreasing collateral blood flow, which is usually achieved by decreasing portal pressure and/or increasing collateral resistance. However, the latter has complex effects on hemodynamics in collateral vessels by directly increasing wall tension and indirectly decreasing it by reducing collateral blood flow. This may explain some of the interindividual variability in hemodynamic response to pharmacologic treatment.

Vasoconstrictors and hepatic vascular bed

Endothelins (ETs) are a family of homologous 21-amino acid vasoactive peptides (ET-1, -2, and -3) that are thought to play a major role in modulating hepatic vascular tone in cirrhosis. The biologic properties of ETs are mediated essentially by two major ET receptors, ET-A and ET-B. The ET-A receptor shows a high affinity for ET-1, but not for ET-3, and mediates constriction; the ET-B receptor has equal affinity for ET-1 and ET-3. Activation of ET-B receptors located on the vascular smooth muscle cells promotes vasoconstriction, whereas activation of ET-B receptors located on endothelial cells promotes vasodilatation, which is mediated by enhanced nitric oxide (NO) and prostacyclin production by the endothelial cell.

Cirrhotic patients have increased circulating plasma levels of ET-1 and ET-3. The increase is greater and more consistently found in cirrhotic patients with ascites. A net release of ET-1 and ET-3 during splanchnic passage has been observed in cirrhotic patients but not in controls, suggesting an increased production of ET-1 and ET-3 in the splanchnic territory. Immunostaining and in situ hybridization studies have detected an increased expression of ET-1 in human cirrhotic livers; endothelial cells, hepatic stellate cells (in their activated phenotype), and bile duct epithelial cells are the major intrahepatic sources of ET-1. A decreased clearance of ET-1 by the liver has also been demonstrated in cirrhotic rats.

ET-1 increases portal pressure by increasing intrahepatic resistance in isolated, perfused normal livers and carbon tetrachloride-induced cirrhotic livers. Although some experimental studies reported a slight reduction of portal pressure in cirrhotic animals after the administration of ET antagonists, this was not confirmed by other studies [2]. Therefore, the role of ETs in increasing the vascular tone in cirrhosis remains unsettled.

Norepinephrine is one of the vasoconstrictive factors, and is involved in the regulation of hepatic vascular tone. The increased resistance promoted by norepinephrine is completely blunted by the administration of α-adrenergic antagonists, such as prazosin. These agents by themselves markedly reduce hepatic resistance and portal pressure in cirrhotic patients. In contrast, the administration of α-adrenergic agonists, such as isoproterenol, reduces intrahepatic vascular resistance in perfused cirrhotic liver. These data suggest that adrenergic receptors may be involved in the regulation of intrahepatic resistance in cirrhosis and that α-adrenergic receptor blockers may decrease portal pressure in cirrhosis. In addition, the hepatic vascular bed of cirrhotic livers exhibits an exaggerated response to the α-adrenergic agonist methoxamine. This hyperresponse is associated with the overproduction of thromboxane A_2 (TXA_2) by cyclooxygenase 1 (COX-1) isoenzyme and is completely corrected by pretreating the livers with nonselective COX blockers, COX-1-selective blockers, or TXA_2 antagonists. Therefore, an increased production of TXA_2 markedly enhances the vasoconstrictive response of the cirrhotic hepatic vascular bed to methoxamine. Whether this effect is also shared by other vasoconstrictors has not been investigated so far. However, it is known that the coupling of different agonists to the membrane G-coupled receptors promotes the release of arachidonic acid from the plasma membrane, facilitating its metabolization to different prostanoids.

Angiotensin II is a powerful vasoconstrictor that may increase hepatic resistance. Strategies based on direct angiotensin II blockade by specific angiotensin II antagonists, inhibitors of the converting enzyme, or angiotensin II receptors blockers may reduce portal pressure but cause systemic hypotension.

Endothelial dysfunction

In normal conditions, the endothelium is able to generate vasodilator stimuli in response to increases in blood volume, blood pressure, or vasoconstrictor agents in an attempt to prevent or attenuate the concomitant increase in pressure. In several pathologic conditions, however, there is impairment in this endothelium-dependent

vasodilatation, called endothelial dysfunction. Endothelial dysfunction is considered one of the main pathologic mechanisms involved in the increased vascular tone observed in several vascular disorders, such as arterial hypertension, diabetes, and atherosclerosis, and has been attributed to a diminished NO bioavailability or to an increased production of endothelial-derived contracting factors, such as prostaglandin H_2 (PGH_2)/TXA_2, ET, or anion superoxide [3].

The hepatic vascular bed in cirrhotic livers also exhibits endothelial dysfunction [4]. Indeed, studies performed both in cirrhotic patients and in experimental models have shown that, contrary to what happens in normal livers, the cirrhotic liver cannot accommodate the increased portal blood flow caused by the postprandial hyperemia, which determines an abrupt postprandial increase in portal pressure [5]. This is important because such repeated brisk increases in portal pressure and portal–collateral blood flow in response to meals and other physiologic stimuli are thought to be a major determinant of the progressive dilatation of the varices in patients with cirrhosis. In addition, endothelial dysfunction has been further characterized in experimental models of cirrhosis by showing that the cirrhotic liver exhibits an impaired response to the endothelium-dependent vasodilator acetylcholine [4,6]. This impaired response to acetylcholine was shown to be associated with an increased production of TXA_2 and completely prevented by selective COX-1 blockers and TXA_2 antagonists. These results suggest that an increased production of a COX-1-derived vasoconstrictor prostanoid, probably TXA_2, is, at least in part, responsible for endothelial dysfunction [6]. Acetylcholine coupling to the endothelial muscarinic M3 receptor has been shown to promote the stimulation of NO synthase and COX-1, with the subsequent release of NO and vasoconstrictor endoperoxides, respectively [3]. In physiologic states, a vasodilating response is the final balance between the interactions of these endothelial vasoactive mediators. However, in cirrhosis, as in other conditions such as hypertension, diabetes, and arteriosclerosis, there is a perturbation of this balance, resulting in endothelial dysfunction with a consequent impaired response to acetylcholine. All these findings suggest that there is an overactivation of the COX-1 pathway with an increased production of vasoconstrictor-derived compounds in cirrhotic livers.

Tetrahydrobiopterin, that is endothelial nitric oxide synthestase (eNOS) cofactor, increases eNOS activity and significantly improves the vasodilator response to acetylcholine in rats with cirrhosis [7]. Tetrahydrobiopterin supplementation may represent an additional treatment of portal hypertension by improving the endothelial dysfunction.

Recent studies suggest that statins decrease intrahepatic vascular reisitance and improve flow-mediated vasodilatation of liver vasculature in cirrhotic liver, due to an increase of NO production and improvement of hepatic endotherail dysfunction [8,9]. There is one clinical study showing the effectiveness of simvastatin to decrease HVPG [10].

Hepatic vasodilators

Nitric oxide

The role of NO in modulating intrahepatic vascular resistance is a subject of considerable interest. NO is a powerful endogenous vasodilator generated in several tissues by NO synthases from the amino acid L-arginine. It is the natural ligand for soluble guanylate cyclase and is responsible for an increase in the levels of cyclic guanosine monophosphate, the final agent responsible for the relaxation of the vascular wall through the extrusion of cytosolic Ca^{2+}.

NO blockade has been shown to increase portal pressure in isolated perfused rat livers. In addition, the hepatic response to norepinephrine is markedly enhanced after NO inhibition, suggesting a role for NO in modulating hepatic vascular tone in normal conditions [3]. In the cirrhotic liver, the synthesis of NO is insufficient to compensate for the activation of vasoconstrictor systems frequently associated with cirrhosis. This occurs despite a normal expression of eNOS mRNA and normal levels of eNOS protein [4], and the decreased activity of hepatic eNOS in cirrhosis is due in part to increased expression of caveolin [11]. This insufficient hepatic NO generation plays a major role in increasing intrahepatic vascular resistance in cirrhosis, thereby worsening portal hypertension. In accordance with this concept, the infusion of L-arginine, the precursor of NO biosynthesis, and the administration of nitrates (exogenous donors of NO) have been shown to decrease portal pressure. In addition, enhancement of the expression of NO synthase in liver cells, through the portal injection of adenovirus coupled with the gene encoding NO synthase, significantly reduces portal pressure. More recently, strategies aimed at increasing NO release by enhancing intrahepatic eNOS activity, on the basis of constitutively active *Akt* gene transfer, or by simvastatin administration have opened new perspectives with potential therapeutic implications [12,13]. NO also promotes hepatic stellate cell apoptosis through a signaling mechanism that involves mitochondria, is mediated by reactive oxygen species, and occurs independently of caspase activation [14]. This NO-dependent apoptosis, which may maintain sinusoidal homeostasis, is expected as a future treatment of portal hypertension.

Carbon monoxide

Carbon monoxide (CO) is a by-product of heme group oxidation by heme oxygenases, and is considered as an important modulator of intrahepatic vascular tone. CO, although less potent than NO, also activates guanylate cyclase and thereby promotes smooth muscle relaxation. The inhibition of CO production increases portal resistance in normal livers, and HO/CO system is activated in patients with liver cirrhosis, and this could contribute to the hyperdynamic circulatory syndrome observed in this condition [15]. Plasma CO levels directly correlated with cardiac output, and inversely with systemic vascular resistance and mean arterial pressure.

Splanchnic vasodilatation

An increased portal-venous inflow is characteristically observed in advanced stages of portal hypertension and is the result of marked arteriolar dilatation in the splanchnic organs draining into the portal vein. The increased blood flow contributes to the pathophysiology of portal hypertension [1].

Different mechanisms have been suggested to explain the observed hemodynamic abnormality, which likely represents a multifactorial phenomenon involving neurogenic, humoral, and local mechanisms. Initial studies focused on the potential role of increased levels of circulating vasodilators. Many candidate substances were proposed, most of them being vasodilators of splanchnic origin that undergo hepatic metabolism and accumulate in the systemic circulation when hepatic uptake is reduced in liver disease or during portosystemic shunting.

Glucagon

Glucagon is a humoral vasodilator that has a significant role in splanchnic hyperemia and portal hypertension. Plasma glucagon levels are elevated in cirrhotic patients and experimental models of portal hypertension, and hyperglucagonemia is caused, in part, by a decreased hepatic clearance of glucagon, but more importantly by an increased secretion of glucagon by pancreatic α cells. Normalizing circulating glucagon levels by administering glucagon antibodies or infusing somatostatin partially reverses the increase in splanchnic blood flow, and the response is specifically blocked by the concomitant infusion of glucagon in the portal hypertensive rat model. In addition, increasing circulating glucagon levels in normal rats to values similar to those observed in portal hypertension causes a significant increase in splanchnic blood flow. These findings suggest that hyperglucagonemia may account for approximately 30–40% of the splanchnic vasodilatation of chronic portal hypertension.

There are two estimated mechanisms for the vasodilatation effect by glucagons: relaxing the vascular smooth muscle and decreasing its sensitivity to endogenous vasoconstrictors, such as norepinephrine, angiotensin II, and vasopressin [16]. The role of glucagon in the splanchnic hyperemia of portal hypertension provides a rationale for the use of somatostatin and its synthetic analogs to reduce glucagon level, thereby treating portal hypertension [17].

Endocannabinoids

Recent data suggest that endocannabinoids have a significant role in the hyperdynamic circulation of portal hypertension [18]. Endogenous cannabinoid anandamide is increased in the monocyte fraction of blood from cirrhotic humans and rats, and expression of the cannabinoid 1 (CB1) receptors is increased in hepatic human endothelial cells. In addition, CB1 receptor blockade reduces portal blood flow and pressure and increases arterial pressure in cirrhotic rats. Although the mechanism of action is not well understood, it has been suggested that it could be due, at least in part, to an increased NO production, mediated by the activation of endothelial CB1 receptors.

Nitric oxide

Nitric oxide is involved in the regulation of splanchnic and systemic hemodynamics in portal hypertension. The splanchnic vasoconstrictive effect caused by NO inhibitors is significantly greater in portal hypertensive than in control animals, suggesting that an excessive production of NO may be responsible, at least in part, for the vasodilatation observed in portal hypertension [1]. In addition, NO inhibition has been shown to reverse the vascular hyporesponsiveness to vasoconstrictors that is characteristic of portal hypertension and is thought to contribute to systemic and splanchnic vasodilatation. Also, an overproduction of NO has been clearly demonstrated in vitro in perfused mesenteric artery preparations from portal hypertensive rats. The finding in cirrhotic patients of increased serum and urinary concentrations of nitrite and nitrate, which are products of NO oxidation, also supports a role for NO in the genesis of the circulatory disturbances of portal hypertension.

The increased production of NO is due both to an increased expression and an increased activity of eNOS. Factors likely to activate the constitutive NO synthase include shear stress, circulating vasoactive factors (e.g., ET, angiotensin II, vasopressin, and norepinephrine) and overexpression of the angiogenic factor vascular endothelial cell growth factor (VEGF) [19]. Recent study suggests that mild increases of portal pressure upregulates eNOS

at the intestinal microcirculation through VEGF upregulation [20].

Prostaglandins

Prostacyclin is an endogenous vasodilator produced by vascular endothelial cells, showing a significant role in portal hemodynamics [21]. It causes vascular smooth muscle relaxation by activating adenylate cyclase and augmenting the intracellular level of cyclic adenosine monophosphate. Two different isoforms of COX are involved in the biosynthesis of prostacyclin. The constitutive isoform (COX-1) may be stimulated by factors similar to those that stimulate the constitutive isoform of NO synthase (eNOS). In addition, the inducible isoform (COX-2), like inducible NO synthase, can be expressed on stimulation with proinflammatory agents. Animal studies have shown a partial reversal of splanchnic vasodilatation after COX blockade. This effect is independent of that of NO. They have further shown that systemic levels of prostacyclin may be increased in patients with cirrhosis. In addition, the inhibition of prostaglandin biosynthesis by indomethacin reduces the hyperdynamic circulation and portal pressure in patients with cirrhosis and portal hypertension. Both isoenzymes COX-1 and COX-2 are involved in increased prostacyclin production by the mesenteric vascular bed of portal vein-ligated rats. The selective inhibition of COX-2, and to a lesser extent of COX-1, improve the endothelial-dependent vasodilatation in response to acetylcholine.

Carbon monoxide

An expression and activity of heme oxygenase is increased in splanchnic tissues in portal hypertensive rats [22]. The simultaneous inhibition of NO and heme oxygenase completely reverse the reduced vasoconstrictor response to potassium chloride in the mesenteric vascular bed. The splanchnic vasodilatation in portal hypertension is likely to be multifactorial in origin, being promoted in part by an excessive release of NO, CO, and other vasoactive mediators. When one of the vasoactive mediators is chronically inhibited, the enhancement of other vasoactive pathways may prevent the correction of splanchnic vasodilatation. Heme oxygenase also plays a detrimental role of stimulating VEGF production, contributing to the development of hyperdynamic splanchnic circulation, as well as a beneficial role of attenuating oxidative stress and inflammation in animal models [22]. Coupling of several vasoactive systems may cause the splanchnic vasodilatation seen in portal hypertensive states.

Portosystemic collateral circulation

The development of portal–collateral circulation is one of the hemodynamic features of portal hypertension. Formation of collaterals is a complex process involving the opening, dilatation, and hypertrophy of preexisting vascular channels. Collaterals develop in response to the increased portal pressure. A minimum HVPG threshold of 10 mmHg should be reached for the development of portosystemic collaterals and esophageal varices. In addition to the increased portal pressure, formation of portosystemic collateral vessels in portal hypertension is influenced by a VEGF-dependent angiogenic process and can be markedly attenuated by interfering with the VEGF/VEGF receptor 2 signaling pathway [19]. This finding suggests that manipulation of the VEGF may be of therapeutic value.

The collateral circulation may carry as much as 90% of the blood entering the portal system. In this circumstance, the vascular resistance of these vessels becomes a major component of the overall resistance to portal blood flow and, therefore, may be important in determining portal pressure. In addition, although it was traditionally thought that the hyperdynamic splanchnic circulatory state associated with portal hypertension was the consequence of active splanchnic vasodilatation, recent data suggest that the increased neovascularization in splanchnic organs plays an important role in allowing the increase in splanchnic blood inflow [19].

The elements that modulate collateral resistance are not well known. Studies performed in perfused portosystemic collateral beds suggest that NO may play a role in the control of portal–collateral vascular resistance. This may be the mechanism by which isosorbide-5-mononitrate (IMN) and nitroglycerin (NTG) reduce collateral resistance in patients with cirrhosis. These vessels are also probably hypersensitive to serotonin (5-HT), which markedly increases their vascular tone. In portal hypertensive animals, the administration of selective 5-HT_2 receptor blockers decreases portal pressure.

Hyperkinetic circulation

Splanchnic vasodilatation is typically associated with peripheral vasodilatation and a systemic hyperkinetic syndrome, which is characterized by reduced arterial pressure and peripheral resistance, and increased plasma volume and cardiac output. The pathophysiologic mechanisms involved in peripheral vasodilatation are similar to those previously described for splanchnic vasodilatation [1]. Peripheral vasodilatation plays a major role in the activation of endogenous neurohumoral systems that cause sodium retention and expansion of the plasma volume, followed by an increase in the cardiac index. Expansion of plasma volume is a necessary step to maintain an increased cardiac index, which in turn aggravates portal hypertension. This provides the rationale for using a

low sodium diet and diuretics in the treatment of portal hypertension.

Pathophysiology-based therapy

The occurrence of clinical events due to portal hypertension is related to the hemodynamic changes observed during treatment, in cirrhotic patients who receive either placebo or long-term pharmacologic therapy. In other words, changes in the HVPG before and during maintenance therapy (or no treatment) are related to likelihood of the occurence of variceal bleeding or rebleeding [23]. HVPG response to treatment can be considered "good" when the HVPG decreases by at least 20% of the baseline value, indicating a very low risk for rebleeding (<10% at 2 years). The HVPG response is "optimal" when the HVPG decreases to 12 mmHg or below, in which case the risk for variceal bleeding is negligible [24]. An optimal response is also associated with a significant reduction of variceal size and a significantly longer survival. Therefore, decreasing the portal pressure below the critical threshold values for clinically significant portal hypertension make it possible to change the natural history of the portal hypertension with an improvement of prognosis. Thus, the goal of long-term pharmacologic therapy in patients with portal hypertension should be a reduction of the HVPG by at least 20% from baseline values, and preferably to below the threshold of 12 mmHg. The rational treatment of portal hypertension requires that the underlying alteration – the increase in HVPG – be modified. Such modification should be based on an understanding of the mechanisms that lead to increased portal pressure in liver disease.

Natural history and clinical manifestations

Esophageal varices

Approximately 8% of patients with cirrhosis without varices develop varices de novo each year. It is estimated that the majority of cirrhotic individuals will develop varices during their lifetimes. However, only about a third of all patients with esophageal varices will ever experience variceal bleeding. According to the cohort study in patients with hepatitis C, the risk of having esophageal varices increases with decreasing platelet counts, increasing bilirubin, and increasing international normalized ratio (INR) [25], and the development of varices is associated with patient race/ethnicity (Hispanic > Caucasian > African-American), lower baseline levels of albumin, and higher levels of hyaluronic acid [26]. Considering the approximately 20–30% mortality from each episode of variceal hemorrhage, it is important to be able to target those at greatest risk of bleeding. The following factors predict the risk of bleeding from esophageal varices:

1. *Portal pressure*: varices do not develop and therefore cannot bleed when the HVPG is under 12 mmHg. Varices are invariably associated with an HVPG >12 mmHg, but the risk of bleeding is not predicted by the absolute value of the HVPG above 12 mmHg.
2. *Size and location of varices*: the likelihood of variceal rupture is directly related to variceal diameter based on the effects of the radius in wall tension. Varices at the GE junction and palisade zone lie in the lamina propria and thus have a thinner coat and are most likely to bleed.
3. *Endoscopic features of varices*: although several endoscopic findings of esophageal varices have been shown to predict the risk of hemorrhage, so-called "red signs" are frequently applied.
   - Red wale marks: longitudinal red streaks on varices that resemble red corduroy wales.
   - Cherry red spots: discrete cherry-colored spots that are flat and overlie varices.
   - Hematocystic spots: raised, discrete red spots overlying varices, resembling "blood blisters."
4. *Degree of liver failure*: more advanced liver failure is a risk factor for variceal hemorrhage. The higher the bilirubin and prothrombin time and the lower the albumin levels, the more frequent the variceal bleeding.
5. *Presence of ascites*: tense ascites is an important risk factor for variceal hemorrhage.

These risk factors have been used to estimate the probability of variceal hemorrhage with relative precision. For example, in a patient with Child–Pugh class C cirrhosis, large varices, and red signs, the risk of hemorrhage is over 76% within 1 year, while another patient with Child–Pugh class A cirrhosis and small varices has a less than 10% likelihood of bleeding. The risk of bleeding also decreases over time from the time that varices are identified; most bleeding episodes occur within the first 2 years after identification of varices. Once bleeding occurs, spontaneous cessation of hemorrhage occurs in only 50% of individuals. Those with Child–Pugh class C cirrhosis and actively spurting varices are particularly prone to continue to bleed without active intervention.

Following cessation of active bleeding, there is a high risk of rebleeding for approximately 6 weeks. The risk of such early rebleeding is greatest within the first 48 hours and about 50% of all early rebleedign episodes occur during this period. The risk factors for early rebleeding are large varices, age >60 years, renal failure, and severe initial bleeding as defined by a hemoglobin <8 g/dL at admission. Also, overly aggressive volume replacement may cause rebound portal hypertension and precipitate early rebleeding. Survival during this acute phase depends not only on the control of active hemorrhage but

also on the recurrence of bleeding. The long-term course after an index bleed is characterized by recurrent variceal hemorrhage, liver failure, and death. The risk of recurrent bleeding is related to the degree of liver failure, continued alcoholism, variceal size, renal failure, and the presence of a hepatoma. Overall, about 70% of untreated individuals rebleed and die within a year of their index bleed. In addition, patients with acute variceal haemorrhage and a model for end-stage liver disease (MELD) score of ≥18, requiring ≥4 units of packed red blood cells within the first 24 hours, or with active bleeding at endoscopy are at increased risk of dying within 6 weeks [27,28]. A MELD score of ≥18 is also a strong predictor of variceal rebleeding within the first 5 days.

Gastric varices

The likelihood of bleeding from gastric varices depends on their location [1]. Although GOV1 varices constitute over 70% of gastric varices, only 11% of gastroesophageal varices ever bleed. In contrast, about 80% of IGV1 varices experience hemorrhage even though they represent only 8% of all gastric varices. Bleeding from IGV1 varices is often associated with lower portal pressures than in non-bleeding subjects with esophageal varices. Furthermore, bleeding from such varices is more severe and the risk of encephalopathy is higher than in patients with bleeding esophageal varices. Overall, gastric varices bleed less frequently but more severely than esophageal varices. Endoscopic sclerotherapy for esophageal varices causes spontaneous obliteration of 60% of GOV1 varices. In those in whom GOV1 varices persist for more than 6 months after esophageal variceal obliteration, the risk for rebleeding is substantially greater than in those whose varices disappear (28 versus 2%). GOV2 varices are less affected by sclerotherapy for esophageal varices. Recently, the risk of bleeding from IGV1 varices was shown to correlate with the size of the varices (>10 mm), Child–Pugh class, and the presence of red spots on the varices. Based on these findings, the following prognostic index was calculated:

$$\text{Prognostic index} = 0.53 \times (\text{Child} - \text{Pugh class} + 0.78) \times (\text{Varices size} + 0.72) \times (\text{Red spot}),$$

where Child–Pugh class A = 0, B = 1, and C = 2; the varices size is scored as small (<5 mm) = 0, medium (5–10 mm) = 1, or large (>10 mm) = 2; and red spot is scored as absent = 0 or present = 1. The risk of bleeding correlated directly with the prognostic index [29].

Portal hypertensive gastropathy and gastric antral vascular ectasia

Portal hypertensive gastropathy (PHG) is a gastric mucosal change associated with portal hypertension. The "mosaic pattern" and the "cherry red spots" are the most frequently observed elementary lesions in PHG. The former consists of multiple erythematous areas outlined by a white reticular network and is generally considered as "mild" PHG. The latter are round, red lesions, slightly raised over the surrounding hyperemic mucosa. These carry a higher bleeding risk and are considered to reflect "severe" PHG [30]. Reliability and the clinical relevance of this classification as mild or severe PHG has been recently validated [31]. The gastric mucosal changes of PHG are associated with increased gastric mucosal and submucosal perfusion and, therefore, are hyperemic – not "congestive" – changes. The term congestive gastropathy is not adequate and should not be used.

During the diagnosis of cirrhosis, the prevalence of PHG is approximately 30% and its incidence is approximately 12% per year [32]. However, patients with severe liver dysfunction and large esophageal varices are at higher risk of developing PHG, whereas large fundal varices may have a protective role, particularly when they are associated with spontaneous gastrorenal shunt [33]. Overall, during the course of cirrhosis, mild PHG may be observed in up to 50–70% of patients and severe PHG in 20–40% [32]. Endoscopic variceal sclerotherapy or banding is a risk factor for PHG.

The clinical course of PHG is characterized by overt or chronic gastric mucosal bleeding. The incidence of overt bleeding from any source in patients with mild PHG is approximately 5% per year, as compared to 15% for severe PHG. The source of bleeding is the gastric mucosa in most of these bleeding episodes. Overt bleeding from PHG is usually manifested by melena and has a far better prognosis than variceal bleeding, with less than 5% mortality per episode. Mortality is higher in patients with severe PHG, but this has been found to be dependent on the severity of liver dysfunction [32].

The incidence of minor mucosal blood loss, without overt bleeding, is approximately 8% per year in patients with mild PHG and up to 25% in those with severe PHG, in whom severe chronic iron deficiency anemia may result, requiring frequent hospital admissions and blood transfusions. It appears that the wide use of β-blockers in patients with cirrhosis is reducing both chronic and overt bleeding from PHG because it has been proved that β-blockers significantly reduce the rebleeding risk in patients who have bleeding from PHG [34].

PHG should be distinguished from gastric antral vascular ectasia (GAVE). This is a distinct entity that may be found in association with conditions other than cirrhosis, such as scleroderma or chronic gastritis. GAVE is characterized by aggregates of red spots, usually with a radial distribution from the pylorus in the antrum of the stomach (in this pattern it is also called *watermelon stomach*). The histology of GAVE is characterized by marked

dilatation of capillaries and collecting venules in the gastric mucosa and submucosa, with areas of intimal thickening in fibromuscular hyperplasia, fibrohyalinosis, and thrombi. From a clinical point of view, GAVE behaves as severe PHG, but it may be less responsive to β-blocker treatment.

Imaging, interventional techniques, and surgical procedures

Ultrasound, computed tomography, and magnetic resonance imaging

The evaluation of patients with portal hypertension is based on the visualization of varices at endoscopy, definition of the portal–collateral anatomy by imaging modalities such as ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), or angiography, and the measurement of portal pressure. There are also techniques to assess changes in pressure and blood flow in the collateral circulation. These have allowed a better understanding of the hemodynamic changes associated with portal hypertension, the mechanism of bleeding, and the effects of new forms of pharmacologic therapy.

Imaging techniques are useful in the initial evaluation of the patient with portal hypertension. Frequently, portal hypertension is first diagnosed when a dilated portal vein, portosystemic collaterals, ascites, or splenomegaly is detected. The patency of the portal vein or the presence of portal-venous thrombosis (PVT) should be investigated in every patient with portal hypertension. Portal venography obtained at the venous phase of splenic and mesenteric angiography is being replaced by noninvasive methods, such as Doppler ultrasonography, contrast-enhanced CT, or MRI. Retrograde wedged hepatic venography, performed with the use of carbon dioxide as a contrast medium during hepatic vein catheterization, is a safe technique that allows an adequate visualization of the portal vein.

Ultrasound, CT, and MRI are as accurate as angiography in detecting PVT. Ultrasonography is the preferred initial investigation because of its low cost and high accuracy. The use of Doppler ultrasound allows the determination of the presence, direction, and velocity of portal blood flow. Multiplying the portal flow velocity by the cross-sectional area of the portal vein provides an estimate of the portal blood flow. However, these estimates are subject to many errors and should be used with caution. Doppler ultrasound is also useful in the assessment of the patency of transjugular intrahepatic or surgical portacaval shunts and in the evaluation of the patency of arterial and venous anastomoses after orthotopic liver transplantation. A recent study has shown that liver stiffness measurement may represent a noninvasive tool for the identification of chronic liver disease patients with clinically significant or severe portal hypertension [35].

Endoscopy

Upper gastrointestinal endoscopy is mandatory in patients with cirrhosis or in those in whom portal hypertension is suspected to assess the number, appearance, and size of any esophageal varix and to note the presence of red color signs. Also, endoscopy should include a careful evaluation for the presence of gastric varices, and the presence, extent, and severity of PHG. Capsule endoscopy is now available for the examination of the upper gastrointestinal tract; initial studies suggest a high sensitivity in the detection of esophageal varices. It may be a possible substitute for conventional endoscopy in patients unable or unwilling to undergo endoscopy in the detection of varices [36].

Endoscopic band ligation

When performing band ligation, rubber rings are placed on the varices, which are sucked into a hollow cylinder attached to the tip of an endoscope (Fig. 14.5). An ischemic necrosis of the mucosa and submucosa occurs after the complete interruption of blood flow, and granulation takes place thereafter, with sloughing of the rubber rings and necrotic tissue. The whole process leaves shallow mucosal ulcerations that heal in 14–21 days [37]. Multiple shot devices allowing the placement of four to ten bands at a time have made the technique easier to perform than was possible with the one shot devices previously available. Application of the bands is started at the gastroesophageal junction and progresses upward in a helical arrangement for approximately 5–8 cm until four to eight bands have been applied. Band ligation sessions are repeated at 7–14-day intervals until the varices are obliterated, which usually requires two to four sessions.

Minor complications such as transient dysphagia and chest discomfort are relatively frequent. The shallow ulcers that develop at the site of ligation bleed less frequently than the ulcers that form after sclerotherapy [37]. Mechanical complications that follow use of the overtube (formerly required when only one shot devices were available) – which range from mucosal tears that cause bleeding to complete esophageal perforation – are less frequent now that multiple band ligating devices are coming into widespread use [38].

Endoscopic sclerotherapy

In endoscopic sclerotherapy, a substance that induces thrombosis in the vessel and inflammation of the surrounding tissue is injected into the variceal lumen (intravariceal technique) or adjacent to the varix (paravariceal technique) to obliterate the varix. The injection

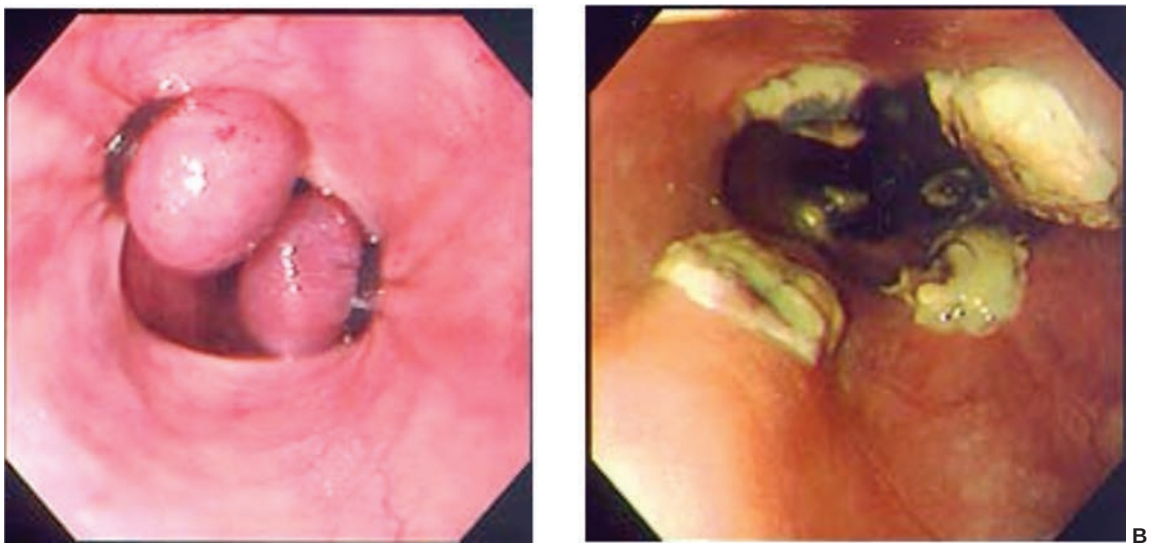

Figure 14.5 Endoscopic appearances of esophageal vaices after band ligation. (A) Esophageal varices just after band ligation with black bands. (B) Endoscopic findings 1 week after band ligation. Shallow mucosal ulcerations with ischemic necrosis of the mucosa are observed but the variceal appearance has almost disappeared.

needle is passed through a flexible endoscope. Injections are initiated at or just above the gastroesophageal junction and proceed upward. About 1–3 mL of sclerosant is injected at each site; the risk for complications increases as the volume of sclerosant injected increases. Variceal obliteration is usually achieved after a couple of sessions. After variceal obliteration, follow-up endoscopic procedures should be carried out at 3-month intervals for the first 6 months and at 12-month intervals thereafter to detect and treat recurrent varices. The most widely used sclerosing agents are 1–3% polidocanol, 5% ethanolamine oleate, 1–2% sodium tetradecyl sulfate, and 5% sodium morrhuate.

Complications of sclerotherapy are relatively frequent and sometimes severe enough to require treatment discontinuation (Table 14.1) [38]. Minor complications such as low-grade fever, retrosternal pain, transient dysphagia, and asymptomatic pleural effusions are common, occur within the first 24–48 hours, and do not require treatment. Asymptomatic transient bacteremia has been reported after treatment in 30–50% of cases. Esophageal ulcers occur in up to 90% of patients within 24–48 hours of injection and heal rapidly in most cases. The ulcers that follow sclerotherapy are frequently asymptomatic but may precipitate bleeding in up to 20% of patients. Esophageal ulcers hamper further injections, delay successful variceal obliteration, and prolong the risk for bleeding that is associated with varices. Sucralfate and omeprazole have been suggested as being potentially useful in healing esophageal ulcers, but convincing proof of such an effect is not available. Esophageal stenosis may occur in 2–10% of patients and frequently requires dilatation. Full-thickness esophageal wall necrosis resulting in esophageal perforation is rare but almost always fatal. PVT, seizures, and sepsis have also been reported. Altogether, the procedure-related mortality is approximately 1% in elective cases [38]. Morbidity and mortality are

Table 14.1 Complications of sclerotherapy.

Local complications	Regional	Systemic	Complications to physician
Ulcers	Esophageal perforation	Sepsis	Sclerotherapist's eye
Bleeding	Mediastinitis	Aspiration	
Stricture	Pleural effusions	Spontaneous bacterial peritonitis and candidemia	
Esophageal dysmotility	Acute gastric dilatation	Ventilation–perfusion mismatch (hypoxia)	
Pain		Adult respiratory distress syndrome	
Odynophagia		Portal vein thrombosis	
Laceration			

higher when the procedure is performed on an emergency basis in actively bleeding patients.

Measurement of portal pressure

The measurement of portal pressure is still the most important assessment of the severity of portal hypertension. Portal pressure should be expressed in terms of the pressure gradient (HVPG) between the porta and the inferior vena cava (IVC), which represents the perfusion pressure within the portal and hepatic circulation. Normal values of HVPG are up to 5 mmHg. Portal pressure expressed as HVPG is not affected by changes in the intra-abdominal pressure caused by tense ascites and total volume paracentesis. An increase in intra-abdominal pressure increases both the portal pressure and the IVC pressure but does not significantly affect the HVPG (except in the case of marked changes in the intra-abdominal pressure that are associated with changes in splanchnic and systemic hemodynamics).

The wide variations in HVPG response of individual patients to pharmacologic treatment suggests that it would be desirable to schedule follow-up measurements of the HVPG during long-term pharmacologic therapy, to determine whether the treatment is likely to offer adequate protection from the risk for bleeding [23]. An important concept that has been strongly substantiated in recent years is that the major factor in determining the development of complications and the clinical significance of portal hypertension is an increase in the HVPG above a critical threshold value. The threshold value of the HVPG for the formation of varices is 10 mmHg and that for the appearance of other complications, such as variceal bleeding, ascites, and PHG, is 12 mmHg [1]. Portal pressure can be assessed by direct or indirect methods.

Direct measurement

Direct measurements of portal pressure are invasive investigations based on surgical, percutaneous transhepatic, or transvenous (transjugular) catheterization of the portal vein. In these techniques, except for the transjugular approach, measurement of the IVC pressure requires the additional and simultaneous puncture of a hepatic vein to determine the HVPG. Because of this inconvenience and the associated surgical or hemorrhagic risk, direct measurements of portal pressure are rarely used. However, the percutaneous transhepatic approach is the preferred technique to measure portal pressure in case of presinusoidal portal hypertension [39]. The safety of percutaneous transhepatic catheterization of the portal vein can be increased by performing the procedure under ultrasonographic guidance. Although the hemorrhagic risk is greater in the percutaneous procedure, the risk can be reduced by using a thin needle. Transjugular catheterization of the portal vein is the first step during a transjugular intrahepatic portosystemic shunt (TIPS) procedure.

Indirect measurement

The indirect measurement of portal pressure is achieved by hepatic vein catheterization, which provides the FHVP and WHVP utilizing a safe procedure. The former, measured when the tip of the catheter is maintained "free" in the hepatic vein, is close to the IVC pressure (maximal difference of 2 mmHg). The latter is measured by occluding the hepatic vein, either by inflating a balloon at the tip of the catheter (Fig. 14.6) or by advancing the catheter until it becomes "wedged" into a small branch of a hepatic vein. The balloon occlusion technique is preferred because it reflects the pressure of a greater hepatic area than does the "manual occlusion" technique. When blood flow in a hepatic vein is stopped by a "wedged" catheter or a balloon catheter, the static column of blood transmits the pressure to the preceding communicating vascular territory (the hepatic sinusoids). Therefore, the WHVP is a measurement of the hepatic sinusoidal pressure, not of the portal pressure itself. However, it is important to note that the WHVP adequately reflects the portal pressure in diseases causing "sinusoidal" portal hypertension, such as alcoholic liver diseases, nonalcoholic steatohepatitis, and cirrhosis due to hepatitis C virus or hepatitis B virus. The

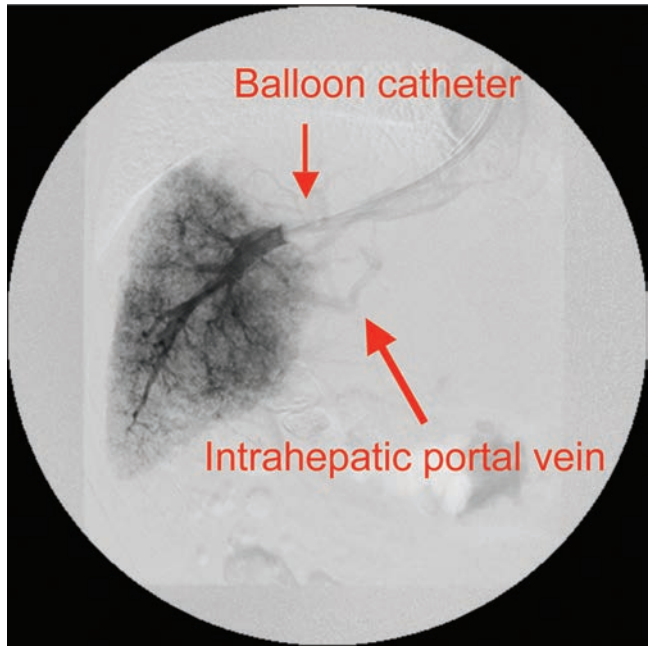

Figure 14.6 Hepatic vein catheterization. The hepatic veins were demonstrated by the injection of iodinated contrast material under balloon occlusion. Thin arrow, balloon catheter; thick arrow, intrahepatic portal vein, which was demonstrated by the inflow of contrast medium in a retrograde manner via hepatic sinuoids.

HVPG is the parameter most commonly used to report portal pressure in the medical literature. In the older literature, the HVPG was frequently referred to as corrected WHVP or corrected sinusoidal pressure.

A limitation of the HVPG is that it does not reflect the portal pressure in cases of portal hypertension with presinusoidal causes, such as PVT and some liver diseases predominantly affecting the portal tracts, including schistosomiasis, the initial stages of primary biliary cirrhosis, and idiopathic portal hypertension. In these cases, a direct measurement of the portal pressure may be preferred. On hepatic vein catheterization, in addition to measuring the HVPG, it is possible to obtain a wedged hepatic retrograde portography using carbon dioxide as a contrast agent. This demonstrates the portal vein in most instances, to the point that a failure to demonstrate the portal vein on carbon dioxide retrograde portography strongly suggests the presence of presinusoidal portal hypertension. An additional advantage of hepatic vein catheterization is that during the procedure (through a jugular vein), it is possible to obtain a liver biopsy specimen, which adds very little time, discomfort, and risk of complications. Furthermore, it is possible to measure the hepatic blood flow with indocyanine green; the intrinsic clearance of indocyanine green is a quantitative test of liver function that assesses overall hepatic metabolic activity.

Diseases causing a hepatic outflow block, classified as "postsinusoidal" or "posthepatic" portal hypertension, show increases in both WHVP and FHVP, with a normal range of HVPG. The main applications of hepatic vein catheterization are evaluation of portal hypertension, assessment of the response to pharmacologic therapy, preoperative evaluation of the risk of resection in patients with small hepatocellular carcinoma, prognostic evaluation during variceal bleeding and acute liver failure, and evaluation of the progression of chronic liver disease, especially severe chronic hepatitis C and alcoholic hepatitis, in which the HVPG may be a good index of the response to therapy [40]. A recent study showed that HVPG predicts clinical decompensation in patients with compensated cirrhosis, and patients with an HVPG of <10 mmHg have a 90% probability of not developing clinical decompensation in a median follow-up of 4 years [41].

The main advantages of the hepatic vein catheterization technique are its simplicity, reproducibility, and safety. Major complications have been limited to local injury to the femoral or jugular vein (e.g., arteriovenous fistulae, leakage, or rupture of venous introducers). Because of its many clinical applications, hepatic vein catheterization is becoming a routine test in many hospitals. Although it is easy and simple to perform, accurate measurements require specific training because the procedure differs from that used in cardiac catheterization laboratories and intensive care units.

Hepatic hemodynamics and its measurement

Under normal circumstances, the total hepatic blood flow represents approximately 25% of the cardiac output, and one third of this flow is contributed by the hepatic artery and the remainder by the portal vein. The methods described in this section are mainly research tools and their utility in routine clinical practice remains unclear.

Regulation of hepatic arterial flow

Hepatic arterial blood flow is regulated automatically, and a reduction in portal flow increases in hepatic arterial flow. Flow in the hepatic artery may increase up to 100% in response to a decrease in portal flow. Although the mechanism of this "hepatic artery buffer response" is not well known, it is considered that it may be mediated in part by adenosine release and washout in the vicinity of the portal tracts [42]. The "buffer response" is important when portal blood flow decreases dramatically, as in PVT and portacaval shunting. It has been suggested that after portacaval anastomosis, the prognosis correlates with the increase in arterial flow that follows the diversion of the portal blood flow. Arterial flow to the liver is not determined by oxygen demand. Under conditions of increased oxygen demand, oxygen extraction rather than arterial flow is augmented in the liver.

Portal-venous flow

The portal system is thought to be a passive vascular bed. The portal blood flow is composed of venous blood draining the stomach, intestines, pancreas, spleen, and omentum. Therefore, the factors that govern portal-venous flow are predominantly those that control the supply of blood to these organs, such as the ingestion of a meal. Contrary to the buffer response of the hepatic artery to decreases in portal blood flow, portal-venous hyperemia does not occur in response to a decrease in hepatic arterial flow, though the mechanism is still unclear.

Azygos blood flow

As most of gastroesophageal collaterals (including esophageal varices) drain into the azygos venous system, an increased azygos blood flow in patients with portal hypertension means the increase of outflow from collateral blood into the azygos vein [43]. However, in 25% of cases, the gastroesophageal collaterals drain into other thoracic veins (i.e., subclavian, innominate, and pulmonary). Therefore, a normal azygos blood flow does not necessarily indicate an absence of esophageal varices. Drainage into other thoracic veins may also be

the reason why the azygos blood flow is not significantly correlated with the size of esophageal varices and the risk for bleeding.

The direct measurement of azygos blood flow requires retrograde catheterization of the azygos vein with a continuous thermal dilution catheter. This is a simple procedure performed in the course of routine hemodynamic investigations. Fick's principle is applied to measure blood flow by the thermodilution technique. Azygos blood flow is usually markedly increased in cases with portal hypertension. Values in healthy subjects range between 0.10 and 0.25 L/min, whereas these are increased on average to 0.65 L/min in cirrhotic patients with portal hypertension. The azygos blood flow is also increased in patients with noncirrhotic portal hypertension. Azygos blood flow is markedly reduced after surgical portacaval shunting, esophageal tamponade, and orthotopic liver transplantation.

The main application of measurements of azygos blood flow has been to monitor the effects of pharmacologic therapy in portal hypertension. The ability of the technique to detect changes in portal–collateral blood flow has increased the understanding of the beneficial effects of the vasoactive drugs currently used in the treatment of portal hypertension. It has been demonstrated that some splanchnic vasoconstrictors, such as propranolol, cause greater decreases in azygos blood flow than in portal pressure. On the other hand, equal falls in portal pressure can be associated with different effects on azygos blood flow. Obviously, a decrease in the HVPG and azygos blood flow, as obtained with propranolol, reflects a greater beneficial effect than a decrease only in the HVPG (as usually happens with vasodilator drugs). Azygos blood flow can also be measured noninvasively with phase-contrast magnetic resonance angiography [43].

Variceal blood pressure

The pressure in esophageal varices can be measured using endoscopy by direct puncture of the varices, with endoscopic pressure-sensitive gauges, or with an inflating–deflating balloon attached to the tip of the endoscope. The two latter techniques measure variceal pressure noninvasively, so that the risk for precipitating variceal hemorrhage is eliminated.

Noninvasive techniques are based on the assumption that because of their thin walls and lack of external tissue support, varices behave as elastic structures; therefore, the pressure needed to compress a varix (which can be sensed by a pressure gauge or directly visualized using a clear balloon) equals the pressure inside the varix. The endoscopic pressure gauge is the method used most commonly in prospective studies. A pressure-sensitive capsule, attached to the tip of an endoscope, consists of a small chamber covered by a thin latex membrane that is continuously perfused with nitrogen. The perfusion pressure is continuously recorded by means of an electromagnetic pressure transducer. It is assumed that when the gauge is applied over a varix, the increase in pressure required to perfuse the gauge equals the pressure inside the varix. The difference between the pressure measured when the gauge is applied over a varix and when the gauge is free in the esophageal lumen equals the transmural variceal pressure, which is the value used to express results [44]. Although the intravenous administration of butyl scopolamine diminishes the artifacts caused by esophageal peristalsis without affecting variceal pressure measurements, endoscopic pressure measurement is not easy in small varices.

Variceal pressure is significantly lower than portal pressure, and this difference is thought to be a consequence of resistance to portal–collateral blood flow in the collaterals feeding the varices and indicates that measurements of variceal pressure cannot be used to estimate portal pressure. It has also been shown that variceal pressure is greater in patients whose varices have bled than in those whose varices have not bled, a finding that supports the concept that increased variceal pressure plays a key role in the mechanism of bleeding and suggests that measurements of variceal pressure may be of prognostic value in assessing the risk for bleeding. Repeated measurements of variceal pressure may detect acute and long-term changes in variceal pressure produced by the administration of pharmacologic agents, though they are difficult to apply for all patients. It has been demonstrated that drugs that decrease portal pressure cause equal or even greater falls in variceal pressure. A reduction of variceal pressure, after pharmacologic therapy, of at least 20% from baseline has been associated with a low actuarial probability of variceal bleeding on follow-up (7% at 3 years versus 46% in patients without this reduction) [45].

Variceal pressure measurement has only been performed in a few cases until now, and clinical significance of the data for the management of the patients is still controversial.

Endoscopic ultrasonography

Endoscopic ultrasonography (EUS) allows the visualization of esophageal and gastric varices, peri-/paraesophageal and peri-/paragastric collateral veins, the portal-venous system, and the azygos vein (Fig. 14.7). EUS, however, does not seem to add further important prognostic information about the risk for complications of portal hypertension in comparison with conventional endoscopy. The clinical use of EUS for gastroesophageal varices is in the diagnosis of gastric fundal varices when the results of endoscopy are doubtful and in the assessment of risk for recurrence after varices have been eradicated by endoscopic sclerotherapy or banding

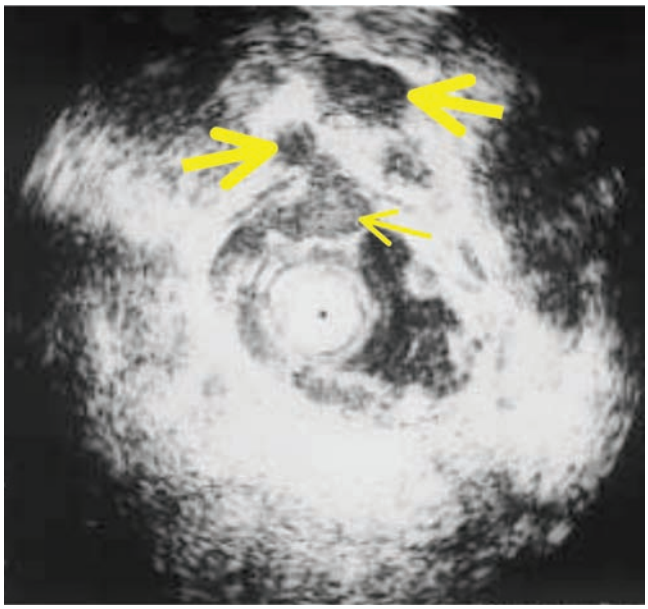

Figure 14.7 Endoscopic ultrasound images of esophageal varices. The images obtained by microprobe show cross-sectional findings of both esophageal varices (thin arrow) and peri- and paraesophageal collateral vessels (thick arrows).

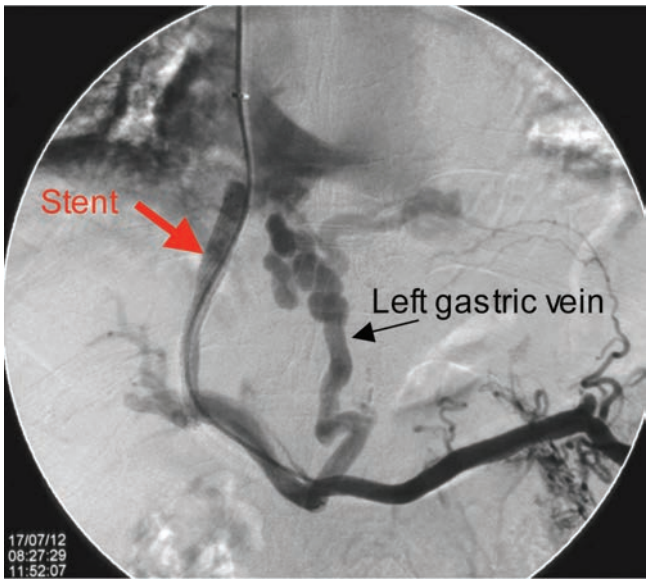

Figure 14.8 Angiogram after a TIPS procedure where the stent was successfully placed. Thin arrow, left gastric vein; thick arrow, stent.

ligation. In the latter situation, the finding of grossly dilated periesophageal veins or patent perforating veins below the gastroesophageal junction carries a high risk for the recurrence of varices. The combined use of EUS for an objective measurement of variceal diameter and endoscopy for the measurement of transmural variceal pressure allows a quantitative estimation of variceal wall tension, which is the relevant parameter in regard to risk for variceal bleeding.

Transjugular intrahepatic portosystemic shunt

A TIPS is an intrahepatic calibrated portosystemic shunt performed between an intrahepatic branch of the portal vein (usually the right) and one hepatic vein (usually the right) using vascular intervention radiologic techniques (Fig. 14.8). The HVPG decreases immediately after TIPS placement because of a marked decrease in absolute portal pressure and a slight increase in the IVC pressure. A reduction in the HVPG after TIPS placement is also associated with a marked reduction in portal–collateral blood flow.

The goal of transjugular intrahepatic portosystemic shunting is to reduce the HVPG below the threshold gradient of 12 mmHg, because complete protection from variceal bleeding is achieved when the HVPG decreases below 12 mmHg [46]. It is very effective where there is repeat variceal bleeding refractory to medical and endoscopic treatments. Despite the marked reduction in HVPG observed after TIPS placement, the HVPG may increase again during follow-up because of thrombosis, stent retraction and kinking, stent stenosis, and development of right heart failure (Box 14.2). These events increase the HVPG above the 12 mmHg threshold (TIPS dysfunction) and patients reenter the bleeding risk zone again.

TIPS thrombosis usually occurs within the first month and is more likely to occur in moribund individuals. It usually develops in association with the presence of a biliary–TIPS fistula. It has been proposed that systemic anticoagulation can prevent TIPS thrombosis but that it increases the risk of inducing hemorrhage. Anticoagulation is not routinely used in North America. Both stent retraction into the parenchymal tissue tract and stent kinking can be avoided by careful attention to technique.

Box 14.2 Causes of gastrointestinal bleeding after transjugular intrahepatic portosystemic shunting.

  - Thrombosis
  - Retraction
  - Kinking
  - Displacement
  - Stenosis
- Hemobilia
- Persistent gastric varices:
  - Associated with spontaneous splenorenal collaterals
  - Associated with massive splenomegapy

The most common cause of recurrent portal hypertension is the ingrowth of the surrounding liver tissue into the stent lumen, with eventual occlusion. Such pseudointimal hyperplasia results from the proliferation and migration of mesenchymal cells of smooth muscle phenotype into the lumen, where they synthesize and secrete collagen. The majority of long-term survivors who have had a TIPS experience stent stenosis within the first 2 years, necessitating surveillance by either Doppler sonography or angiography. As the former technique is specific but somewhat insensitive, depending on the specific cutoffs used for the diagnosis of stent stenosis, angiography is the gold standard for the detection of stent stenosis and is required for its treatment. A commonly used regimen is angiography at 6 and 12 months after TIPS and annually thereafter for the first 3 years. The propensity for development of stent stenosis decreases after 4 years. Although the actuarial probability of TIPS dysfunction with the use of bare stents is greater than 75% after 1 year of follow-up, the introduction of ePTFE-covered stents has completely changed this scenario, with a reported 1-year actual rate of dysfunction as low as 10% [47].

There are some adverse effects related to TIPS procedures (Table 14.2). The most common event is hepatic encephalopathy, which occurs in about 30% of individuals. It manifests itself as altered mental status and usually appears about 2–3 weeks after TIPS placement. It is often precipitated by dietary indiscretion, constipation, urinary tract infections, or electrolyte imbalances. Most episodes are related to recurrent gastrointestinal bleeding 6 weeks after the procedure. Advanced age (>60 years), Child–Pugh class C, a prior history of encephalopathy, and shunt diameter are risk factors for encephalopathy.

Surgical procedures

Decompressive surgical shunts

Total portosystemic shunts

In the end-to-side portacaval shunt (Eck fistula) procedure, the liver end of the portal vein is ligated and the splanchnic end is anastomosed to the vena cava. As the hepatic sinusoids maintain their hypertension after this surgery, it does not relieve ascites. There are currently almost no indications for this surgery at present.

By contrast, side-to-side shunts decompress the portal hypertension both in the splanchnic bed and in the liver. The common factors n these shunts are that they are 10 mm or more in diameter and include side-to-side portacaval, mesocaval, and central splenorenal shunts. They may either be direct vein-to-vein anastomoses or incorporate prosthetic material. The pathophysiology of these shunts is associated with the portal vein acting as an outflow tract from the obstructed sinusoids, showing reversal of blood flow in the portal vein to the low-pressure shunt. Side-to-side shunts are excellent for controlling variceal bleeding and ascites but deprive the liver of prograde portal flow and increase the risks of progressive liver failure and encephalopathy [48]. The other major disadvantage of these shunts is that when prosthetic material is used as an interposition graft, there is increased risk of thrombosis. The indications for side-to-side shunts are at present relatively limited. A patient with massive continued bleeding who also has ascites can be treated with a side-to-side shunt, although TIPS achieves the same goal without surgery. The strongest advocates of emergency side-to-side portacaval shunts are Orloff et al. who in 1995 reported an extensive series with excellent outcome in a largely alcoholic group of patients [48].

Partial portosystemic shunts

Partial portosystemic shunts can be achieved by reducing the side-to-side portosystemic shunt diameter to 8 mm, which make it possible to maintain portal flow in 80% of patients, and to reduce portal pressure to 12 mmHg. A prospective, randomized controlled trial (RCT) showed a control of bleeding in 90% of patients [49]. The maintenance of some portal flow has been associated with a lower incidence of encephalopathy and liver failure than that with total portosystemic shunting. One randomized

Table 14.2 Adverse effects of transjugular intrahepatic portosystemic shunting (TIPS).

Technique-related	Complications related to portosystemic shunting	Unique complications
Neck hematoma Cardiac arrhythmias Perihepatic hematoma Rupture of liver capsule Extrahepatic puncture of portal vein	Hepatic encephalopathy Increased susceptibility to bacteremia[a] Liver failure	TIPS-associated hemolysis Infection of the stents

[a] A hypothetical possibility, as yet unproven, that TIPS increases susceptibility to sepsis.

trial compared the 8 mm portacaval surgical shunt to TIPS in a study population of 50% of patients with Child–Pugh class C cirrhosis and 63% of the patients with alcoholic liver disease. There was significantly better control of bleeding and lower need for transplantation in the surgical shunt group compared to the TIPS group, but survival was not significantly different [49].

Selective shunts

In selective variceal decompression, a different pathophysiologic concept is applied for the control of variceal bleeding. Varices are selectively decompressed, usually by a distal splenorenal shunt (DSRS) through the short gastric veins, spleen, and splenic vein to the left renal vein. Portal hypertension is maintained in the splanchnic and portal-venous system to maintain prograde portal flow to the cirrhotic liver. This surgery should be part of the repertoire of liver transplantation surgeons for patients who have refractory bleeding but still have good liver function.

Long-term patency of a DSRS is excellent with vein-to-vein anastomosis, and bleeding is controlled in more than 90% of patients [50]. Rebleeding is most frequent in the first 4–6 weeks while the short gastric and renal veins accommodate the increased flow from the enlarged spleen and varices. Maintenance of portal perfusion is achieved in 90% of patients in the short term. Long-term maintenance of portal perfusion has proved excellent in nonalcoholic patients, but 50% of alcoholic patients lose portal perfusion unless splenopancreatic disconnection is performed. This has resulted in the maintenance of portal flow in 84% of patients with alcoholic cirrhosis.

Studies in which the use of DSRS was compared with total shunts have shown almost equivalent control of bleeding. Recent multicenter trial comparing TIPS with distal splenirenal shunt showed similar rates of rebleeding, encephalopathy, and mortality in patients with Child–Pugh class A or B cirrhosis who had failed pharmacologic/endoscopic treatment, although reintervention was significantly greater with TIPS [51].

Devascularization procedures

Devascularization procedures include splenectomy, gastric and esophageal devascularization, and, in some situations, esophageal transection. The advantage of these procedures is that they maintain portal hypertension and portal flow to the cirrhotic liver and do not accelerate liver failure or encephalopathy. The disadvantage is that they have a higher rate of rebleeding, which probably depends on the extent of the surgical procedure. In patients who have extensive portal-venous thrombosis and in whom no vessels can be shunted, devascularization procedures are the only surgical option. When these patients do not have bleeding controlled by pharmacologic and endoscopic therapy, extensive devascularization may significantly reduce the risk of rebleeding. This is the major indication for devascularization procedures.

Liver transplantation

Liver transplantation has dramatically altered the outcome for patients with advanced liver disease, portal hypertension, and variceal bleeding. It is the one therapy that has significantly improved survival of patients with bleeding varices and Child–Pugh class C cirrhosis. The indication for liver transplantation, however, is end-stage liver disease rather than variceal bleeding.

Liver transplantation restores both hepatic function and relieves portal hypertension, making it the most effective shunt in the management of variceal bleeding. However, supply and demand dictates that transplantation cannot be the therapy for all cirrhotic patients with variceal bleeding. Nowadays, the sickest patients from the perspective of the severity of the liver disease receive priority, and variceal bleeding per se does not increase priority.

The outcome of liver transplantation has dramatically improved in the last decade. Currently, patients can anticipate an initial 6-month mortality of approximately 10%, with a continuing long-term risk of 2–5% per year for death or major morbidity. The major risk factors facing transplantation patients are recurrent disease (especially viral hepatitis), chronic rejection, and immunosuppression-related infection.

Liver transplantation is the most viable long-term treatment option for patients with variceal bleeding and end-stage disease. Timing is always a major issue, and with the increasing lengthening of waiting lists it becomes more problematic. Determining the correct "bridge" to transplantation is key, and the least therapy that can be used as a bridge, the better it is for the patient. However, when patients have bleeding refractory to endoscopic therapy, it may be appropriate to decompress the portal hypertension with TIPS. Surgical decompression is also an appropriate bridge for a patient who has a disease that may not necessitate transplantation for 5–10 years.

Treatment of portal hypertension

Primary prophylaxis of variceal hemorrhage

A key objective in the management of the cirrhotic patients is the primary prevention of variceal hemorrhage. The importance of primary prevention is underscored by the continuing high mortality from active hemorrhage as well as the progressive decline in survival following the index bleed (Table 14.3) [52–55].

Table 14.3 Primary prevention of variceal bleeding with pharmacologic and/or endoscopic treatment.

Pharmacologic treatment

Nonselective β-blockers

An important determinant of portal pressure is the portal-venous inflow, which is dependent on mesenteric anteriolar resistance. α-Adrenergic agents constrict mesenteric arterioles, while β-adrenergic agents dilate these vessels. Conversely, β-adrenergic antagonists block the dilatory effects mediated via the β-receptors and allow unopposed α-adrenergic effects, resulting in mesenteric anteriolar constriction. Propranolol and nadolol are the two most studied β-adrenergic antagonists.

Pharmacodynamics

The HVPG decreases by 9–31% after either an oral or intravenous administration of propranolol. This decrease is primarily due to a decrease in hepatic wedge pressures, with a much lesser contribution from increased systemic venous pressures. In addition, decreases in heart rate and cardiac output contribute, to a lesser degree, to the portal hypotensive effects of these agents at higher doses.

Up to 50% of patients have failed to show a greater than 10% decrease in HVPG upon propranolol administration. The reason may be that a concomitant increase in collateral and/or hepatic sinusoidal resistance may negate the hypotensive effects of decreased portal inflow and/or a compensatory increase in hepatic arterial flow may maintain sinusoidal perfusion and maintain the increased wedge pressures. The site of portal obstruction, cause of cirrhosis, plasma propranolol levels, severity of liver failure, presence of ascites, basal hemodynamic values, and heart rate response to propranolol do not correlate with the portal hypotensive effects of propranolol.

In the long-term clinical course, the portal hypotensive effects are maintained in most patients. Tachyphylaxis does occur in some patients and is clinically important because only those with a sustained decrease in portal pressure may benefit from β-blockade. Four recent studies have shown that an acute hemodynamic response to β-blockers (intravenous propranolol, measured 20 minutes later) can be used to predict the long-term risk of first bleeding. An HVPG reduction of >10% from

baseline is the best target to define response in primary prophylaxis [56].

Effects on portal hemodynamics

Propranolol has a highly lipophilic property and is almost completely absorbed after oral administration. It undergoes first-pass elimination to a variable degree, causing plasma levels to vary by up to 20-fold. With increasing doses, the relative hepatic extraction decreases, allowing plasma levels to rise. A sustained-release form of propranolol has also been developed that allows once-daily dosing. The clinical effects often do not correlate well with the plasma levels because of the formation of active metabolites, especially the (–) enantiomer, which are taken up by sympathetic nerve endings and then released slowly.

In contrast, nadolol is water soluble and only incompletely absorbed orally. Also, its interindividual pharmacokinetic variability is much less than that of propranolol. Although it does not cross the blood–brain barrier well due to its hydrophilic nature, clinical trials have not shown a significant decrease in the incidence of side effects in central nerve system compared to those of propranolol. Nadolol is excreted via the kidneys and its dose must be modified in response to renal insufficiency.

Adverse effects of β-blockade are numerous and there are multiple drug interactions. The most clinically important side effects involve bronchoconstriction, the development of heart failure, and impotence in cirrhosis. Despite the increase in activity and decrease in renal blood flow, renal dysfunction occurs only occasionally due to propranolol administration. The administration of β-blockers has not been shown to impair the hemodynamic response to acute blood loss.

The efficacy of nonselective β-blockers in the prevention of variceal rebleeding has been proved by many RCTs, and these drugs are now widely accepted as the first-line pharmacologic therapy in this setting [57,58]. Several meta-analyses of these studies consistently found a marked benefit from β-blockers. The rebleeding rate is reduced from 63% in controls to 42% in treated patients, with an absolute risk reduction (ARR) of –21% (95% CI, –30% to –13%) [59]. This means that the number of patients needed to treat (NNT) to prevent one rebleeding episode is 5. Mortality was significantly reduced, from 27% to 20% (ARR = –7%; 95% CI, –12% to –2%; NNT = 14) [59,60]. β-Blockers were compared with endoscopic sclerotherapy in ten RCTs including 862 patients. No significant differences were found between the two treatments, either for rebleeding (ARR = 7%; 95% CI, –2% to 17%) or for mortality (ARR = 2%; 95% CI, –5% to 8%). Side effects were significantly less frequent and less severe with β-blockers (ARR = –22%; 95% CI, –38% to –6%). The number of patients needed to be treated with β-blockers to prevent a harmful event, compared with sclerotherapy, is four [59]. Meanwhile, an ineffective result of timolol has been reported in preventing varices in unselected patients with cirrhosis and portal hypertension, being associated with an increased number of adverse events. A recent study has shown that β2-AR gene polymorphisms influence the response to β-blockade, though HVPG reduction cannot be predicted from polymorphism analysis. Patients with the Gly16-Glu/Gln27 haplotypes may benefit from the association of hepatic vasodilators to propranolol therapy [61].

More recently, carvediol, a noncardioselective vasodilating β-blocker, has attracted attention because one study revealed that it is more effective in reducing portal pressure than propranolol [62]. Furthermore, the rate of first bleed was significantly lower in the carvediol group than in the band ligation group. It may become an option for primary prophylaxis in patients with high-risk varices.

Nitrosovasodilators

Pharmacodynamics

Nitric oxide is a potent vasodilator and an important mediator of the vasodilated state seen in cirrhosis. The "nitrosovasodilator" group of drugs acts via the NO pathway, producing vasodilatation in their target vascular beds. At usual pharmacologic doses, these agents are primarily venodilators and decrease cardiac output by decreasing venous return in those with normal myocardial length–tension relationships. Systemic venodilatation decreases postsinusoidal resistance and decreases portal pressure. At high doses of the drugs, arterial dilatation and systemic hypotension occur, causing reflex splanchnic vasoconstriction and further decreases in portal pressures. Also, nitrate-mediated baroreceptor reflexes in the pulmonary capillary bed trigger splanchnic vasoconstriction and contribute to the drugs' portal hypotensive action.

Nitrovasodilators such as NTG, isosorbide dinitrate (ISDN), and IMN, through their capacity to release NO, may compensate for the NO deficit within a cirrhotic liver and thereby reduce the intrahepatic vascular resistance. IMN, the most extensively studied nitrate, has been shown to reduce HVPG in cirrhotic patients without reducing the hepatic blood flow; its effect reflects a reduction in the hepatic vascular resistance. Although it is possible to determine the effect of pharmacologic agents on the individual factors that determine portal pressure (i.e., resistance and flow) in the experimental setting, it is not easy to do so in clinical studies. A further complication is the fact that the vasodilator action of these drugs is not limited to the hepatic and portal circulation but extends to the systemic circulation, where they cause arterial hypotension. This in turn may elicit reflex splanchnic vasoconstriction, with an ensuing reduction in portal blood flow. Vasodilators usually decrease the

cardiac preload and hence the cardiac output, which may further decrease the splanchnic blood flow. Moreover, many vasodilators reduce the vascular resistance in the portal–collateral circulation. This represents another mechanism by which a vasodilator may reduce the HVPG, but at the expense of increased blood flow in the portosystemic collaterals and esophageal varices. In some instances, the beneficial effect of decreasing intrahepatic resistance by means of a vasodilator, in terms of a reduction in portal pressure, is offset by the splanchnic vasodilator effect of the drug, which increases the portal–collateral blood flow and prevents any decrease in portal pressure [63].

Another important limitation of vasodilators is that they may be dangerous in patients with advanced cirrhosis. These drugs, by enhancing preexisting peripheral vasodilatation, further decrease the arterial blood pressure and activate endogenous vasoactive systems, which may worsen sodium retention and ascites. However, it is reported that long-term treatment with IMN is safe when combined with β-blockade in patients with compensated cirrhosis [64]. Combined treatment, unlike treatment with IMN alone, does not cause adverse effects on renal function, sodium handling, or endogenous vasoactive systems. This is because the mild systemic vasoconstriction and suppression of renin release resulting from β-blockade oppose the adverse systemic and renal effects of IMN.

Another method to increase the intrahepatic production of NO is to administer agents that act preferentially in the liver [65–67]. Interest in this method has increased because of recent studies showing that in experimental models of cirrhosis the expression of NO synthase in liver cells can be enhanced by the portal injection of adenovirus transfected with the gene encoding neural NOS or eNOS, and that such treatment may significantly reduce portal pressure for some weeks [66]. Similarly, transfer of the constitutively active Akt results in enhanced eNOS activity and reduces portal pressure in carbon tetrachloride-induced cirrhotic rats [12]. Treatment with nitroflurbiprofen, an NO-releasing cyclooxygenase inhibitor, also improves portal hypertension without major adverse effects in thiacetamide-induced cirrhotic rats by attenuating intrahepatic vascular resistance, endothelial dysfunction, and hepatic hyperreactivity to vasoconstrictors [68].

Effects on portal hemodynamics

Acute administration of either isosorbide mononitrate (ISMN) or ISDN may cause up to a 40% decrease in HVPG, a 30% decrease in portal flow, and a 15% decrease in azygous flow. Plasma norepinephrine and renin activity increase, indicating increased sympathetic activity and an enhanced tendency to retain sodium. In the long term, the degree of portal decompression is variable and the systemic hemodynamic effects become less pronounced. The effects of ISDN are less predictable than ISMN presumably due to their variable hepatic extraction in cirrhotic patients. Therefore, ISMN is the long-acting nitrate of choice for the treatment of portal hypertension.

A prospective randomized study including 118 patients to receive either ISMN (20 mg thrice daily) or propranolol (to the maximum tolerated dose) has shown no significant differences in either bleeding rates (18 versus 14%) or mortality (18 versus 15%) after a median follow-up of 29 months [69]. However, after 7 years, an increased mortality, especially in those over 51 years of age (72 versus 48%), were noted in those receiving ISMN. It is unclear whether these results reflect a beneficial effect of propranolol or an adverse effect of nitrates. Interpretation of the data is further confounded by the fact that about 50% of patients enrolled in each arm withdrew from the study. Another study shows that there was no benefit from ISMN in the prevention of first bleeding [70]. The combination of ISMN and β-blockers has also been compared with β-blockers alone in some RCTs, but the results do not support the use of combination therapy for the prevention of first variceal bleeding. At this time, the data do not support a role for nitrates as monotherapy for the primary prophylaxis of variceal hemorrhage.

Endoscopic treatment

Endoscopic sclerotherapy

Injection of sclerosant substances into varices results in the obliteration of varices and hemostasis of variceal bleeding. However, it requires a skilled endoscopist and is associated with serious complications in 10–20% of patients [59]. The clinical trials of sclerotherapy for primary prevention of variceal hemorrhage are difficult to compare because of the variability in patient populations and the use of sclerotherapy during episodes of active bleeding [71,72]. A large multicenter study found a significantly higher mortality in those treated with sclerotherapy despite a decrease in variceal hemorrhage in these patients [73]. β-Blockers alone are superior to sclerotherapy and equivalent to β-blocker plus sclerotherapy for this indication. Thus, sclerotherapy should not be used either alone or with β-blockers for primary prevention of variceal hemorrhage.

Endoscopic band ligation

Band ligation was compared with β-blockers in a numbers of RCTs [52,73–78]. Overall, they showed that band ligation is superior to no treatment, and that two meta-analyses of 12 trials comparing them showed that band ligation is associated with a small but significantly lower incidence of first variceal bleeding but without

differences in mortality [79,80]. From the point of cost effectiveness, band ligation is more effective than β-blockers in the cost per quality-adjusted life-year [81]. The current American Association for the Study of Liver Diseases/American College of Gastroenterology (AASLD/ACG) practice guideline recommends either nonselective β-blockers or band ligation as an effective treatment to prevent first variceal bleeds, and that the appropriate therapy may be decided according to patient preferences and local resources.

Transjugular intrahepatic portosystemic shunt

Currently, no data exist to support a role for TIPS for primary prevention of variceal hemorrhage. In addition, TIPS does not improve the outcome following liver transplantation and in some cases may render the operation technically more difficult [82]. TIPS is thus not recommended for the primary prevention of variceal hemorrhage.

Surgical treatment

Four prospective randomized trials comparing surgical portacaval shunts with medical therapy were carried out over 25 years ago. They demonstrated that while surgery could effectively prevent variceal hemorrhage, the benefit was offset by sereve encephalopathy, which ensued in 30–60% of patients [72]. Moreover, as medically treated patients survived longer, the modality has been eliminated as an option for the primary prevention of variceal hemorrhage. Surgical procedures are not a recommended treatment for the primary prevention of variceal hemorrhage.

Clinical recommendations for primary prevention of variceal hemorrhage

All cirrhotic patients should undergo an endoscopic examination as part of their evaluation. Patients with Child–Pugh class B or C cirrhosis with esophageal varices of any grade and those with Child–Pugh class A cirrhosis and large varices, especially with red signs, should be targeted for treatment. In those in whom varices are not present, endoscopy should be repeated at 2–3-year intervals.

Nonselective β-blockers or band ligation is the recommended treatment for the primary prevention of variceal hemorrhage in cirrhotic patients. No evaluable data currently exist for the clinical utility of β-blockers for the various types of gastric varices, although it appears to make intuitive sense to treat those at high risk for bleeding. Recent studies suggest that combined treatment with β-blockers and band ligation has little benefit for primary prophylaxis of variceal bleeding over monotherapy with band ligation (Table 14.4) [83,84].

It has been shown that patients who experience a 25% or greater drop in HVPG or an HVPG of <12 mmHg and maintain these changes over time, are most likely to remain free of bleeding. It has therefore been recommended that the HVPG be measured prior to initiation of therapy and after 1–3 months of treatment and that the dosage of the drug be changed appropriately to achieve the desired end-points. However, the cost effectiveness of this approach remains to be demonstrated. Moreover, HVPG measurement is not possible at many medical centers. Where such facilities are not available, the dose should be titrated to achieve a decrease in resting heart rate to 55–60 beats per minute.

Management of active variceal hemorrhage

Although active variceal hemorrhage accounted for about one third of all deaths realted to cirrhosis before the 1990s, recent studies have shown an improved survival of acute variceal hemorrhage due to current treatment strategies [85–87]. Recently, the Baveno V consensus meeting

Table 14.4 Primary prevention of variceal bleeding and the role of combined therapy with endoscopic and pharmacologic treatment.

modified the Baveno IV consensus statement to define "*Failure to control bleeding*" as follows [88,89]:

1 The timeframe for the acute bleeding episode should be 120 hours (5days).
2 Failure is defined as death or need to change therapy defined by one of the following criteria:
   - Fresh hematemesis or nasogastric aspiration of ≥100 mL of fresh blood ≥2 hours after the start of a specific drug treatment or therapeutic endoscopy.
   - Development of hypovolemic shock.
   - A 3 g drop in hemoglobin (9% drop of hematocrit) within any 24-hour period if no transfusion is administered. This timeframe needs to be further validated.
   - The potential value of an index of blood transfusion requires prospective validation.

Any bleeding occurring after initial hemostasis and more than 48 hours from time zero but less than 6 weeks after is considered to represent early rebleeding. There are three primary goals of management during the active bleeding episode. These include hemodynamic resuscitation, prevention and treatment of complications, and treatment of bleeding. All three need to be pursued simultaneously and often require coordinated critical care.

Hemodynamic resuscitation

The goal of resuscitation is to preserve tissue perfusion. Volume restitution should be initiated to restore and maintain hemodynamic stability [89]. Packed red blood cell transfusion should be done conservatively at a target hemoglobin level of between 7 and 8 g/dL, although transfusion policy in individual patients should also consider other factors such as comorbidities, age, hemodynamic status, and ongoing bleeding.

Although transfusion of platelets and fresh frozen plasma can be considered in patients with significant coagulopathy and/or thrombocytopenia, there are no available data to make a recommendation regarding management of them. Care should be taken to avoid overtransfusion with volume overload because of the risk of rebound portal hypertension and rebleeding. Also, in those receiving large volumes of blood products, the ionized [Ca^{2+}] and platelet counts must be monitored and corrected as necessary.

Prevention and management of complications (Box 14.3)

Complications related to bleeding can lead to mortality from active hemorrhage. A severe complication with a frequently fatal outcome is aspiration pneumonia. All patients with altered mental status and active bleeding or those with massive hematemesis should be intubated for airway protection to avoid this complication. Also, renal function and fluid administration must be monitored to maintain a urine output of at least 50 mL/h. If renal failure develops, it must be evaluated quickly and managed appropriately. Lactulose should be given orally or by enema once bleeding is controlled to remove blood from the gastrointestinal tract and also to prevent encephalopathy.

Box 14.3 Clinical management for active variceal hemorrhage.

- Hemodynamic resuscitation:
  - Packed cell transfusion
  - Correction of coagulopathy
  - Correction of thrombocytopenia
  - Monitor for side effects of blood product administration
- Airway protection
- Prophylactic antibiotics
- Renal support:
  - Maintain urine output >50 mL/h
  - Avoid aminoglycosides
  - Avoids nonsteroidal anti-inflammatory drugs (NSAIDs) for fever
- Neurologic support:
  - Monitor mental status
- Avoid sedation
- Metabolic:
  - Thiamine when indicated
  - Monitor and treat delirium tremens
  - Moonitor and treat acidosis or alkalosis
  - Monitor phosphate levels, treat hypophosphatemia
  - Monitor blood sugar

Up to 20% of patients with bleeding have a bacterial infection at the time of hospital admission, and the risk of a nosocomial bacterial infection is nearly 50% in these patients compared to 5–7% of hospital-acquired infections in the general population [90]. Furthermore, bacterial infections significantly increase the risk of failure to control bleeding and increase the hospital mortality rate for patients with cirrhosis and gastrointestinal bleeding. The most frequent bacterial infections seen in patients with cirrhosis are urinary tract infection (12–29%, mostly *Escherichia coli* or *Klebsiella*), spontaneous bacterial peritonitis (7–23%, Gram-negative bacilli and aerobic Gram-positive cocci), respiratory tract infection (6–10%), and primary bacteremia (4–11%).

A recent meta-analysis including five RCTs (534 patients) has shown that antibiotic prophylaxis decreases the incidence of bacterial infections and increases the survival rate in patients admitted because of variceal bleeding [91]. An updated meta-analysis of the eight RCTs (789 patients) now available confirms a significant beneficial effect of antibiotic prophylaxis in decreasing both mortality (relative risk (RR) = 0.73; 95% CI, 0.55–0.95) and the incidence of bacterial infections (RR = 0.40; 95% CI, 0.32–0.51), bacteremia, pneumonia, spontaneous bacterial peritonitis, and urinary tract infection [92]. Decreased incidence of early rebleeding after receiving prophylactic antibiotics may be one of the reasons for improved survival [93].

The recommended antibiotics schedule is norfloxacin administered orally at a dose of 400 mg b.i.d. for 7 days [94]. Another study performed in patients with advanced cirrhosis and hemorrhage showed that intravenous (IV) ceftriaxone (1 g/day) was more effective than oral norfloxacin in preventing bacterial infections [95]. Following these studies, a recent consensus conference stated that antibiotic prophylaxis should be an integral part of the therapy for acute gastrointestinal bleeding in cirrhosis and should be instituted from admission [89].

Treatment of active hemorrhage

Pharmacological treatment

Vasopressin

Vasopressin directly constricts mesenteric arterioles and decreases portal-venous inflow, resulting in reduction of portal pressures. A recommended dose of vasopressin is a continuous IV infusion of 0.2–0.4 units/min, which can be increased to a maximal dose of 0.8 units/min. It should always be accompanied by IV nitroglycerin at a starting dose of 40 μg/min, which can be increased to a maximum of 400 μg/min, adjusted to maintain a systolic blood pressure of >90 mmHg. Vasopressin can achieve initial hemostasis in 60–80% of individuals but has only marginal effects on early rebleeding episodes. Also, vasopressin does not improve survival from active variceal hemorrhage. In fact, it may contribute to mortality owing to its coronary vasoconstrictive properties and the resultant myocardial, cerebral, and bowel ischemia. A fibrinolytic state induced by vasopressin, theoretically, can worsen the bleeding diathesis. Recent consensus shows that the portal hypotensive effect of vasopressin in nonbleeding cirrhosis is attenuated when variceal hemorrhage occurs.

Terlipressin

Terlipressin is a long-acting vasopressin derivative with much less severe side effects [63]. The effects of terlipressin are an increase in arterial pressure and splanchnic vasoconstriction. Compared with placebo or nonactive treatment, terlipressin significantly improves the rate of control of bleeding and survival, with one death prevented in every six patients treated [96]. Terlipressin is used in bolus IV injections at doses of 2 mg every 4–6 hours for up to 48 hours. After achieving an initial control of bleeding (a 24-hour bleeding-free period), the dose can be halved and the treatment maintained for 5 days to prevent early rebleeding. The more frequent side effects are relatively mild: abdominal cramps, diarrhea, bradycardia, and hypertension. Severe side effects (e.g., arrhythmias, angina, cerebrovascular accident, and limb ischemia) requiring discontinuation of the drug are in the order of 2–4% [96,97]. Terlipressin has been compared with vasopressin in some trials, and two studies combined vasopressin with transdermal or sublingual NTG [59]. Overall, these studies did not show significant differences between the two drugs in the control of bleeding, rebleeding, or mortality, but side effects were significantly less frequent and less severe with terlipressin. The overall efficacy of terlipressin in controlling acute variceal bleeding is 75–80% across trials [96], and the results of terlipressin were similar to those of sclerotherapy in overall control rate, rebleeding, complications, and mortality [97]. There are two clinical studies regarding the control of variceal bleeding with terlipressin. One study showed that very early rebleeding (0% in terlipressin plus band ligation, 15% in terlipressin alone) and therapeutic failure (2% in terlipression plus band ligation, 24% in terlipressin alone) were less in terlipressin plus band ligation treatment than in terlipressin alone. The other study showed that hospital stay was significantly shorter in the terlipressin plus band ligation group than in the octreotide plus band ligation group (108 versus 126 days) [98,99].

Somatostatin and its analogs

Somatostatin is a 14-amino acid peptide named for its growth hormone-inhibiting properties. As somatostatin inhibits the release of vasodilator hormones (e.g., glucagon), it indirectly causes splanchnic vasoconstriction and a reduction of portal inflow. It disappears within minutes of a bolus infusion due to its very short half-life. Portal-venous inflow, portal pressures, azygous flow, and intravariceal pressures decrease within seconds after a bolus injection. Of these effects, the changes in portal pressure, as measured by wedged hepatic pressure, are most variable and the decrease in collateral flow (azygous flow) are those most consistently observed.

Somatostatin is usually administerd as a continuous IV infusion of 250 μg/h following an initial bolus of 250 μg. A recent study suggested that in high-risk patients (with active bleeding at the time of diagnostic endoscopy) it is wise to increase the infusion dose to 500 μg/h and to provide repeat 250 μg boluses during the initial hours of therapy [100]. Treatment may be maintained for up to 5 days. Side effects of somatostatin are usually mild, most frequently bradycardia, hyperglycemia, diarrhea, and abdominal cramps.

Several RCTs showed that somatostatin significantly improves the rate of control of bleeding compared with placebo or nonactive treatment. Although the results of these studies were heterogeneous, their meta-analysis showed that this heterogeneity was mainly due to one study with an unusually high rate of spontaneous bleeding cessation (83%, the highest ever reported) in the placebo-treated group [59]. However, despite the beneficial effect on the control of bleeding, somatostatin does not affect mortality. Compared with vasopressin, somatostatin is equivalent for mortality and control of bleeding

but is associated with less frequent and less severe side effects than vasopressin.

Three studies compared somatostatin with terlipressin, including a total of 302 patients [59]. The two larger studies were double-blind placebo-controlled RCTs. Overall, no differences were found for failure to control bleeding, rebleeding, and mortality. Total side effects were 21% with somatostatin versus 29% with terlipressin (not significant), and major side effects requiring withdrawal of treatment or specific therapy were 4% in both treatment groups. Contrary to what has been shown for vasopressin, the addition of NTG to somatostatin does not improve therapeutic efficacy and induces more adverse effects.

Octreotide

Octreotide is a synthetic somatostatin analog with a longer half-life. Like somatostatin, bolus injections of octreotide cause a transient increase in mean arterial pressure and systemic vascular resistance, suggesting a systemic effect [101]. However, infusion of octreotide does not cause a sustained decrease in portal pressure or collateral blood flow at the doses generally used for variceal hemorrhage, or at even higher doses, and a rapid desensitization of the hemodynamic effects of octreotide after intravenous administration may be the reason [101]. Therefore, the hemodynamic effects of octreotide, the optimal dose, and the administration method have not been established.

Octreotide is usually used as a continuous IV infusion, at empiric dosages of 25–50 μg/h, in some instances after an initial IV bolus of 50 μg. Treatment duration was from 1 to 5 days. The efficacy of octreotide as a single therapy for variceal bleeding is controversial. Among four RCTs comparing octreotide with placebo, no benefit from octreotide was found in the only one using octreotide or placebo as the initial treatment, whereas in the three using sclerotherapy or ligation before or at the same time as octreotide administration, a significant benefit was found in two studies and was nearly significant in the third [59]. These results suggest that octreotide may improve the results of endoscopic therapy but has no or little effect if used alone. In addition, there is no benefit of octreotide on rebleeding or survival. When compared with other vasoactive drugs, octreotide was better than vasopressin for the control of bleeding in two RCTs and similar to terlipressin in another two, again suggesting a clinical value for the use of octreotide. However, the studies were not sized to test for equivalence. Side effects were less frequent and severe with octreotide than with either vasopressin or terlipressin, but the difference was significant only for vasopressin [59].

As summarized in a recent consensus conference, somatosatin appears to be more effective than placebo or vasopressin and has fewer side effects than vasopressin. It has therefore replaced vasopressin as the pharmacologic treatment of choice in the actively bleeding patient. Although the role of octreotide is less well established, it is the current drug of choice in the United States because of its easy availability as compared with somatostatin.

Endoscopic treatment

Endoscopic treatment is currently the definitive treatment of choice for active variceal hemorrhage. It can be performed at the same time as diagnostic endoscopy at the bedside by a trained gastroenterologist. Two forms of endoscopic treatment are available: endoscopic sclerotherapy and endoscopic variceal band ligation.

Endoscopic sclerotherapy

Endoscopic sclerotherapy had been widely used as a first-choice treatment because it is effective in about 80–90% of patients with variceal bleeding. Moreover, it allows the start of specific treatment for the prevention of long-term rebleeding at the time of diagnostic endoscopy. However, it requires a skilled endoscopist and is associated with serious complications in 10–20% of patients, with an overall mortality of 2% [59]. Furthermore, when compared with vasoactive drugs, sclerotherapy is similar to terlipressin, somatostatin, or octreotide as regards control of bleeding/early rebleeding or mortality (Tables 14.5 and 14.6) [97,102–105]. Nowadays, sclerotherapy is usually performed when band ligation is not possible.

Endoscopic band ligation

Endoscopic band ligation has been used worldwide because of its simple technique and effectiveness (Tables 14.7 and 14.8) [106–110]. A number of RCTs indicate significant benefit of band ligation in the initial control of bleeding compared to sclerotherapy. Sclerotherapy requires a skilled endoscopist and is associated with serious complications in 10–20% of patients, with an overall mortality of 2% [59]. Furtheremore, endoscopic sclerotherapy, not band ligation, causes a sustained increase in HVPG, which is followed by a higher rebleeding rate [111]. Although the choice of one or another procedure may depend on the expertise with each of these techniques, band ligation is a preferred treatment for acute variceal bleeding.

Combined endoscopic and pharmacologic therapy

The combination of endoscopic therapy (either sclerotherapy or banding) with pharmacologic therapy significantly improves initial control of bleeding and reduces the 5-day failure rate in terms of control of bleeding or rebleeding when compared with endoscopic therapy alone [112]. The use of band ligation instead of sclerotherapy added to somatostatin for the treatment of

[a]Not significant.

acute variceal bleeding significantly improved efficacy and safety, and the 6-week survival probability without therapeutic failure was better with band ligation [113]. A recent study has shown that HVPG independently predicts short-term prognosis in patients with acute variceal bleeding treated with pharmacologic and endoscopic therapy [114].

Salvage therapy for patients with endoscopic treatment failure

Emergent endoscopic treatment fails to control bleeding in about 10–20% of patients. These patients are at high risk for exsanguination as well as all of the complications related to active bleeding. Usually by the time a diagnosis of failed endoscopic treatment is established, patients have already received a trial of pharmacologic treatment as well. In such patients, second attempts at endoscopic hemostasis may be made. However, if bleeding is not quickly and effectively stopped, more definitive therapy must be instituted immediately.

Balloon tamponade

Balloon tamponade is effective in achieving short-term hemostasis. However, it has a high risk of rebleeding following deflation of the balloon. Also, the airway must be protected in all patients receiving such treatment owing to their failure to clear oral secretions and the high risk of aspiration. The only role of such treatment is to temporarily stabilize the patient so that more definitive treatment can be instituted.

Variceal embolization

Variceal embolization using an angiographic technique is one of the options to control variceal bleeding. Percutaneous transhepatic embolization of gastroesophageal varices was proposed in the early 1970s, and was performed by catheterizing the gastric collaterals that supply blood to varices through the transhepatic route. However, it was practically abandoned because of its invasiveness and lesser effectiveness compared with sclerotherapy. Nowadays, variceal embolization is used as a complement to TIPS in patients with severe acute bleeding that is not controlled with endoscopic treatment, especially in patients with gastric varices.

Transjugular intrahepatic portosystemic shunt

A TIPS can stop bleeding in most patients with acute variceal hemorrhage [115]. Some centers use coil embolization of the vessels feeding the varices. The selection of patients with uncontrolled bleeding, many of them with advanced liver failure, probably accounts for the high 6-week mortality, ranging from 27% to 55%. One RCT showed that the best candidates for emergency TIPS for variceal bleeding are those with an HVPG of ≥20 mmHg in whom TIPS placement reduced the 6-week mortality from 38% to 17%, while the corresponding figure was 5% in patients with an HVPG of <20 mmHg not so treated [116]. This result suggests that high-risk patients benefit from TIPS placement if applied soon. Whether other clinical risk indicators may be used in clinical practice instead of HVPG measurement should be assessed in future trials. Until such studies are available, given the very high proportion of patients in whom variceal bleeding is controlled by medical and/or endoscopic therapy, transjugular intrahepatic portosystemic shunting is confined to the rare patients (approximately 10% of cases) with uncontrollable variceal bleeding.

Surgery

Surgical intervention is rarely indicated for acute variceal bleeding. More than 90% of patients can be treated with pharmacologic and/or endoscopic therapy. In the small minority of cases in which this therapy fails, balloon tamponade with emergency decompression using TIPS in the next 24 hours is the best approach. An emergency portacaval shunting has been performed in limited facilities [48].

An algorithm for the management of active variceal hemorrhage (Fig. 14.9)

The initial management of active hemorrhage should include hemodynamic resuscitation, prevention of complications, and early endoscopy to establish the diagnosis and initiate specific treatment. Terlipressin, somatostatin, or octreotide (50 μg bolus followed by 50 μg/h by IV infusion) may be started in the emergency room in those at high risk for variceal hemorrhage. At diagnostic endoscopy, bleeding esophageal varices are usually treated by band ligation or sclerotherapy. If active bleeding persists or recurs within 48 hours, the application of TIPS or surgery should be considered. The choice of the definitive procedure depends on the patient's clinical condition and the expertise available. When bleeding occurs

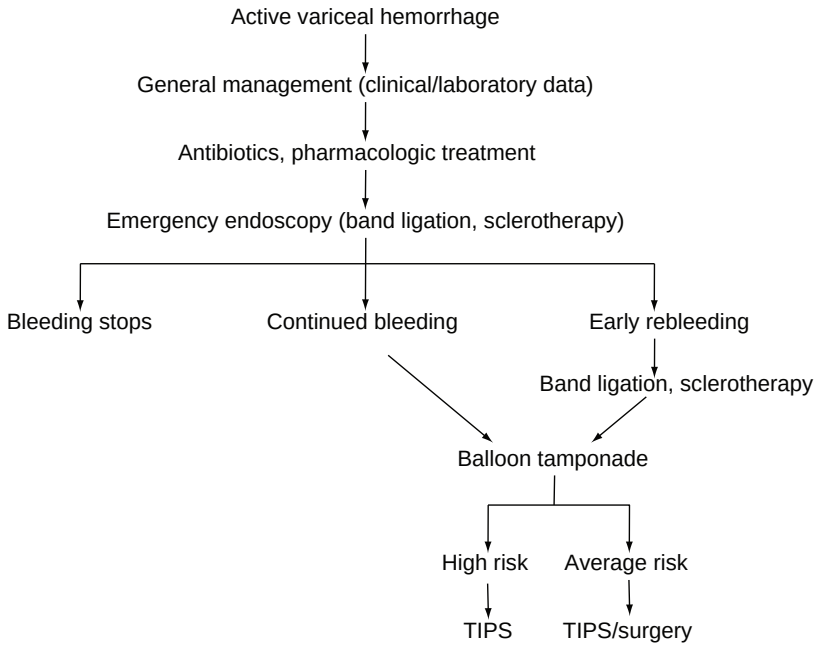

Figure 14.9 Algorithm for the clinical management of acute variceal bleeding.

more than 48 hours after initial endoscopic treatment, a second attempt at controlling hemorrhage by endoscopy is reasonable before proceeding to salvage therapy. The need for balloon tamponade prior to TIPS placement is important, because temporarily stabilizing the patients by balloon tamponade allows the procedure to be performed under more controlled circumstances without detracting the attention of the angiography personnel from the procedure.

Prevention of recurrent variceal hemorrhage

The natural history of an untreated patient who has survived an episode of variceal hemorrhage is characterized by recurrent hemorrhage with consequent liver failure, hepatic encephalopathy, and eventually death [117]. As the median rebleeding rate in untreated individuals is around 60% within 1–2 years of the index hemorrhage, with a mortality of 33%, it is imperative to prevent rebleeding.

Recently, the Baveno IV consensus statements were modified at Baveno V, and "*Failure of secondary prophylaxis*" was defined as follows [88,89]:

1 Failure to prevent rebleeding is defined as a single episode of clinically significant rebleeding from portal hypertensive sources after day 5.
2 Clinically significant rebleeding is recurrent melena or hematemesis resulting in any of the following:
   - Hospital admission.
   - Blood transfusion.
   - A 3 g drop in hemoglobin.
   - Death within 6 weeks.

Pharmacologic treatment

Nonselective β-blockers and combined pharmacologic treatment

The efficacy of nonselective β-blockers in the prevention of variceal rebleeding has been proved by many RCTs, and these drugs are now widely accepted as the first-line pharmacologic therapy in this setting (Table 14.9) [117]. Several meta-analyses of these studies consistently found a marked benefit from β-blockers. The rebleeding rate is reduced from 63% in controls to 42% in treated patients, with an ARR of –21% (95% CI, –30% to –13%) [67]. Nonselective β-blockers plus organic nitrates – the combined administration of propranolol or nadolol plus ISMN – was introduced after demonstrating that ISMN enhanced the portal pressure-reducing effect of nonselective β-blockers [118]. The combination of ISMN with propranolol or nadolol has been found to be superior to endoscopic sclerotherapy in one study [119]. However, there was no significance in the reduction of bleeding risk with combination pharmacologic therapy as compared with band ligation [120–122]. The heterogenous results in these studies may be explained by a different proportion of patients with large varices and/or different doses of medication.

Nowadays, there is a majority agreement that, as incorporated in the AASLD/ACG guidelines, the best approach in the prevention of recurrent esophageal variceal bleeding is the combination of nonselective β-blockers plus band ligation [123]. Two trials have shown the advantage of combined therapy over band ligation alone: 23% and 14% of rebleeding rate, respectively, for band ligation plus nadolol, compared to 47% and 38% for band ligation alone [124,125]. However,

further discussion is necessary to establish the preferred treatment, because two recent papers showed negative results for this approach [126,127]. Compared with transjugular intrahepatic portosystemic shunting, the combination of IMN and propranolol is less effective for the prevention of rebleeding but is associated with significantly less encephalopathy, similar mortality, and much lower cost [128].

Monitoring the pharmacologic treatment response

Many studies, including RCTs and prospective consecutive series, have shown that the pharmacologic (or spontaneous) reduction of HVPG to less than 12 mmHg or by as much as or more than 20% of the baseline value virtually abolishes the risk of rebleeding [24,119–121,129,130]. When the results of these studies are combined in a meta-analysis, the odds ratio for rebleeding in patients achieving one of these hemodynamic targets compared with those not reaching any of them is 0.20 (95% CI, 0.08–0.47). Therefore, patients reaching one (or both) of these targets are considered hemodynamic responders to pharmacologic therapy. The evaluation of acute HVPG response to IV propranolol before initiating secondary prophylaxis for variceal bleeding is a useful tool in predicting the efficacy of nonselective β-blockers [131]. However, because it is still unclear whether patients with an insufficient hemodynamic response to pharmacologic therapy would benefit from alternative treatments, hemodynamic monitoring of pharmacologic therapy is presently recommended only in the setting of clinical research.

Endoscopic treatment

Endoscopic sclerotherapy

Endoscopic sclerotherapy had been extensively evaluated for the long-term prevention of recurrent variceal hemorrhage. However, the risk of variceal rebleeding is significantly reduced by band ligation when compared with sclerotherapy [110]. Furthermore, while there were no differences in mortality, complications were significantly less frequent and less severe with band ligation, and the number of endoscopic sessions needed to achieve eradication was significantly lower that with sclerotherapy. Also, sclerotherapy has no advantage over drug therapy and causes more frequent and severe side effects. Therefore, sclerotherapy may not be appropriate as a treatment of choice for secondary prophylaxis of variceal hemorrhage.

Endoscopic band ligation

Endoscopic band ligation has been developed as an alternate endoscopic treatment over the last 20 years [117]. Many studies have evaluated the relative efficacy of band ligation with sclerotherapy, showing that the former is associated with earlier variceal obliteration, less complications, and less rebleeding as well as improved survival when compared with the latter [110,132]. Because of this, band ligation has replaced sclerotherapy as the first-line treatment for the prevention of recurrent hemorrhage. However, as band ligation is associated with a greater risk of variceal recurrence and is technically difficult when varices are very small, sclerotherapy may be appropriate for such patients.

The meta-analysis comparing band ligation alone with combination endoscopic band ligation and sclerotherapy did not show any benefit either for rebleeding or for mortality. Furthermore, as complication rate was higher in combination endoscopic therapy, it is not a recommened therapy [110,133].

As described in the pharmacologic treatment section, there is majority agreement that the best approach in the prevention of recurrent esophageal variceal bleeding is the combination of nonselective β-blockers plus band ligation, as incorporated in AASLD/ACG guidelines.

Transjugular intrahepatic portosystemic shunt

A recent meta-analysis of 11 trials that compared TIPS with endoscopic treatment showed that hepatic encephalopathy occurred more frequently after TIPS placement with no difference of mortality between the two treatments, in spite of less frequent rebleeding with TIPS [134,135]. Although pharmacologic treatment, propranolol plus nitrates, was less effective than a TIPS in the prevention of rebleeding, it was associated with less hepatic encephalopathy, identical survival, and more frequent improvement of Child–Pugh class with lower costs than TIPS [128]. Therefore, despite the beneficial effects on bleeding, a TIPS procedure should not be used as first-line treatment but as a salvage therapy for those with recurrent bleeding. A major drawback of TIPS is the high rate of occlusion or dysfunction at 2 years, in the order of 60–80%. However, one recent multicenter randomized trial and two studies including consecutive patients with Budd–Chiari syndrome or cirrhosis reported much lower obstruction and reintervention rates with PTFE-covered stents and lower rates of recurrent bleeding or ascites, without an increased incidence of encephalopathy [47,58]. It is generally redommended that a coated stent be used for the TIPS procedure.

Surgery and orthotopic liver transplantation

There are several studies regarding the value of surgical treatment for the prevention of recurrent variceal hemorrhage. In general, surgical treatment may be considered to either achieve portal decompression or mechanically disconnect the varices. A complete shunt formation decompresses both the portal vein and hepatic sinusoids and converts the portal vein into an outflow tract. In contrast, the latter approach preserves some sinusoidal perfusion while decompressing the portal veins. Each particular operation has its proponents, but their data are not easily generalizable due to the failure of others to obtain similar results. Virtually all of the operations described are effective in arresting hemorrhage and preventing rebleeding. However, these procedures often do not provide any survival advantage over endoscopic treatment [72]. Recent multicenter trial comparing a TIPS with a distal splenorenal shunt showed similar rates of rebleeding, encephalopathy, and mortality in patients with Child–Pugh class A or B cirrhosis who had failed pharmacologic/endoscopic treatment, though reintervention was significantly greater with TIPS [51]. The choice between them may depend on available expertise and ability to monitor the shunt and reintervene when needed.

Orthotopic liver transplantation is the only treatment that not only effectively corrects the portal hypertension but also removes the cirrhotic liver and corrects liver failure. It is the only treatment that substantially improves the long-term outcome after variceal hemorrhage and must be considered in all patients who have survived an episode of variceal bleeding unless a contraindication exists.

Algorithm for the prevention of recurrent variceal hemorrhage

The goal of long-term treatment in patients with portal hypertension is the prevention of rebleeding, hepatic decompensation, and death. Orthotopic liver transplantation is the only treatment that reliably achieves all three objectives. Thus, all survivors of a variceal hemorrhage should be evaluated for liver transplantation. While those with Child–Pugh class B or C cirrhosis should be listed right away unless a contraindication exists, listing for those with Child–Pugh class A cirrhosis should be individualized. While patients are waiting for transplant, endoscopic band ligation is the initial treatment of choice in most cases. Some patients with Child–Pugh class A cirrhosis who are compliant with therapy may be treated with propranolol or nadolol. Selected patients with Child–Pugh class A cirrhosis may benefit from surgical portal decompression.

If bleeding recurs, the acute bleeding is managed by pharmacologic and endoscopic treatment, as described in the previous section. Those who continue to bleed or have bled despite adequate endoscopic band ligation combined with a nonselective β-blocker should be considered for salvage treatment with either TIPS or surgery. The choice of procedure should be individualized based on the patient's condition and operator expertise. Bleeding occurring after surgery or transjugular intrahepatic portosystemic shunting should lead to a workup for shunt thrombosis or stenosis. Angiography is the procedure of choice in such a patient because a patent Doppler sonogram does not exclude the possibility of TIPS stenosis.

Treatment of gastric varices, portal hypertensive gastropathy, and gastric antral vascular ectasia

Gastric varices

There are no specific measures or significant evidence for the prevention of first bleeding from gastric varices. It is conceivable that the results of pharmacologic therapy are similar to those achieved in the prevention of first bleeding from esophageal varices. Therefore, nonselective β-blockers should be given to patients with large gastric varices to prevent the first bleeding episode.

The usual initial treatment for bleeding gastric varices is a vasoactive drug, while balloon tamponade has been used with limited success. The tissue adhesive isobutyl-2-cyanoacrylate (bucrylate), mixed with lipiodol, has been found to be efficacious and superior to ethanolamine in nonrandomized studies, achieving hemostasis in 90% of patients. In a recent randomized trial, endoscopic obturation using cyanoacrylate proved more effective and

safer than band ligation in the management of bleeding gastric varices [136]. However, cerebral embolism has been reported with the tissue adhesives, and interest is therefore focused on thrombin, which provides good hemostasis. Another randomized trial comparing *N*-butyl-2-cyanoacrylate with sclerotherapy in 37 patients had a subset of 17 patients with actively bleeding gastric varices [137]. Nonsignificant trends in favor of tissue adhesive were also seen in this small group, and variceal obliteration was significantly more common in the overall group (100% versus 44%). Because the rebleeding rate after endoscopic treatment is high, it is recommended that an early decision should be made for TIPS or surgery in patients rebleeding from gastric varices. A recent study has shown that cyanoacrylate therapy achieved better long-term morbidity than a TIPS procedure with similar results in the control and prevention of gastric variceal bleeding [138].

As no specific measures had been studied for the prevention of recurrent bleeding, nonselective β-blockers have been applied as first-line therapy in clinical practice. However, recently, a randomized controlled trial reported that cynanoacrylate injection was more effective than β-blockers for the prevention of gastric variceal rebleeding (GOV2 or IGV1) and improving survival [139]. In any event, TIPS or shunt surgery may be recommended as an additional treatment in case of failure after pharmacologic or endoscopic treatment. Over the past two decades, an interventional technique – the so-called "balloon-occluded retrograde transvenous obliteration (B-RTO)" – has been used in the treatment of gastric varices, and has shown more than 90% embolization effect with less recurrence [140]. However, as there is no randomized control study, clinical significance of this treatment remains unestablished.

Portal hypertensive gastropathy and gastric antral vascular ectasia

Acute bleeding from PHG should first be treated with the same vasoactive drugs as those for variceal bleeding, although there is no randomized control study specifically designed for PHG [141]. Oral propranolol may be used in hemodynamically stable patients, starting at 40 mg/day in two divided doses; the dosage may be then titrated up to the maximum tolerated amount. Recurrent bleeding from PHG should be prevented using nonselective β-blockers, at the same dosage as that used for treating esophageal varices [34]. Adequate iron supplementation may be useful to prevent or correct chronic iron deficiency anemia in patients with severe PHG. A TIPS may be considered as an alternative therapy for the rare patient who has repeated severe bleeding from PHG despite pharmacologic therapy. Portal decompressive surgery is reserved for those who are not candidates for orthotopic liver transplantation. There is no indication supporting the primary prophylaxis of bleeding from PHG.

Patients bleeding from GAVE may benefit from endoscopic ablation by argon plasma coagulation, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, or heater probe. There is no proof that TIPS and β-blockers are effective in the prevention of recurrent bleeding from GAVE. For select patients with severe recurrent bleeding or uncontrollable acute bleeding from GAVE, an antrectomy with Billroth I anastomosis may be considered [141].

Management protocol of acute variceal bleeding

Day 0 (just after the arrival of the patient), general management

- Clinical and laboratory data to assess the severity of hemorrhage and liver disease:
  - Hemoglobin/hematocrit, white cell count, platelet count
  - Plasma urea and electrolytes, creatinine, prothrombin and partial thromboplastin times, baseline liver function tests
  - Routine cultures of blood, urine, and ascitic fluid
  - Chest X-ray and electrocardiogram
  - Blood gases (in decompensated patients and in those with chest problems?)

Day 0–1, initial therapy

- Correct hypovolemic shock to maintain hemodynamic stability:
  - Blood volume restitution: hemoglobin at approximately 8 g/dL
- Prevent complications associated with gastrointestinal bleeding:
  - Antibiotic prophylaxis against Gram-negative bacilli and Gram-positive cocci
- Achieve hemostasis at the bleeding site:
  - Give pharmacologic treatment immediately when variceal bleeding is suspected, before endoscopic confirmation of diagnosis:
    - terlipressin (in countries where it is available) is the first choice of treatment
    - somatostatin is an alternative to terlipressin
    - other drugs: octreotide and vasopressin (should be combined with nitroglycerin)
- Use emergent endoscopic therapy (preferably by banding ligation)
- Transjugular intrahepatic portosystemic shunting (TIPS) should be used in cases of failure of medical and endoscopic therapy
- Shunt surgery using interposition mesocaval graft shunts or traditional portacaval shunts may be an alternative to TIPS in Child–Pugh class A patients (preferably in nontransplantation candidates)

Days 2–5, general management

- Clinical and laboratory data to assess the severity of hemorrhage and liver disease and to confirm stability of general status
- Pharmacologic therapy should be maintained even after endoscopic therapy for 2–5 days

Multiple choice questions

14.1 What is the treatment that should not be chosen for actively bleeding esophageal varices in cirrhotic patients?

- **a** Endoscopic sclerotherapy.
- **b** Endoscopic band ligation.
- **c** Nonselective β-blocker.
- **d** Terlipressin.
- **e** Somatostatin.

14.2 Which of these has the lowest risk of bleeding?

- **a** Small esophageal varices in Child–Pugh class A patients.
- **b** Esophageal varices with red signs.
- **c** Esophageal varices with large size.
- **d** Isolated gastric varices with large size.
- **e** Isolated gastric varices with red signs.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 15

Renal Complications of Liver Disease and the Hepatorenal Syndrome

Florence Wong

Department of Medicine, University of Toronto and Toronto General Hospital, Toronto, Canada

Key concepts

- Renal impairment commonly occurs in patients with cirrhosis, and it can be due to structural damage in the kidneys or changes related to the renal circulation leading to impairment in renal function, so-called functional renal failure.
- Functional renal failure is usually related to a decreased renal blood flow, secondary to a decrease in the effective arterial blood volume. Cirrhotic patients with functional renal failure can respond to intravascular volume replacement with a reduction in serum creatinine. These patients are said to have prerenal renal failure.
- Cirrhotic patients with functional renal failure whose serum creatinine does not reduce with intravascular volume replacement are said to have hepatorenal syndrome. These patients tend to have a much worse prognosis.
- Acute kidney failure is a concept coined by nephrologists and is increasingly being used in hepatology literature. It encompasses all causes of acute kidney failure including causes that can produce structural damage in the kidneys such as glomerulonephritis or acute tubular necrosis. The acute cases of functional renal failure can be regarded as cases of acute kidney failure.
- Functional renal failure can be precipitated by various events that can cause either further arterial vasodilatation or further reduction of intravascular volume. These include bacterial infections, overdiuresis, gastrointestinal blood loss, vomiting or diarrhea, and large volume paracentesis without intravascular volume replacement.
- Drugs that compromise either the systemic circulation, by lowering the systemic blood pressure, or the renal circulation, such as nonsteroidal anti-inflammatory agents can also precipitate functional renal failure.
- It is imperative that clinicians caring for patients with advanced cirrhosis are vigilant for potential precipitating factors for functional renal failure, and to institute treatment as soon as possible.
- Treatment for functional renal failure, whether prerenal failure or hepatorenal syndrome, begins with intravascular volume replacement. Patients with hepatorenal syndrome will also need vasoconstrictor therapy. A transjugular intrahepatic portosystemic shunt may also be inserted in the appropriate patient with hepatorenal syndrome following vasoconstrictor therapy.
- Liver transplantation is the treatment of choice for patients with cirrhosis and hepatorenal syndrome, as it corrects many aspects of pathophysiology. Simultaneous liver–kidney transplant appears to yield worse outcomes for both patient and graft, and therefore is not recommended unless the patient has been waiting for more than 3 months on dialysis.
- Prevention is the best treatment for cirrhotic patients who are at risk for the development of functional renal disorder.

Renal dysfunction commonly occurs in patients with cirrhosis, especially in those with advanced cirrhosis with ascites. It has been estimated that chronic kidney disease occurs in approximately 1% of all hospitalized patients with cirrhosis, whereas acute kidney injury (AKI) occurs in up to 19% of cirrhotic patients admitted to hospital for whatever reason [1]. The prevalence of renal dysfunction in cirrhosis seems to be rising, due to an increasing number of patients worldwide affected by viral hepatitis, obesity, diabetes, and hypertension, and the propensity of these patients to develop various infections which are then complicated by renal failure [2].

The combination of liver disease and kidney dysfunction can occur as a result of systemic conditions that affect the liver and the kidney simultaneously, or the derangement of renal function can secondarily complicate primary disorders of the liver. In the latter scenario, the renal dysfunction can be related to intrinsic renal disorders, where there is structural renal damage. More often, the renal disorder is functional in nature, where no structural renal damage occurs. The most severe form of functional renal disorder complicating liver cirrhosis is the hepatorenal syndrome (HRS).

Structural renal disease in patients with liver disease

Simultaneous involvement of both the liver and the kidney occurs in many systemic conditions, causing both structural renal damage and liver injury. These include collagen vascular diseases, infiltrative disorders such as amyloidosis and sarcoidosis, inherited conditions such as polycystic disease, and acute fatty liver or toxemia of pregnancy.

Much more common are renal diseases that occur as a result of the liver disease (Table 15.1) [3]. Glomerulonephritis and polyarteritis nodosum are important extrahepatic manifestations of chronic hepatitis B virus (HBV) infection, related to the deposition of HBV antigen–antibody complexes in extrahepatic tissues. With the advent of effective antiviral therapy, the renal complications of HBV infection are rapidly becoming infrequent except in endemic areas. Hepatitis C virus infection-associated glomerulopathies, in contrast, are more commonly seen, possibly related to the frequent occurrence of cryoglobulinemia in these patients. Recent reports suggest that the hepatitis C virus itself may be involved directly in the pathogenesis of the various glomerulopathies as the viral RNA has been found along glomerular capillaries and in the mesangium. Alcoholic liver disease is uniquely linked to immunoglobulin A (IgA) nephropathy, a condition whereby circulating IgA immune complexes are deposited in renal glomeruli, due to their impaired clearance. Hematuria and proteinuria are common clinical features of IgA nephropathy, and patients can rarely present with nephrotic syndrome. Renal tubular acidosis, a syndrome associated with failure of the kidney to acidify the urine, can occasionally be seen in alcoholic hepatitis as well, although it is more often observed with autoimmune hepatitis, primary biliary cirrhosis, and Wilson disease.

Table 15.1 Coexisting liver and kidney disorders.

Liver disease	Associated renal disease
Hepatitis B virus infection	Membranoproliferative glomerulonephritis Membraneous glomerulonephritis Polyarteritis nodosum
Hepatitis C virus infection	Cryoglobulinemia Membranoproliferative glomerulonephritis Membraneous glomerulonephritis
Alcoholic cirrhosis	IgA nephropathy Renal tubular acidosis
Primary biliary cirrhosis	Interstitial nephritis Renal tubular acidosis
Autoimmune hepatitis	Renal tubular acidosis
Wilson disease	Renal tubular acidosis
Nonalcoholic fatty liver disease/ Steatohepatitis	Diabetic nephropathy
Drug-induced hepatic injuries (use of ACE inhibitors or angiotensin II receptor antagonists): cholestatic hepatitis hepatocellular damage	Chronic renal failure

ACE, angiotensin-converting enzyme.

An emerging combination of renal disease coexisting with liver disease is the presence of diabetic nephropathy in a patient with nonalcoholic fatty liver disease (NAFLD) or nonalcoholic steatohepatitis (NASH). A recent study showed that 31% of patients with NAFLD or NASH also had type 2 diabetes [4]. Both are part of the metabolic syndrome, and are linked to obesity. The key feature of the metabolic syndrome is insulin resistance; NAFLD and NASH are considered the hepatic manifestations of this syndrome, while type 2 diabetes is the direct result of insulin resistance. Hyperinsulinemia and poor glycemic control in type 2 diabetes is associated with an increased risk for diabetic microangiopathy, affecting the capillaries of the kidney, accounting for 41% of all cases of chronic renal failure [5]. With the incidence of obesity on the rise, the combination of diabetic nephropathy and NAFLD or NASH will become an important cause of simultaneous liver and renal dysfunction in the future.

Drug toxicity is also an important cause of combined renal and liver dysfunction. Exposure to toxins such as acetaminophen overdose is frequently associated with both liver and renal failure. The fluorinated anesthetic agents methoxyfluorane and fluroxene can occasionally cause both hepatic and renal damage. The patient with cirrhosis is susceptible to renal damage when prescribed certain classes of drugs such as the nonsteroidal anti-inflammatory drugs (NSAIDs) or aminoglycosides. NSAIDs inhibit the enzymes cyclooxygenase 1 and 2 that are responsible for renal prostaglandin synthesis, which cirrhotic patients depend on as renal vasodilators to maintain renal hemodynamics. There are numerous reports of renal failure following the use of NSAIDs. The recent development of cyclooxygenase type 2 inhibitors seems to be less renally toxic when given in the short term [6], whether long-term use of these agents is equally safe is unknown. Aminoglycosides can cause glomerular congestion, epithelial edema of proximal tubules, cellular desquamation, and ultimately glomerular atrophy and tubular necrosis. Awareness of susceptibility of cirrhotic patients to aminoglycoside toxicity has greatly reduced its

use in the cirrhotic population. Therefore aminoglycoside nephrotoxicity is less of an issue amongst such patients in recent years.

Patients with diabetic nephropathy or hypertensive nephrosclerosis are frequently prescribed drugs that inhibit the renin–angiotensin pathway to provide either renal protection against proteinuria or for the control of their systemic hypertension. There are now an increasing number of post marketing reports of hepatotoxicity with these agents. Angiotensin-converting enzyme inhibitors mainly cause a cholestatic injury, which sometimes can be prolonged, and several members of this class of drugs – including ramipril, fosinopril, lisinopril, and enalapril – have been incriminated. Hepatotoxicity related to the use of angiotensin II receptor antagonists is less common; however, a clinical picture of acute hepatitis has been reported with losartan, valsartan, and candasartan. Therefore, it is important to consider hepatotoxicity when presented with a patient with hepatitis and chronic renal failure.

Functional renal disorders

Functional renal disorders, as opposed to intrinsic renal disorders as described above, occur much more frequently in patients with advanced liver cirrhosis, especially in those with ascites. Functional renal disorders are the results of hemodynamic changes that occur in advanced cirrhosis. A common presentation of functional renal disorder in cirrhosis is renal sodium retention, which starts at a very early stage of cirrhosis, even before the clinical appearance of ascites, and which becomes more avid as the cirrhosis progresses. Simultaneous to the progressive worsening of renal sodium retention is the development of renal vasoconstriction, which eventually leads to the development of functional renal failure (FRF) [7]. When the FRF is responsive to intravascular volume replacement with return of the renal function to a prefailure level, the patient is said to have prerenal renal failure. Hepatorenal syndrome is the most severe form of FRF and is not responsive to intravascular volume challenge. More recently, some investigators have recognized that episodes of FRF associated with bacterial infections seem to have a slightly different natural history and have subclassified those patients with infection-associated FRF as a separate group [8]. In a series of 263 cirrhotic patients with ascites admitted to two large tertiary centers in Barcelona for the management of ascites, 27.4% of patients developed prerenal renal failure, 14.1% developed infection-related FRF, and 7.6% developed HRS during a mean follow-up period of 41 months [8]. Interestingly, 7.6% of patients also developed renal failure due to structural renal diseases during follow-up. The probability of developing the different types of FRF is depicted in Fig. 15.1 [8].

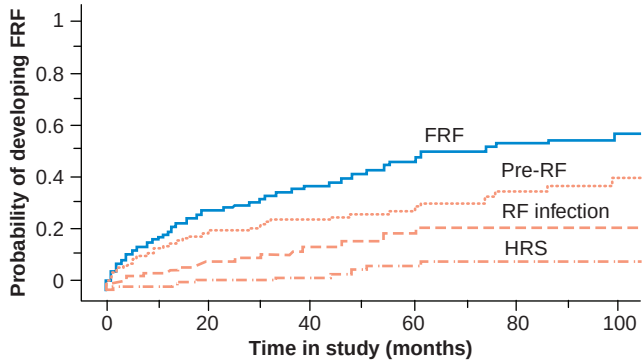

Figure 15.1 Actuarial probability of developing functional renal failure (FRF) in cirrhotic patients with ascites admitted into hospital. $P < 0.001$ between the different subtypes. HRS, hepatorenal syndrome; RF, renal failure. (Adapted from Montoliu et al. [2] with permission from Elsevier.)

Definition of functional renal failure

Functional renal failure is defined as renal failure in which renal structure remains intact, and when the serum creatinine reaches above 1.5 mg/dL (133 μmol/L) [9]. The first mention of FRF occurred almost 70 years ago when the term hepatorenal syndrome was coined to describe acute renal failure following biliary surgery or hepatic trauma. Over the following decades, several key features of FRF were described. In the 1950s, Sherlock noted that the renal failure observed in patients with terminal stages of cirrhosis was associated with low urinary sodium and an absence of proteinuria [10]. Then later, Papper and his colleagues suggested that the pathogenesis of HRS was related to circulatory disturbance of an otherwise normal kidney [11]. This circulatory disturbance was found to be one of intense renal vasoconstriction, as demonstrated by Epstein in 1970 on a renal angiogram in a cirrhotic patient dying from renal failure. The same kidney at postmortem showed filling of all renal vessels to the periphery of the cortex, proving the functional nature of HRS [12]. Finally, in 1966, the International Ascites Club – an organization consisting of experts in hepatology as well as in renal physiology, hemodynamics, electrolyte disorders, cardiopulmonary function, and transplant medicine – set down the definition and diagnostic criteria of the most severe form of FRF, HRS [9], thereby allowing precise diagnosis that then helped develop treatment strategies.

In 2005, the International Ascites Club refined its previous definition and diagnostic criteria of HRS [12]. This occurred because treatment for HRS in the form of vasoconstrictor therapy was becoming available and HRS was no longer a universally fatal condition. Therefore, the group wanted to encourage early diagnosis of HRS,

Box 15.1 Diagnostic criteria of the hepatorenal syndrome.

- Cirrhosis with ascites
- Serum creatinine >1.5 mg/dL (133 μmol/L)
- No improvement of serum creatinine (decrease to a level of 1.5 mg/dL or less) after at least 2 days of diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg of body weight per day up to a maximum of 100 g/day
- Absence of shock
- No current or recent treatment with nephrotoxic drugs
- Absence of parenchymal kidney disease as indicated by proteinuria of >500 mg/day, microhematuria (>50 red blood cells per high power field), and/or abnormal renal ultrasonography

Adapted from Salerno et al. [12].

to allow prompt institution of treatment. Furthermore, newer insights into the pathophysiology of HRS meant that the development of preventative measures was also becoming possible. The new definition of HRS [12] states that:

> HRS is a potentially reversible syndrome occurring in patients with cirrhosis, ascites, and liver failure. It is characterized by impaired renal function, marked alterations in the cardiovascular function and overactivity of the endogenous vasoactive systems. Marked vasoconstriction in the kidney causes low GFR, whereas in the systemic circulation, there is decreased vascular resistance due to splanchnic and peripheral arterial vasodilatation. A similar syndrome can also occur in acute liver failure and acute alcoholic hepatitis.

It is important to note that the definition of HRS also encompasses the hemodynamic changes that occur in a patient with cirrhosis and renal failure, emphasizing the functional nature of the condition, which is consequent upon abnormal hemodynamics.

Box 15.1 sets out the most recent criteria for the diagnosis of HRS, which continues to mandate a diagnosis of exclusion. The following changes from the earlier set of diagnostic criteria made the diagnosis of HRS much simpler:

- Creatinine clearance is removed because it is more complicated than simple serum creatinine for routine purposes, and it does not increase the accuracy of renal function estimation in cirrhotic patients
- Renal failure in the setting of an ongoing bacterial infection, but in the absence of septic shock, is considered as HRS. This enables the physician to start treatment of HRS without waiting for a complete infection recovery.
- Albumin replaces normal saline as the plasma volume expander of choice as saline is isotonic to serum and will mainly be transferred to the peritoneal cavity as ascites without helping the systemic circulatory volume.
- Previous minor diagnostic criteria of HRS describing urinary findings are eliminated as they are not essential for the diagnosis.

Serum creatinine as an assessment of renal function: potential pitfalls

The current diagnosis of FRF requires a serum creatinine level of >1.5 mg/dL (133 μmol/L). However, deterioration of renal function in cirrhosis is not an all-or-none phenomenon, but rather a slow progression over time as the patient advances through the various stages of cirrhosis. The question is then raised as to whether a patient with cirrhosis and a serum creatinine of 1.3 mg/dL (114 μmol/L) is worthy of consideration for treatment of renal dysfunction, as recent literature has suggested that even small increases in serum creatinine are associated with a 2–6-fold increase in mortality risk in patients undergoing cardiothoracic surgery [13]. Furthermore, the measurement of serum creatinine is notoriously inaccurate in the diagnosis of renal dysfunction in cirrhosis; it is affected by gender, age, ethnicity, nutritional state, protein intake, and, importantly, liver disease [14]. Patients with cirrhosis of the liver often have low serum creatinine levels due to reduced production of creatinine from creatine in the liver, a greater volume of distribution due to increases in extracellular fluid, and significant muscle wasting. Furthermore, the serum creatinine measured by the Jaffe method can be artificially lowered in jaundiced patients as chromogens such as bilirubin can interfere with the assay by up to 25%. Conversely, the use of antibiotics such as the cephalosporins can artificially raise the serum creatinine levels as they positively interfere with the creatinine measurement using the Jaffe method. Therefore, a serum creatinine level within the laboratory's normal range may not represent normal renal function. In fact, it has been estimated that the baseline serum creatinine for the cirrhotic population should be 0.40–0.85 mg/dL (35–75 μmol/L) [3]. Consequently, using the rigid diagnostic criteria of a serum creatinine of >1.5 mg/dL will only diagnose patients in an advanced stage of renal failure. The measurement of renal function using creatinine clearance is similarly unreliable because of the falsely low serum creatinine in these patients. Furthermore, this requires a 24-hour urine collection, which is often incomplete, especially in an outpatient setting. Likewise, formulae such as the Cockcroft–Gault and "Modification of Diet in Renal Disease" that use serum creatinine to calculate the glomerular filtration rate (GFR) will tend to overestimate the GFR.

Therefore, until better measurements of GFR can be found, serum creatinine measurement still remains the most useful and widely accepted method for estimating

renal function in clinical practice in patients with cirrhosis [15]. However, there is now interest in lowering the serum creatinine cutoff for the diagnosis of FRF, as a serum creatinine of 1 mg/dL (88μmol/L) represents a GFR of 50 ml/min in a malnourished, wasted, cirrhotic patient [16]. Others have also advocated allowing smaller rises in serum creatinine such as 0.3 mg/dL (26.4 μmol/L), or a 50% increase in serum creatinine in a patient whose baseline creatinine level is within the normal laboratory range, to be diagnosed as having renal failure [2], especially in the setting of a precipitating event in a patient with severe cirrhosis and ascites.

Acute kidney injury in cirrhosis

Nephrologists have been defining acute kidney injury as a percentage rise rather an absolute increase in serum creatinine, as this seems to better represent the change in the patient's renal function. For example, a doubling of a patient's serum creatinine represents a significant deviation from the patient's normal renal function, even if the final creatinine level is still within the laboratory's normal range, and this may have implications for the patient's clinical outcome. Therefore, in 2004, the Acute Dialysis Quality Initiatives (ADQI) Workgroup developed a consensus definition and classification known as the RIFLE classification (R, renal risk; I, injury; F, failure; L, loss of kidney function; E, end-stage renal disease) for AKI, which stratified renal failure into grades of increasing severity based on changes in patients' serum creatinine or GFR and/or urine output (Fig. 15.2) [17]. Another collaborative network consisting of members of the ADQI group and experts from several nephrology societies and intensive care medicine societies known as the Acute Kidney Injury Network (AKIN) further modified the RIFLE criteria [18], so that even smaller increases in serum creatinine than those considered in the RIFLE classification might be considered as AKI (Table 15.2), as patients with these minor increases in serum creatinine have been shown to have an adverse outcome [19]. It is interesting to note that both the ADQI and the AKIN groups do not reference the absolute level of the serum creatinine in the diagnosis of AKI except when renal failure sets in.

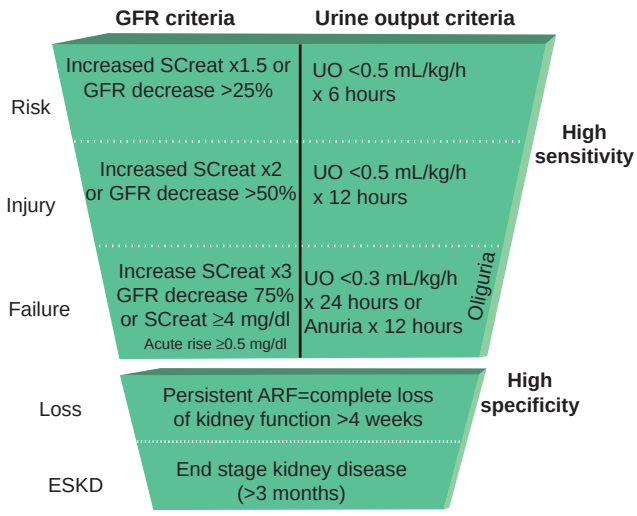

Figure 15.2 The RIFLE diagnostic criteria of acute kidney injury. A patient can fulfill the diagnostic criteria either through changes in serum creatinine or changes in urine output. ARF, acute renal failure; ESKD, end-stage kidney disease; GFR, glomerular filtration rate; SCreat, serum creatinine; UO, urine output. (Adapted from Bellomo et al. [17] with permission from Biomed Central Ltd.)

Table 15.2 Stages of acute kidney injury.

Stage	Serum creatinine criteria	Urine output criteria
1	↑ Serum creatinine of ≥0.3 mg/dL (≥26.4 μmol/L) or ≥150–200% (1.5–2-fold) from baseline	<0.5 mL/kg/hour for >6 hours
2	↑ Serum creatinine to >200% but ≤300% (>2–3-fold) from baseline	<0.5 mL/kg/h for >12 hours
3	↑ Serum creatinine to >300% (>3-fold) from baseline or serum creatinine of ≥4.0 mg/dL (≥354 μmol/L) with an acute increase of ≥0.5 mg/dL (44 μmol/L)	<0.3 mL/kg/h for 24 hours or anuria for 12 hours

Adapted from Francoz et al. [15].

Both the RIFLE and AKIN diagnostic criteria address the issue of smaller increases in serum creatinine as being clinically significant. However, their direct applicability to the cirrhotic population is questionable. For example, cirrhotic patients with refractory ascites usually have a low urine output of approximately 500 mL/day because of their avid renal sodium and water retention even in the absence of AKI. A significant proportion of these patients will be regarded as having renal failure if these diagnostic criteria are used. The only accurate method of measuring GFR is to use clearance techniques employing exogenous markers such as inulin or iothalamate, but they are labor intensive and expensive and therefore cannot be used in routine clinical practice. All formulae that estimate the GFR tend to provide an overestimation of GFR in cirrhosis and therefore will underdiagnose renal failure. However, hepatologists are now beginning to embrace the concept of AKI [1,3], as this allows cirrhotic patients with renal dysfunction to be properly classified, thereby allowing appropriate studies to be conducted to define their prognosis and to devise treatment options. However, the hepatology community will need to tailor the AKI definitions to suit the cirrhotic population, and to validate such definitions in a large cohort of patients with cirrhosis.

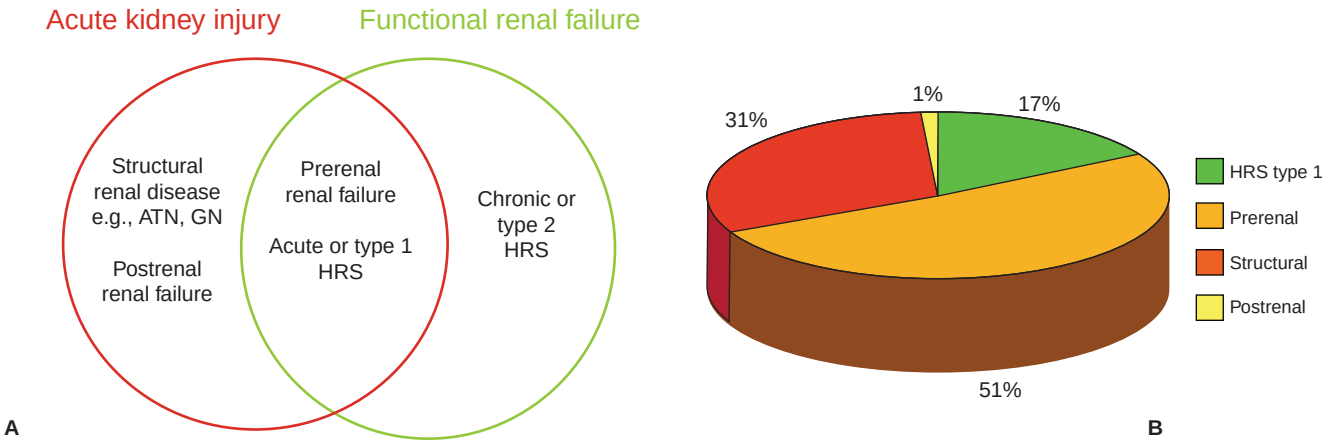

Figure 15.3 (A) Classification of the different types of renal dysfunction in cirrhosis. (B) Relative proportions of the different causes of acute kidney injury in cirrhosis. ATN, acute tubular necrosis; GN, glomerulonephritis; HRS, hepatorenal syndrome. (Data from references [1,16].)

One needs to be clear that AKI definitions describe acute renal failure from all causes, whether structural or functional renal diseases. Thus in this new classification of AKI, the entire spectrum of acute kidney failure is included. FRF, in contrast, only describes renal failure from functional changes in the kidneys related to hemodynamic changes in the systemic circulation and it can be acute or chronic (Fig. 15.3A). Acute or type 1 HRS only makes up a small proportion of patients with AKI (Fig. 15.3B). The common causes of AKI in cirrhosis are listed in Table 15.3, with the relative proportions of the different causes in hospitalized patients described in Figure 15.3B.

Table 15.3 Causes of acute kidney injury in cirrhosis.

Type	Disease entity
Functional renal failure, volume responsive	Prerenal renal failure: overdiuresis gastrointestinal bleeding vomiting and diarrhea infection
Functional renal failure, not volume responsive	Acute or type 1 hepatorenal syndrome
Structural	Acute glomerulonephritis Acute tubular necrosis: following type 1 hepatorenal syndrome following prerenal renal failure drug toxicity with aminoglycosides or nonsteroidal anti-inflammatory agents Osmotic tulopathy from: contrast agents hydroxyethyl starch
Postrenal	Bladder neck obstruction

Pathophysiology of functional renal failure

Most intrarenal or postrenal causes of AKI in cirrhosis are related to structural abnormalities in either the kidneys or the lower urinary tract. In contrast, FRF, be it volume responsive or not, is a direct result of the hemodynamic derangement and cardiaovascular changes of liver cirrhosis. The following is a summary of our understanding of the pathophysiology that has been implicated in the development of FRF, including HRS.

Portal hypertension as an initiator of hemodynamic changes in cirrhosis

The development of cirrhosis of the liver is associated with the laying down of fibrous tissues together with the formation of nodules, leading to a distortion of liver architecture. This results in alteration, compression, and sometime even obliteration of the hepatic vasculature, so the portal inflow is met with increased resistance. In addition, there is decreased production of vasodilators within the hepatic microcirculation, causing further increases in the resistance to portal inflow [20] and the development of portal hypertension. Changes in shear stress of the portal vessel wall lead to the production of various vasodilators such as nitric oxide, carbon monoxide, and endogeneous cannabinoids in the portal circulation [21–23]. As a result, portal-venous blood flow is increased and this contributes incrementally to the elevated portal pressure. It has been postulated that the increased flow to the splanchnic circulation can augment the shear stress on the splanchnic vasculature, causing further increased production of vasodilators such as nitric oxide. This portal-venous dilatation is eventually transferred to its tributaries, leading to splanchnic vasodilatation. Several other factors, including increased bacterial

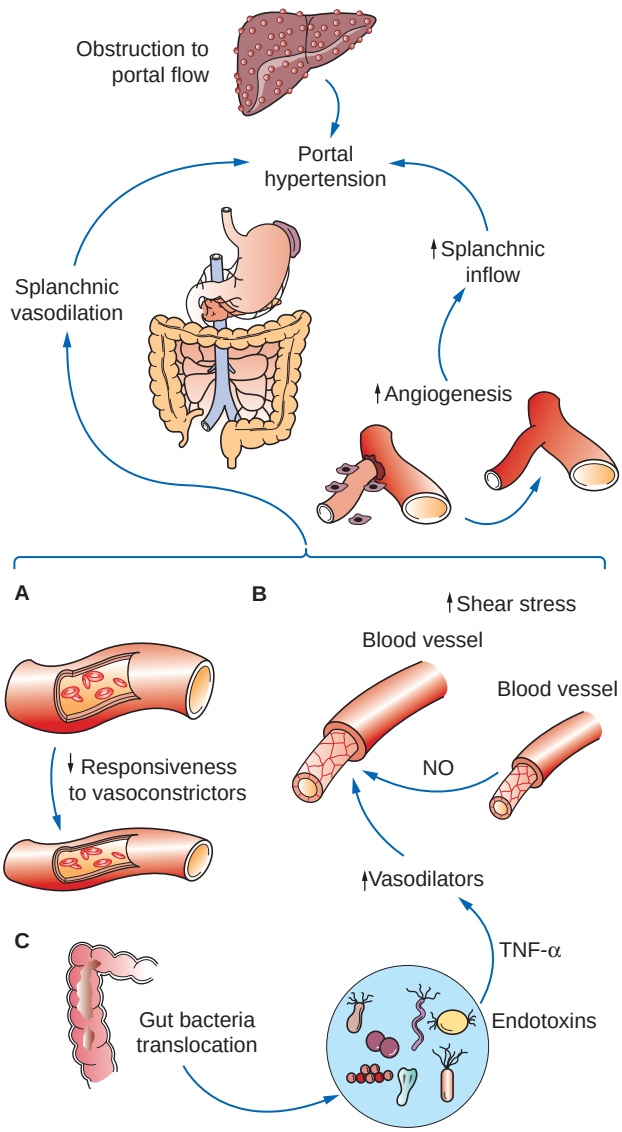

Figure 15.4 Portal hypertension as an initiator of hemodynamic changes in cirrhosis. There are three pathways that can lead to splanchnic vasodilatation: (a) decreased responsiveness to vasoconstrictors; (b) increased shear stress causing increased nitric oxide (NO) production, which in turn causes splanchnic vasodilatation; and (c) increased gut bacterial translocation leading to the production of bacterial products such as endotoxins and tumor necrosis factor α ((TNF-α), which are themselves vasodilators, causing splanchnic vasodilatation.

translocation, increased mesenteric angiogenesis, and hyporesponsiveness of the splanchnic vessels to vasoconstrictors, also contribute to the splanchnic vasodilatation and maintenance of the increased portal inflow (Fig. 15.4) [24].

Independent of the portal hypertension-related hemodynamic changes that occur in the splanchnic circulation and that eventually affect the systemic circulation, sinusoidal portal hypertension per se also has a direct effect on the renal circulation. For example, the infusion of glutamine into the mesenteric vein – which enters the portal circulation, causing hepatocyte swelling that increases hepatic sinusoidal pressure, mimicking portal hypertension – has been shown to result in a reduction of GFR. The same glutamine, when infused into the jugular vein, has no effect on the renal circulation [25]. In cirrhotic patients who have a patent transjugular intrahepatic portosystemic stent (TIPS) shunt and therefore no portal hypertension, the placement and subsequent inflation of an angioplasty balloon into the TIPS tract instantly recreates portal hypertension, associated with an almost instantaneous reduction of renal blood flow. Deflation of the angioplasty balloon removes the portal hypertension and results in an immediate return of the renal blood flow to baseline levels [26]. Finally, lumbar sympathetic blockade in patients with HRS has been shown to increase renal blood flow, suggesting that the renal sympathetic activity is implicated in the efferent arm of this hepatorenal reflex [27].

Hemodynamic changes and circulatory dysfunction in cirrhosis

Although the splanchnic circulation is the major site of arterial vasodilatation in cirrhosis, the presence of portal hypertension can lead to the opening of portosystemic shunts, which divert some of the splanchnic blood to the systemic circulation. It is possible that excess vasodilators are being shunted from the splanchnic to the systemic circulation, causing either a direct vasodilatory effect on the systemic circulation or an increase in the release of nitric oxide, or both. The systemic circulation initially responds to the vasodilatation or reduction in systemic vascular resistance by increasing its cardiac output, and by improving the intravascular volume through renal sodium retention, thereby maintaining hemodynamic stability [28]. However, as the liver cirrhosis advances, arterial vasodilatation continues. In the splanchnic circulation, the increased portal inflow together with increased resistance to portal flow means that there is pooling of blood in this vascular bed. In the systemic circulation, the progressive arterial vasodilatation is compensated for by a further rise in cardiac output and more avid renal sodium retention. Therefore, the total blood volume is increased. However, the maldistribution of the blood volume to the splanchnic circulation means that there is effectively a subtraction of volume from the systemic circulation, despite no actual loss of total blood volume, akin to a splanchnic steal syndrome. This condition is known as a "reduction in the effective arterial blood volume." Therefore, the systemic circulation becomes more hyperdynamic and other compensatory mechanisms are recruited to maintain hemodynamic stability (Fig. 15.5).

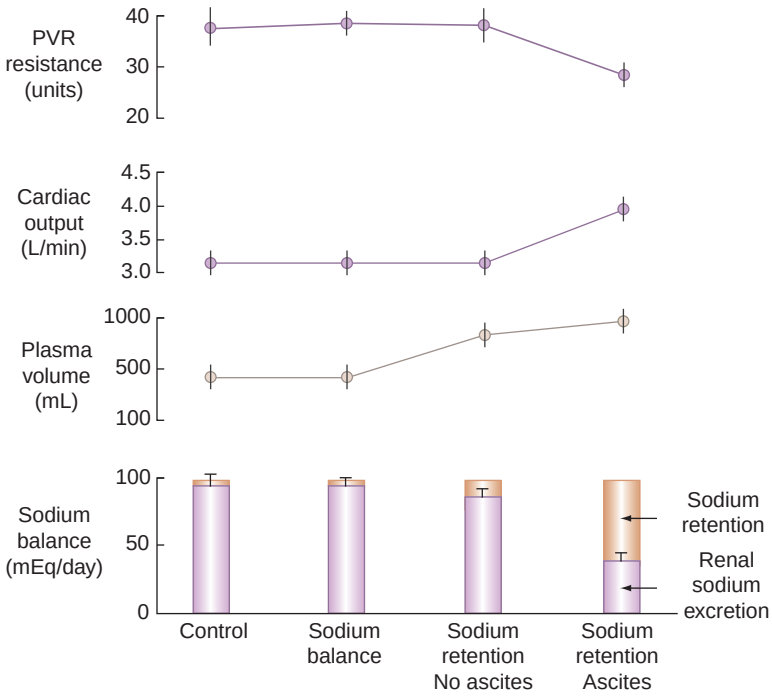

Figure 15.5 Schematic representation of hemodynamic changes and sodium retention during various stages in the natural history of cirrhosis. PVR, peripheral vascular resistance. (Adapted from Oliver and Verna [29].)

Excess renal vasoconstriction versus insufficient renal vasodilators

One of the consequences of a reduction in the effective arterial blood volume is the activation of various compensatory vasoconstrictor systems. These include the renin–angiotensin system, the sympathetic nervous system, and the nonosmotic release of vasopressin. Since the renal circulation is particularly sensitive to the effects of these vasoconstrictors, there is a decrease in renal blood flow with a consequent reduction in GFR. The relative renal ischemia from vasoconstriction of the renal artery also increases the production of various intrarenal vasoconstrictors such as angiotensin II, adenosine, and endothelin, causing further deterioration of renal hemodynamics and renal function. Normally, the kidneys maintain the renal circulation by increasing the production of renal vasodilators, which include nitric oxide, prostaglandins, and members of the natriuretic peptide family such as urodilatin. However, an overall reduction in the production of renal vasodilators in the presence of excess vasoconstrictors in advanced cirrhosis will render the cirrhotic patient susceptible to the development of renal failure. Any event that further disturbs this vasoconstrictor–vasodilator balance favoring the vasoconstrictors will precipitate renal failure [29].

Abnormal renal autoregulation in advanced cirrhosis

Acute renal failure in cirrhosis is not simply a case of too many vasoconstrictors versus too few vasodilators, otherwise reducing the mismatch between the extent of arterial vasodilatation and the volume within the circulation by improving the effective arterial blood volume should reverse every case of renal failure in cirrhosis. It has been adequately shown in various treatment studies that albumin alone, which improves the intravascular volume, does not have any effect on the renal impairment in patients with HRS [30,31]. Changes in renal autoregulation in advanced cirrhosis also contribute to the further development of renal dysfunction in these patients. Renal autoregulation is the process whereby regulatory mechanisms ensure that the kidneys receive an approximately constant blood supply regardless of the day-to-day fluctuations in blood pressure. In healthy individuals, renal autoregulation is operational above a renal perfusion pressure of >65 mmHg. Below that level, renal perfusion falls in proportion to renal perfusion pressure. However, in cirrhosis, there is a shift of the autoregulation curve to the right [32]; the more severe the cirrhosis, the more the renal autoregulation curve moves to the right. That is, as the cirrhosis process advances, for every given level of renal perfusion pressure, the renal blood flow progressively falls. Therefore, in end-stage cirrhosis, despite a decent renal perfusion pressure, the renal blood flow is severely compromised (Fig. 15.6).

Abnormal cardiac function in cirrhosis

The hyperdynamic circulation observed in cirrhosis is thought to be a compensatory mechanism in response to the decreased systemic vascular resistance to maintain

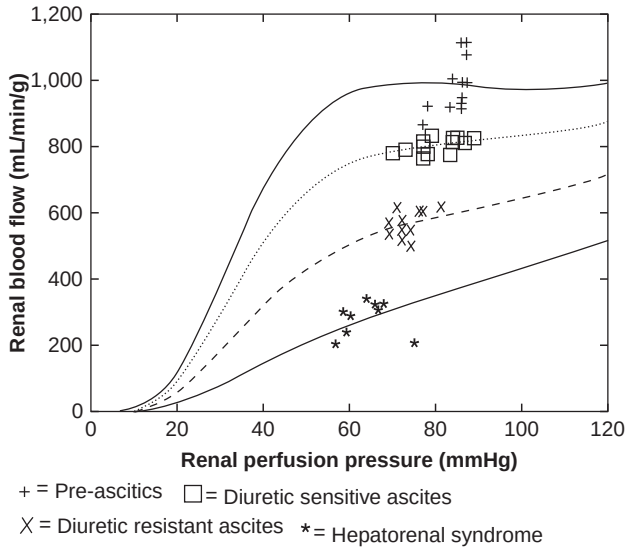

Figure 15.6 Changes in renal autoregulation with advancing stages of cirrhosis. (Adapted from Stadlbauer et al. [32] with permission from Nature Publishing Group.)

hemodynamic stability. This also means that patients with decompensated cirrhosis are encroaching on their cardiac reserve, and therefore any further reduction in the systemic vascular resistance may not be met with a similar increase in cardiac output. This is known as systolic incompetence, which can be brought out when there is further arterial vasodilatation such as during an episode of bacterial infection. When this happens, the circulation starts to fail, the blood pressure falls, and the renal circulation can be compromised and HRS can be precipitated. This systolic incompetence is now recognized as part of a syndrome known as cirrhotic cardiomyopathy, which also includes diastolic dysfunction and electrophysiologic abnormalities [33]. Indeed, in patients with cirrhosis and ascites, a relative low cardiac output and high plasma renin activity were significant predictors for the development of HRS [34]. A recent study indicated a correlation between low cardiac output, low mean arterial pressure, and low renal blood flow, supporting the role of cirrhotic cardiomyopathy in contributing to the development of renal failure in cirrhosis [35]. In a cohort of cirrhotic patients with ascites and spontaneous bacterial peritonitis, those who went on to develop HRS had significantly lower cardiac output at the time of infection resolution when compared to baseline, and also when compared to those who did not develop HRS at the time of infection resolution [36].

Factors that can precipitate functional renal failure in cirrhosis

Given the fact that one of the pathogenetic mechanisms for renal failure in cirrhosis is a reduction of effective arterial blood volume secondary to systemic vasodilatation, any event that reduces the circulatory volume further, or increases the extent of arterial vasodilatation, will likely precipitate acute renal failure in these patients. Therefore events such as gastrointestinal bleed, overdiuresis, excess vomiting, or diarrhea can all cause intravascular volume contraction, and put the cirrhotic patient at risk for the development of acute renal failure.

However, bacterial infections are by far the commonest cause of acute renal failure in cirrhosis. In fact, renal failure occurs in approximately one third of patients with bacterial infections [37,38]. This is related to the fact that the proinflammatory response in a host with cirrhosis is significantly enhanced. The myriads of inflammatory cytokines, such as tumor necrosis factor α and interleukin 6, released by the bacteria can induce various changes in the microcirculation of many organs including the kidneys. These include impairment of capillary flow due to the development of microthrombi, endothelial dysfunction as a result of impairment in mitochondrial respiration related to nitric oxide overproduction, and increased capillary permeability leading to capillary leaks. The end result is decreased perfusion and cellular injury in the organs affected [39]. Since the renal circulation in cirrhosis is hypoperfused in advanced cirrhosis, further compromise of the renal circulation with bacterial infection places the patient at great risk for acute renal failure. The incidence of renal impairment is most significant among patients with a serum bilirubin level >4 mg/dL (68 μmol/L) and a serum creatinine level >1 mg/dL (88 μmol/L), that is, patients who have some degree of liver dysfunction and underlying renal impairment [40].

Various drugs can also precipitate acute renal failure in cirrhosis. NSAIDs inhibit the synthesis of prostaglandins and therefore put cirrhotic patients at risk for acute renal failure since renal prostaglandins are important in maintaining the intrarenal circulation. Cirrhotic patients who have coexisting diabetes are often given angiotensin II antagonists for renal protection. Since cirrhotic patients are dependent on the activated renin–angiotensin system to maintain systemic blood pressure, the use of these agents can result in arterial hypotension and renal failure in these patients.

Clinical presentation of functional renal failure

There are no specific clinical features that can identify a cirrhotic patient who is developing FRF. The patient is usually ill with severe cirrhosis and ascites with or without jaundice or hepatic encephalopathy. Laboratory tests usually reveal hyperbilirubinemia, hypoalbuminemia, anemia, coagulopathy, and thrombocytopenia. For those

patients who are on diuretics, electrolyte abnormalities such as hyponatremia or hyperkalemia are common. Renal function can slowly deteriorate over weeks to months, due to the progressive hemodynamic changes that occur with advanced cirrhosis. When the serum creatinine reaches 1.5 mg/dL (133 μmol/L), the patient is said to have chronic or type 2 HRS [12] and this tends to follow a slowly downhill course. Occasionally, the renal function can spontaneously deteriorate rapidly, and this can be an episode that occurs in a patient whose serum creatinine suddenly rises from a normal level to higher than 1.5 mg/dL, or a patient who already has type 2 HRS suddenly shows an increase of serum creatinine to >2.5 mg/dL (220 μmol/L). More often, there is an event that precipitates a sudden worsening of renal function, and this is usually an episode of infection. Many of these episodes of acute renal failure are responsive to intravascular volume replacement, which can return the serum creatinine to baseline levels. Such episodes of acute renal failure are said to be episodes of prerenal renal failure. If the rise in serum creatinine reaches more than 2.5 mg/dL (220 μmol/L) in less than 2 weeks, associated with non-responsiveness to intravascular volume replacement, the patient is said to have acute or type 1 HRS [12].

Therefore, regular monitoring of renal function in patients with cirrhosis and ascites is of paramount importance, and the clinician caring for these patients has to be vigilant for potential clinical events that could precipitate acute deterioration in renal function. When a patient presents with a change in clinical state, whether it is the development of jaundice, excessive bruising, or hepatic encephalopathy, every effort should be made to exclude the development of acute renal failure and/or infection. The patient needs to be assessed for evidence of gastrointestinal blood loss, or dehydration from excess diuretic doses, or evidence of infection such as fever and tachycardia. Blood has to be taken for liver function and renal function tests. A full blood examination needs to be done to assess for leukocytosis or a fall in hemoglobin. A full septic workup including a chest X-ray, two sets of blood culture, ascitic fluid culture, and urine culture also need to be performed. An abdominal ultrasound and urinalysis, as well as a 24-hour urine collection, will need to be performed to exclude organic causes of renal failure (Table 15.4).

Table 15.4 Evaluation of patient who presents with acute deterioration of renal function

Type of evaluation	Investigations
Clinical assessment	Enquire about: excess diuretic doses excess fluid loss such as vomiting/diarrhea gastrointestinal bleeds potential nephrotoxic drugs fever, or symptoms to suggest infection Physical examination to look for: dehydration anemia evidence of infection worsening liver function
Laboratory tests	Liver function tests: INR, bilirubin, protein, albumin Liver enzymes: AST, ALT, ALP Renal function: daily serum creatinine and electrolytes Complete blood count: hemoglobin and white cell count
Full septic workup	Blood cultures × 2 Urine culture Ascitic fluid cell count and culture Chest X-ray
Exclude other causes of renal failure	Abdominal ultrasound to assess kidney sizes and exclude bladder neck obstruction Urinalysis to assess for casts and sediments 24-hour urine collection to assess for proteinuria

ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; INR, international normalized ratio.

Management of functional renal failure including hepatorenal syndrome

General measures

Initial management of these patients requires the exclusion of reversible or treatable conditions. A diligent search should be made for precipitating factors (infection, gastrointestinal bleeding) and treated accordingly (Fig. 15.7). Likewise nephrotoxic drugs should be removed. Cirrhotic patients with acute gastrointestinal bleed, poor liver function, and renal failure preferably should be managed in intensive care units to protect effective circulating blood volume and renal perfusion. Patients whose renal failure is due to hypovolemia from gastrointestinal bleeding should receive volume replacement in the form of blood or blood products. Arrangements should be made to perform endoscopies as soon as feasible.

Albumin as volume replacement therapy

Since one of the pathogenetic mechanisms for the development of FRF is a relative reduction in effective arterial blood volume, it stands to reason to replenish the intravascular volume. Albumin is preferred over normal saline as albumin is hypertonic to plasma and therefore able to maintain oncotic pressure better than saline, which can be easily transferred to the peritoneal cavity to

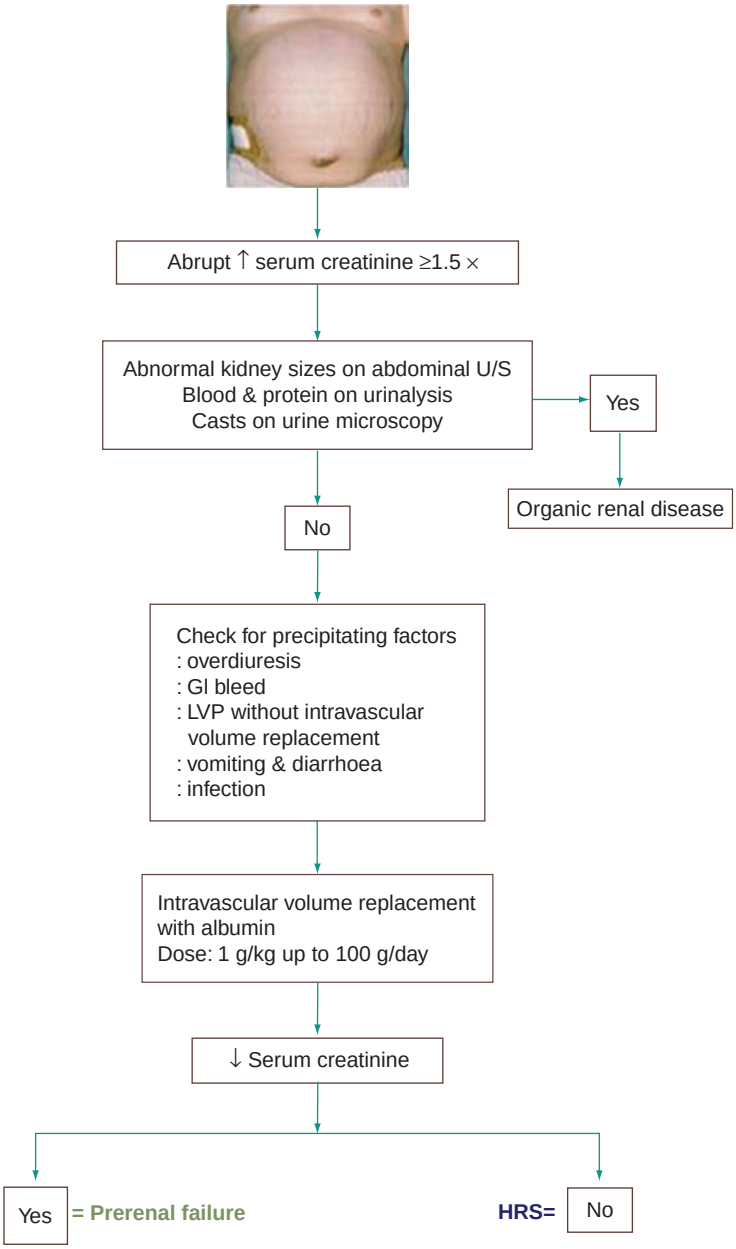

Figure 15.7 Suggested algorithm to differentiate the various causes of renal failure in a cirrhotic patient with ascites who presents with an acute rise in serum creatinine. GI, gastrointestinal; HRS, hepatorenal syndrome; LVP, large volume paracentesis; U/S, ultrasound.

worsen the ascites. In addition, albumin is a negatively charged molecule, which has ligand-binding, antioxidant, and endothelial protective properties [41]. Therefore, albumin potentially can also reduce the extent of systemic arterial vasodilatation by binding various vasodilators. Patients with prerenal renal failure should respond to volume replacement with albumin, with a gradual reduction of serum creatinine back to baseline levels. The International Ascites Club recommends an albumin dose of 1 g/kg up to 100 g/day [12].

Hepatorenal syndrome by definition is a diagnosis of exclusion and, therefore, patients with HRS will not respond to volume replacement with albumin. It has certainly been demonstrated that albumin alone is ineffective in the treatment of HRS [31]. There is some suggestion that albumin may not have any additional beneficial effects on renal function when used in combination with vasoconstrictors in the treatment of HRS. The largest retrospective study on the use of a vasoconstrictor, terlipressin, for HRS did not find any difference in the outcome of patients irrespective of whether albumin was added to terlipressin or not [42]. However, there is actually no study comparing vasoconstrictor therapy with or without albumin. Given the fact that there is no evidence that albumin actually does harm, it seems prudent to use albumin in the treatment of HRS. The International

Ascites Club recommends the use of 20–40 g of albumin per day in combination with vasoconstrictors, after an initial dose of 1 g/kg of body weight up to 100 g/day on the initial 2 days [12].

Treatment of hepatorenal syndrome

Vasoconstrictor therapy

The rationale of using systemic vasoconstrictors is to reduce the extent of the systemic vasodilatation. Their use should lead to a rise in the systemic arterial blood pressure, which in turn will improve the renal perfusion pressure. In addition, there will be a reduction in the difference between the vascular capacitance and the blood volume within in. The resultant improvement in the effective arterial blood volume will lead to a dampening of the activities of the various vasoconstrictors, thereby decreasing the renal vasoconstriction, with overall improvement in renal blood flow and glomerular filtration.

Terlipressin

Terlipressin is a vasopressin analog and has a similar mode of action as vasopressin but without many of the potential ischemic side effects. It is essentially a vasoconstrictor for both the systemic and splanchnic circulations. Its efficacy as a treatment for type 1 HRS has been reported in two large randomized controlled trials [31,43]. The infusion of terlipressin at a dose of 0.5–2 mg/4–6 hours intravenously for up to 15 days was associated with a reduction of serum creatinine to less than 1.5 mg/dL in 34–43% of patients. Treatment-related serious side effects were not excessive (9% and 22% in the two studies) and these included abdominal cramps and increased bowel movements, arrhythmia, and ischemia to the bowels, heart, and limbs. Upon withdrawal of terlipressin, the recurrence of HRS was infrequent. In those patients whose HRS recurred, retreatment with the same dose of terlipressin invariably led to the same favorable response [31,43]. There was no overall improvement in survival with terlipressin over placebo. However, in the subgroup of patients who responded to terlipressin with reversal of HRS, there was a significant increase in survival [43]. Recent meta-analyses of all the terlipressin studies have also not shown a significant improvement in survival with terlipressin [44,45]. However, when terlipressin was analyzed together with other vasoconstrictors used in the treatment of HRS, there was a slight improvement of survival favoring the vasoconstrictors [46]. It is not clear how much weight the terlipressin studies had on the outcome of the meta-analysis of all vasoconstrictors. However, if the outcome is even slightly improved, then the use of terlipressin may be sufficient to allow these patients to wait for a liver transplant. Predictors of response to terlipressin include a bilirubin level of <10 mg/dL and a rise in mean arterial pressure by >5 mmHg on day 3 of treatment [47]. In those patients who do not respond to terlipressin, the prognosis remains poor.

Terlipressin has also been used in a total of 43 patients with type 2 HRS with similar response rates [48–51]. However, the number of patients studied is too small to draw any firm conclusions on its use for type 2 HRS patients.

Norepinephrine

In a pilot study of 12 patients with cirrhosis, refractory ascites, and type 1 HRS, the use of intravenous norepinephrine (0.5–3 mg/h) in combination with albumin and intravenous furosemide resulted in the reversal of HRS in ten of the 12 patients after a median of 7 days [52]. In a follow-up study, comparing the efficacy of norepinephrine versus terlipressin in the treatment for both type 1 and type 2 HRS, norepinephrine resulted in a 70% complete response rate compared to that of $\geq$80% with terlipressin [50]. The response rate in this study is higher than expected, perhaps due to the large number of patients with type 2 HRS included in the study. Nonetheless, the results are very encouraging, especially since the patients receiving norepinephrine did not have significant ischemic side effects. Most of the patients in the study received a liver transplant within 1 month after completion of vasoconstrictor therapy, making it impossible to assess the role of improved renal function on ascites elimination and on survival.

In another head-to-head study comparing the efficacy of norepinephrine versus terlipressin in the management of type 1 HRS, 20 patients who received 0.5–3 mg/h of norepinephrine as a continuous infusion were compared to 20 patients who received 0.5–2 mg/4–6 hours of terlipressin as boluses [53]. There was no significant difference in terms of the response rate (ten patients in the norepinephrine group versus eight patients in the terlipressin group), associated with significant and similar reductions in plasma renin activity, suggesting that both drugs had induced a marked improvement in the effective arterial blood volume. The ischemic side effects were similar in both groups. The authors concluded that norepinephrine could be an effective and safe alternative to terlipressin as a treatment for HRS without the attendant high costs.

Midodrine and octreotide

Midodrine is an α-agonist that improves systemic blood pressure and hence improves renal perfusion pressure. Traditionally, it has been used in the management of postural hypotension. Despite this, midodrine alone has not been shown to be effective in patients with HRS [54]. Octreotide is a long-acting analog of somatostatin, which antagonizes the action of various splanchnic vasodilators and potentially can reduce the extent of splanchnic

vasodilatation. The use of octreotide alone also has not been proven to be useful for patients with HRS [55]. However, when midodrine is combined with octreotide and plasma volume expansion with albumin, several studies, both prospective [56,57] and retrospective [58], have shown a significant reduction in serum creatinine, although renal function does not return to normal despite suppression of all measured neurohormonal systems to within their normal ranges. The systemic and renal hemodynamics, and urinary sodium excretion, all improve in patients with type 1 HRS but remain at subnormal levels. The doses used differed between the various studies. In general, the dose of midodrine was titrated to reach a mean arterial blood pressure of at least 90 mmHg, with a starting dose varying between 2.5 and 7.5 mg t.i.d. Likewise, octreotide can be given either subcutaneously at a dose of 100 μg t.i.d. or intravenously at 25 μg/h after an initial bolus of 25 μg. Recent retrospective data suggest that the combination can also improve short-term survival for up to 3 months [58,59]. Clearly, larger randomized controlled trials are needed to establish the combination as an effective treatment for type 1 HRS. Despite this, the combination is very popular in North America as a treatment for HRS because of the nonavailability of terlipressin. However, with the pharmaceutic industry actively trying to have terlipressin approved in North America, these randomized controlled trials may never be done.

Transjugular intrahepatic portosystemic stent shunt

Since sinusoidal portal hypertension is the initiator of the hemodynamic changes that lead to relative renal ischemia and hence decreased renal function, it makes physiologic sense to reduce the sinusoidal portal pressure with TIPS insertion. In addition, TIPS returns a significant portion of the splanchnic volume into the systemic circulation, leading to suppression of various vasoactive neurohormones and resulting in better renal perfusion.

To date, there are no controlled studies assessing the efficacy of TIPS for the management of HRS. Of the eight studies published so far [57,60–66], most have focused on patients with type 1 HRS, while two studies assessed a mixed population of type 1 and type 2 HRS patients [60,61], and one study only included type 2 HRS patients [62]. TIPS produced an improvement in renal function in all reported studies, associated with a significant suppression of the endogenous vasoactive systems [61]. The improvement was observed to last for up to 6 months in the study that had the longest duration of follow-up [61]. Despite the improvement in renal function, neither the GFR nor the renal plasma flow returned to normal in the studies where this was systematically examined [57,66]. Ascites was also reported to decrease significantly. TIPS appears to confer a survival advantage over conventional medical treatment, with one study reporting an 18-month survival of 35% [61]. This may be related to the fact that TIPS can only be inserted in patients with relatively preserved hepatic function, thereby preselecting patients whose survival would have been expected to be reasonable even without TIPS. It is interesting to note that TIPS has not been cited in any recent publications on the treatment for HRS, suggesting that other treatment modalities may have supplanted its use. However, in the latest review on the clinical applications for TIPS, it has been suggested that it should be considered as a treatment for HRS in those patients whose liver function is relatively preserved, such as abstinent alcoholics, and/or patients who are candidates for liver transplantation [67].

Combined vasoconstrictor therapy and TIPS

The combination of vasoconstrictor therapy followed by TIPS effectively corrects different aspects of the pathophysiology of HRS, namely the elimination of portal hypertension and reduction of the extent of systemic arterial vasodilatation. Therefore, combination therapy should have an additive effect in improving renal function in patients with HRS. Midodrine, octreotide, and albumin were administered to 14 patients with type 1 HRS [57]. In those patients who responded to pharmacotherapy with improvement of renal function, TIPS insertion followed in those who were deemed suitable for such a procedure, and this normalized renal function over the course of 12 months and allowed the eventual elimination of ascites. The overall survival rate was 50%, with the longest patient surviving 30 months. In another study, 11 patients with type 2 HRS received terlipressin together with albumin, which maintained the central venous pressure to 10 cmH_2O [49]. TIPS placement was possible for nine of the 11 patients who showed a reduction in serum creatinine with terlipressin. The combination eventually brought the serum creatinine down to 1.36 ± 0.3 mg/dL at 1 month post TIPS. As expected, TIPS improved 24-hour urinary volume in all patients, leading to a lower post-procedure diuretic requirement. Ascites also significantly decreased in all patients and eventually disappeared from the second week onwards after TIPS [49,57].

Extracorporal albumin dialysis

Extracorporeal albumin dialysis is a procedure that uses a cell-free albumin-containing dialysate to remove albumin-bound substances, including bilirubin, bile acids, aromatic amino acids, medium chain fatty acids, and cytokines [68]. One such system is the molecular adsorbent recycling system or MARS. The rationale for using MARS to treat HRS is because some of the cytokines and bile acids are vasoactive substances. Therefore, they could be contributing to the vasodilatation and

consequent reduction in effective arterial blood volume that is central to the pathogenesis of HRS. In a prospective, randomized controlled study, MARS improved clinical and biochemical parameters as well as survival in eight patients with type 1 HRS who were not candidates for TIPS insertion, when compared with a well-matched group of patients who were treated with volume expansion and standard dialysis [69]. In another study of eight patients with acute liver failure, five of whom had established HRS, the use of MARS also led to similar results [70]. In both studies, serum creatinine was used as a marker of renal function. Creatinine is a water-soluble compound, and therefore can be removed during dialysis with MARS treatment. In another study on MARS for HRS, renal function was assessed using inulin clearance as an index of GFR, while simultaneously measuring serum creatinine [71]. As expected, the serum creatinine decreased during the course of MARS treatment, while inulin clearance or GFR remained low and unchanged. Cessation of MARS treatment led to a prompt return of serum creatinine to the pretreatment elevated levels. Therefore, the seemingly beneficial effect of MARS on serum creatinine is transient and artificial. Furthermore, MARS is a very expensive therapy and is demanding on physician and nursing time. Based on the findings of the latest study, MARS may not be recommended for type 1 HRS in cirrhotic patients with refractory ascites.

Renal replacement therapy

Dialysis has been ineffective in the management of HRS [72,73]. The systemic hypotension induced by hemodialysis often compromises the patient's hemodynamic instability even further. However, in the patients who have potentially reversible liver damage due to toxins or sepsis, dialysis may have a role in supporting the patient over the critical period. In patients who are awaiting liver transplantation, dialysis may be life saving as a bridging therapy [74]. The use of continuous arteriovenous hemofiltration may prove to be more effective as the procedure induces less hypotension [75]. Careful maintenance of circulating blood volume and cardiac filling pressures is key to successful dialysis in suitably selected patients.

Liver transplantation

Liver transplantation is the definitive treatment for HRS. It corrects liver dysfunction and eliminates portal hypertension. The main limiting factor is the availability of donor organs, and many patients die while waiting for one. The model for end-stage liver disease (MELD) scoring system of organ allocation means that cirrhotic patients with severe liver dysfunction and renal failure are given preference for earlier transplantation [76]. Renal function improves in many patients with HRS after transplantation, associated with a reduction in plasma levels of vasoactive factors [77]. However, up to 40% of patients can remain dependent on dialysis after liver transplantation [78]. This may be related to the persistence of the hyperdynamic circulation with high cardiac output and high splanchnic blood flow after liver transplantation [79]. The presence of pretransplant renal dysfunction predicts a worse outcome after liver transplantation with a longer stay in intensive care units, longer hospitalization, more dialysis treatments, and reduced survival (Fig. 15.8) [80,81]. In addition, patients with HRS who are transplanted have a lower probability of both graft and patient survival after liver transplantation, compared with patients without HRS [82]. However, treatment of HRS with vasoconstrictors before liver transplant can improve the post-transplant outcome [83]. Longer follow-up is required to confirm that pretransplant normalization of renal function will improve post-transplant survival.

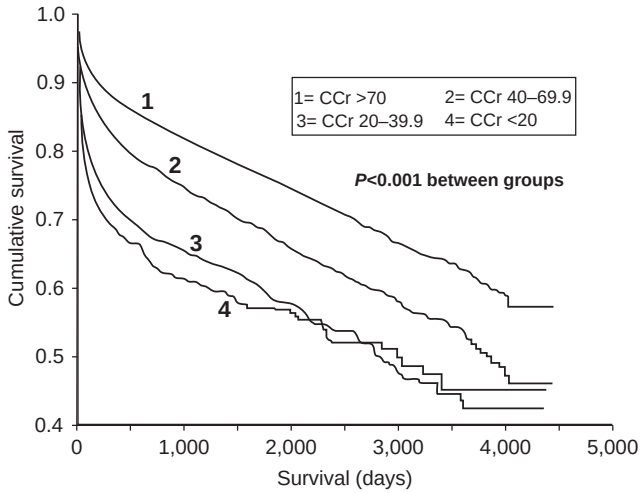

Figure 15.8 Pre liver transplant renal dysfunction is associated with a significantly reduced survival after transplant. CCr, creatinine clearance. (Adapted from Nair et al. [80] with permission from Plenum Publishers.)

Because of the fact that not all patients with HRS will recover their renal function post transplant, there have been efforts to identify early those patients who will not do well after liver transplant and offer them a combined liver–kidney transplant (CLKT). Since the implementation of the MELD scoring system for the allocation of donor organs for liver transplantation, the number of patients who possibly need CLKT has risen significantly. Despite established guidelines, it is still difficult to separate those patients with structural renal disease from those with HRS, especially since HRS may evolve into acute tubular necrosis if the renal failure persists. The presence of alcoholic hepatitis, a need for pretransplant dialysis [78], as well as a duration of dialysis for more than 8 weeks pretransplant [84] have been found to be

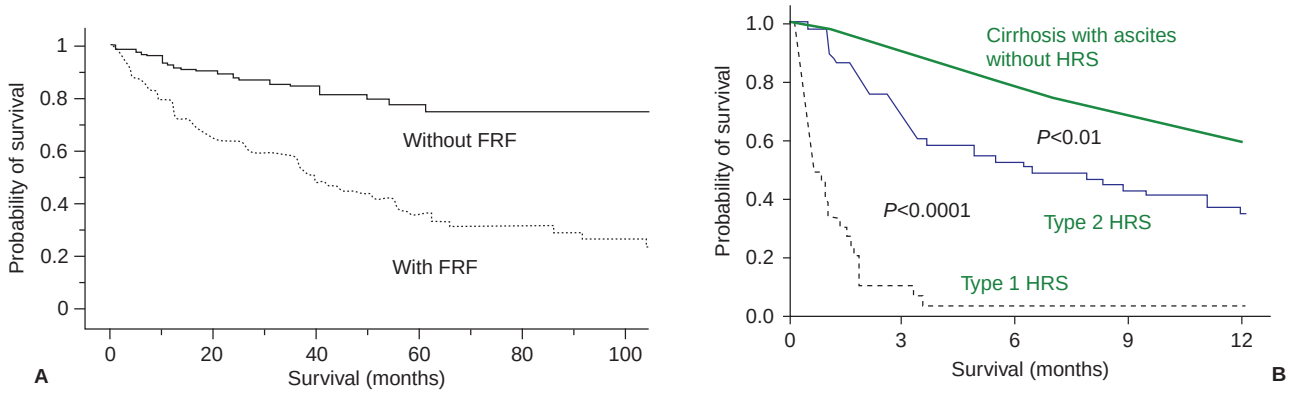

Figure 15.9 Actuarial probability of survival: (A) in patients with or without functional renal failure (FRF); and (B) in patients with hepatorenal syndrome (HRS). (Adapted from Montoliu et al. [2] with permission from Elsevier; Alessandria et al. [87] with permission from Plenum Publishers.)

predictors of poor renal recovery post transplant. Therefore, it has been proposed that patients who have had more than 8–12 weeks of pretransplant dialysis should be considered for CLKT [84,85]. However, recent data suggest that a wait-and-see approach is preferred, as patient and graft survivals are inferior for CLKT when compared to a liver transplant alone [86]. Therefore, there is merit in performing a liver transplant first and then considering a kidney transplant if there is no renal recovery after the first transplant.

Prognosis

The prognosis of patients with cirrhosis and FRF is poor [2]; this is in part related to the associated liver failure. Compared to patients with advanced cirrhosis but without FRF, who have an 80% survival over 8 years, the 50% survival of these patients is reduced to 40 months (Fig. 15.9A). When HRS develops, survival without treatment is reduced even further (Fig. 15.9B) [87], with a median survival for type 1 HRS of 10 days. Predictive factors for the development of FRF in cirrhosis include advancing age, rising serum creatinine, and a high Child–Pugh score (Table 15.5) [2]. Once the patient has developed FRF, independent predictors of poor prognosis include advancing age, a high MELD score, a high Child–Pugh score, hyponatremia, and the presence of HRS [2,88]. If the patient has established type 1 HRS, a Child–Pugh score of >10, a MELD score of >20, and

Table 15.5 Predictive factors for the development of functional renal failure and for the survival of cirrhotic patients after the development of functional renal failure.

Condition	Predictors
Functional renal failure	Increasing age Increasing serum creatinine High Child–Pugh score
Poor survival after the development of functional renal failure	Increasing age High Child–Pugh score High MELD score Hyponatremia Presence of HRS
Poor survival after the development of type 1 HRS	Child–Pugh score >10 MELD score >20 Nonresponsiveness to treatment

HRS, hepatorenal syndrome; MELD, model for end-stage liver disease.

Table 15.6 Prevention of functional renal failure.

Condition	Action
Diuretic use	Frequent monitoring of electrolytes and serum creatinine Be willing to withdraw diuretics when there are electrolyte abnormalities or a rise in serum creatinine occurs
Gastrointestinal blood loss	Prompt replacement of intravascular blood volume Administer antibiotic prophylaxis to prevent infection
Bacterial infection	Administer albumin 20-40 mg/day in patients with a serum bilirubin level >4 mg/dL (68 μmol/L) and serum creatinine level >1 mg/dL (88 μmol/L)
Low ascitic fluid protein (<15 g/L), with poor liver renal functions [90]	Long-term norfloxacin 400 mg/day in patients with a serum bilirubin >3 mg/dL, Child–Pugh score >10, serum sodium <130 mmol/L, and serum creatinine >1.2 mg/dL to reduce the risk of infection
Nephrotoxic drugs	Do not administer nonsteroidal anti-inflammatory agents

failure to respond to treatment will predict an adverse outcome [87,89]. Therefore, to improve the overall prognosis of these patients, the treating clinician will need to be vigilant for tell-tale signs of impending liver failure and/or kidney failure, and to promptly correct any clinical or laboratory abnormalities to prevent the development of FRF (Table 15.6). The good news is that FRF used to be a condition with an almost certain fatal outcome, but is now rapidly becoming a treatable complication of liver cirrhosis.

Management protocol of functional renal failure in cirrhosis

A patient with cirrhosis and ascites presents with an acute increase in serum creatinine of 1.5 times baseline.

Initial assessment

- Enquire about:
  - Excess diuretic doses
  - Excess fluid loss such as vomiting/diarrhea
  - Gastrointestinal bleeds
  - Potential nephrotoxic drugs
  - Fever, or symptoms to suggest infection
- Physical examination for:
  - Dehydration
  - Anemia
  - Evidence of infection
  - Worsening liver function such as the development of jaundice or encephalopathy

Laboratory investigations

- Liver function tests: INR, bilirubin, protein, and albumin
- Liver enzymes: AST, ALT, and ALP
- Renal function: daily serum creatinine and electrolytes
- Complete blood count: hemoglobin and white cell count

Full septic workup

- Blood cultures ×2
- Urine culture
- Ascitic fluid cell count and culture
- Chest X-ray

Exclude other causes of renal failure

- Abdominal ultrasound to assess kidney sizes and exclude bladder neck obstruction
- Urinalysis to assess for casts and sediments
- 24-hour urine collection to assess for proteinuria

Initial management

- Intravascular volume expansion with albumin 1 g/kg up to a total dose of 100 g
- Empirical dose of an antibiotic such as a third generation cephalosporin until infection can be excluded. If infection is confirmed, change the antibiotic according to sensitivity testing
- If serum creatinine decreases with volume expansion, continue with daily albumin until the serum creatinine returns to baseline
- If serum creatinine does not change or increase despite volume expansion for 2 days, initiate treatment for hepatorenal syndrome

Treatment of hepatorenal syndrome

- Vasoconstrictor therapy:
  - Terlipressin as intravenous boluses 1–2 mg every 4–6 hours for 15 days, *or*
  - Norepinephrine 0.5–3 mg/h as a continuous infusion, *or*
  - Midodrine 2.5–7.5 mg orally t.i.d. plus octreotide either as 100 μg subcutaneous injections t.i.d. or as a continuous infusion of 25 μg/h after a 25 μg bolus
- A transjugular intrahepatic portosystemic stent shunt can be inserted either as a stand-alone treatment or following improvement of renal function with vasoconstrictor therapy in appropriate patients
- Renal replacement therapy is of no proven value unless patient is awaiting liver transplantation, and therefore needs dialysis as a bridge therapy

Liver transplantation

- Assessment should be initiated in all patients who do not have a contraindication for liver transplant
- Correction of renal function before transplant will significantly improve post-transplant survival

ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; INR, international normalized ratio.

Multiple choice questions

15.1 Which of the following statements describes functional renal failure in cirrhosis?

- **a** Renal failure where there is no structural damage in the kidneys.
- **b** Diagnosed when the serum creatinine is >2 mg/dL.
- **c** Acute renal failure that occurs in patients with cirrhosis.
- **d** The same as hepatorenal syndrome.

15.2 Acute kidney failure in cirrhosis is which of the following?

- **a** It is renal failure that occurs rapidly as a result of advanced cirrhosis.
- **b** It can include conditions such as glomerulonephritis in cirrhosis.
- **c** It requires an abnormal serum creatinine reading for diagnosis.
- **d** It is a widely accepted concept in the hepatology community.

15.3 Which of the following statements applies in assessing a patient for a diagnosis of acute or type 1 hepatorenal syndrome?

- **a** One should always look for a precipitating event as hepatorenal syndrome never occurs spontaneously.
- **b** The patient usually has signs to suggest a hyperdynamic circulation.
- **c** The rise in serum creatinine occurs within 48 hours.
- **d** The urinary sodium is always <10 mmol/day.

15.4 Which of the following is true for the treatment for acute or type 1 hepatorenal syndrome?

- **a** It should start as soon as all other cause of acute renal failure have been excluded.
- **b** It includes the empirical use of a broad-spectrum antibiotic.
- **c** It should continue for at least 15 days in order to determine whether the patient is likely to respond or not.
- **d** It could be either vasoconstrictor therapy or the insertion of a transjugular intrahepatic portosystemic stent shunt.

15.5 Which of the following is true with regard to liver transplantation for patients with type 1 hepatorenal syndrome?

- **a** The patient should receive a simultaneous kidney transplant.
- **b** The length of dialysis pre transplant has no impact on the decision regarding whether to perform a liver transplant alone or a combined liver–kidney transplant.
- **c** Since hepatorenal syndrome is a totally reversible condition, the presence of hepatorenal syndrome pre transplant does not have any effect on post-transplant graft and patient survival.
- **d** Correcting the renal failure pre transplant can significant improve patient survival post transplant.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 16
Pulmonary Manifestations of Liver Disease

Rajan Kochar & Michael B. Fallon

Division of Gastroenterology, Hepatology and Nutrition, The University of Texas Health Science Center at Houston, Houston, TX, USA

Key concepts

- Liver disease, most commonly cirrhosis, is associated with unique pulmonary vascular abnormalities independent of intrinsic cardiopulmonary disease.
- About 15–30% of patients with cirrhosis develop hepatopulmonary syndrome (HPS), which results when vasodilatation in the pulmonary microvasculature leads to impaired gas exchange. The presence of HPS increases mortality in cirrhosis. Currently, liver transplantation is the only established therapy for HPS. However, when HPS is severe, the outcome of liver transplantation may be adversely affected.
- Portopulmonary hypertension (POPH) results when vasoconstriction and vascular remodeling increases pulmonary vascular resistance and elevates the mean pulmonary artery pressure. POPH occurs in 4–8% of patients with cirrhosis, and when moderate or severe prohibitively increases mortality after liver transplantation. Medical therapies can improve pressures but it is unclear whether liver transplantation reliably improves POPH.
- Screening for HPS and POPH is important in cirrhosis because the presence of these disorders influence survival and liver transplantation candidacy.

Dyspnea is common in patients with chronic liver disease, and an estimated 50–70% of patients with cirrhosis undergoing evaluation for liver transplantation complain of shortness of breath [1]. The differential diagnosis of dyspnea in chronic liver disease is broad and there a number of important causes to consider. The most common causes of these abnormalities are intrinsic cardiopulmonary disorders independent of liver disease (i.e., chronic obstructive pulmonary disease, interstitial lung disease, and congestive heart failure). Additionally, symptoms may result from general complications of cirrhosis such as patient deconditioning, muscular wasting, the presence of tense ascites, and/or hepatic hydrothorax (Chapter 17). Finally, certain liver diseases may be associated with specific pulmonary abnormalities such as panacinar emphysema in α_1-antitrypsin deficiency (Chapter 31) and fibrosing alveolitis, pulmonary hemorrhage, and granulomas in primary biliary cirrhosis (Chapter 21).

In a subset of patients though, two distinct pulmonary vascular complications of liver disease, the hepatopulmonary syndrome (HPS) and portopulmonary hypertension (POPH), are observed as important causes of pulmonary dysfunction. This chapter will review the epidemiology, clinical characteristics, and treatment of these disorders.

Hepatopulmonary syndrome

Definition

Hepatopulmonary syndrome is commonly defined as a widened age-corrected alveolar–arterial oxygen gradient ($AaPO_2$) on room air with or without hypoxemia that occurs as a result of intrapulmonary vasodilatation in the presence of hepatic dysfunction or portal hypertension [2,3].

Epidemiology, risk factors, and disease associations

Intrapulmonary vasodilatation is present in over 50% of cirrhotics evaluated for orthotopic liver transplantation (OLT). In addition, 15–30% of those with intrapulmonary shunting have impaired oxygenation leading to the diagnosis of HPS [4]. Prior definitions of HPS emphasized the need to exclude intrinsic cardiopulmonary disease in order to establish the diagnosis. However, recent data support the view that HPS may occur in the setting of other cardiopulmonary abnormalities [5,6].

Typically, HPS is diagnosed in subjects with cirrhosis and portal hypertension regardless of the underlying etiology of liver disease. However, cases of HPS have been

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

described in patients with portal hypertension without cirrhosis (prehepatic portal hypertension, nodular regenerative hyperplasia, congenital hepatic fibrosis, and hepatic venous outflow obstruction [7–10]) and in patients with hepatic dysfunction in the absence of established portal hypertension (acute and chronic hepatitis [11–13]). These findings support that advanced liver disease is not required for HPS to develop. Controversy exists regarding whether HPS is more common or severe in patients with advanced cirrhosis, although a recent prospective multicenter study did not find an association between HPS and severity of liver disease in patients being evaluated for OLT [14].

Pathogenesis

The most important alteration in HPS is dilatation of the precapillary and postcapillary pulmonary vasculature [15], which leads to impaired oxygenation of venous blood as it passes through the lung [16,17].

Human studies have demonstrated increased pulmonary production of nitric oxide (NO), which may contribute to intrapulmonary vasodilatation. Exhaled NO levels are increased in cirrhotic HPS patients and normalize after liver transplantation [18–20], as HPS resolves. However, the increase in NO production is not unique to HPS and inhibition of NO production or action does not reliably improve HPS [21–25].

In animal models, increased pulmonary production of NO appears to be a central event in the development of HPS through increased pulmonary vascular expression and activity of endothelial nitric oxide synthase (eNOS) [25–28]. Enhanced hepatic production and release of endothelin 1 (ET-1) and shear stress-mediated increase in pulmonary endothelial endothelin B (ET_B) receptor expression appear to be major contributors to the observed increase in eNOS [29–31]. These events lead to enhanced ET-1 activation of eNOS through the ET_B receptor and are followed by the intravascular accumulation of macrophages and the production of inducible nitric oxide synthase (iNOS) [25,27,28] and heme oxygenase 1 (HO-1) [27,32] leading to increased NO and carbon monoxide production, respectively, which result in vasodilatation. In addition, a recent study has shown that angiogenesis is an important contributor to the development of experimental HPS and is associated with activation of the angiogenic pathways (such as vascular endothelial cell growth factor A (VEGF-A)), in part by intravascular monocytes [33]. Figure 16.1 summarizes the current understanding of mechanisms of pulmonary microvascular dilatation in experimental HPS. However, whether similar mechanisms are operative in human disease is unknown.

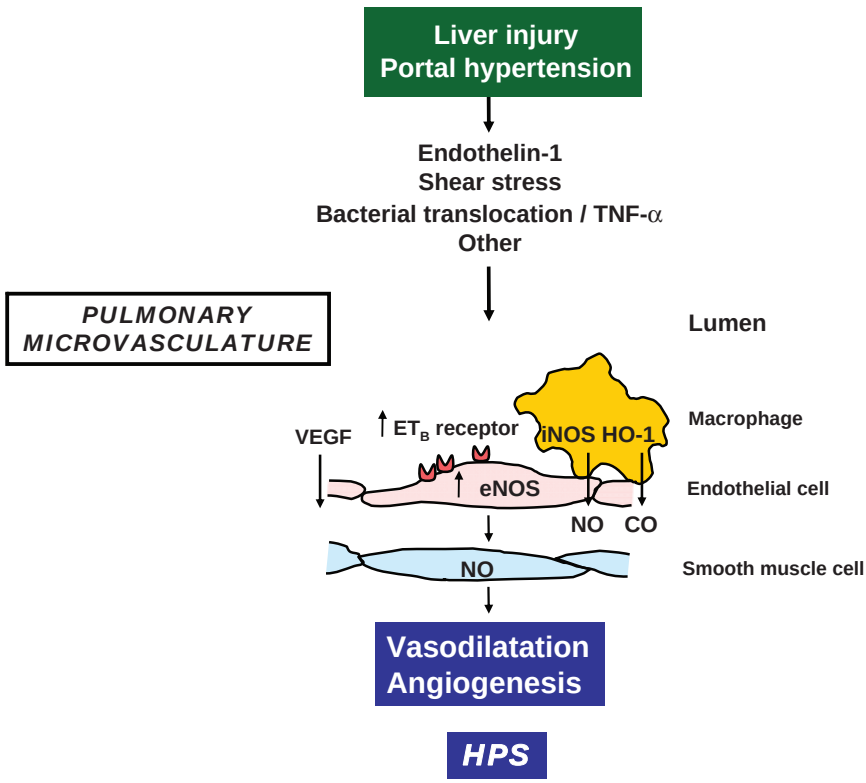

Figure 16.1 Proposed mechanisms of hepatopulmonary syndrome (HPS) based on findings in experimental models. Liver injury and/or portal hypertension trigger the production of cytokines and vasoactive mediators that increase vascular shear stress. Pulmonary microvascular dilatation is initiated by hepatic endothelin 1 production and release and endothelial nitric oxide synthase (eNOS)-derived nitric oxide (NO) production through an increased number of endothelial endothelin B (ET-B) receptors. Macrophage accumulate in the microvascular also contributes to vasodilatation by producing NO from inducible nitric oxide synthase (iNOS) and carbon monoxide (CO) from heme oxygenase 1 (HO-1). Activation of angiogenic pathways such as vascular endothelial growth factor A are also facilitated through intravascular mononuclear cells leading to angiogenesis. TNF-α, tumor necrosis factor α.

Clinical features

The diagnosis of HPS may be overlooked or delayed since many patients with HPS are asymptomatic or respiratory symptoms may be attributed to intrinsic lung disease, therefore a high index of suspicion is necessary to establish the diagnosis. In symptomatic patients, the insidious onset of dyspnea [1] is the most frequent complaint. Platypnea (increased dyspnea upon standing) and orthodeoxia (hypoxemia exacerbated in the upright position) are classic features of HPS. They are attributed to the predominance of vasodilatation in the lung bases and the increased "shunting" through these regions when upright leading to hypoxemia [34,35]. Spider angiomata, digital clubbing, and cyanosis are also commonly described in subjects with HPS and may increase the clinical suspicion for the diagnosis when present [35,36]. Chest radiographs are most commonly normal, but may reveal lower lobe interstitial changes that may be confused with interstitial lung disease [37]. Pulmonary function tests typically demonstrate well-preserved spirometry and lung volumes; however, the diffusing capacity for lung carbon monoxide (DLCO) is often significantly reduced. The DLCO is also commonly decreased in cirrhosis in the absence of HPS and the diagnostic utility of a reduced value has not been established [38].

Evaluation for hepatopulmonary syndrome

Pursuing the diagnosis of HPS is appropriate in patients complaining of dyspnea and/or in those who display digital clubbing or cyanosis. In patients being considered for liver transplantation, regardless of the presence of symptoms, screening is important as the presence of HPS may influence transplant candidacy and priority. Figure 16.2 summarizes one approach to the diagnosis of HPS.

The diagnosis of HPS is established by: (i) the presence of arterial gas exchange abnormalities; and (ii) documenting intrapulmonary vasodilatation. Gas exchange abnormalities, detected by arterial blood gas measurements, are defined as a widened A$a$$P$$O_2$ (>15–20 mmHg) with or without hypoxemia (PaO_2 <70 mmHg) [3]. Obtaining arterial blood gases in the sitting position may enhance the detection of hypoxemia in HPS due to the predominance of vasodilatation in the lower lung fields. Pulse oximetry is a noninvasive screening modality that indirectly measures oxygen saturation (SpO_2) and is a useful screening test for arterial hypoxemia and HPS [39]. From a clinical perspective, SpO_2 measurements can guide subsequent use of arterial blood gases and contrast echocardiography.

Two-dimensional transthoracic contrast echocardiography is the most sensitive and most commonly employed screening technique to detect intrapulmonary vasodilatation (Fig. 16.3). It is performed by injecting agitated saline intravenously during normal transthoracic echocardiography, producing microbubbles that are visible on sonography. This bolus opacifies the right ventricle within seconds and in the absence of right-to-left shunting, bubbles are absorbed in the lungs. If an intracardiac shunt is present, contrast agent enters the left ventricle within three heartbeats (early shunting). If intrapulmonary shunting, characteristic of HPS, is present, the left ventricle opacifies at least three heartbeats after the right (delayed shunting).

Radionuclide lung perfusion scanning, using technetium-labeled macroaggregated albumin particles (^{99m}Tc-MAA scan), is another method for detecting intrapulmonary vasodilatation (Fig. 16.4). In this test, macroaggregated albumin particles 50–100 μm in size are injected intravenously. Normally, all the particles are trapped in the lung microvasculature. In HPS, some particles escape through dilated pulmonary capillaries and lodge in beds supplied by systemic arteries. Quantitative imaging of the lung and brain using a standardized methodology allows calculation of a shunt fraction [40]. The ^{99m}Tc-MAA scan offers one significant advantage over contrast echocardiography: a positive scan (shunt fraction >6%) is specific for the presence of HPS even in the setting of coexistent intrinsic lung disease [40]. It is valuable in determining the relative importance of intrapulmonary vasodilatation or the underlying pulmonary process as the major contributor for observed gas exchange abnormalities. However, as a screening test for intrapulmonary vasodilatation, ^{99m}Tc-MAA scanning is less sensitive than contrast echocardiography in adults.

Pulmonary angiography and high-resolution chest computerized tomography (CT) are other modalities to detect intrapulmonary vasodilatation that are more invasive and less sensitive compared with contrast echocardiography [41].

Prognosis and natural history

The natural history of HPS is incompletely characterized but available data indicate that most patients develop progressive intrapulmonary vasodilatation and worsening gas exchange over time and that spontaneous improvement is rare [42,43]. Mortality is significantly higher and quality of life is significantly lower in patients with HPS compared with cirrhotics without HPS [14]. The success of liver transplantation in reversing HPS and the policy of increasing priority for transplantation in HPS associated with significant hypoxemia, currently in place in the United States, may improve prognosis in this disorder.

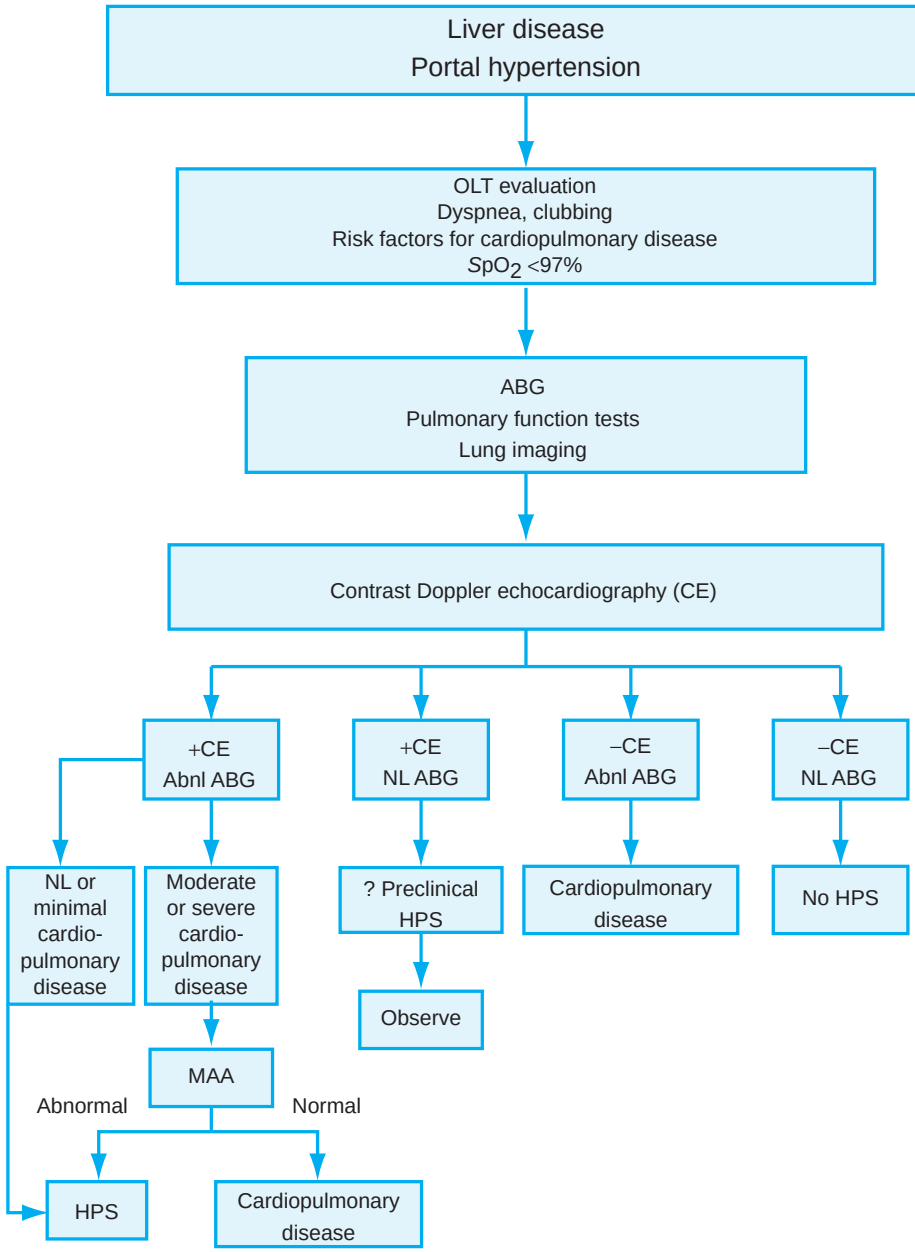

Figure 16.2 Diagnostic approach to hepatopulmonary syndrome (HPS) (see text for details). ABG, arterial blood gases; Abnl, abnormal; OLT, orthotopic liver transplantation; NL, normal; SpO_2, pulse oximetry oxygen saturation; MAA, technetium-labeled macroaggregated albumin scan.

Therapy

Case reports and small studies have suggested that a number of agents, including aspirin [44], garlic [45,46], norfloxacin [47], and inhaled nitro-L-arginine methyl ester (L-NAME) [48], might improve HPS. Recently, conflicting results were obtained from two small pilot studies using pentoxifylline in HPS. In a study that enrolled patients with more advanced liver disease and HPS, the drug was poorly tolerated, while benefit was found in those with mild disease [49]. However, no randomized trials have been performed. In patients with resting or exertional hypoxemia, supplemental oxygen therapy is appropriate although no studies have evaluated whether clinical benefit occurs. Portal decompression with transjugular intrahepatic portosystemic shunt (TIPS) has been attempted in a small number of cases. However, convincing evidence for sustained improvement is lacking and TIPS should be considered an experimental treatment. OLT is the only proven therapy for HPS based upon resolution or significant improvement in gas exchange

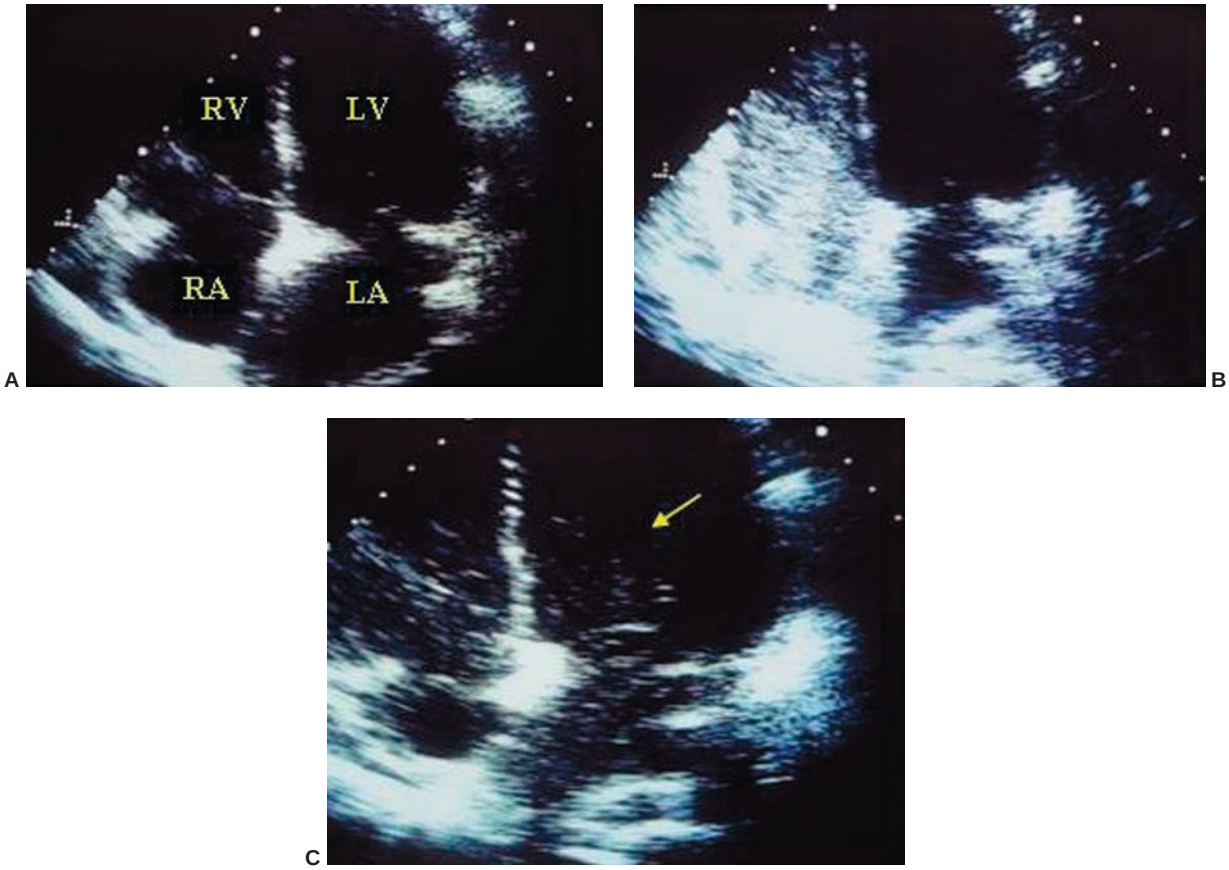

Figure 16.3 Contrast echocardiogram for detecting intrapulmonary vasodilatation. (A) Parasternal four-chamber view of the heart (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle) prior to the administration of agitated saline contrast. (B) Four-chamber view immediately after the administration of demonstrating the presence of echogenic microbubbles in the right atrium and ventricle immediately after injection of agitated saline into the antecubital vein. (C) Visualization of echogenic microbubbles in the left atrium (arrow) and ventricle three cardiac cycles after visualization on the right due to intrapulmonary vasodilatation in a patient with hepatopulmonary syndrome. Intracardiac shunting results in immediate passage of microbubbles from the right to left chambers without a three cycle delay and can be excluded using this technique.

postoperatively in more than 85% of reported patients [8]. However, the length of time for resolution after transplantation varies and may be more than 1 year. In addition, mortality is increased after transplantation in HPS patients compared to subjects without HPS, particularly when hypoxemia is severe [50]. Currently, HPS patients with a PaO_2 <60 mmHg are eligible for increased priority for OLT (model for end-stage liver disease (MELD) exception), based on increased mortality and reduced survival after OLT with increased HPS severity. Therefore, screening for HPS and consideration of liver transplantation prior to the development of severe hypoxemia is appropriate.

Portopulmonary hypertension

Definition

Portopulmonary hypertension is defined by a mean pulmonary artery pressure (mPAP) >25 mmHg and a pulmonary capillary wedge pressure <15 mmHg occurring in the setting of portal hypertension [51]. An elevated transpulmonary gradient (mean pulmonary artery pressure – pulmonary capillary wedge pressure of >10 mmHg) and/or pulmonary vascular resistance (>120 dyne/s/cm$^{5)}$ are additional criteria included in the definition of this syndrome.

Epidemiology, risk factors, and disease associations

Changes consistent with pulmonary hypertension were found in 0.7% of patients with cirrhosis compared to a prevalence of 0.1% in subjects without chronic liver disease in a series of 17,901 autopsies [52]. A subsequent prospective study of 507 patients who underwent right heart catheterization revealed a 2% prevalence of POPH [53]. More recently, retrospective studies in liver transplantation candidates have found a prevalence ranging from 3.5% to 16% [54–57]. To date, POPH has only been

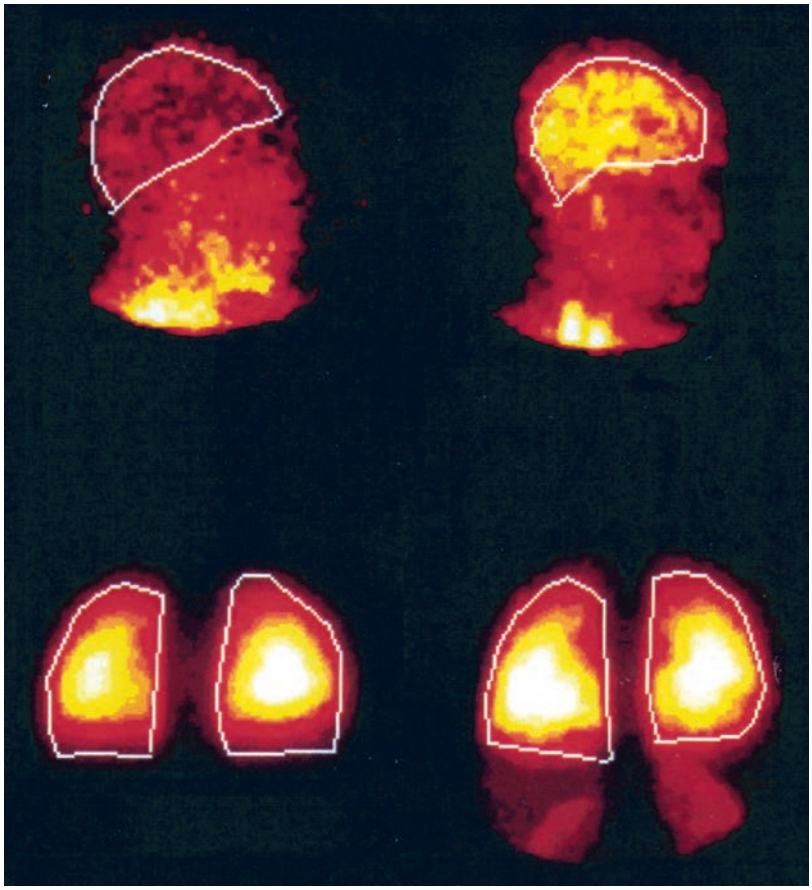

Figure 16.4 Technetium-labeled macroaggregated albumin (^{99m}Tc-MAA) scanning. (A) A normal ^{99m}Tc-MAA scan from a patient without hepatopulmonary syndrome with the regions of interest drawn around the lungs (below) and cerebrum (above). In the absence of intrapulmonary vasodilatation, there is a minimal passage of intravenously administered labeled albumin through the lungs and signal intensity is low in the cerebrum. Shunting is quantified by comparing the relative signal intensity in the lung and the brain. (B) A ^{99m}Tc-MAA scan in hepatopulmonary syndrome demonstrating significant cerebral uptake due to passage of labeled albumin through the dilated pulmonary microvasculature. (Reproduced from Abrams et al. [5] with permission from Elsevier.)

described in the presence of portal hypertension with or without cirrhosis. Although there are no definitive clinical predictors of POPH, a recent multicenter study found an increased risk of developing POPH in female patients and patients with autoimmune hepatitis; and a decreased risk in patients with hepatitis C as the etiology of liver disease [58]. Generally, the diagnosis of portal hypertension precedes the diagnosis of POPH by several years and data are controversial as to the relationship between severity of portal hypertension and risk or severity of POPH [57].

Pathology and pathogenesis

The histologic features of POPH are similar to those seen in primary pulmonary hypertension. These include smooth muscle hypertrophy and hyperplasia, concentric intimal fibrosis, plexogenic arteriopathy, and necrotizing vasculitis [15,51,59–61]. The underlying mechanisms in POPH remain incompletely understood and no animal models have been developed. Elevated portal pressure is critical for the development of pulmonary hypertension [53]. The hyperdynamic circulatory state, causing increased vascular shear stress, and portosystemic shunting, causing altered production or metabolism of vasoactive substances, have been hypothesized to contribute to vascular changes in POPH [17]. Endothelial and circulating factors (endothelin 1, prostacyclin, and thromboxane) and polymorphisms in genes regulating estrogen signaling and cell growth regulators are associated with the risk of POPH. In addition, a recent study showed no association between serotonin transporter polymorphisms and POPH [62,63]. One hypothesis suggested that endothelial injury or dysfunction may be a key early event that contributes to vascular proliferation and inflammation leading to POPH (Fig. 16.5). In addition, HPS may coexist with POPH suggesting that these two entities may share underlying pathogenetic mechanisms. One emerging hypothesis is that the pulmonary endothelial response to alterations in liver disease and portal hypertension (NO overproduction and activation of angiogenic pathways in HPS versus dysfunction and injury in POPH) is important in determining whether HPS or POPH develops.

Clinical features

A majority of POPH patients may be asymptomatic [57]. The most common symptom described in POPH is dyspnea on exertion, with the development of progressive fatigue, dyspnea at rest, peripheral edema, syncope, and

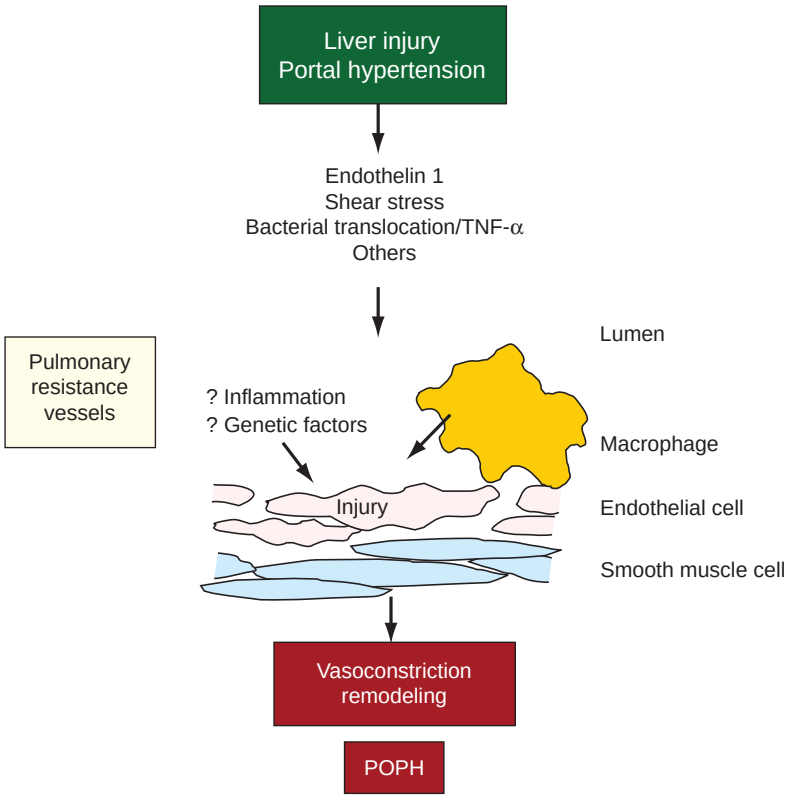

Figure 16.5 Proposed mechanisms of portopulmonary hypertension (POPH). Liver injury and/or portal hypertension trigger the production of cytokines and vasoactive mediators that increase vascular shear stress as is proposed for hepatopulmonary syndrome. In contrast, in the setting of POPH, modifying factors including inflammation and genetic factors may trigger endothelial injury resulting in smooth muscle proliferation and vascular remodeling. These events lead to pulmonary arterial hypertension. TNF-α, tumor necrosis factor α.

chest pain as severity increases [64]. Physical examination reveals jugular venous distention, a loud pulmonary component of the second heart sound, and a systolic murmur resulting from tricuspid regurgitation. Lower extremity edema is commonly noted. Electrocardiographic abnormalities are similar to those seen in primary pulmonary hypertension and include evidence of right atrial enlargement, right ventricular hypertrophy, right axis deviation, and/or right bundle branch block. Radiographic findings are generally subtle, but in advanced cases a prominent main pulmonary artery or cardiomegaly due to prominent right cardiac chambers may occur. Gas exchange abnormalities are generally mild and less severe than in HPS. An increased AaPO_2 with mild hypoxemia and hypocarbia may be seen, particularly in more severe disease [17,65].

Evaluation for portopulmonary hypertension

Patients with POPH are often asymptomatic and the diagnostic utility of various clinical features is low [55,66]. Therefore, the diagnosis of POPH requires a high index of suspicion (Fig. 16.6). Other causes of elevated pulmonary pressures and/or right heart failure, including left ventricular dysfunction, volume overload, and chronic obstructive lung disease, have to be excluded. In general, in patients not being evaluated for liver transplantation, the presence of suggestive symptoms and signs – after exclusion of other cardiopulmonary diseases – makes it reasonable to screen for POPH. In all patients being evaluated for liver transplantation, regardless of signs or symptoms, screening is warranted because the presence of POPH may influence transplant candidacy [67].

Transthoracic Doppler echocardiography is the best noninvasive screening study. If combined with intravenous contrast injection, screening for HPS and POPH can be accomplished at the same time. The presence of pulmonary hypertension is suggested by an increased estimated pulmonary artery systolic pressure (derived from measuring the velocity of the tricuspid regurgitant jet), pulmonary valve insufficiency, right atrial enlargement, and/or right ventricular hypertrophy or dilatation. An estimated systolic pulmonary arterial pressure of >40–50 mmHg is used to define the need for direct measurement of pulmonary pressures by right heart catheterization. A mPAP of >25 mmHg with a pulmonary capillary wedge pressure of <15 mmHg confirms the diagnosis of pulmonary arterial hypertension. An elevated transpulmonary gradient (mean pulmonary artery pressure – pulmonary capillary wedge pressure of >10 mmHg) and pulmonary vascular resistance (>120 dyne/s/cm^5) are additional measurements used

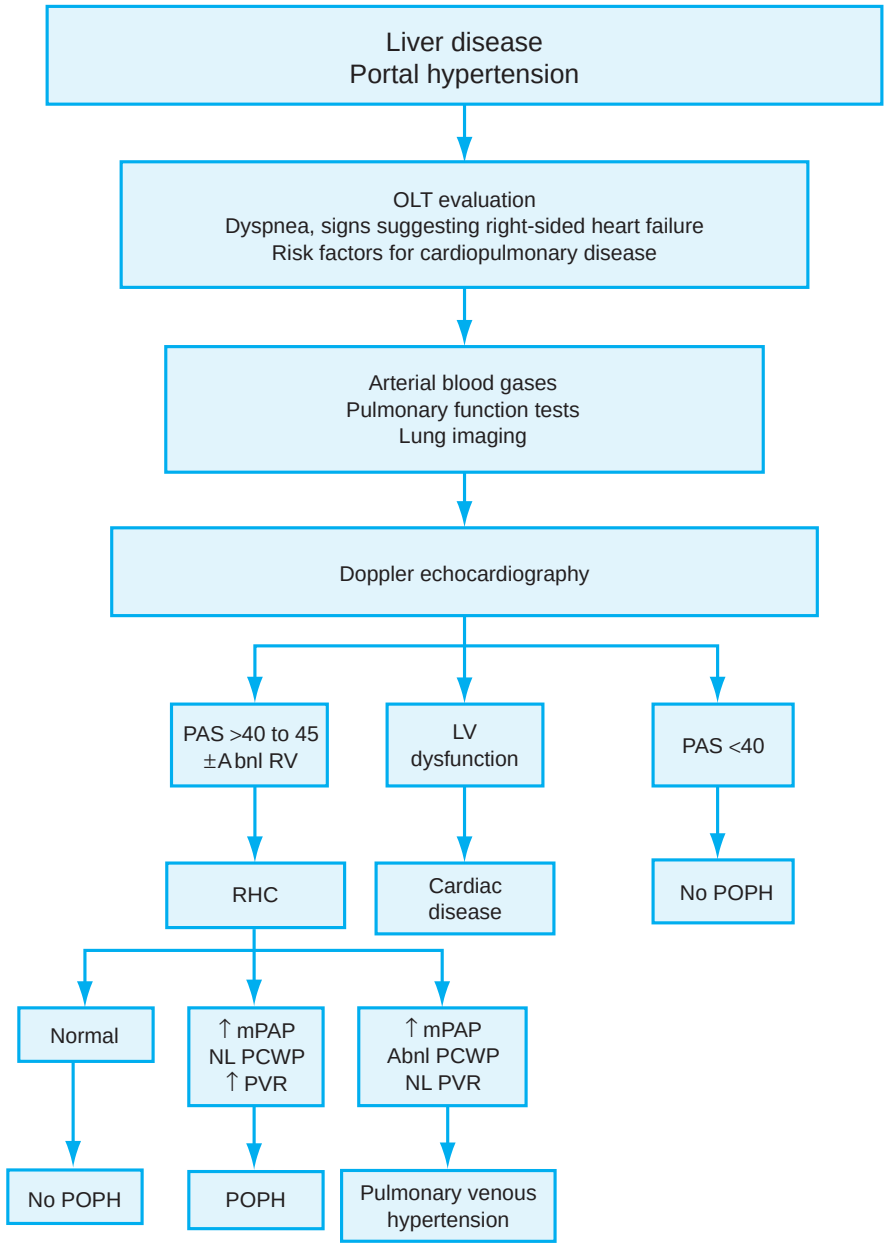

Figure 16.6 Diagnostic approach to portopulmonary hypertension (POPH) (see text for details). Abnl, abnormal; LV, left ventricle; mPAP, mean pulmonary artery pressure; NL, normal; OLT, orthotopic liver transplantation; PAS, estimated pulmonary artery systolic pressure; PCWP, pulmonary capillary wedge pressure; PVR, pulmonary vascular resistance; RHC, right heart catheterization; RV, right ventricle.

to distinguish pulmonary arterial hypertension from pulmonary venous hypertension that may be present due to the hyperdynamic circulation and volume overload that accompany cirrhosis.

Vasodilator responsiveness with a number of agents, most frequently nitric oxide and/or epoprostenol, may be undertaken in those with confirmed POPH in an effort to predict a favorable response to long-term vasodilator therapy [17]. However, the utility of vasodilator testing in the management of POPH has not been studied.

Prognosis and natural history

The major complication of POPH is the development of progressive right ventricular dysfunction and cor pulmonale. Survival in pulmonary hypertension correlates with the severity of right-sided cardiac dysfunction as assessed by the degree of elevation in the right-sided cardiac pressures and the degree of decline in the cardiac output [68]. Previous studies have suggested that survival in POPH was similar or even prolonged compared with primary pulmonary hypertension, possibly related to the

beneficial effects of the hyperdynamic circulatory state [17]. Recent work has challenged this concept and found that mortality was higher in POPH relative to primary pulmonary hypertension despite a higher cardiac index and lower systemic and pulmonary vascular resistance [69]. To date, no studies have demonstrated that medical therapy for POPH improves survival. Liver transplantation in patients with mild POPH (<35 mmHg) appears to have comparable outcomes relative to patients without pulmonary hypertension although long-term follow-up has not been reported. At higher mean pulmonary artery pressures, perioperative mortality is increased, particularly in those with higher pulmonary vascular resistance values or lower cardiac output [67].

Therapy

Medical treatment for POPH is based largely on experience in primary pulmonary hypertension. However, anticoagulants and calcium channel blockers are not recommended due to their potential to increase bleeding and portal pressure, respectively. The use of β-adrenergic blockers for the prevention of variceal bleeding should be considered with caution given the potential for cardiac depression [70]. A number of medical therapies have been successfully used in POPH both as monotherapy or in combination. They include endothelin receptor antagonists (bosentan), phosphodiesterase V inhibitor (sildenafil), prostacyclin analogs (epoprostenol, treprostinil, iloprost), vasopressin analogs (terlipressin), and tyrosine kinase inhibitors (imantinib) [71,72]. However, most therapeutic interventions are described in case reports and retrospective analysis. No controlled trials have been undertaken. and whether medical therapy impacts survival is unknown. Bosentan has the potential for hepatotoxicity and its safety is uncertain in patients with advanced liver disease.

The safety and efficacy of OLT in patients with POPH is controversial. There are no well-designed, prospective studies to guide decision making, and the effect of OLT on the natural history of POPH is not well defined. Retrospective studies and case reports confirm that moderate to severe POPH (mPAP >35 mmHg), particularly if right ventricular dysfunction is present, is associated with substantial perioperative mortality and is a contraindication for transplantation [67]. Less severe POPH (mPAP <35 mmHg) is generally not considered a contraindication to OLT, but patients need to be evaluated individually to minimize risks. Several recent retrospective studies suggest that OLT may be feasible and beneficial in patients with moderate to severe POPH who are otherwise suitable OLT candidates if medical therapy lowers the mPAP to <35 mmHg [73,74]. Some guidelines recommend, and several United Network for Organ Sharing (UNOS) regions provide, MELD exception points for patients whose mPAP decreases below 35 mmHg on medical therapy [75]. However, the outcomes using such a strategy are unknown.

Summary and conclusions

Hepatopulmonary syndrome and POPH are unique pulmonary vascular complications of liver disease and/or portal hypertension that may cause significant morbidity and influence survival and liver transplant candidacy. HPS occurs in approximately 20% and POPH occurs in approximately 6% of patients with cirrhosis being evaluated for liver transplantation. Dilatation in the pulmonary microvasculature is an important event that leads to hypoxemia and symptoms in HPS. Vasoconstriction and remodeling in resistance vessels occur in POPH and may lead to right-sided cardiac dysfunction. The pathogenesis of pulmonary vascular abnormalities in HPS and POPH are areas of ongoing investigation and similar mechanisms may play a role in each syndrome. There are no effective medical therapies for HPS, but liver transplantation can reverse the syndrome in the majority of patients. In contrast, there are symptomatic medical therapies for POPH, but for many patients liver transplantation is currently contraindicated or controversial. Transplantation carries increased mortality in both severe HPS and POPH, underscoring the importance of screening for these disorders in patients undergoing liver transplantation evaluation.

Multiple choice questions

16.1 **A 65-year-old male with hepatitis C cirrhosis is seen in clinic for a follow-up visit. The patient complains of gradually worsening dyspnea on exertion over the past 3–4 months. He has no prior history of lung disease and quit smoking 20 years back with a cumulative 10-pack-year smoking history. He has ascites that is well controlled on diuretics. Physical examination reveals a nondistended abdomen, clear lungs, and no lower extremity edema. The chest X-ray and ECG are normal. Pulmonary function tests show normal spirometry and lung volumes, and the diffusion capacity of carbon monoxide is 43%. Lab results are: arterial blood gases – pH 7.43, PCO_2 36 mmHg, PO_2 62 mmHg; total bilirubin 1.6 mg/dL, AST : ALT 58 : 68, albumin 3.1 g/dL, and international normalized ratio (INR) 1.5. Which of the following is the most appropriate next step?**

- **a** CT angiography of the chest.
- **b** Contrast Doppler echocardiography.
- **c** Start supplemental oxygen therapy.
- **d** Right heart catheterization.

16.2 **A 54-year-old male with cryptogenic cirrhosis is being evaluated for liver transplantation. The patient has noticed decreased exercise tolerance gradually over the past 6 months and complains of fatigue. He has developed worsening ascites and marked lower extremity despite sodium restriction and the addition of spironolactone 100 mg per day and furosemide 40 mg per day. Physical examination reveals moderate ascites and 3+ pitting edema in the lower extremities. The chest X-ray and three-phase abdominal CT scan are unremarkable. Doppler cardiac echography reveals an estimated pulmonary artery systolic pressure of 50 mmHg, dilated right ventricle, and normal left ventricular function. Adenosine MIBI shows normal cardiac perfusion. Lab results are: total bilirubin 4.8 mg/dL, AST : ALT 70 : 84, albumin 2.8 g/dL, INR 2.0, BUN/Cr 21/1.4, Na 132, K +4.2, TSH 3.5, and MELD (model for end-stage liver disease) score 23. Which of the following is the most appropriate next step?**

- **a** Increase diuretics, follow-up closely, and perform a repeat Doppler cardiac echogram.
- **b** List for liver transplantation.
- **c** Right heart catheterization.
- **d** Coronary angiography.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 17
Ascites and Spontaneous Bacterial Peritonitis

Bruce A. Runyon
Division of Gastroenterology/Hepatology, Loma Linda University Medical Center, Loma Linda, CA, USA

Key concepts

- The most common cause of ascites, by a huge margin, is cirrhosis, followed by heart failure, malignancy, tuberculosis, and miscellaneous causes. A careful history, physical examination, ascitic fluid analysis, imaging, and special testing in unusual situations usually provide definitive diagnoses regarding the cause(s) of ascites and complications, such as spontaneous bacterial peritonitis.
- Treatment of patients with ascites is dependent on the cause(s) of fluid formation. For example, peritoneal carcinomatosis does not respond to diuretic therapy.
- Ascitic fluid forms in the setting of cirrhosis due to intrahepatic portal hypertension, splanchnic vasodilatation, and renal retention of sodium and water, in an effort to refill what is perceived as an underfilled intravascular space.
- A detailed history provides information regarding risk factors (alcohol, needle use, country of origin, obesity, etc.) as well as risk factors for heart failure, malignancy, and tuberculosis.
- Most patients with cirrhosis as the cause for ascites formation have physical findings that raise suspicion for liver disease, including vascular spiders, palmar erythema, and abdominal wall collaterals.
- Abdominal paracentesis with ascitic fluid analysis is crucial in detecting the cause of ascites formation and in detecting ascitic fluid infection. This simple, safe bedside or clinic procedure can be performed by an experienced operator, a person on the "procedure team," or an interventional radiologist. Despite coagulopathy in most patients, bleeding is rare. Patients with cirrhosis usually have a balanced deficiency of procoagulants and anticoagulants and normal global coagulation despite abnormal screening coagulation tests. Prophylactic transfusion of blood products is not data supported and is discouraged.
- The appearance of the fluid and the test results guide therapy. Patients with evidence of cirrhosis and a serum–ascites albumin gradient $\geq$1.1 g/dL should receive diet education regarding a 2000 mg/day sodium diet and dual diuretics. Patients with an elevated neutrophil count in the fluid should be pancultured and urgently started on an antibiotic that is known to penetrate the fluid in high enough concentrations to kill the bacteria. Cefotaxime 2 g intravenously every 8 hours is the most data-supported empirical antibiotic. Once susceptibility tests are available, a narrower spectrum drug can be chosen. Drugs with no data on ascitic fluid penetration should not be used.
- Ascitic fluid-specific leukocyte esterase strips or "dipsticks" are under investigation and should lead to a diagnosis of infection in 90–180 seconds. A delay in detection and treatment of infection worsens survival.
- Patients in specific subgroups benefit from selective intestinal decontamination with drugs such as norfloxacin to prevent recurrence of spontaneous bacterial peritonitis and ceftriaxone to prevent infection that regularly complicates gut hemorrhage in these patients.
- Diet combined with spironolactone and furosemide in single morning doses can control the fluid in >90% of compliant patients. Fluid restriction is unnecessary and not data supported. Treatment options for diuretic-resistant patients include therapeutic paracentesis every 2 weeks, transjugular intrahepatic portosystemic shunt (TIPS), and rarely peritoneovenous shunt. Liver transplantation is the ultimate solution to liver failure, but few organs are available and many of these patients have psychosocial contraindications to transplantation.

The patient with ascites is a common diagnostic and therapeutic challenge to the internist and gastroenterologist. Ascites due to cirrhosis is associated with significant morbidity and mortality, in part related to the severe underlying liver disease and in part due to the ascites per se. Approximately one half of patients in whom cirrhosis is detected prior to the development of "decompensation" (i.e., prior to development of ascites, jaundice, encephalopathy, or gastrointestinal hemorrhage) develop ascites within 10 years [1]. Once ascites, or other evidence of decompensation is present, the expected mortality is ~50% in just 2 years [2].

The word "ascites" is of Greek derivation (*askos*) and refers to a bag or sack. The word is a noun, is singular, and is used to refer to the condition of pathologic fluid accumulation within the abdominal cavity. The adjective,

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.
© 2012 John Wiley & Sons, Ltd. Published 2012 by John Wiley & Sons, Ltd.

ascitic, is used in conjunction with the word, fluid, to describe the liquid per se. The proper term is "ascitic fluid" not "ascites fluid."

Diagnosis and differential diagnosis

The most common setting in which ascites develops is in a patient with known cirrhosis or a patient with a risk factor for development of cirrhosis, e.g., alcohol abuse or chronic hepatitis C. As the patient develops jaundice or loses muscle mass, or deteriorates in another fashion, the abdomen swells, frequently as body weight increases. In this context, the diagnosis is readily suspected from the patient's history and is easily confirmed by the presence of shifting dullness on physical examination and by a successful abdominal paracentesis. Some patients are less cognizant of their physical appearance and weight; in this setting, when there is not a large volume of fluid, the diagnosis may be first detected on imaging. The presence of abdominal fullness and bulging flanks should lead to percussion of the flanks. If the amount of flank dullness is greater than usual – i.e., if the percussed air–fluid level is higher than normally found on the lateral aspect of the abdomen with the patient supine – then "shifting" of the dullness should be checked. If there is no flank dullness, there is no reason to check for shifting dullness. Approximately 1500 mL of fluid must be present before dullness is detected [3]. If no flank dullness is present, the patient has less than a 10% chance of having large volume ascites [3]. The fluid wave and "puddle sign" were found to be much less helpful in a study of physical findings in patients with small volume ascites [3].

A thick panniculus, gaseous distension of the bowel, and an ovarian mass can be confused with the presence of ascites. An obese abdomen may be diffusely dull to percussion, and an attempt at paracentesis (if there is significant suspicion of ascites) or abdominal ultrasound may be required to settle the question. Ultrasound or computerized tomography can detect as little as 100 mL of fluid in the abdomen. Gaseous distension should be apparent on percussion. Ovarian masses characteristically cause tympanitic flanks with central dullness.

Although parenchymal liver disease is the cause of ascites formation in most patients evaluated by internists and gastroenterologists, approximately 15% of patients have a cause other than liver disease (Table 17.1) [4]. Approximately 5% of patients with ascites have two causes of ascites formation, i.e., "mixed" ascites. Usually these patients have cirrhosis as well as one of the following: hepatocellular carcinoma, peritoneal carcinomatosis, or peritoneal tuberculosis (Table 17.1). Since tuberculosis is curable and potentially fatal, one must not assume that a patient has *only* liver disease as the cause of ascites formation, if the clinical situation is atypical. For example, if the ascitic fluid lymphocyte count is unusually high or there is persistent unexplained fever in the setting of cirrhosis, peritoneal tuberculosis may be present. Interpretation of ascitic fluid analysis is difficult in patients with mixed ascites but crucial to appropriate diagnosis and treatment (see below on ascitic fluid analysis). Additionally, not all patients with liver disease and ascites have cirrhosis. Ascites regularly develops in the setting of severe alcoholic hepatitis. Ascites along with hepatic coma can develop as manifestations of acute liver failure in viral hepatitis. However, because fulminant liver failure itself is quite uncommon, the total number of patients with ascites who have acute liver failure is quite small. One percent of the large series detailed in Table 17.1 involved acute liver failure, and 1% occurred in the setting of acute hepatitis superimposed on cirrhosis.

Cancer is an uncommon cause of ascites formation as seen by the hepatologist/general internist. Unfortunately, most patients with malignancy-related ascites (except ovarian cancer and lymphoma) only survive a few weeks after the onset of fluid retention [5]. If there is a delay in diagnosis because of confusion about the diagnosis, many of these patients will die during the hospitalization for which they presented with ascites. The physician's goal in treating this subgroup of patients with ascites should be to rapidly make a diagnosis and maximize the time that the patient can spend out of hospital. Not all malignancy-related ascites is due to peritoneal carcinomatosis; the characteristics of the ascitic fluid and the treatments vary depending on the pathophysiology of the ascites formation, e.g., peritoneal carcinomatosis versus

Table 17.1 Causes of ascites.

Cause	% of total number of patients
Parenchymal liver disease with or without infection:	84
"Mixed" ascites	5
Acute hepatitis with underlying cirrhosis	1
Chylous ascites due to cirrhosis	1
Fulminant hepatic failure	1
Heart failure	3
Malignancy	2.5
Tuberculosis	<1
Pancreatic	<1
Nephrogenous ("dialysis ascites")	<1
Chlamydia	<1
Nephrotic	<1
Miscellaneous	~5%

Based on a series of 901 paracenteses performed in a predominantly inpatient hepatology/general internal medicine setting [4].

massive liver metastases versus malignant lymph node obstruction with chylous ascites [5] (see also the section on ascitic fluid analysis).

In the past, heart failure was a common cause of ascites. Improved treatment of heart failure and a decreasing prevalence of heart disease have led to its decline to ~3% as a cause of ascites formation. Ascites is currently an uncommon complication of heart disease [6]. Meanwhile liver disease has increased dramatically as a cause of ascites.

In the United States, tuberculous peritonitis is a disease of immigrants and of patients with underlying cirrhosis, usually due to alcohol. More than 50% of patients with tuberculous peritonitis are found to have underlying cirrhosis, i.e., mixed ascites.

Pancreatitic ascites develops as a complication of severe acute pancreatitis or as a complication of chronic pancreatitis with pancreatic duct rupture or leakage from a pseudocyst. Patients with this form of ascites may also have underlying cirrhosis. Pancreatic ascites may be complicated by bacterial infection. This combination is frequently misdiagnosed and usually fatal.

Nephrogenous ascites is a poorly understood form of fluid overload that develops in patients undergoing hemodialysis [7]. On careful evaluation many of these patients are found to have underlying chronic liver disease or peritoneal disease. The presence of underlying liver disease may be the reason that they develop fluid overload more readily than dialysis patients who do not have liver disease.

In sexually active young women with fever and neutrocytic ascites, *Chlamydia* peritonitis should be placed near the top of the differential diagnosis. *Chlamydia* causes a Fitz-Hugh–Curtis syndrome [8]. This rapidly responds to doxycycline and is one of the few curable causes of ascites formation.

Although nephrotic syndrome used to be a common cause of ascites formation in children, it is quite rare in adults, causing <1% in the series reported in Table 17.1.

Some patients develop pathologic accumulations of fluid in the peritoneal cavity due to leakage from a ruptured viscus, e.g., "bile ascites" in the setting of a ruptured gallbladder [9]. The ascitic fluid analysis can be crucial to making a preoperative diagnosis of this condition (see below).

Conditions excluded from or not encountered in the series detailed in Table 17.1 include ambulatory peritoneal dialysis fluid, Budd–Chiari syndrome, myxedema ascites, ascites associated with benign ovarian disease, and ascites associated with connective tissue diseases. The iatrogenic form of ascites associated with peritoneal dialysis is usually under the management of nephrologists. Although Budd–Chiari syndrome is regularly (if not always) complicated by ascites, hepatic vein thrombosis itself is rare enough that it causes <1% (probably <0.1%) of cases of ascites. Ascites in patients with myxedema appears to be cardiac ascites, related to the subtle heart failure that these patients develop [10]. Treatment of the thyroid insufficiency cures the fluid retention. In recent years most ascites that is caused by ovarian disease involves peritoneal carcinomatosis [5]. Meigs syndrome (i.e., ascites and pleural effusion caused by benign ovarian neoplasms) is no longer a common cause of ascites formation. Serositis with ascites formation may complicate systemic lupus erythematosus [11].

Pathogenesis of ascites formation in liver disease

Simplistically, ascites forms in severe chronic and/or acute liver disease as a result of portal hypertension, baroreceptor activation, and neurohumorally mediated abnormalities in renal perfusion, with resulting sodium retention. The clinically apparent problem is that of intravascular and extravascular volume overload. The site of spillover of fluid is the peritoneal cavity because of the portal hypertension.

The questions that have puzzled investigators in this field are: (i) what is the *initial* event; and (ii) why is there neurohumoral excitation (which should be characteristic of volume depletion) in the setting of volume overload? Animals (including humans) have very sophisticated and duplicative systems for the detection and preservation of normal or near normal vascular perfusion pressures and intravascular osmolality. However, the animal's ability to sense abnormalities in intravascular *volume* status (especially volume overload) is limited and is linked largely to pressure receptors. This may partially explain the paradox of dramatic volume overload in the face of sympathetic nervous traffic and hormone levels that are indicative of intravascular volume depletion.

All current investigators in the field of the pathogenesis of ascites formation agree that patients are intravascularly volume overloaded once they reach the stage of large volume ascites. Now we recognize "compensated" and "decompensated" stages and that there is a spectrum of renal failure in patients with cirrhosis. Hepatorenal syndrome is the extreme end of the spectrum. The most recent theory – the peripheral arterial vasodilatation hypothesis – has proposed that both the older "underfill" and "overflow" theories of ascites formation are correct, but that each is operative at a different stage [12]. The first abnormality that eventually leads to fluid retention, according to this theory, is peripheral arterial vasodilatation that is mediated by nitric oxide. Intravascular underfilling occurs because the compartment enlarges. The vasodilatation hypothesis proposes that in the early

compensated stage of cirrhosis (i.e., before fluid retention occurs), intravascular hypervolemia suppresses renin, aldosterone, vasopressin, and norepinephrine concentrations such that abnormally elevated levels of these hormones are usually not detected. Also, these patients usually have normal indices of renal function. As the state of vasodilatation worsens, renal function deteriorates and plasma levels of vasoconstrictor, sodium-retentive hormones increase; ascites develops, that is "decompensation" occurs. Hepatorenal syndrome is the extreme end of the spectrum.

Intrahepatic portal hypertension plays a crucial role in ascites formation. Patients with prehepatic portal hypertension (e.g., portal vein thrombosis) rarely develop ascites, usually in the setting of fluid resuscitation for gut hemorrhage. Only patients with high sinusoidal pressure regularly develop fluid retention. Patients or dogs with cirrhosis but normal portal pressures due to surgical decompression do not develop ascites [13].

The site of ascites formation is also dependent on the presence of portal hypertension. Theoretically, fluid could form from the surface of the liver or the gut. However, the data support the liver as the site of ascites formation. The hepatic sinusoid lacks a basement membrane and is therefore more permeable than the bowel. Lymph flow is linearly related to pressure. The large hydrostatic pressure gradient present in the portal hypertensive liver leads to loss of intravascular fluid across the hepatic sinusoids into the space of Disse, and weeping of the fluid from the liver surface as extravasated lymph. Older animal experiments confirm the liver as the source of ascites formation also. If the liver of a portal hypertensive dog is moved into the chest, the dog develops a pleural effusion rather than ascites [14]. If the liver is placed in a cellophane bag in situ, fluid forms within the bag [15].

In summary, in the early phase of ascites formation there is vasodilatation and renal retention of sodium with eventual overflow of fluid into the peritoneal cavity from the hepatic sinusoids. After ascites is formed, underfilling assumes a more prominent role. The sequestration of intravascular fluid in the abdomen in large quantities results in decreased "effective intravascular volume" and triggers: (i) increased non-osmotic secretion of antidiuretic hormone; (ii) renin and aldosterone release; (iii) further stimulation of sympathetic nervous system activity; and (v) further sodium and water retention. The cycle is self-perpetuating.

Evaluation of patients with ascites

History

Most ascites is due to cirrhosis. In the past most cirrhosis in the United States was caused by alcohol. Now many patients have chronic hepatitis C *and* excess alcohol use in the setting of obesity. Multiple insults are probably synergistic in causing cirrhosis. Patients who have a component of alcoholic liver disease and who intermittently reduce alcohol consumption may experience wet/dry cycles in terms of fluid retention. The cycles of ascites may be separated by years of normal sodium balance and tend to parallel their alcohol consumption. In contrast, patients who develop ascites with nonalcoholic liver disease tend to be persistently fluid overloaded, probably due to the late stage at which ascites forms in nonalcoholic liver disease and the lack of effective therapy other than liver transplantation. Cirrhosis due to reactivated hepatitis B is the exception here. These patients can also have a dramatic response to (non-interferon-based) antiviral therapy.

When the patient has a very long history of stable cirrhosis and then develops ascites, the possibility of hepatocellular carcinoma should be considered as the cause for decompensation.

Patients with ascites should also be questioned about risk factors for liver disease other than alcohol, e.g., intravenous drug use, homosexuality (a risk factor for hepatitis B), transfusions, acupuncture, tattoos, country of origin, etc. In the current obesity epidemic, nonalcoholic fatty liver disease (NAFLD) is also contributing to the development of cirrhosis, with or without other risk factors. Asking the patient about lifetime maximum body weight, diabetes, and number of years of being overweight/obese can provide a cause for cirrhosis that may have been thought to be "cryptogenic" [16].

Patients who have a history of cancer and develop ascites should be suspected of having malignancy-related ascites. Breast, colon, and pancreatic cancer are regularly complicated by ascites [5]. Patients with malignancy-related ascites frequently have abdominal pain, whereas ascites due to cirrhosis is usually not associated with abdominal pain unless there is superimposed bacterial peritonitis or alcoholic hepatitis.

Patients with cardiac ascites often have a past history of heart failure or restrictive lung disease. Alcoholics who develop ascites may have alcoholic cardiomyopathy or liver disease. The serum pro-BNP can help in the differential diagnosis of ascites due to heart failure from ascites due to cirrhosis [17] (see below).

Tuberculous peritonitis is usually manifested by fever and abdominal pain in a patient who has recently emigrated from an endemic area or a US resident with cirrhosis. More than one half of patients with tuberculous peritonitis have underlying cirrhosis as a second cause for ascites formation.

Patients who develop ascites and anasarca in the setting of longstanding diabetes should be suspected of having nephrotic ascites. Ascites developing in a patient with cold intolerance, lethargy, altered bowel motility, changes

in the skin, etc. should prompt measurement of thyroid function tests. Serositis in connective tissue diseases may be complicated by ascites [11].

Physical examination

The details of the physical examination in detecting ascites are also discussed at the beginning of this chapter. The fluid wave has not been found to be of much value in the detection of ascites [3]. The puddle sign can detect 120 mL of fluid, but feeble patients cannot cooperate in the performance of this test; patients must remain in a hands-knees position during the examination. A simple ultrasound, which is available to many hepatologists now, can rule in ascites very rapidly, especially in the obese patient, where physical examination is difficult due to the thick panniculus.

The presence of palmar erythema or large pulsatile vascular spiders is very suggestive of the presence of cirrhosis. The presence of pathologically large abdominal wall collateral veins suggests that portal hypertension is present. The presence of large veins on the flanks and dorsum of the patient suggests inferior vena cava blockage by a fibrous caval web or malignant obstruction. A firm nodule in the umbilicus, the Sister Mary Joseph nodule, is very suggestive of peritoneal carcinomatosis – usually from a gastric primary. The neck veins of ascites patients should always be examined for distension in pursuit of a cardiac origin of ascites. Some patients with cardiac ascites will have bulging forehead veins that can be seen from across the room. Some will have no visible jugular venous distension. When patients with liver disease have peripheral edema, it is usually in the lower extremities and spares the arms. Patients with cardiac failure or nephrotic syndrome may have leg and arm edema, e.g., anasarca.

Ascites may be quantified using the following system:

- 1+: detectable only by careful examination.
- 2+: easily detected but of relatively small volume.
- 3+: obvious ascites but not tense.
- 4+: tense ascites.

This system works relatively well for patients with chronic ascites and flaccid abdominal wall muscles. However, patients with acute-onset ascites and good musculature, as in fulminant hepatic failure, may have a tense abdomen without a large volume of fluid.

Abdominal paracentesis

In the past many physicians avoided diagnostic paracentesis in the evaluation of patients with ascites, in part because of concern regarding complications of paracentesis. However, in view of the documented safety of this procedure and the frequency of ascitic fluid infection, paracentesis should: (i) be performed as a routine part of the evaluation of "new-onset" ascites; (ii) be repeated as part of the admission physical examination of patients hospitalized with ascites; and (iii) be repeated again in outpatients or during hospitalization if the patient develops any signs or symptoms suggestive of infection [18,19].

Choice of needle entry site and needle

In the past, the avascular midline was often chosen as the site for paracentesis. However, in the current obesity epidemic, the midline may be extremely thick. Also, many paracenteses these days are therapeutic. One cannot aspirate much fluid from the midline unless the patient is positioned such that the fluid is dependent. A recent prospective study has shown that the abdominal wall is thinner and the size of the pool of fluid is larger in the left lower quadrant [20]. The needle is inserted 3 cm cephalad and 3 cm medial to the anterior superior iliac spine. The left side is preferable to the right side to avoid appendectomy scars and to avoid a gas-filled cecum, common in patients taking lactulose.

Surgical scars pose a significant problem in the selection of a site for needle entry of the abdominal wall. Needles inserted near abdominal wall scars may enter the bowel, which may be adherent to the serosal surface of the abdomen [18]. The needle must be placed several centimeters from the scar.

If only a tiny amount is fluid is present, an image-guided tap by an interventional radiologist may be appropriate.

This author prefers to use standard metal 1.5 inch needles: 22-gauge for diagnostic taps and 16–18 gauge for therapeutic taps. Spinal needles (i.e., 3.5 inch needles) are needed if the abdominal wall is thick. Bare steel needles are preferable to plastic-sheathed cannulas because of the risk of the sheath shearing off into the peritoneal cavity and the tendency of the plastic sheath to kink. Metal needles do not puncture the bowel unless there is a surgical scar (tethering the bowel to the abdominal wall) or severe gaseous bowel distension. The steel needle can be left in the abdomen during a therapeutic tap for many minutes without injury, unless the needle is allowed to drift subcutaneously. Larger bore needles may speed drainage but leave larger defects if they inadvertently enter vessels or the bowel. A multihole disposable needle is now available.

Technique of diagnostic paracentesis

The skin is disinfected with an iodine solution. The skin and subcutaneous tissue should be infiltrated with a local anesthetic. Drapes, gown, hat, and mask are optional but sterile gloves should be used when actually obtaining the fluid. The sterile paper package insert in which the gloves are enclosed can be used as a sterile field on which to place syringes, needles, etc. If sterile gloves are not

used there may be a high prevalence of skin contaminants growing from the cultures that are obtained.

The manner in which the needle is inserted is important in preventing continued leakage of fluid after the needle is withdrawn. Use of a "Z tract" minimizes leakage. To create a Z tract, the operator uses one gloved hand to move the skin ~2 cm caudad in relation to the deep abdominal wall and then inserts the paracentesis needle with the other hand. The key is to be able to manipulate the syringe with only one hand. The skin is not released until the needle has penetrated the peritoneum and fluid begins to flow. When the needle is removed, the skin slips back into its original position and seals the needle pathway. If the needle is inserted without a "Z", the fluid leaks out easily because its pathway is straight.

The needle should be advanced slowly in ~5 mm increments. If it is inserted in one rapid motion, vessels and bowel may be impaled by the needle. A slow insertion allows the operator to see a flash of blood if he enters a vessel; the needle can then be withdrawn before further damage is done. A slow insertion also allows the bowel to float away from the needle without needle penetration of it. The syringe that is attached to the needle should not be aspirated until there is fluid visible in the needle hub. If there is continuous suction on the needle during its insertion, bowel or omentum may be drawn to the end of the needle as soon as the needle enters the peritoneal cavity – giving the appearance of a "dry tap." Therefore, the needle should be inserted ~5 mm, then the syringe should be aspirated for a few seconds while the needle is stationary, then advanced, then aspirated, etc. until the peritoneum is entered and fluid is aspirated. A slow insertion also allows time for the elastic peritoneum to tent over and be pierced by the needle. Once fluid is flowing, the needle should be stabilized so that its position can be maintained in order to insure a steady flow. It is not unusual for flow to stop as bowel or omentum is suctioned over the bevel of the needle. When flow ceases, the syringe is removed from the needle, the needle is twisted 90° and then inserted in 1–2 mm increments until dripping of fluid from the needle hub is achieved. The syringe is then reattached and fluid is aspirated. Occasionally, fluid cannot be aspirated but it drips nicely from the needle hub. In this situation, as in a lumbar puncture, fluid is allowed to drip into a sterile container for collection.

Indications

Abdominal paracentesis is probably the most rapid and cost-effective method of diagnosing the cause of ascites and the only method of detecting ascitic fluid infection. In view of the relatively high prevalence of ascitic fluid infection at the time ascites patients are admitted to the hospital, a surveillance tap may detect unexpected infection at the time of hospitalization. Not all patients with ascitic fluid infection are symptomatic, and the detection of infection at an early asymptomatic stage may reduce mortality [21]. Therefore, this investigator advocates sampling ascitic fluid in all inpatients and outpatients with *new-onset* ascites and in all patients admitted to hospital with ascites, i.e., a tap at the time of each hospitalization. Paracentesis should be *repeated* in outpatients and inpatients who develop signs or symptoms of infection. Signs, symptoms, and lab abnormalities suggestive of infection include hypotension, abdominal pain or tenderness, fever, encephalopathy, renal failure, acidosis, and peripheral leukocytosis.

Contraindications

Prospective studies regarding paracentesis complications in patients with ascites have documented its safety [18, 19,22]. Complications included 2/229 (0.9%) transfusion-requiring abdominal wall hematomas, and 2/229 (0.9%) small hematomas in one study [18]. No serious complications or death were reported in two of the studies [18,19]; the third study reported a bleeding rate of 1% and the death in two patients after a total of 515 paracenteses [22]. This study also reported the breakage of a plastic catheter into the peritoneum and other complications that cause the reader to be concerned about the attention to detail involved in the study [22]. The breakage of a plastic catheter confirms the wisdom of using steel needles (see above).

Most patients who undergo paracentesis have significant coagulopathy. In one series the international normalized ratio (INR) was as high as 8.7 and the platelet count was as low as 19,000 cells/mm^3, yet no one had a bleeding complication and no one received transfusions of blood products before or after paracentesis [19]. No study has showed a correlation of bleeding with INR [18,19,22], and none of the prospective studies gave prophylactic transfusions [18,19,22].

There are few contraindications to paracentesis. Coagulopathy is frequently viewed as a potential contraindication. Coagulopathy has only precluded this author from performing a paracentesis when there was clinically evident primary fibrinolysis or disseminated intravascular coagulation; these conditions occur less than once per 1,000 taps. There is no cutoff of coagulation parameters beyond which paracentesis should not be performed. Even patients with severe prolongation of prothrombin time usually have a trivial ascitic fluid red cell count after multiple paracenteses. Patients with cirrhosis and ascites but without clinically obvious coagulopathy do not bleed excessively from needle sticks unless a blood vessel is entered [18,19,22].

There is a common misconception that the INR correlates with bleeding risk. It is powerful in predicting death in the setting of cirrhosis, but is not a good predictor of

bleeding risk. The liver makes most of the procoagulants and most of the anticoagulants. The INR measures only the absence of procoagulants [23]. When the liver is functioning poorly, there is usually a *balanced deficiency of both pro- as well as anticoagulants, such that global coagulation is normal* [23].

It is the policy of some physicians to give prophylactic blood products (fresh frozen plasma and/or platelets) routinely before paracentesis in patients with cirrhosis and coagulopathy. This practice is not supported by the data.

Differential diagnosis by ascitic fluid analysis

Gross appearance of the fluid

Most ascitic fluid is transparent and yellow-tinged. Deeply bile-stained ascitic fluid from jaundiced patients is less bile stained than paired serum. Fluid as dark as molasses usually indicates biliary perforation [9]. The opacity of most cloudy ascitic fluid specimens is caused by neutrophils. The presence of particulate matter, such as neutrophils, leads to a shimmering effect when a glass tube of the fluid is held in front of a bright light. Absolute neutrophil counts under 1,000/mm^3 may be nearly clear. Counts over 5,000/mm^3 are quite cloudy, and counts over 50,000/mm^3 have a purulent consistency.

Ascitic fluid specimens are occasionally blood-tinged or frankly bloody. A red cell count of 10,000/mm^3 is the threshold for a pink appearance; smaller concentrations result in clear or "turbid" fluid. Ascitic fluid with a red cell count >20,000/mm^3 is distinctly blood-tinged. Many ascitic fluid specimens are bloody due to a traumatic tap in the setting of cirrhosis; these specimens are heterogenously bloody and clot. In contrast, nontraumatic or remotely traumatic bloody ascitic fluid is homogenously pigmented and does not clot because it has already clotted and lysed. Some patients with portal hypertension have bloody hepatic lymph leading to bloody ascitic fluid, perhaps because of the rupture of high-pressure lymphatics. Greater than one half of samples from patients with hepatocellular carcinoma that this investigator has encountered are bloody, but only about 10% of samples from patients with peritoneal carcinomatosis have this appearance [5]. Overall only 22% of malignancy-related samples (including primary liver cancer) are bloody [5]. Although many physicians are of the opinion that tuberculosis (TB) results in bloody ascites, less than 5% of TB samples are hemorrhagic in this author's experience [24].

There is a spectrum of "milkiness" in ascitic fluid ranging from slightly cloudy "opalescent" fluid to completely opaque chylous fluid. The most opaque milky fluid has a triglyceride concentration >200 mg/dL, usually >1,000 mg/dL. Fluids that look like dilute skimmed milk usually have a concentration of between 100 and 200 mg/dL. A substantial minority of ascitic fluid samples are neither transparent nor frankly milky. Some physicians mistake this fluid for pus; it is not viscous enough to be pus. In this condition, which this author labels "opalescent" ascitic fluid, the cloudiness of the fluid has been found to be caused by a slightly elevated triglyceride concentration of 50–200 mg/dL [25]. The lipid will usually layer out in the refrigerator over a 48–72-hour interval.

Pancreatic ascites may appear tea-colored due to the effect of pancreatic enzymes on ascitic fluid red cells. Such fluid may have to be centrifuged to spin the red cells down and reveal the discolored supernatant. In hemorrhagic pancreatitis, the fluid may be so darkly pigmented that it appears black. Malignant melanoma can also result in black ascites.

Ascitic fluid tests

Some physicians order every test that they can think of when analyzing ascitic fluid. This practice can be expensive and can be more confusing than helpful, especially when unexpectedly abnormal results are encountered. An algorithm approach to ascitic fluid analysis is more appropriate. Screening tests are performed on the initial specimen, and additional testing is performed (usually necessitating another paracentesis) based on the results of the screening tests. Most specimens will consist of uncomplicated ascites in the setting of cirrhosis. No further testing will usually be needed in this setting.

Based on cost analysis, this author has developed a list of routine, optional, unusual, and unhelpful tests (Box 17.1). The strategy used in this algorithm is discussed below.

Cell count

The cell count is the single most helpful ascitic fluid test. If only one drop of fluid is obtained, it should be sent for cell count. Only a few microliters are required for a standard manual hemocytometer count. The fluid should be submitted in an anticoagulant tube, i.e., ethylenediaminetetra-acetic acid (EDTA), to prevent clotting. Since the decision to begin empirical antibiotic treatment of suspected ascitic fluid infection is based largely on the rapidly available absolute neutrophil count rather than the not-so-rapidly available culture, the cell count is more important than the culture in the early approach to these patients with regard to ascitic fluid infection.

The mean total white blood cell count in uncomplicated ascites in the setting of cirrhosis is reported to be 281 ± 25 cells/mm^3; the upper limit is said to be 500 cells/mm^3 [26]. However, during diuresis in patients with cirrhosis and ascites, the cells exit the peritoneal

cavity more slowly than the fluid and the mean ascitic fluid white cell count has been shown to increase to >1,000 cells/mm^3 [27]. This author has encountered several examples of end-of-diuresis white cell counts >3,000/mm^3 and one example of 7,000/mm^3. However, before a patient can be diagnosed as having a diuresis-related elevation of ascitic fluid white cell count, three criteria must be fulfilled: (i) a prediuresis count must be available and must be normal; (ii) there must be a predominance of lymphocytes; and (iii) there must be no unexplained clinical signs or symptoms, e.g., fever or abdominal pain.

The mean percentage of polymorphonuclear cells (PMNs) in uncomplicated ascites due to cirrhosis is $27 \pm 2\%$; the upper limit of the absolute PMN count in uncomplicated cirrhotic ascitic fluid is usually stated to be 250/mm^3 [21]. Fortunately, the short life expectancy of PMNs (hours only) results in a relative stability in the absolute PMN count during diuresis (42 to 68 cells/mm^3 from the beginning to end; difference not significant) [26]. Therefore, the 250 cells/mm^3 "cutoff" pertains even at the end of diuresis.

Leukocyte esterase strips or dipsticks have been proposed as useful tools in making a diagnosis of ascitic fluid infection in 90–180 seconds. However, the early studies used strips that were calibrated for urine and had a very high PMN threshold for positivity and therefore a low sensitivity in detecting spontaneous bacterial peritonitis (SBP). A more recent strip has been developed specifically for ascitic fluid and has been shown to have 100% sensitivity in detecting a PMN count of 250 cells/mm^3 [27]. Use of such a strip permits the physician to write an order for a life-saving antibiotic before leaving the patient's ward. Too often the laboratory delays the availability of the cell count, and the physician may not follow through in looking up the cell count until the bacterial culture is reported positive the next day. The patient may have expired by that time.

Inflammation is the most common cause of an elevated ascitic fluid white cell count. SBP is the most common form of inflammation of ascitic fluid. In the setting of SBP, the total white cell count is elevated as well as the absolute PMN count; PMNs comprise more than 50% of the total white cells and usually more than 70%. Also, in tuberculous peritonitis and peritoneal carcinomatosis there is usually an elevated total white cell count but with a predominance of lymphocytes [5,24]. The white cell count of chylous ascites may be increased because of the leakage of lymphocytes from ruptured lymphatics.

Most bloody ascites is the result of a slightly traumatic tap in a patient with cirrhosis. If a tap is traumatic, white cells from peripheral blood enter the peritoneal cavity with the red cells, and the ascitic fluid white cell count usually increases because of this. Since neutrophils predominate the white cell differential in blood, the ascitic fluid differential may be altered by contamination of ascitic fluid with blood. To correct for this contamination one simply subtracts one PMN per 250 red cells [26]. If the leakage of blood is not recent, the PMNs will have lysed and the corrected PMN count will be a negative number. If the corrected PMN count in a bloody specimen is ≥250 cells/mm^3, the patient must be assumed to be infected until proven otherwise.

Serum–ascites albumin gradient

In the past, the ascitic fluid total protein concentration was used to classify ascites into exudates (≥2.5g/dL) and transudates (<2.5 g/dL). Unfortunately this form of classification is an extrapolation from pleural fluid analysis that does not work well in ascitic fluid [4,28,29]. In fact these terms as applied to ascitic fluid were never carefully defined or validated. Similarly, analysis of lactate dehydrogenase (LDH) and serum : ascitic fluid ratios of LDH or protein have not been found to work well in classifying ascitic fluid into exudates and transudates [30]. The *serum–ascites albumin gradient* (SAAG) has been shown in multiple studies to categorize ascites better than the total protein concentration and better than other parameters [4,29–30]. The "gradient" is based on oncotic–hydrostatic balance. If there is an abnormally high hydrostatic pressure gradient between the portal bed and ascitic fluid (i.e., portal hypertension), there must be a commensurately

Box 17.2 Classification of ascites by the serum–ascites albumin concentration gradient.

Low gradient (<1.1 g/dL)

- Peritoneal carcinomatosis
- Tuberculous peritonitis
- Pancreatic ascites
- Biliary ascites
- Nephrotic syndrome
- Serositis in connective tissue diseases

High gradient (≥1.1 g/dL)

- Cirrhosis
- Alcoholic hepatitis
- Cardiac ascites
- Massive liver metastases
- Fulminant hepatic failure
- Budd–Chiari syndrome
- Portal vein thrombosis
- Venoocclusive disease
- Fatty liver of pregnancy
- Myxedema
- "Mixed" ascites

large difference between ascitic fluid and intravascular oncotic forces [29]. Albumin exerts more oncotic force per unit weight than other proteins. The difference between serum and ascitic fluid albumin concentration correlates directly with portal pressure [29].

It is this author's experience that some physicians try to make this simple concept more difficult to understand than it really is. The albumin gradient does not explain the pathogenesis of ascites formation. It does not explain where the albumin came from, i.e., liver or bowel. It simply gives the physician an accurate indirect index of portal pressure. Stated in another way, the higher the SAAG, the greater the portal pressure (Box 17.2). If the SAAG is ≥1.1 g/dL, the patient has portal hypertension with >95% accuracy [4,28–30]. Also, if the serum albumin-ascitic fluid *total protein* is ≥1.1 g/dL, the patient has portal hypertension, since ascitic fluid albumin cannot be greater than ascitic fluid total protein. Conversely, if the SAAG is <1.1 g/dL, the patient does not have portal hypertension. Calculating the SAAG involves measuring the albumin concentration of serum and ascitic fluid specimens and then simply *subtracting* the ascitic fluid value from the serum value. Again, there has been some confusion here. *It is a subtraction not a ratio*.

If the SAAG is obtained under the correct circumstances and performed properly, accuracy approaches 100%. In the largest series reported (involving 901 paired specimens), accuracy was 96.7% [4]. This test is accurate despite SBP, diuresis, therapeutic paracentesis, albumin infusion (both serum and ascitic fluid albumin concentrations increase in parallel), and etiology of liver disease [29]. However, there are situations in which accuracy decreases. Specimens should be obtained relatively simultaneously. The ascitic fluid value from last week or last year cannot be subtracted from today's serum value; the state of hydration or nutrition of the patient may be different at different times. The specimens should be obtained on the same day – better yet, within the same hour. Both serum and ascitic fluid albumin concentrations change over time; however, the beauty of this test is that these values change in parallel such that the difference is stable. Another situation in which the test is potentially inaccurate is in the unstable (e.g., hypotensive) patient. If the arterial pressure is low, the portal pressure and albumin gradient may be lowered.

Accuracy of the albumin assay at low albumin concentrations, e.g. <1 g/dL, is important because many ascites patients have serum albumins in the 2.0–3.0 g/dL range and ascitic fluid albumins in the 0–1.0 g/dL range. Usually, the lab's albumin standards must be diluted to insure linearity of the assay at low range. Nephelometry is not appropriate for testing ascites. If the albumin assay is not accurate at a low range, errors will occur. Also, if a patient with cirrhosis has a serum albumin of <1.1 g/dL (this occurs in <1% of ascites patients), the gradient will be falsely low. In some labs lipid interferes with the albumin assay, therefore chylous ascites may have a falsely high albumin gradient.

A high serum globulin (>5 g/dL) is occasionally found in a patient with cirrhosis and ascites. A high serum globulin concentration leads to a high ascitic fluid globulin concentration and can narrow the albumin gradient by contributing to the oncotic forces. A narrowed gradient due to high globulin occurs in only ~1% of ascitic fluid specimens. Correcting the gradient for high globulin increases accuracy of the gradient from ~97% to ~98% and explains some otherwise confusing cases. To correct the SAAG in the setting of a high serum globulin, the uncorrected SAAG is multiplied by (0.21 + (0.208 × serum globulin)) [31].

"High albumin gradient" and "low albumin gradient" should replace the terms "transudative" and "exudative" in the classification of ascites [4,28–30]. Another problem with the exudate/transudate system of classification is that it has no provision for patients with two causes for ascites formation, i.e., mixed ascites. Most of these patients have portal hypertension due to cirrhosis *plus* another cause for ascites formation, e.g., TB or peritoneal carcinomatosis [4]. Approximately 5% of ascites patients have mixed ascites (see Table 17.1) [4]. The presence of TB or peritoneal carcinomatosis would not be expected to lower the portal pressure. The albumin gradient remains high

(≥1.1 g/dL) in mixed ascites, as a reflection of the underlying portal hypertension.

Some physicians have the impression that a high albumin gradient is equivalent to a liver biopsy demonstrating cirrhosis and a low albumin gradient is equivalent to a peritoneal biopsy demonstrating carcinomatosis. However, the albumin gradient provides no histologic diagnosis; it is only an indirect measurement of portal pressure. Cirrhosis is the most common cause of a high albumin gradient, and peritoneal carcinomatosis is the most common cause of a low albumin gradient [4]. However, there are other causes of high and low gradients (see Box 17.2). The albumin gradient need only be performed on the first paracentesis in a given patient, it need not be repeated in subsequent specimens if the first value is definitive. If the first is borderline, e.g., 1.0 or 1.1 g/dL, a repeat paracentesis (performed at a time near when the blood is obtained) and analysis usually is definitive.

Box 17.3 Problems with the "exudate/transudate" system of ascites classification.

- Approximately two thirds of patients with cirrhosis develop total protein ≥2.5 g/dL during diuresis
- ~20% of patients with cirrhosis have ascitic fluid total protein ≥2.5 g/dL
- ~0% of SBP samples have ascitic fluid total protein ≥2.5 g/dL
- Exudate concept does not acknowledge "mixed" ascites
- Patients with massive liver metastases and hepatocellular carcinoma have ascitic fluid total protein <2.5 g/dL
- 100% of cardiac ascites samples have ascitic fluid total protein ≥2.5 g/dL
- 50% of tuberculous peritonitis patients have underlying cirrhosis and ascitic fluid total protein <2.5 g/dL

Culture

The most common bacterial infection of ascitic fluid is SBP [32]. The sensitivity of bacterial culture in detecting bacterial growth in neutrocytic ascites (i.e., ascitic fluid with a PMN count ≥250 cells/mm^3) varies dramatically depending on the method of culture used. In the studies that have been conducted, the older culture method has been found to detect bacterial growth in 42–43% of samples of neutrocytic ascites, whereas bedside inoculation of blood culture bottles with ascitic fluid detects growth in 91–93% [33,34]. In many hospitals, the sensitivity of older culture is only ~20–30% in this investigator's experience. The older method of culture consisted of inoculation of three agar plates and some culture broth with a few drops of fluid each, in the microbiology laboratory. At least one plate was designed to selectively support the growth of Gram-negative organisms and to suppress growth of other flora; the older method assumes that polymicrobial infection is the rule and that a large concentration of bacteria is common. However, SBP is essentially always a monomicrobial infection with a low colony count – very similar to bacteremia. Culturing ascitic fluid as if it is blood might be predicted to be superior to culturing the fluid as if it is urine or stool. In fact, multiple prospective studies have demonstrated the superiority of the blood culture bottle method; no study has demonstrated the superiority of the older method [33,34].

Some laboratories culture the centrifuged sediment of ~50 mL of fluid, presuming that this modification of the conventional method is superior to the older method of culture per se. Unfortunately, spinning the bacteria into the pelleted neutrophils results in a lower detection rate of bacteria than that of the conventional method, presumably because of the neutrophil-mediated killing of bacteria [33].

Some laboratories do not release blood culture bottles to the patient wards. Technicians bring the bottles with them when they draw blood for cultures. In this setting, bedside inoculation of the bottles would be difficult. However, bedside inoculation has been shown to be superior to delayed laboratory inoculation of blood culture bottles with ascitic fluid [35]. Laboratories should release the bottles to the physicians who are performing the paracenteses, so that bedside inoculation is possible.

Total protein

The old exudate/transudate system of ascitic fluid classification, which is based on ascitic fluid total protein concentration, is problematic (see above and Box 17.3). The protein concentration in ascites due to cirrhosis is entirely dependent on serum total protein concentration and portal pressure [29]. Therefore, a patient with a relatively high serum protein will have a relatively high ascitic fluid protein. Almost 20% of samples of uncomplicated ascites due to cirrhosis have >2.5 g/dL of protein [36]. During a 10 kg diuresis, ascitic fluid total protein increases from 1.4 to 2.9 g/dL; 67% of patients with ascites due to cirrhosis develop a protein >2.5 g/dL at the end of diuresis [26]. Ascitic fluid total protein concentration does not increase during SBP [37]. In fact, patients with the lowest protein ascites are the most prone to develop SBP [38]. Almost one third of patients with malignancy-related ascites have portal hypertension due to massive liver metastases or hepatocellular carcinoma as the cause of ascites formation; their fluid total protein is <2.5 g/dL [5]. Cardiac ascites protein concentration is always greater than 2.5 g/dL in this investigator's experience [6]. Therefore, cardiac ascites is classified in the exudate category while ascites due to cirrhosis is classified in the transudate category. A method of classification that categorizes

cardiac and ascites due to cirrhosis in opposite groups is not very useful. In contrast, the albumin gradient classifies cardiac ascites in the high albumin gradient category, similar to cirrhosis with ascites. The high SAAG of cardiac ascites is presumably due to high right-sided heart pressures [6].

Measurement of ascitic fluid total protein, glucose, and LDH has been reported to be of value in distinguishing SBP from gut perforation into ascites [39]. Patients whose neutrocytic ascitic fluid meets two out of the following three criteria are likely to have surgical peritonitis and warrant immediate radiologic evaluation to determine if gut perforation into ascites has occurred: total protein >1 g/dL, glucose <50 mg/dL, and LDH above the upper limit of normal for serum [39,40]. A recent study has shown that these criteria and/or polymicrobial infection are 96% sensitive in detecting secondary bacterial peritonitis; 5% of patients in the series had secondary bacterial peritonitis [40].

Glucose

The ascitic fluid glucose concentration is similar to that of serum unless glucose is being consumed in the peritoneal cavity by white blood cells or bacteria [41]. However, the ascitic fluid glucose in early detected SBP is similar to that of sterile fluid [37]. If the gut perforates into ascitic fluid, e.g., perforated peptic ulcer or colonic diverticulum, the glucose usually drops to 0 mg/dL [39].

Lactate dehydrogenase

The ascitic fluid : serum (AF : S) ratio of LDH is 0.40 ± 0.20 in uncomplicated ascites due to cirrhosis; LDH is too large a molecule to readily enter the fluid from blood [37]. In SBP, the ascitic fluid LDH level rises because of neutrophil release of LDH, such that the mean ratio is 0.85 ± 0.29 [37].

Amylase

The ascitic fluid amylase concentration is 42 ± 44 IU/L and the AF : S ratio of amylase is 0.44 ± 0.33 in uncomplicated ascites due to cirrhosis [42]. The ascitic fluid amylase concentrations are markedly above these levels in patients with pancreatitis or gut perforation (with release of luminal amylase into the fluid). In pancreatic ascites, the ascitic fluid amylase concentration is $2{,}000 \pm 1{,}000$ IU/L and the AF : S ratio in pancreatic ascites 5 ± 0.0 [42].

Gram stain

A Gram stain of ascitic fluid for the detection of SBP is analagous to a Gram stain of blood in detecting bacteremia: it is only positive when there is an overwhelming infection present. The Gram stain of ascitic fluid is most helpful in ruling in or ruling out free perforation of the gut into ascites; sheets of multiple bacterial forms are found in gut perforation. In contrast, careful inspection of the centrifuged sediment of 50 mL of ascites is only 10% sensitive in visualizing bacteria in early-detected SBP [33]. Approximately 10,000 bacteria/mL are required for detection by Gram stain; the median concentration of bacteria in SBP is only 1 organism/mL [33].

Tests for tuberculosis

The direct smear of ascitic fluid for mycobacteria is almost never positive, for the same reason that the Gram stain is seldom positive in SBP [43,44]. This author has only seen one positive TB smear and that was a false positive. Although some older papers suggest the culture of a liter of fluid, most labs can only process 50 mL for TB culture [43,44]. The fluid is centrifuged and the pellet is cultured, but 50 mL centrifuge tubes and carriers are the largest commonly used. The sensitivity of peritoneoscopy, with histology and culture of peritoneal biopsies, in detecting tuberculous peritonitis approaches 100% [43]. Tuberculous peritonitis may mimic the culture-negative variant of SBP, but the predominance of cells is usually mononuclear in the setting of TB.

The ascitic fluid adenosine deaminase is helpful in detecting tuberculous peritonitis in endemic areas such as India [45]. However, in the United States >50% of patients with tuberculous peritonitis also have cirrhosis; in this setting adenosine deaminase is very insensitive [24]. DNA probes for TB are also available for body fluids and tissue [46].

Cytology

Cytology is reported to be only 58–75% sensitive in detecting "malignant ascites" [47,48]. However, these older studies did not compare cytology with a "gold standard" diagnosis such as autopsy or laparoscopy. Based on a study that did involve a gold standard diagnosis as to the location and type of tumor causing ascites formation, we now know that only about two thirds of patients with malignancy-related ascites have peritoneal carcinomatosis [5]. Essentially 100% of patients with peritoneal carcinomatosis have viable malignant cells exfoliating into their ascitic fluid and therefore have these cells detected in their ascitic fluid cytologies [5]. The remaining one third of patients with malignancy-related ascites have massive liver metastases, chylous ascites due to lymphoma, or hepatocellular carcinoma; these patients have negative cytologies [5]. The percentage of false-positive cytologies approaches zero [5,47,48]; this investigator has never encountered an example. Hepatomas rarely metastasize to the peritoneum, therefore cytology is almost never positive in patients with this tumor [5,48].

DNA cytometry has been shown to improve the sensitivity of effusion cell analysis to 95% [49].

Malignancy-related ascites may also have an elevated PMN count (16% of cases in one series) presumably because dying tumor cells may attract neutrophils into the fluid [5]. Usually, as in tuberculous peritonitis, there is a predominance of lymphocytes.

Triglyceride

If the ascitic fluid is opalescent or frankly milky, a triglyceride level should be obtained. Chylous ascites has a triglyceride concentration of >200 mg/dL and usually >1,000 mg/dL [50]. The sterile ascitic fluid specimens (in cirrhosis) that are slightly cloudy without an elevated cell count have an elevated triglyceride concentration: 64 ± 43mg/dL compared to 18 ± 9 mg/dL for clear cirrhotic ascites [25].

Bilirubin

Ascitic fluid that is as brown as molasses should be tested for bilirubin concentration. An ascitic fluid bilirubin level greater than 6 mg/dL and greater than the serum level of bilirubin suggests biliary or upper gut perforation into ascites [9,39].

Tests that are seldom helpful

Ascitic fluid pH and lactate were proposed in the 1980s as helpful tests in the differential diagnosis of ascites, in particular in separating infected samples from uncomplicated ascites due to cirrhosis [51]. Unfortunately, the studies that attempted to validate the pH and lactate included only 6–18 infected patients per study, did not use optimal culture technique, and included an unusually high percentage (up to 67%) of surgical peritonitis patients. Surgical peritonitis patients have ascitic fluid that is at the extreme end of the spectrum of abnormality and would be predicted to have the lowest pH. Most series of peritonitis cases in the setting of ascites consist of ~95% SBP patients and ~5% secondary peritonitis patients [40]. In the two largest and most recent studies, which did not have some of the problems of the earlier studies, the ascitic fluid pH and lactate were not found to be helpful [52,53]. In one study the pH was found to be only about 40% sensitive in detecting infection, and the pH was found to remain normal (>7.35) until the PMN count rose over 2,000/mm^3 [52]. The pH was found to have no impact on decision making regarding the use of empirical antibiotics since patients were given antibiotics based on the PMN count even if the pH was normal. Measurement of arterial pH and pH gradient did not improve the sensitivity of the tests over that of ascitic fluid values alone and did not improve decision making [52]. Ascitic fluid pH appears to be simply an indirect measure of the presence of neutrophils. Why not just measure the neutrophils?

Measurement of carcinoembryonic antigen (CEA) in ascitic fluid has been proposed as a helpful test in detecting malignant ascites [54]. Patients with malignancy-related ascites were not subgrouped into those with and without peritoneal carcinomatosis in the only reported CEA study. Few patients were studied and no subsequent studies have been reported. Theoretically, this test should only be helpful in detecting the few tumors that make CEA. More studies, with subgrouping of patients and positive results, are required before CEA can be considered validated as a test of ascitic fluid.

Several ascitic fluid tests, such as fibronectin, cholesterol, α_1-antitrypsin, cyclic adenosine monophosphate (cAMP), and glycosaminoglycans, have been proposed as useful tests in detecting "malignant ascites." The large number of tests signifies that none of them is helpful enough to have been selected above the others. The basic premise of these studies is that the ascitic fluid cytology is too insensitive to be the only test used in detecting malignancy-related ascites. Unfortunately, most of these studies did not acknowledge that there are several subgroups of malignancy-related ascites and did not appreciate that the cytology would only be helpful in detecting peritoneal carcinomatosis. Also, appropriate control groups (patients with ascites caused by *conditions other than* cirrhosis or peritoneal carcinomatosis) were not included in these studies, and they had no provision for examples of mixed ascites. Other studies have demonstrated that the subgroup of patients with massive liver metastases do not have abnormally elevated ascitic fluid fibronectin or cholesterol concentrations [55,56]. Therefore, patients with negative cytologies also usually have negative "humoral tests of malignancy." In addition, patients with high protein ascites due to conditions other than cirrhosis essentially always have been reported to have false-positive "humoral tests of malignancy" [4,55,56]; these tests are more confusing than helpful.

Serum analysis

Measurement of serum albumin concentration is required to determine the albumin gradient. In patients with suspected SBP, blood should be cultured in addition to ascitic fluid, even if the patient is not febrile (only 67% of patients with SBP have fever) [32]. Profound peripheral hypoglycemia (as low as 5 mg/dL) can be found in patients with systemic bacterial infection and cirrhosis. If the ascitic fluid glucose is unusually low in a patient with neutrocytic ascites, measurement of serum glucose may explain the ascitic fluid hypoglycemia and lead to potentially life-saving emergency administration of glucose intravenously. Measurement of serum bilirubin or triglyceride concentration may be of value in comparison to the ascitic fluid concentrations. Measurement of serum α-fetoprotein (AFP) concentration (which is always higher in serum than in ascitic fluid) may be of value in

detecting hepatocellular carcinoma as the explanation for the clinical deterioration of a patient with known cirrhosis [4].

The serum pro-BNP is a very useful test in separating ascites due to cirrhosis from ascites due to heart failure [17]. In the former, the median value is 166 pg/mL and the latter is 6,100 pg/mL, with complete separation of the data points [17]. Patients with cirrhosis *and* heart failure have values in the heart failure range. This test can be performed within ~20 minutes in the emergency department in a patient with alcohol abuse and ascites, to help determine whether alcoholic cirrhosis or alcoholic cardiomyopathy is present. This test can help direct the patient to the appropriate inpatient unit – the general medicine floor or the cardiac unit.

Complications of ascites

Infection

Ascitic fluid infection can be classified into five categories based on culture, PMN count, and the presence or absence of a surgical source of infection (Box 17.4). An abdominal paracentesis must be performed and ascitic fluid must be analyzed before a confident diagnosis of ascitic fluid infection can be made. A "clinical diagnosis" of infected ascitic fluid without a paracentesis is not enough.

Definitions

Of the three types of spontaneous ascitic fluid infection, the prototype form is spontaneous bacterial peritonitis (Box 17.4). This diagnosis is made when there is a positive ascitic fluid culture (essentially always a monomicrobial infection) and there is an elevated ascitic fluid absolute PMN count (i.e., $\geq$250 cells/mm^3) without an evident intra-abdominal source of infection that requires surgical treatment [32]. When Harold Conn coined the phrase spontaneous bacterial peritonitis in 1975, his goal was to distinguish this form of infection from surgical peritonitis [57]. This author agrees with the importance of this distinction. Therefore, although many patients with SBP have a focus of infection, e.g., urinary tract infection or pneumonia, they are labeled as having SBP unless the focus requires surgical intervention, e.g., ruptured viscus [39,40].

Box 17.4 Classification of ascitic fluid infection.[a]

Spontaneous ascitic fluid infection

- *Spontaneous bacterial peritonitis*
- *Monomicrobial nonneutrocytic bacterascites*
- *Culture-negative neutrocytic ascites*

Secondary bacterial peritonitis

- *Gut perforation*
- Nonperforation

Polymicrobial bacterascites

[a]The five main categories are emphasized in italic.

The criteria for a diagnosis of monomicrobial nonneutrocytic bacterascites (MNB) include a positive ascitic fluid culture for a single organism, an ascitic fluid PMN count <250 cells/mm^3, and no evident intra-abdominal source of infection that requires surgical treatment [58]. The adjective "monomicrobial" is used to distinguish this form of ascitic fluid infection from polymicrobial bacterascites (see below). In the older literature this condition was either grouped with SBP or called asymptomatic bacterascites [59]. Since many patients with bacterascites have symptoms, the modifier "asymptomatic" does not seem appropriate [58]. The absence of PMNs in this variant has implications for prognosis as well as for understanding the pathogenesis and natural history of ascitic fluid infection (see below).

Culture-negative neutrocytic ascites (CNNA) is diagnosed when: (i) the ascitic fluid culture grows no bacteria; (ii) the ascitic fluid PMN count is $\geq$250 cells/cmm^3; (iii) no antibiotics have been given (even a single dose usually makes the culture negative); and (iv) there is no other explanation for an elevated PMN count (e.g., hemorrhage into ascites, peritoneal carcinomatosis, TB, or pancreatitis) [60]. This variant of ascitic fluid infection is seldom diagnosed when sensitive culture methods are used [33,34].

Secondary bacterial peritonitis is diagnosed when: (i) the ascitic fluid culture is positive (usually for multiple organisms); (ii) the PMN count is $\geq$250 cells/mm^3; and (iii) there is an identified intra-abdominal surgically treatable primary source of infection (e.g., perforated gut, perinephric abscess) [39,40]. The importance of distinguishing this variant from SBP is that secondary peritonitis is usually treated with antibiotics *and* surgery, whereas SBP is essentially always treated *only* with antibiotics [39,40]. Performing a laparotomy in the setting of SBP or treating secondary peritonitis with antibiotics and no surgical intervention usually results in the death of the patient.

Polymicrobial bacterascites is diagnosed when: (i) multiple organisms are cultured from ascitic fluid; and (ii) the PMN count is <250 cells/mm^3 [61]. This diagnosis should be suspected when: (i) the paracentesis is difficult because of ileus and/or it is traumatic; (ii) stool and/or air are aspirated into the paracentesis syringe; or (iii) multiple organisms but no PMNs are seen on Gram stain. Polymicrobial bacterascites is essentially diagnostic of inadvertent gut perforation by the paracentesis needle.

Setting

For all practical purposes the spontaneous variants of ascitic fluid infection, i.e., SBP, CNNA, and MNB, occur only in the setting of advanced liver disease. Spontaneous infection of ascites that is not due to cirrhosis is rare enough to be the subject of case reports [62–64]. Ninety-five percent of patients with SBP have an elevated serum bilirubin and 98% have an abnormal prothrombin time [32]. The liver disease is usually chronic, as in cirrhosis, but may be acute, as in fulminant hepatic failure, or subacute, as in alcoholic hepatitis. All forms of cirrhosis have been reported to be complicated by spontaneous ascitic fluid infection. Ascites is a prerequisite to the development of SBP; fluid is almost always clinically detectable at the time of infection. It is unlikely that SBP precedes the development of ascites. Usually this infection develops at the time of maximum ascites volume. Although nephrotic ascites was regularly complicated by SBP in the pre-antibiotic era, the use of diuretics and antibiotics have now made SBP uncommon in this setting.

About one half of SBP episodes are detected at the time of admission to hospital. The remainder develop during hospitalization [32].

Secondary bacterial peritonitis and polymicrobial bacterascites can develop in ascites of any type. The only prerequisite, in addition to the presence of ascites, for the development of the former infection is the presence of a surgical source of infection (e.g., ruptured viscus, perinephric abscess) [39,40]. The latter infection occurs due to needle entry of the bowel during attempted paracentesis [61].

Pathogenesis

In 1975 Harold Conn used the adjective "spontaneous" in describing bacterial peritonitis in the ascites patient to indicate that the infection appeared from nowhere [57]. Over the past 35 years the pathogenesis and natural history of the spontaneous forms of ascitic fluid infection have become more clear (Fig. 17.1; see Box 17.4). The enteric nature of most organisms that cause these infections implicates the gut as their source [32]. The pneumococcus is the only frequently isolated organism that does not reside in the gut. The body of currently available evidence suggests that SBP, CNNA, and MNB are probably the result of the colonization of susceptible ascitic fluid as a result of spontaneous bacteremia or the weeping of bacteria-laden lymph from the liver capsule as it forms ascitic fluid (Fig. 17.1). Although direct transmural migration of bacteria from the gut into ascites has been postulated as a route of colonization of ascitic fluid, this has been documented only after the loss of gut mucosal integrity [65]. If organisms could easily traverse the gut wall and directly enter the fluid, polymicrobial infections would be the rule rather the exception, and the flora of spontaneous ascitic fluid infections would be more representative of the flora of the gut. Although *Escherichia coli* and *Klebsiella pneumoniae* are present in the gut, they are outnumbered by 2–4 orders of magnitude by anaerobes and enterococci. Yet anaerobes and enterococci seldom cause spontaneous ascitic fluid infection [32].

Monomicrobial infections imply that the source of the infection is also monomicrobial, or that there is a filter mechanism or a series of filters between a polymocrobial source, such as the gut, and the ascitic fluid. Studies in rodents have demonstrated that under certain circumstances bacteria can "translocate" from the gut lumen across the mucosa into submucosal lymphatics and be detected in mesenteric lymph nodes [66]. Circumstances that promote translocation include bacterial overgrowth in the gut, chemotherapy-induced immunodeficiency, thermal burn, and hemorrhagic shock [66]. Translocation may explain how bacteria access the bloodstream in shock, leukemia, thermal burn, and multiple trauma. Patients with cirrhosis have altered gut flora, which would promote translocation. The inability of anaerobes to translocate is also of interest [66].

The gut mucosa is abnormally permeable in the setting of cirrhosis, leading to increased translocation of bacteria from the gut to the mesenteric lymph nodes and on to the peripheral blood (see Fig. 17.1). Bacteremia is common in patients with severe liver disease; more than 50% of patients with SBP have bacteremia documented at the time of diagnosis of peritoneal infection [32]. The flora of spontaneous bacteremia is similar to that of SBP and MNB and is also monomicrobial [32].

Complement is synthesized in the liver, and patients with severe enough liver disease to develop ascites usually have serum complement deficiency [67]. Neutrophil dysfunction and reticuloendothelial system dysfunction are also common in cirrhosis [68]. These defects in host defense against infection would be expected to lead to frequent and prolonged bacteremia.

Rats with cirrhosis and ascites have been shown to uniformly develop bacteremia after intratracheal exposure to pneumococci. These rats also have more prolonged bacteremia and more fatalities compared with rats without ascites and compared with normal rats [69].

Another animal model of cirrhosis and ascites has shown that the flora of the gut is altered as cirrhosis develops and that translocation of the overgrowing organism to mesenteric lymph nodes is common [70–72].

In summary, there is significant evidence favoring the gut as the source of most of the bacteria that cause spontaneous ascitic fluid infection. Translocation of bacteria from the gut to the mesenteric lymphatics of normal rodents is common under certain circumstances [66]. Translocation is more common in the setting of cirrhosis [71,72]. Seeding of ascitic fluid with gut-derived bacteria

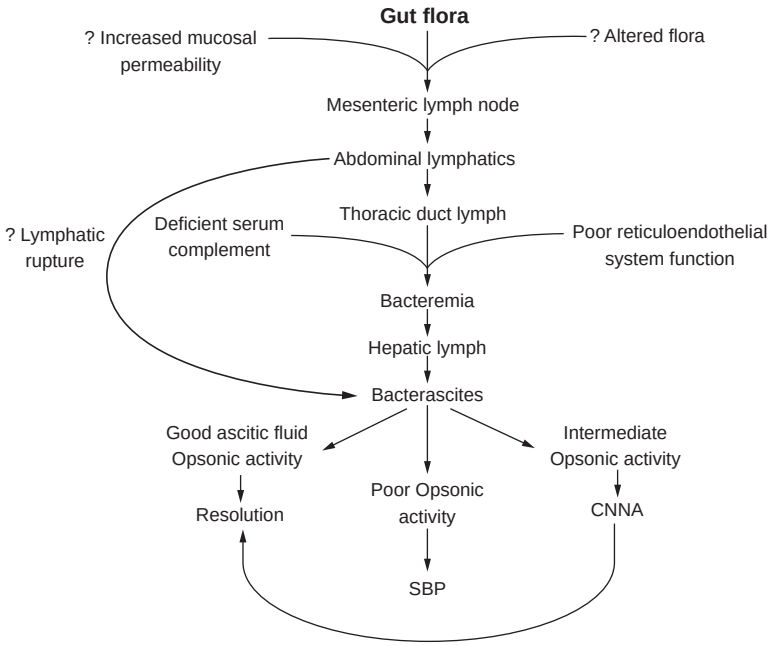

Figure 17.1 Pathogenesis of spontaneous ascitic fluid infection. CNNA, culture-negative neutrocytic ascites; SBP, spontaneous bacterial peritonitis.

could then be the result of at least two possible bacterial routes (see Fig. 17.1). Mesenteric lymphatic bacteria could (i) pass through lymph nodes, on to the thoracic duct, enter the bloodstream, and then leak across the sinusoids of the liver as ascites forms from the blood; or (ii) directly leak into ascitic fluid due to intra-abdominal lymphatic rupture.

Once bacteria enter the fluid in the abdomen, by whatever route, a battle ensues between the organism's virulence factors and the host's immune defenses. Several studies shed some light on the events that take place in this battle [37,38,58,71–73]. The protein concentration does not change with development of spontaneous infection [37]. Low protein concentration ascitic fluid, e.g., <1 g/dL, has been shown to be particularly prone to SBP [38]. The opsonic activity (endogenous antimicrobial activity) of human ascitic fluid correlates directly with the fluid's protein concentration [67]. Patients with deficient ascitic fluid opsonic activity have been shown to be predisposed to SBP [73]. Patients with detectable ascitic fluid opsonic activity are protected from SBP unless a particularly virulent organism, e.g., *Salmonella*, is involved [64,73].

Studies in both humans with cirrhosis and rats with experimental cirrhosis demonstrate that MNB is common [58,74]. In both humans and rats, most episodes (up to 62%) of bacterascites resolve without antibiotic treatment [58,74]. The fluid frequently becomes sterile without an evident PMN response. Apparently the host defense mechanisms are able to eradicate the invading bacteria on most occasions. Perhaps it is only when the defenses are particularly weak or the organism is particularly virulent that uncontrolled fatal infection develops. Those patients with clinically apparent ascitic fluid infection may represent only the "tip of the iceberg." Bacterascites is probably much more common than SBP. Only frequent surveillance paracenteses would settle this question. Perhaps patients with ascites regularly have their ascitic fluid colonized by bacteria, and almost just as regularly these patients resolve the colonization. The entry of PMNs into the fluid likely signals failure of opsonins in combination with peritoneal macrophages to control the infection. As a rule MNB resolves spontaneously in rats and humans, whereas SBP is frequently fatal [58,70,74]. In summary, MNB probably represents an early stage of ascitic fluid infection that can resolve to sterile non-neutrocytic ascites or progress to SBP.

Most episodes of CNNA are diagnosed using insensitive culture methods where there are insufficient numbers of bacteria to reach the threshold of detectability [34,35]. Blood culture bottles can detect a single organism in the cultured aliquot of fluid, whereas the conventional method of culture probably requires at least 100 organisms/mL [35]. However, even when optimal culture methods are used, a small percentage of patients grow no bacteria in their neutrocytic ascitic fluid [60]. A study of rapid sequential paracenteses (before initiation of antibiotic treatment) in patients with CNNA demonstrated that in most cases the PMN count dropped spontaneously and the culture remained negative [74]. In the setting of sensitive culture technique, CNNA probably represents spontaneously resolving SBP in which the tap is performed after all bacteria have been killed by the host defenses but before the PMN count has normalized.

The pathogenesis of secondary bacterial peritonitis is no mystery compared to the pathogenesis of SBP. When the gut perforates into the ascitic fluid, billions of bacteria flood in. When there is secondary peritonitis without a frank perforation (e.g., a perinephric abscess or empyema of the gallbladder) bacteria cross inflamed tissue planes and enter ascites.

The pathogenesis of polymicrobial bacterascites is also apparent [61]. The paracentesis needle enters the bowel and the bowel contents are released. Fortunately, this event is rare. Even when needle puncture occurs, it usually resolves without antibiotic therapy, especially in high protein ascites [61].

Signs and symptoms

Although most patients with SBP are symptomatic at the time of diagnosis of infection, the symptoms or signs of infection may be very subtle or misinterpreted (Table 17.2) [32,58]. Minor changes in mental status that would only be detected by family members or a physician who is very familiar with the patient, may be the sole clinical evidence of infection. Unless such changes prompt paracentesis, the diagnosis and treatment of the ascitic fluid infection may be delayed.

Delays in the initiation of therapy regularly result in a fatal outcome. Survival decreases by 8% per hour of delay in the initiation of antibiotic treatment in one recent study of sepsis [75]. The signs and symptoms manifested in all five variants of ascitic fluid infection are listed in Table 17.2.

Prevalence

Prior to the 1980s abdominal paracentesis was not performed regularly because of the fear of complications of the procedure and because the utility of ascitic fluid analysis in the differential diagnosis of ascites was not fully recognized. Now that the complication rate is known to be usually <1% and the details of ascitic fluid analysis have been better defined, routine paracentesis is performed at the time of admission of many ascites patients [4,18,19,21,33,37,39]. Of patients with culture-positive ascitic fluid, about two thirds will have neutrocytic ascitic fluid, i.e., SBP, and one third will have monomicrobial bacterascites [58,74]. The prevalence of CNNA found amongst a series of neutrocytic ascitic fluid is largely dependent on culture technique [33,34]. Polymicrobial bacterascites is present in only about one per 1,000 patients [61]. Secondary bacterial peritonitis occurs in only 0–2% of ascites patients at the time of admission to hospital [21]. About 5% of patients that initially appear to have SBP will be shown to have secondary peritonitis; too often this diagnosis is made at autopsy [39,40].

Flora

Eshcerichia coli, streptococci (mostly pneumococci), and *Klebsiella* cause most episodes of SBP and MNB (Table 17.3). CNNA is by definition culture-negative. Polymicrobial bacterascites is by definition polymicrobial. The most apparent difference between the spontaneous forms of ascitic fluid infection and the non-spontaneous forms is that the former are nearly always monomicrobial and the latter are usually polymicrobial. Although older papers report ~6% of SBP cases to be caused by anaerobes, this is probably a reflection of the presence of unrecognized secondary bacterial peritonitis cases in series of purported SBP cases [21]. The high prevalence of polymicrobial infection among episodes of

Table 17.2 Signs and symptoms of ascitic fluid infection.[a]

Signs/symptoms	SBP	MNB	CNNA	2BP	Poly
Fever	68	57	50	33	10

Adapted from references [39,58,60,61].

anaerobic "SBP" further supports the contention that these represent misdiagnosed secondary peritonitis. Anaerobes cause ~1% of SBP [33,34,58]. The infrequency of anaerobic SBP is probably due to the relatively high PO_2 of ascites and the inability of anaerobes to translocate across the gut mucosa [66,72]. Fungi do not cause SBP. Fungal infection of ascitic fluid occurs only in the setting of disseminated systemic mycosis in the immunosuppressed patient or in secondary peritonitis with gut release of fungi into ascitic fluid [39,40].

Gram-negative organisms do not colonize the skin, and must be interpreted as pathogens, whereas Gram-positive organisms are routine skin flora and must be considered to be contaminants in the absence of a PMN response. *Staphylococcus epidermidis* cannot be interpreted as a pathogen in ascitic fluid unless there is a foreign body (e.g., peritoneovenous shunt) present. α-Hemolytic streptococcus should also be considered a skin contaminant unless there is a PMN response or bacteremia with the same organism. Failure to use a sterile technique when performing a paracentesis or failure to sterilize the blood culture bottle tops with iodine before inoculation will increase the presence of contaminants in the cultures.

Risk factors

Patients with cirrhosis are unusually prone to bacterial infections because of multiple defects in their immune defense (see section on pathogenesis above). Two prospective studies have shown that up to 47% of patients with cirrhosis had a bacterial infection (ranging from asymptomatic urinary tract infections to fatal sepsis) during one hospitalization and 34% developed a bacterial infection during 1 year of follow-up [76,77]. Thirty-five percent of 87 women with primary biliary cirrhosis developed bacteriuria (70% *E. coli*, 7% *Klebsiella*, 6% streptococcal) during a 12-month period [78].

Some physicians have been taught that paracentesis itself poses a significant risk of causing ascitic fluid infection. This theoretical risk has not been substantiated in prospective studies of paracentesis complications [18,19]. In one study, SBP was statistically more likely to be diagnosed at the time of the first paracentesis compared to subsequent taps [18]. The most likely setting in which to expect iatrogenic peritonitis is when the paracentesis needle enters the bowel inadvertantly during attempted paracentesis [61]. Fortunately, this is very unusual. Skin flora, e.g. *Staphylococcus aureus*, would be expected to be isolated if poor paracentesis technique were the cause of many cases of SBP, yet skin flora are seldom isolated [33].

Gastrointestinal hemorrhage is temporally associated with the development of spontaneous bacteremia and SBP; prevention of infection with the use of antibiotics improves survival [79] (see below).

Diagnosis

An accurate and timely diagnosis of ascitic fluid infection requires a low threshold for performing a paracentesis and a high index of suspicion of infection. Clinical deterioration in a patient with ascites should always raise suspicion, especially if there is fever or abdominal pain. If the ascitic fluid PMN is elevated, the working diagnosis is ascitic fluid infection until proven otherwise.

Although peritoneal carcinomatosis, pancreatitis, hemorrhage into ascites, pancreatitis, and tuberculosis can lead to an elevated ascitic fluid PMN count, most cases of neutrocytic ascitic fluid are due to infection. A majority of PMNs in the white cell differential further lends credence to the diagnosis of infection. An elevated absolute ascitic fluid PMN count with a predominance of neutrophils in a clinical setting compatible with infection (e.g., a febrile patient with cirrhosis) should prompt empirical antibiotic therapy (see below).

Once the presumptive diagnosis of ascitic fluid infection is made, the next consideration should be whether there is a surgically treatable source of infection. Secondary peritonitis should be *considered* in any patient with neutrocytic ascites. However, because of the rarity of SBP in peritoneal carcinomatosis or cardiac ascites, a surgical source of peritonitis should be *presumed* in these conditions until proven otherwise. Surprisingly, even with free perforation of the colon into ascitic fluid, patients do not develop a classic surgical abdomen [39]. Peritoneal signs, such as rigid abdomen, require the contact of inflamed visceral and parietal peritoneal surfaces. This does not happen when there is a large volume of fluid present. Therefore, clinical signs and symptoms do not separate patients with secondary peritonitis from those with SBP [39,40]. Gut perforation can be suspected and pursued if neutrocytic ascitic fluid analysis meets two of the following three criteria: total protein >1 g/dL, glucose <50 mg/dL, or LDH >225 mU/mL (or more than the upper limit of normal for serum) [39,40]. Essentially all ascitic fluids culture multiple organisms in the setting of a perforated viscus [39,40]. If multiple organisms and PMNs are seen on Gram stain, the likehood of perforation is very high. Brown ascitic fluid with a bilirubin concentration >6 mg/dL (and greater than the serum level) is indicative of biliary or upper gut perforation into ascites [9].

The initial ascitic fluid analysis is very helpful in delineating which patients are likely to have a ruptured viscus. These patients need an emergent (within minutes) radiologic evaluation (usually computed tomography scan) to confirm and localize the site of rupture [39,40]. If perforation is documented, emergency intervention is mandatory to maximize survival; survivors have been reported. Antibiotic therapy without surgical intervention in the treatment of a ruptured viscus is predictably unsuccessful.

Patients with *nonperforation* secondary peritonitis tend *not* to have a diagnostic *initial* ascitic fluid analysis [39,40]. Fortunately, it is less urgent to make the diagnosis of secondary peritonitis in nonperforation peritonitis compared with perforation peritonitis. Therefore, there may be time to evaluate the response of the ascitic fluid culture and PMN count to treatment. These parameters have been shown to be helpful in distinguishing secondary from spontaneous peritonitis [39]. The best time to perform a single repeat paracentesis to assess response is after 48 hours of treatment; by 48 hours essentially every SBP patient who has been treated with an appropriate antibiotic will have a PMN count lower than the pretreatment value and the culture will be negative [39]. Prior to 48 hours of treatment, i.e., at 12 or 24 hours, the PMN count may higher than baseline even in SBP. Also, the culture remains positive in secondary peritonitis and becomes rapidly negative in SBP [39,40].

Treatment

Patients with ascitic fluid PMN counts $\geq$250 cells/mm^3 in a clinical setting compatible with ascitic fluid infection should receive empirical antibiotics [32]. Patients with hemorrhage into ascites, peritoneal carcinomatosis, pancreatic ascites, or tuberculous peritonitis may have an elevated PMN count that is not related to SBP. These patients usually do not require empirical treatment. However, if the situation is initially unclear, the physician should err on the side of overtreatment so long as non-nephrotoxic antibiotics are used. Usually patients with uninfected neutrocytic ascitic fluid (except those with hemorrhage) have a predominance of lymphocytes in their ascitic fluid differential. This helps distinguish them from patients with SBP, in which PMNs predominate. Patients with bloody ascites should have a "corrected" PMN count calculated (see "Cell count" above). Patients with bloody ascites do not need antibiotics unless their corrected PMN count is $\geq$250 cells/mm^3.

Patients with MNB are "special cases" regarding empirical antibiotic treatment. Many episodes resolve without treatment [58]. However, because of the hospitalization mortality associated with monomicrobial bacterascites, treatment appears to be warranted in many patients [58]. By definition, the PMN count is $<$250 cells/mm^3 in this variant of ascitic fluid infection. Because of this variant, the PMN count cannot be the only parameter upon which to hinge the decision about empirical therapy. Most of the patients with MNB who do not resolve the colonization and progress to SBP have signs or symptoms of infection [58]. Therefore, patients with cirrhosis, ascites, and *convincing signs or symptoms of infection* should receive treatment regardless of the PMN count in ascitic fluid. Empirical treatment can be discontinued after only 2–3 days if the culture remains negative and suspicion of infection has diminished.

Patients with *asymptomatic* monomicrobial bacterascites should undergo a repeat paracentesis for cell count and culture, once it is known that the initial culture is growing bacteria. If the PMN count has risen above 250 cells/mm^3 in the follow-up ascitic fluid analysis, treatment should be started. Patients who have developed no PMN response or clinical evidence of infection do not require treatment [58]. These are the patients who have probably eradicated the colonization by their own immune defenses.

When initially faced with a patient who has CNNA, the physician does not know that the culture is destined to be "no growth." Therefore empirical treatment should be given. When the preliminary report demonstrates no growth, it is helpful to repeat the paracentesis to assess the response of the PMN count to therapy. A decline in PMN count confirms a response to treatment and probably warrants a few more days of therapy. A stable PMN count, especially if there is not a predominance of PMNs, indicates that a nonbacterial (or mycobacterial) cause of the neutrocytosis is present. Cytology and culture for TB may be appropriate. Because improper culture techniques result in negative cultures, one of the most important methods to reduce the prevalence of CNNA in a hospital that is still using the conventional method of culture is to convince the microbiology laboratory to convert to the optimal method of culture [33].

The ascitic fluid Gram stain is not very helpful in the choice of empirical antibiotic. This investigator has not found that the Gram stain allowed a narrowed spectrum of antibiotic coverage in even one patient out of ~300 with SBP. Only ~10% of Gram stains demonstrate organisms in early detected SBP [33]. The actual utility of the Gram stain is in assisting with the differential diagnosis of spontaneous versus nonspontaneous ascitic fluid infection [39,40]. Sheets of multiple different types of bacteria are found in gut perforation – this requires coverage of anaerobic flora in addition to aerobic and facultative anaerobic flora, as well as an emergency search for a source for the bacteria [39,40]. Therefore, a positive Gram stain may lead to broader spectrum coverage rather than narrower coverage. Choosing very narrow spectrum coverage, e.g., penicillin, based on a misinterpreted Gram stain may lead to the patient's death from uncontrolled infection before it is known that the isolated organism is resistant to the antibiotic that is in use. Patients with suspected ascitic fluid infection require relatively broad spectrum therapy until the results of susceptibility testing are available.

Cefotaxime, the first third-generation cephalosporin, is the most data-supported drug for the treatment of SBP [32,80–82]. This drug covers ~95% of flora and is usually the treatment of choice for suspected SBP. In contrast, ceftriaxone is highly protein bound and penetrates low

protein ascites poorly. If it is used due to formulary issues, the minimum dose is 2 g daily. Ceftriaxone has a role in the prevention of bacterial infections in patients with cirrhosis and gut hemorrhage (see below).

Most drugs have not been tested for their ability to penetrate ascites. One cannot assume that just because a drug covers the flora that cause SBP, that it will treat this infection well. If it does not reach the ascites in a high concentration, it may not be efficacious.

For cefotaxime, 2 g intravenous doses are appropriate, and the dosing interval is 8–12 hours; 8 hours for a serum creatinine less than ~3 mg/dL and 12 hours for more severe renal failure [81]. The dosing interval does not *have* to be altered in renal failure because of the lack of toxicity of the drug. Ascitic fluid levels can exceed 300 μg/mL in the setting of renal failure and dosing every 8 hours [81]. Dosing more frequently than every 8 hours is not necessary because high ascitic fluid concentrations (>20-fold the minimal inhibitory concentrations of >90% of the flora) of the drug are attained after one dose and are sustained during every-8-hour dosing [81].

When susceptibility testing results are available, a more narrow spectrum drug can usually be substituted, e.g., pneumococci will usually be sensitive to penicillin and most *E. coli* species will usually be sensitive to ampicillin.

Many infectious disease experts treat life-threatening infections with 10–14 days of therapy. However, there are no data to support this duration of treatment of spontaneous ascitic fluid infection. The ascitic fluid cultures of culture-positive patients become sterile after one dose of cefotaxime in 86% of patients [39]. The ascitic fluid PMN count, in general, drops exponentially after treatment is started such that the PMN count after 48 hours of therapy is always less than the pretreatment value in patients with spontaneous ascitic fluid infection treated with appropriate antibiotics [39]. A randomized controlled trial involving 100 patients has demonstrated that 5 days of treatment is as efficacious as 10 days in the treatment of SBP and CNNA [82].

Bacterial infection further increases vasodilatation and can lead to impaired renal function and even death [83]. Intravenous albumin has been shown in a randomized trial to help prevent azotemia and to improve survival, presumably by "refilling the underfilled tank" related to this vasodilatation [83]. A dose of 1.5 g/kg body weight should be given within 6 hours of diagnosis of an elevated PMN count with a 1 g/kg dose at 72 hours [83]. This trial reports the lowest SBP hospitalization mortality ever: 10% [83].

Patients suspected of having secondary peritonitis require broader spectrum empirical antibiotic coverage than those with SBP, in addition to an emergency evaluation to assess the need for surgical intervention [39,40]. Cefotaxime plus metronidazole provide excellent initial empirical therapy of suspected secondary peritonitis while the radiologic workup is underway [39,40].

Surprisingly, needle perforation of the bowel (polymicrobial bacterascites) is relatively well tolerated. Only 10% (1/10) of patients with needle perforation of the gut into ascitic fluid developed peritonitis, and only 0.06% (1/1578) of paracenteses were documented to cause peritonitis in one large study [61]. The paracentesis-related peritonitis was not fatal. It appears that patients with low protein ascitic fluid are at most risk of developing a PMN response and clinical peritonitis related to needle perforation of the gut [61]. Most of the patients with high protein ascites (e.g., > 1g/dL) did not even receive antibiotics and yet did well. However, most physicians would probably feel uncomfortable withholding antibiotic treatment if needle perforation is suspected. If a decision to treat is made, anaerobic coverage should be included, e.g., cefotaxime and metronidazole. If a decision not to treat is made, follow-up paracentesis is helpful in following the PMN count and culture. If the number of organisms does not decrease and/or a PMN response occurs, antibiotic treatment should be initiated.

Prognosis

In the past, in spite of treatment, 48–95% of patients with spontaneous ascitic fluid infection died during the hospitalization in which the diagnosis was made [21,59]. The most recent series report the lowest mortality rates [82,83], some even as low as 10% hospitalization mortality [83]. This is a reflection of the earlier detection of infection as well as the avoidance of nephrotoxic antibiotics. In the older series about half of SBP patients died of the infection despite antibiotic treatment; now <5% of patients die of infection if timely and appropriate antibiotics are used [82,83]. However, because of the severity of the underlying liver disease, even now many patients are cured of their infection and yet die of liver and/or renal failure gastrointestinal bleeding, etc. Because spontaneous ascitic fluid infection is a marker of end-stage liver disease, it has been proposed as an indication for liver transplantation in a patient who is otherwise a candidate [21,32].

In the past a delay in diagnosis was, at least in part, responsible for the excessive mortality. If the physician waited until the patient developed convincing signs and symptoms of infection before performing a paracentesis, the infection was likely to be very advanced by the time the diagnosis is made. There have been no reported survivors of SBP in the absence of liver transplant when the diagnosis was made after the creatinine had risen above 4 mg/dL. In order to maximize survival, it is important to perform paracentesis on hospital admission so that infection can be diagnosed and treated early. In addition, paracentesis should be repeated during hospitalization if any deterioration occurs – including pain, fever, mental status

change, renal failure, acidosis, peripheral leukocytosis, or gastrointestinal bleeding.

Early diagnosis and surgical intervention reduce the hospitalization mortality of secondary peritonitis into the same range as that of SBP [39,40]. Without surgical intervention, mortality approaches 100%.

Prevention

All series of patients with SBP report recurrences. The older series did not report a high rate, in part, because few patients survived the first episode. A prospective study reported in 1988 documented a 69% recurrence rate at 1 year [84]. An ascitic fluid protein concentration of <1.0 g/dL was the best predictor of recurrence. This impressive recurrence rate prompted studies of antibiotic prophylaxis. Norfloxacin 400 mg/day orally has been reported to successfully prevent recurrences of SBP with essentially no toxicity or superinfection (Table 17.4) [85]. In the United States norfloxacin is no longer being manufactured. If a generic company does not produce it, trimethoprim-sulfamethoxazole can be substituted at a dose of one double-strength tablet daily [32].

Antibiotic prevention of SBP (and other bacterial infections) in the setting of low protein ascites and gut hemorrhage has also been reported [86,87]. Norfloxacin is effective in the former situation and ceftriaxone intravenously in the latter [86,87]. There has been confusion regarding which patients with gut hemorrhage qualify. Any patient with cirrhosis (with or without ascites) who has a hemodynamically significant amount of bleeding (variceal or nonvariceal) warrants ceftriaxone [32,87]. It is ischemia/reperfusion of the gut and translocation of bacteria that lead to the high risk of bacterial infections. This investigator provides the intravenous drug during active bleeding and converts to norfloxacin or trimethoprim-sulfamethoxazole twice daily once the patient begins to eat again – to complete a 7-day total course of antibiotics.

Primary prevention of SBP has been documented when norfloxacin is given to patients who meet a complicated number of inclusion criteria (Table 17.4) [88].

It is optimal to give these antibiotics only to patients who meet study inclusion criteria. Giving antibiotics more liberally can lead to selection of resistant flora and subsequent infection by these organisms, as well as fungal superinfection.

Table 17.4 Prevention of spontaneous bacterial peritonitis.[a]

High-risk group	Drug	Duration
Prior SBP	Norfloxacin 400 mg daily or one trim-sulfa DS daily	Indefinitely
Ascitic fluid total protein <1.5 g/dL	Norfloxacin 400 mg daily	Duration of hospitalization
Gut hemorrhage	Ceftriaxone 1 g intravenously	7 days
Primary prophylaxis	Norfloxacin 400 mg daily	12 months

[a] Candidates for primary prophylaxis must meet the following criteria:
1) Cirrhosis with ascitic fluid total protein <1.5 g/dL.
2) Advanced liver failure with Child–Pugh score ≥9 and bilirubin ≥3 mg/dL, or impaired renal function with creatinine ≥1.2 mg/dL, or blood urea nitrogen ≥25 mg/dL, or serum sodium ≤130 mEq/L.
Trim-sulfa DS, trimethaprim-sulfamethoxazole double strength.
Adapted from references [85–88].

Tense ascites

Some patients with ascites do not seek medical attention until their intra-abdominal fluid exerts such pressure on their diaphragms that they can no longer breathe comfortably. The volume of fluid required before "tenseness" occurs is usually ~10 L. However, young patients with good muscle tone may develop a tense abdomen with only a few liters of fluid. Rapid accumulation of fluid (e.g., postoperatively in a patient with no prior fluid retention) does not give the abdominal wall time to stretch; these patients can also have small volume tense ascites.

Tense ascites requires urgent treatment – therapeutic paracentesis. Tense ascites can be drained without untoward hemodynamic effects [89]. "Total paracentesis" (i.e., removal of all mobilizable fluid) has recently been demonstrated to be safe [89]. Therapeutic paracentesis of ascites due to cirrhosis is less problematic than the textbooks and folklore of medicine would indicate. Many physicians were taught that large volume paracentesis leads to hemodynamic disasters. However, this concept was based on anecdotal observations in small numbers of patients and has been disproven by carefully conducted controlled trials [89].

Abdominal wall hernias

Abdominal wall hernias (usually umbilical or incisional, occasionally inguinal) are common in patients with ascites. Unfortunately, there is little published information available about these hernias. In one study, 17% of patients with cirrhosis and ascites were found to have umbilical hernias at the time of admission to the hospital [90]. The hernia recurs in 73% of patients who have ascites at the time of hernia repair but only in 14% of patients who have no ascites at the time of repair [91]. In general, patients with cirrhosis and ascites should avoid surgery and wear an abdominal binder. Hernias can be repaired electively during liver transplantation. If skin ulceration, crusting, or black discoloration develop surgery should be performed semiemergently. Emergent surgery should be performed for rupture or incarceration that is unresponsive to medical therapy [90]. Rupture, i.e., Flood syndrome (an eponym as well as a descriptive label), is the

most feared complication of abdominal hernias. If surgical repair of Flood syndrome is delayed, fatal *Staphylococcus aureus* peritonitis usually develops.

Pleural effusions

Pleural effusions are common in patients with cirrhosis and ascites. They are usually unilateral and right-sided, but occasionally may be bilateral with the amount of fluid in the right being greater than that on the left. When there is a unilateral left-sided effusion, tuberculosis and pancreatitis should be high in the differential diagnosis.

When the effusion is large and obscures most of the right lung, it is referred to as hepatic hydrothorax [92]. Most carefully studied examples of hepatic hydrothorax have been shown to be due to a small defect in the right hemidiaphragm. Occasionally, a hydrothorax results in sudden shortness of breath as the abdomen decompresses. Occasionally, ascites is undetected in the face of a hepatic hydrothorax.

The predominant symptom associated with hepatic hydrothorax is shortness of breath. Infection of this fluid occurs, usually a result of SBP and transmission of bacteria across the diaphragm. Usually the fluid resembles ascites, but the total protein is higher (by 0.75–1.0 g/dL) in the pleural fluid than in ascites because the pleural fluid is subject to different pressures than those of the portal bed [92].

Treatment of hepatic hydrothorax is usually more difficult than anticipated [92]. These large right-sided effusions tend to occur in patients who are the least compliant or most refractory. Some authors have recommended tetracycline sclerosis using a chest tube. However, chest tube insertion with suction has been reported to lead to serious fluid and protein depletion and death [93]. Once a chest tube is inserted, usually it becomes very difficult to remove. Clamping the tube may lead to a leak of fluid around the tube's insertion site. Direct surgical repair of the defect can be considered, but typically these patients are very poor operative candidates. Medical therapy, i.e., sodium restriction and diuretics, is probably the safest and most effective form of therapy of hepatic hydrothorax. Transjugular intrahepatic portosystemic shunting (TIPS) or even liver transplantation can be performed when the fluid is unresponsive to medical therapy [92].

Treatment of ascites

Ascites is not always due to liver disease (see Table 17.1). Not all patients with ascites respond to routine salt restriction and diuretics. Therefore, an accurate diagnosis of the cause of ascites formation is important so that treatment can be tailored appropriately. The serum–ascites albumin gradient is helpful in therapeutic decision making. Patients with low SAAG ascites (except for those with nephrotic syndrome) usually do not respond to salt restriction and diuretics, whereas patients with a high SAAG usually are responsive.

Nonportal hypertension-related (low albumin gradient) ascites

The most common form of low albumin gradient ascites is peritoneal carcinomatosis [5]. Peripheral edema in these patients responds to diuretics, but the ascitic fluid usually does not; edema-free patients treated with diuretics lose only intravascular volume without loss of ascites. The cornerstone of treatment of peritoneal carcinomatosis is therapeutic paracentesis [5]. Patients with peritoneal carcinomatosis usually live only a matter of weeks, therefore the total number of taps required to minimize symptoms is not great. Patients with ovarian malignancy are an exception to this rule. They may have a good response to surgical debulking and chemotherapy.

Tuberculous peritonitis is cured by antituberculous therapy; there is no point in using diuretics unless the patient has concomitant portal hypertension from cirrhosis. Pancreatic ascites may resolve spontaneously or may require endoscopic stenting or operative intervention. *Chlamydia* peritonitis is cured by doxycycline therapy [8]. "Nephrogenous" ascites (dialysis ascites) may respond to vigorous dialysis [7].

Portal hypertension-related (high albumin gradient) ascites

The most common cause of portal hypertension-related ascites is cirrhosis, usually caused by chronic hepatitis C and/or alcohol abuse and/or obesity/nonalcoholic steatohepatitis (NASH). One of the most important steps in treating this form of ascites is to treat the underlying liver disease by convincing the patient to stop drinking alcohol. With time and healing of the reversible component of alcoholic liver disease, the ascites may resolve or at least convert from refractory to medical therapy to being nonrefractory to medical therapy. Patients with multiple causes for their cirrhosis can improve dramatically with abstinence from alcohol. Baclofen has been shown in a randomized trial to reduce alcohol craving and reduce alcohol consumption in patients with alcoholic liver disease; this drug works well in this regard in this author's experience [94]. Noninterferon-based antiviral treatment of decompensated cirrhosis due to hepatitis B can also lead to better control or loss of ascites.

Patients with autoimmune chronic active hepatitis, iron-storage disease, or Wilson disease should receive specific therapy for those diseases. This may improve their overall liver function and the management of their ascites. However, these diseases seem to be less reversible

than alcoholic liver disease or chronic hepatitis B, and by the time ascites is present the patient may be a better candidate for liver transplantation than protracted medical therapy.

Patients who have ascites due to cirrhosis, based on history, physical examination, and ascitic fluid analysis, may require hospitalization for the diagnosis and management of their liver disease as well as their fluid overload, especially if the fluid retention is "new onset." Frequently, ascites formation is only part of the overall picture of decompensation of liver disease. Although outpatient treatment of ascites patients can be successful, frequently it fails and an intensive period of inpatient education and treatment is required. Once the patient realizes that the diet and diuretics are effective, he or she is frequently more compliant with the regimen.

Precipitating cause

In the initial management of the patient with ascites, it is usually of value to determine the precipitating cause of ascites formation. Frequently, ascites accumulates because of noncompliance either with the dietary sodium or diuretics, or ascites may accumulate because of the fluid resuscitation given in the treatment of variceal hemorrhage. Education regarding compliance may help prevent future hospitalizations for ascites. Ascites that is initiated by variceal hemorrhage may resolve after the bleeding is controlled without need for long-term diuretics.

Diet

In portal hypertension-related ascites, fluid loss and weight change are directly and predictably related to sodium balance. Dietary sodium restriction is essential, so the patient and the patient's cook (who is frequently not the patient) should be educated by a dietician in a salt-restricted diet. The more contact the dietician has with the patient and the cook, the better. A severe sodium-restricted diet, e.g., 500 mg or 22 mEq sodium per day, is feasible in an inpatient setting. However, this is an unrealistic diet for most outpatients as they will not follow a diet that contains less than 2 g/day (88 mEq/day) sodium. Such a diet is thus the preferred one [32] and the patient should be able to follow it at home. Using this diet in the hospital offers the opportunity to tailor a diuretic regimen that will match the salt intake in and out of the hospital.

Fluid restriction

Fluid restriction of all patients with ascites is inappropriate. There is no evidence that fluid restriction speeds weight loss. It is the sodium restriction that is important. Although rapidly developing hyponatremia (e.g., postoperative hyponatremia in a previously healthy patient) is associated with a high mortality, the chronic hyponatremia usually seen in cirrhotic ascites patients is far less morbid. Attempts to rapidly correct it can be much worse that the hyponatremia itself. The only indication for fluid restriction in the cirrhotic ascites patient is severe hyponatremia. This investigator does not restrict fluids in ascites patients unless their serum sodium drops below 120 mEq/L [32]. Patients with cirrhosis do not usually have symptoms from hyponatremia until the sodium is below 110 mEq/L or unless the decline in sodium is very rapid. To restrict fluids in patients with a serum sodium of >120 mEq/L serves only to alienate patients, nurses, and dieticians.

Urinary sodium concentration

Twenty-four hour urinary sodium measurements are useful in patients with portal hypertension-related ascites. Although a 24-hour collection is optimal, a random "spot" urinary sodium : potassium (Na : K) ratio is a satisfactory substitute in many cases. If the urine sodium is greater than the potassium in a random sample, the 24-hour urinary sodium excretion is usually enough to lead to weight loss [32].

If body weight is not declining satisfactorily, this may be due to inadequate natriuresis or failure to properly restrict sodium intake or both. Monitoring the random urine Na : K ratio and daily weight will usually clarify the problem. Since urinary excretion is the most important route of excretion of sodium in the absence of diarrhea or hyperthermia, dietary intake and urinary excretion should be equivalent (except for ~10 mEq/day of nonurinary losses) if the weight is stable. If 88 mEq are taken in with the diet and 10 mEq are lost by nonurinary routes, weight should be stable if urinary sodium excretion is >78 mEq/day. A random urine Na > K correlates with a 24-hour excretion of >78 mEq of sodium [32]. If the weight is increasing despite urine Na > K, one can assume that the patient is eating more than his/her allotted salt.

Diuretics

Spironolactone is the mainstay diuretic for treatment of patients with cirrhosis and ascites. The half-life of spironolactone in normal control patients is approximately 24 hours but is markedly prolonged in cirrhosis [32]. There is no reason to dose the drug multiple times per day in view of its long half-life. Single daily doses of pills are most appropriate and enhance compliance; 100 mg spironolactone pills are available. In general, spironolactone *and* furosemide are used together, starting with 100 mg/day spironolactone and 40 mg/day furosemide, then increasing both drugs simultaneously as needed. If weight loss is inadequate and urine Na is <K, diuretics are increased, usually in increments of

100 mg and 40 mg respectively, up to maximum doses of 400 mg/day spironolactone and 160 mg/day furosemide. The ratio of spironolactone and furosemide can be adjusted to correct serum potassium problems. Combined with a sodium-restricted diet, the spironoactone/furosemide regimen is effective in >90% of patients [32].

Intravenous furosemide causes an acute reduction in glomerular filtration rate in these patients and should be avoided. If rapid weight loss is desired, therapeutic paracenteses should be performed (see refractory ascites below). For patients who have massive edema, there is no limit to the daily weight loss; once the edema has resolved, 0.5 kg/24 hours is probably a reasonable maximum [32]. If patients develop encephalopathy, serum sodium is <120 mEq/L despite fluid restriction, or serum creatinine is >1.5 mg/dL, diuretics are usually stopped and then carefully reinstituted after the reason for discontinuation improves. The ratio of the doses of the diuretics is adjusted to maintain a normal serum potassium. Serious hyperkalemia despite adjustment of diuretics usually indicates intrinsic renal disease, e.g., diabetic nephropathy. Many of the patients who develop complications of diuretic treatment will be considered failures of first-line treatment and require second-line therapy.

Prostaglandin inhibitors, e.g., nonsteroidal anti-inflammatory drugs, should not be used in patients with ascites because they curtail diuresis, may promote renal failure, and cause gastrointestinal bleeding.

Complete removal of ascites may not always be achieved. However, a diuresis-mediated concentration of ascitic fluid increases the fluid's opsonic activity tenfold, and, theoretically, may be of value in attempting to prevent spontaneous ascitic fluid infection [32]. The maximum concentration of opsonins occurs at the end of diuresis. It is reasonable to attempt to achieve a dry abdomen in order to minimize the risk of infection and to decrease the risk of abdominal wall hernias and hepatic hydrothorax. However, the risks must be weighed against the benefits. Patients who become somewhat dehydrated may develop hepatic encephalopathy, dizziness, lightheadedness, and may even fall. Dame Sheila Sherlock used to say "wet and wise or dry and demented" to describe the patient with fluid overload versus the patient with diuretic-induced dehydration.

Refractory ascites

A patient with refractory ascites is defined as fluid overload unresponsive to inpatient salt restriction and diuretic treatment. The failure may be manifested by minimal to no weight loss despite high-dose diuretics or the development of complications of diuretics. Randomized trials have shown that <10% of patients with cirrhosis and ascites are refractory to standard medical therapy [95].

Second-line therapy options include therapeutic paracenteses, TIPS, and liver transplantation. Peritoneovenous shunts are third-line options and are reserved for very special circumstances (see below).

Abdominal paracentesis is one of the oldest medical procedures. From the time of Celsus, who is credited with first describing the technique in ~20 BC, until the late 1940s, therapeutic paracentesis was essentially the only available therapy for ascites. This laborious procedure rapidly fell out of favor as a treatment option for patients with ascites. In the 1980s there was renewed interest in therapeutic paracentesis after randomized trials proved its safety [96]. However, no differences in morbidity or mortality could be demonstrated in this study [96]. Physically removing the fluid is predictably faster than diuretic treatment in achieving a dry abdomen. Some physicians have concluded from this study that therapeutic paracentesis should be first-line therapy for patients with tense cirrhotic ascites, but few physicians agree with this conclusion. In view of the ease and efficacy of diuretic therapy in >90% of patients, therapeutic paracentesis should probably be reserved for the treatment of tense ascites and ascites that is refractory to diuretic therapy [32]. Also, therapeutic paracentesis lacks the ascitic fluid opsonin-conserving advantage of diuresis; theoretically depletion of opsonins by paracentesis could predispose to spontaneous bacterial peritonitis.

One practical issue regarding therapeutic paracentesis is that of colloid replacement. In one study patients were randomized to receive albumin (10 g/L of fluid removed) versus no albumin after therapeutic paracentesis [97]. The group that received no albumin developed statistically significant greater (asymptomatic) changes in electrolytes, plasma renin, and serum creatinine than the albumin group, but no more clinical morbidity or mortality. The authors of this study recommend routine albumin infusion after therapeutic paracentesis. However, not all physicians agree with this recommendation. Albumin is very expensive. It is difficult to justify the expense of routine albumin infusion after every therapeutic paracentesis worldwide based on the data at hand [98]. Albumin infusion is not needed after the removal of <5 L of fluid; albumin infusion (6–8 g/L of fluid removed) is *optional* after the removal of a larger volume of fluid [32].

TIPS has become the main second-line option for the treatment of ascites due to cirrhosis [99]. Patients and their drivers (these patients are usually too ill to drive) get tired of therapeutic paracenteses after patients have undergone several. A TIPS is placed by an interventional radiologist. It is preferable to choose a radiologist who does a few TIPS per month. This is a technically challenging procedure. TIPS can convert diuretic-resistant ascites back to diuretic-sensitive ascites [99]. The main problem with this option is hepatic encephalopathy, which

Box 17.5 Criteria for TIPS.

- Age <65 years
- Caregiver in house to help monitor mental status and give more lactulose as needed
- Child–Pugh score ≤12 points
- MELD score <18
- No alcoholic hepatitis
- Cardiac ejection fraction ≥60%
- No severe spontaneous hepatic encephalopathy or other significant insult to the brain, e.g., prior subdural hematoma, stroke, or brain abscess

MELD, model for end-stage liver disease.

develops in ~25% of patients [99]. The model for end-stage liver disease (MELD) score was developed to assess risk of death within 90 days of TIPS insertion [100].

This author prefers to proceed with this procedure only when the patient meets the criteria detailed in Box 17.5. Although these criteria are not rigid, the risks of TIPS versus the benefits must be carefully weighed in each patient, involving the caregiver in the decision making as well. Patients who live alone should not undergo TIPS. There must be someone in the house to monitor the patient's mental status and provide extra lactulose as needed to avoid severe confusion.

A successful TIPS procedure can prevent the need for future therapeutic paracenteses. When patients have less ascitic fluid in their abdomens, they can eat better and actually gain weight. TIPS is perhaps the most important breakthrough in the treatment of ascites in the past two decades. Most of the published randomized trials of TIPS versus paracenteses used the obsolete uncovered stent. Trials of the covered stent are underway and will probably show a convincing survival advantage.

Orthotopic liver transplantation should be considered in the treatment options of a refractory ascites patient who is otherwise a transplant candidate. Unfortunately there are only ~6,000 transplants per year in the United States and it is estimated that there are 10 million patients with cirrhosis. There is less than one liver per 1,000 patients with cirrhosis. Transplant helps only a tiny percentage of patients with ascites in the United States and worldwide.

In the mid 1970s the peritoneovenous shunt was promoted as a new "physiologic" treatment in the management of ascites. The study that placed peritoneovenous shunts in the "third-line" category of options for the therapy of ascites due to cirrhosis was the Veterans Administration Cooperative Study [95]. This study documented: (i) no improved survival in shunted patients compared with medically treated patients; (ii) excessive infections in shunted patients; (iii) a continued need for sodium restriction and diuretics despite a functional shunt; (iv) frequent shunt failure; and (v) most importantly *only ~10% failure of diuretic therapy* [95]. It is currently difficult to find a surgeon who has experience with and enthusiasm for these peritoneovenous shunts. At the present time peritoneovenous shunting is reserved for the very small group of patients who fail diuretic therapy and are not candidates for TIPS or transplant and have too many abdominal scars or too thick of an abdominal wall for paracentesis therapy. This does not happen very often.

Peritoneovenous shunts also have a role in the treatment of postoperative chylous ascites, e.g., after radical pelvic lymphadenectomy. This author has seen miraculous results in this setting. Once the ascites disappears, the shunt can be removed.

Summary of treatment of patients with cirrhosis and ascites

The mainstay of therapy of patients with cirrhosis and ascites is dietary sodium restriction and diuretics. Standard medical therapy is effective in >90% of patients. Therapeutic paracentesis should be performed to acutely treat tense ascites and as second-line chronic treatment of a portion of the 10% of patients who are refractory to medical therapy. Many patients who are refractory to medical therapy should be considered for TIPS (see Box 17.5). Patients who are liver transplant candidates and who develop refractory ascites should be prioritized for transplantation. Peritoneovenous shunting is third-line therapy and should be reserved for special circumstances, such as ascites due to surgical lymphatic tear that does not respond to medical therapy and for patients with ascites refractory to medical treatment and circumstances that preclude chronic therapeutic paracenteses, TIPS, or transplant.

Management protocol of patients with cirrhosis and ascites

Patients with new-onset ascites of large volume and patients with ascites and failure of outpatient management may require admission to the hospital for further evaluation and treatment.

Where to hospitalize?

If the patient is a possible liver transplant candidate, admission to a transplant center is appropriate. Candidates for transplant are usually <65 years old, nonsmokers (or ex-smokers), have no ongoing alcohol or drug abuse (with at least 6 months of being "clean and sober"), no malignancy within 5 years, no serious cardiopulmonary disease, compliance with clinic appointments and medications, and with a committed care giver. Nontransplant candidates should be admitted to hospitals where hepatologists or liver-focused gastroenterologists are available for consultation. These patients are very easily harmed by inappropriate treatments provided by well meaning, but inexperienced, physicians.

History and physical examination

A careful initial history and physical examination should provide evidence for or against the presence of cirrhosis. Body weight information should be sought. Many newly diagnosed patients with cirrhosis have nonalcoholic fatty liver disease as the cause of their cirrhosis. Most patients with cirrhosis and ascites will have palmar erythema, vascular spiders, and/or abdominal wall collaterals.

Initial laboratory testing and imaging

A complete blood count with platelet count, comprehensive metabolic panel, INR, serologic screening for causes for cirrhosis, α-fetoprotein, random urine Na/K, and liver and spleen ultrasound with Doppler should be obtained. If the α-fetoprotein or ultrasound suggest malignancy, a triphasic computed tomography scan should be obtained. If the estimated creatinine clearance is <30 mL/min, no contrast should be given unless a special protocol is used.

Paracentesis

A diagnostic paracentesis is performed on the day of admission and the tests detailed in Table 17.2 should be ordered. "The sun should not set on untapped ascites." If the patient has tense ascites, 4–5 L should be removed to relieve the pressure and prevent a leak.

Diet

The patient and their cook should be educated by a dietician in a 2 g/day sodium diet. Fluid restriction is not ordered unless the serum sodium is <120 mEq/L. This occurs in only 1% of patients with cirrhosis and ascites.

Diuretics

In general, daily doses of oral spironolactone (100 mg) and furosemide (40 mg) are ordered. If a patient has failed those doses, doubling the doses is appropriate.

Daily testing

Weights, basic metabolic panel, and urine Na/K should be followed daily. Diuretics should rapidly increase urine sodium. If urine Na is >K, the patient should be losing weight. If he/she is not, attention should be drawn to the diet. Many patients eat food brought in by friends or relatives.

Maintenance fluids

It is amazing to this author how often physicians infuse saline into patients with massive fluid overload. This is obviously counterproductive and should not happen unless the patient develops gut hemorrhage or azotemia. Albumin is usually given for azotemia rather than saline. Intravenous fluids should be avoided, even when patients are scheduled to be without food in preparation for endoscopy, etc. The massive buffer of fluid in the abdomen and tissues prevents dehydration for brief periods of time.

Folllow-up

Approximately 90% of patients will lose fluid weight on this regimen. If the weight does not decrease and the urine Na is <K despite maximum tolerated doses of diuretics, second-line options should be considered. When the patient is discharged from the hospital, he/she should be seen in the clinic within 1–2 weeks to prevent rapid readmission due to volume depletion or further fluid overload.

Multiple choice questions

17.1 **First-line treatment of patients with cirrhosis and ascites includes 2 g/day sodium diet and which of the following?**

- **a** Intravenous furosemide.
- **b** Oral furosemide.
- **c** Large volume paracentesis.
- **d** Oral spironolactone and furosemide.

17.2 **Standard treatment of spontaneous bacterial peritonitis (SBP) includes which of the following?**

- **a** Ampicillin and gentamicin.
- **b** Ceftriaxone 1 g intravenously daily for 5 days.
- **c** Cefotaxime 2 g intravenously every 8 hours for 5 days.
- **d** Cefotaxime and metronidazole.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 18
Hepatic Encephalopathy

Ravi K. Prakash & Kevin D. Mullen
Division of Gastroenterology, MetroHealth Medical Center, Case Western Reserve University, Cleveland, OH, USA

Key concepts

- Hepatic encephalopathy (HE) is a serious complication of liver disease that encompasses a broad range of neurologic and neuropsychiatric abnormalities.
- HE is mainly classified into three types: type A is seen acute liver failure, type B is seen in subjects with large portosystemic shunts in the absence of intrinsic liver disease, and type C is the most common variety seen in cirrhosis.
- Overt HE is the clinical manifestation of HE where changes in consciousness and motor abnormalities are observed.
- Minimal HE is defined as patients with completely normal neurologic examination but who have cognitive deficits in specific domains which are detected by psychometric tests.
- Covert HE is a new term that has been proposed to encompass minimal HE and the mildest form of overt HE (stage I HE on the New Haven scale).
- Ammonia is still considered the most important factor in the pathogenesis of HE.
- Cerebral edema is seen in most patients with advanced liver disease, which can be explained by the entry of ammonia into astrocytes.
- Recent advances in a number of modalities of magnetic resonance imaging has shown cerebral edema mainly in the white matter in cirrhotics.
- The approach to treatment of HE is four pronged: supportive care of the patient, to identify and treat precipitating factors, to rule out other concomitant causes of encephalopathy, and to initiate empirical therapy.
- Lactulose, despite paucity of convincing randomized controlled trial data, is still considered the first-line therapeutic agent.
- Another therapeutic agent (nonabsorbable antibiotic, rifaximin) has been approved by the US FDA (Food and Drug Administration) for treatment of patients with recurrent episodes of overt HE.
- Rifaximin has also shown to improve driving skills in patients with minimal HE.

Hepatic encephalopathy (HE) is a term used to describe a broad range of neurologic and neuropsychiatric impairments seen in patients with significant underlying liver disease [1–4] Neurologic syndromes associated with liver disease were described as early as Hippocrates (460–370 BC), but the clinical syndrome of HE in chronic liver disease as we know it today was described by Adams and Foley (and Summerskill, Sherlock, and colleagues) in a series of papers published in the mid-twentieth century [1,3,5].

As this information was disseminated it became apparent to investigators like Gabuzda and others that they were encountering a similar syndrome in patients participating in clinical trials [6]. The study in particular was on resins to treat ascites associated with chronic liver disease which exchanged sodium for ammonia. It was noticed that these patients developed a neurologic syndrome similar to the one described by Foley and Adams. It was during this time that ammonia was implicated firmly in the pathogenesis of HE [7]. However, in the ensuing decades there was some disenchantment about his theory as there was very little correlation between the levels of ammonia and the severity of HE. This in retrospect was due to unreliable ammonia assays [8]. Indeed, in that era there was only one report that showed good correlation between ammonia and HE [9,10]. As a result of this poor correlation a number of other theories were devised to explain the pathogenesis of HE, which will be discussing in the forthcoming sections.

The next major event in the understanding of hepatic encephalopathy came when it was realized that patients with both acute and chronic liver disease had cerebral edema [11,12]. It was already well known that patients with acute liver failure had pronounced cerebral edema and often developed intracranial hypertension. In contrast, a low grade of cerebral edema was identified in cirrhosis in the ensuing years [10,11]. What may have hidden this from view is the fact that some degree of cerebral

atrophy is present in most patients with cirrhosis. Also, there are compensatory mechanisms to limit the degree of cerebral edema that operate in chronic liver disease states.

Nomenclature

The first significant effort to standardize the definitions of the different syndromes in HE was performed by the Hepatic Encephalopathy Consensus Group in 1998 at the World Congress of Gastroenterology meeting in Vienna. Prior to this "portosystemic encephalopathy" and "hepatic encephalopathy" were interchangeably used [2,13]. It was decided, with the permission of Dame Sheila Sherlock, to discard the term portosystemic encephalopathy, which indicated the influence of portosystemic shunts as being largely responsible for the development of changes in mental state. This is in fact rare in the absence of intrinsic liver disease. Therefore, hepatic encephalopathy was classified into three main categories as shown in Figure 18.1. As noted in this figure, type A is associated with acute liver failure, type B (B for bypass) is associated with portosystemic shunts without intrinsic liver disease, and type C is associated with chronic liver failure or cirrhosis. Type A HE, formerly known as alfa HE, is remarkably different from type B and type C. Some differences between type A and type C HE are shown in Table 18.1. Type C is the most commonly encountered clinical syndrome and is further subclassified into episodic, persistent, and minimal hepatic encephalopathy. This standardization of the nomenclature for HE has sucessfully enhanced communication throughout the world [14].

Table 18.1 Differences between type A (α) and type C hepatic encephalopathy (HE).

	Type A HE	Type C HE
Hepatic injury	Acute onset (<8 weeks)	Chronic (at least >6 months)
Animal model	Galactosamine in rabbits/rats	Bile duct ligation and/or carbon tetrachloride in rats
Pathology	Acute hepatocellular necrosis and hepatic insufficiency	Chronic hepatocellular injury, fibrosis, nodular regeneration, and circulatory bypass of liver
Clinical profile		
Onset	Acute	Variable: insidious versus acute
Precipitating factors	Uncommon	Common
Cerebral edema	High-grade edema present	Low-grade edema present
Nutritional state	Normal	Cachexia may be present
Ascites	Absent	Usually present
Portosystemic shunts	Absent	Present
Treatment.	Treat cause of liver failure. Usually need liver transplant	Treat precipitating cause along with empirical therapy
Immediate survival	Low without transplant	High
Persistent neuropsychiatric sequelae after acute episode	No	Prior overt HE patients have worse cognition

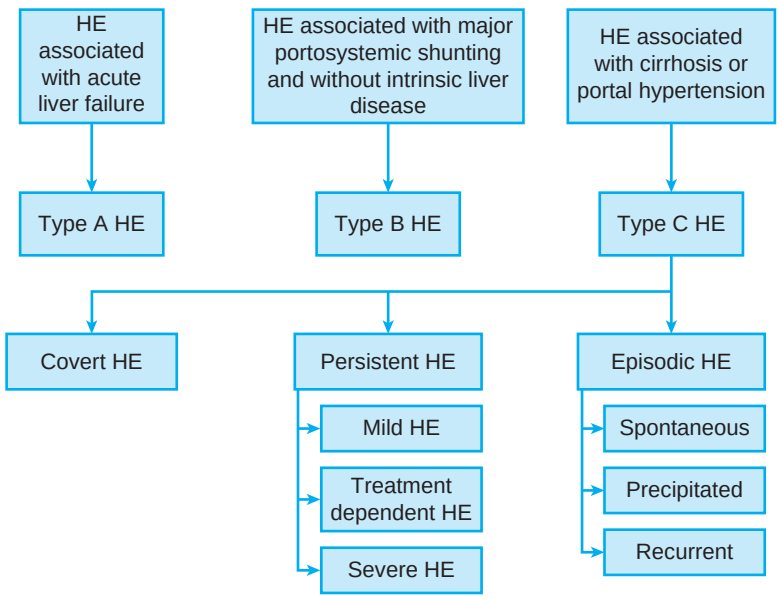

Figure 18.1 World Congress of Gastroenterology classification of hepatic encephalopathy (HE).

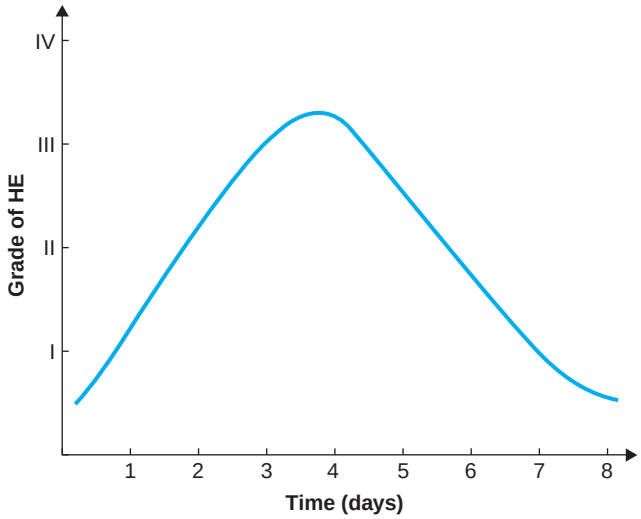

Figure 18.2 Episodic hepatic encephalopathy (HE).

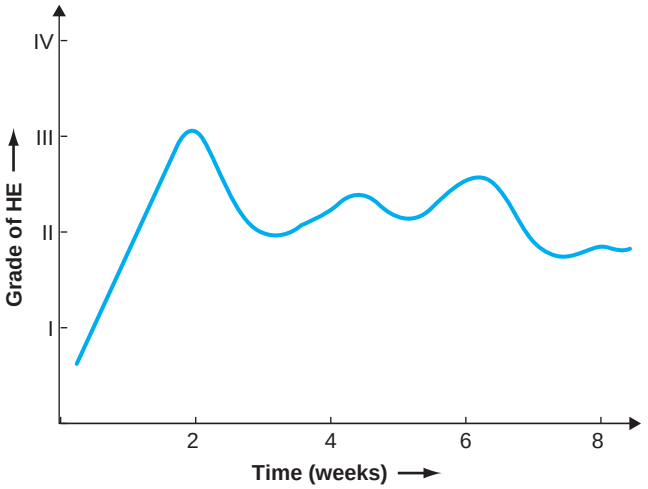

Figure 18.4 Persistent hepatic encephalopathy (HE).

Episodic HE is characterized by changes in the mental state that vary in severity and duration (Fig. 18.2). These episodes can be either secondary to a known precipitating factor, otherwise called precipitated HE, or can occur in the absence of any recognized precipitating factor, and called spontaneous HE. Recurrent HE is defined as occurring twice or more in 1 year (Fig. 18.3). Persistent HE is defined as the presence of cognitive impairment at baseline (lasting beyond 2 weeks) secondary to liver disease that negatively impacts on social and occupational functioning (Fig. 18.4).

The other term that perished during this time of terminology metamorphosis was "subclinical hepatic encephalopathy" [15]. Instead, the term "minimal hepatic encephalopathy" was introduced. This is defined as HE occurring in patients with liver disease who have completely normal mental status and neurologic examination but who have cognitive deficits in specific neuropsychometric tests [2]. It is seen in a large proportion of cirrhotic subjects and has received a lot of attention by hepatic encephalopathy researchers over the last decade.

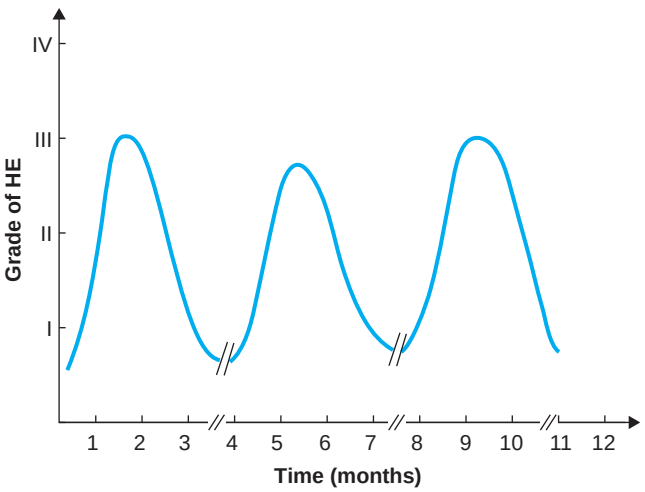

Figure 18.3 Recurrent hepatic encephalopathy (HE) (two or more episodes in 12 months).

Overt HE is the clinical syndrome of HE, with varying degree of mental and neurologic changes, seen in patients with liver disease. Classification and semiquantification of the severity of overt HE was developed by Harold Conn in the 1970s and is well known as the West Haven criteria [16]. Table 18.2 illustrates the modified West Haven criteria along with the operative definition, which was proposed by Amodio et al. [17,18]. This has five stages ranging from stage 0, where the mental status is completely normal, to stage IV, where the patient is comatose. More recently it has been observed that there is a lot of variation amongst clinicians and researchers in the diagnosis of stage I HE. This is because the clinical criteria defining stage I are prone to a lot of subjective bias [19]. To eliminate this subjectivity and introduce an objective way of defining the various grades of HE, the International Society for Hepatic Encephalopathy and Nitrogen Metabolism (ISHEN) has proposed some further changes in terminology at the meeting held in Quebec, Canada in 2010. The term "covert HE" was introduced, which will encompass minimal HE and stage I HE (Fig. 18.5). Covert HE is diagnosed mainly by neuropsychiatric tests as most patients in stage I HE will have very subtle signs of mental status changes. This change in classification is very similar to the proposed low grade to high grade HE concept by Kircheis and Haussinger [19]. The spectrum of neurologic impairment in hepatic encephalopathy (SONIC) extends from patients with normal mental status at one end, to covert HE and various grades of overt HE on the other end (Fig. 18.6) [20].

Grade	Description	Operative definition
0	No abnormality detected	
Minimal HE	No neurologic symptoms Normal clinical examination Abnormal psychometric test performance	PHES >2 SD in two or more tests ICT >5 lures CF: critical frequency of 39 Hz or less
1	Trivial lack of awareness Euphoria or anxiety Shortened attention span Impairment of addition or subtraction	Naming ≤7 animals in 120 seconds Oriented in time and space
2	Lethargy or apathy Disorientation for time Obvious personality change Inappropriate behaviours	Disoriented in time (≥3 items incorrect): day of the week day of the month the month the year Oriented in place
3	Somnolence to semistupor Responsive to stimuli Confused Gross disorientation Bizzare behaviour	Disoriented in place (≥2 items incorrect): state/country region/country city place floor/ward Disoriented in time, and reduction in Glasgow coma scale(8–14)
4	Coma, unable to test mental state	Unresponsive to painful stimuli (Glasgow coma scale <8)

CF, critical frequency; ICT, inhibitory control test; PHES, psychometric hepatic encephalopathy score; SD, standard deviation.

Table 18.2 Modified West Haven criteria for grading hepatic encephalopathy (HE) with operative definitions.

Pathogenesis

The precise molecular mechanisms responsible for the pathogenesis of hepatic encephalopathy still remain largely unknown. There is an agreed principle that the cause of HE is primarily due to gut-derived toxins (Fig. 18.7). This concept has largely stemmed from the observation that gut lavage and catharsis leads to the resolution of overt HE. In addition, as noted above, bouts of overt HE have been observed when ammonia-containing resins have been introduced into the gut [6]. In addition to ammonia quite a number of other putative toxins have been proposed as potential mediators of HE (Table 18.3) [21].

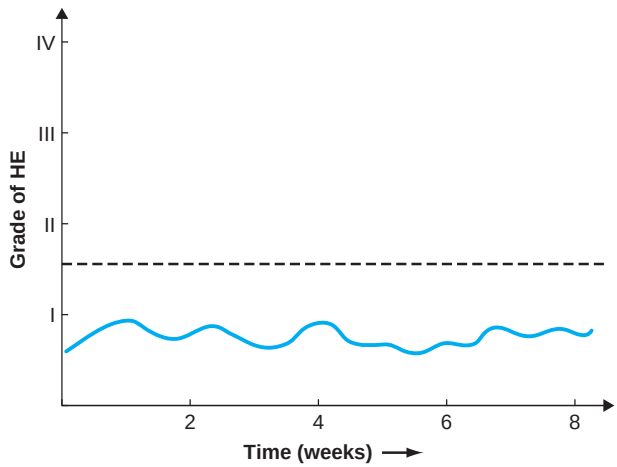

Figure 18.5 Covert hepatic encephalopathy (HE) (minimal HE plus grade I HE).

One interesting aspect of HE is the general lack of the syndrome in patients with major portosystemic shunting of blood but who do not have underlying liver disease. Many cases have been published that provide some exception to the rule that overt HE in this group is rarely seen [22]. Why the vast majority of patients with major portosystemic bypass and little intrinsic liver disease are largely free of overt HE is a bit of a mystery. Box 18.1 lists conditions that lead to this situation. It seems probable that quite a number of these patients may have evidence for minimal HE even though overt HE is rarely encountered.

Before discussing briefly some of the individual theories about the pathogenesis of HE, it is useful to think

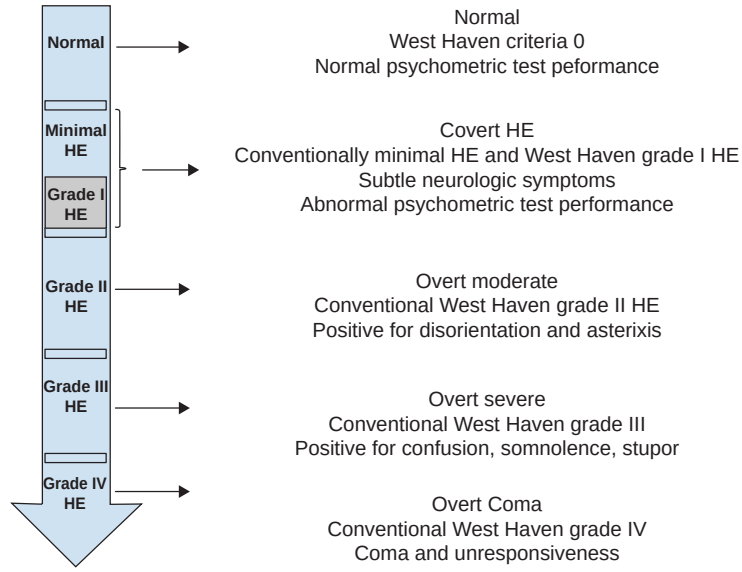

Figure 18.6 Spectrum of neurologic impairment in cirrhosis. HE, hepatic encephalopathy.

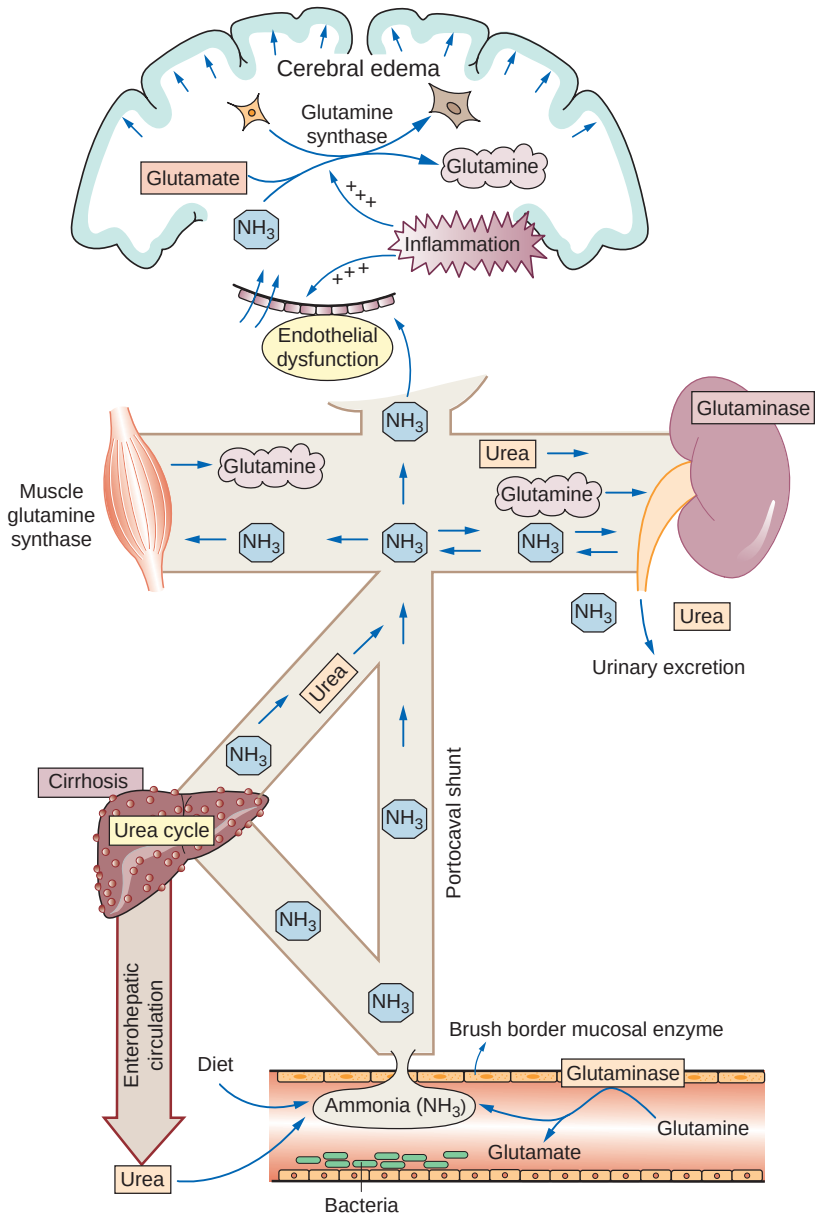

Figure 18.7 Pathogenesis of hepatic encephalopathy.

Table 18.3 Pathogenesis of hepatic encephalopathy.

Pathogenic factors	Some proposed mechanism
Ammonia	Combines with glutamate to form glutamine Intracelluar accumulation of glutamine causes astrocyte swelling and cerebral edema Involved in generation of reactive oxygen species(ROS)
Inflammation	Astrocytes and microglial cells release cytokines Cytokines affect the integrity of the blood–brain barrier and increase ammonia diffusion into the brain
Neurosteroids	Increased expression of protein 18 kDa stimulates neurosteroid synthesis Enhances GABAergic tone by a positive allosteric action on GABA-A receptor
Oxidative and nitrosative stress	Synthesized and released in response to ammonia, inflammatory mediators, hyponatremia, and benzodizepines Has a role in astrocyte swelling and tyrosine nitration of intracellular proteins
Manganese	Preferential accumulation in basal ganglia in cirrhotics with extensive portosystemic shunts Has role in formation of type II Alzheimer cells, stimulating neurosteroid synthesis and increasing GABAergic tone

GABA, γ-aminobutyric acid.

in broader terms. Assuming hepatic clearance of putative intestinal toxins is important to prevent HE, one can postulate that a lack of portal perfusion of the liver (because of spontaneous shunts or shunts formed after portal vein thrombosis) is usually not sufficient to cause hepatic encephalopathy on its own. Looking at it another way there may be compensatory mechanisms to make up for the loss of portal perfusion. Reasonably strong evidence exists that augmentation of hepatic arterial flow is seen in these patients that makes up for the lack of portal perfusion [23]. Other modulatory influences have been postulated to ameliorate the tendency to develop overt HE with portosystemic shunting alone. Interestingly, any type of further manipulation of splanchnic venous circulation, such as proximal splenorenal shunts, can result in the onset of multiple bouts of overt HE, even though there still is minimal structural disease in these patients with noncirrhotic portal hypertension. Much more research on this issue of the modulation of the expression of HE is necessary.

Box 18.1 Causes of noncirrhotic portal hypertension with no intrinsic liver disease.

- Portal vein thrombosis/splanchnic vein thrombosis
- Congenital
- Hypercoagulable conditions
- Noncirrhotic portal fibrosis
- Large retroperitoneal and intrasplenic arteriovenous malformations
- Massive splenomegaly

Ammonia

There is a large body of information implicating ammonia as a major mediator of HE. During the period when many other theories were developed, few if any studies showed a correlation between the ammonia blood level and the severity of HE. As mentioned previously, this particular problem was presumably due to ammonia assay problems prevalent at that time. In the current quoted literature at least three studies show good correlation between ammonia levels and the severity of HE [8,10,24]. We will discuss in the next section on diagnosis the fact that these findings do not signify that ammonia levels are particularly useful in the diagnosis of HE.

Direct neurotoxicity of ammonia is clearly an issue when ammonia levels are extremely high, as seen in patients with urea cycle defects [25]. Seizures and florid cerebral edema are seen in acute liver failure with ammonia levels above established thresholds (over 200 μmol/L) [26]. However, in chronic liver failure seizures are rare and quite subtle cerebral edema is present. There are a lot of data indicating that ammonia is responsible for cerebral edema primarily through increasing intracerebral glutamine by combining with glutamate [27–30]. The mechanism for the effect of ammonia on the brain has been studied most extensively in astrocytes but it is assumed that the neurons are affected in a similar fashion (Fig. 18.8) [11,31,32]. The reason that brain swelling rarely results in intracranial hypertension in chronic liver disease patients is thought to be due to: (i) preexisting cerebral atrophy, especially in alcoholic liver disease patients; and (ii) compensatory extrusion of intracellular myoinositol in response to the intracellular osmolyte increases [33,34]. However, there are some rare cases of intracranial hypertension in chronic liver disease reported [35].

While there is a general acceptance of cerebral edema being present in the brain in chronic liver disease patients, the question remains as to how that specifically leads to the manifestation of overt HE [36]. Moreover, in all alcoholic patients whether they have no HE, minimal HE, or overt HE evidence exists for cerebral edema, especially in the white matter [37]. Successful liver transplantation removes all evidence of cerebral edema over time in parallel with the resolution of most of the neurologic problems existing pretransplant [12,38]. However,

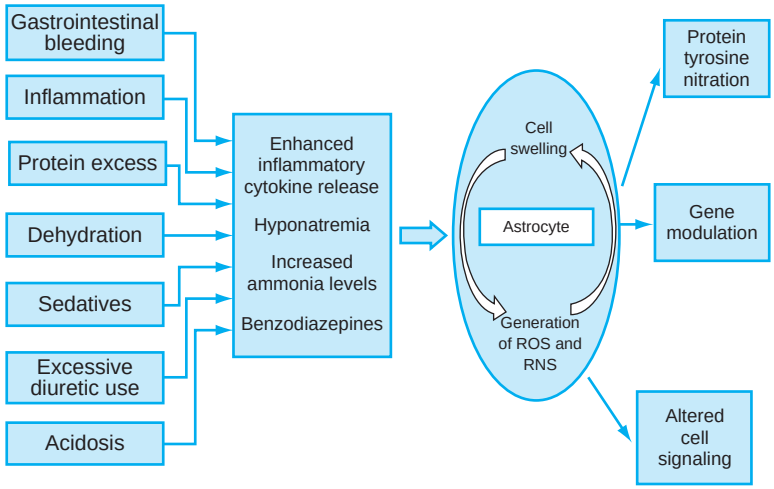

Figure 18.8 Astrocyte changes in the pathogenesis of hepatic encephalopathy. ROS, reactive oxygen species; RNS, reactive nitrogen species.

recently there have been a few reports suggesting that HE may not be totally reversible in all circumstances [39,40].

GABA/benzodiazepines

The original γ-aminobutyric acid (GABA) HE hypothesis was based on the observation of increased GABA receptors in brains in an animal model of HE [41]. This apparent increase in receptor density may have arisen from an effect of HE on the susceptibility of synaptosomes to solubilization in the assay used at that time [42,43]. There still remains evidence for increased GABA neurotransmission in some animal models of HE.

Experiments with a series of drugs active at the GABA/benzodiazepine receptor complex revealed that RO-15-1788 (a benzodiazepine receptor antagonist now called flumazenil) reversed HE in a rabbit model of liver failure [44]. The only plausible explanation for this observation was that there must be an accumulation of endogenous benzodiazepines in the brains of these animals [45]. The same phenomenon was noted in a rat model of HE, and the paper by Basile and Gammal identified benzodizepines in the brains of humans with HE [46]. Endogenous benzodiazepines have been identified in animals and plants for decades. However, the levels of these compounds are generally an order of magnitude less than required to cause "coma." Despite over 30% reversal of overt HE within minutes of administration of flumazenil, little attention has been paid to endogenous benzodiazepines in recent years [47]. Publications on the findings of these compounds in liver disease patients continue to appear [48]. One assumes more studies will arise in the coming years.

Endogenous opiates

There is quite strong evidence that the accumulation of endogenous opiates plays a major role in the pathogenesis of pruritis in cholestatic liver disease [49]. A number of reports have indicated reversal of HE with naloxone in animal models. This reversal effect has not been easy to reproduce and may have a very specific dose-dependent therapeutic action. Anecdotal human reports of HE reversal have been published with opiate antagonists [50]. Ruling out occult narcotic intake prior to bouts of HE in these reports may have been ineffective.

Plasma amino acid imbalance/false neurotransmitter

The ratio of plasma branched chain amino acids to aromatic amino acids is greatly altered in cirrhotic patients. This imbalance led to the hypothesis that the accumulation of aromatic amino acids (phenylalanine, tyrosine and tryptophan) was occurring in the brains of patients with advanced liver disease because of the loss of normal competition between aromatic amino acids and branched chain amino acids (leucine, isoleucine, and valine) across the blood–brain barrier. It was proposed that these aromatic amino acids were leading to the production of intracerebral false neurotransmitters and serotonin [51]. This process was thought to be even further enhanced by the exchange of intracerebral glutamine across the blood–brain barrier [52].

This rather intricate hypothesis would have had more support if the proposed treatment to correct this plasma amino acid imbalance – with branched chain amino acid-enriched parenteral solutions – had been demonstrated to work, i.e., reversed HE [53]. A number of treatment trials were conducted without clear benefit. It is worth noting that at the time, and for nearly two decades after, barely any form of HE treatment was found to be effective. These trials were done in patients with very advanced liver disease, which made performing controlled trials nearly impossible [18]. Multiple precipitating factors and concomitant causes of encephalopathy may have been present in these patients, which may be why it was so

difficult to prove therapies were effective. One can argue that the benefit of parenteral branched chain amino acid-enriched therapy may have been unfairly tested using the study design available at that time. In support of this therapeutic approach, it has been noted that oral branched chain amino acid supplements have been shown to be reasonably effective in reducing HE in a number of studies [54,55]. Another largely ignored aspect of branched chain amino acid therapy is the potential that this therapy may reduce HE by promoting maintenance or repletion of lean body mass. It may well transpire that this effect, especially noted with leucine, could be important in managing HE [56].

An additional point about branched chain amino acids is that hemoglobin is devoid of isoleucine. Since isoleucine is an essential amino acid, the tendency of patients to develop HE after major gastrointestinal hemorrhage can lead to the failure of whole-body protein synthesis and more pronounced hyperammonemia compared with the ingestion of other proteins [57]. Synthetic solutions simulating the amino acid composition of hemoglobin are now used as challenge tests to induce a worsening of HE in humans in a very controlled setting. These may simply reflect an oral ammonia challenge, but if the same solution with added isoleucine does not induce changes in HE (generally only covert or minimal HE is induced) there may be an incentive to explore this area of HE research further [58].

Role of systemic sepsis/inflammation

It has been noted for decades that infections in cirrhotic patients often precipitate bouts of overt HE. Indeed, the majority of very severe HE episodes are seen in septic patients. Severe infections in the absence of liver disease can cause an independent encephalopathy so perhaps the syndrome in septic patients is mediated by other mechanisms [59].

Many investigators now believe that sepsis or systemic inflammatory processes play a major role in modulating the expression of overt HE [60]. The same has been argued for covert or minimal HE, which has been reported to first appear once systemic inflammatory markers appear in the blood [61].

Various cytokines and standard markers of inflammation have been used in examining the role that inflammation may play in covert HE. The best illustration of this is the induction of hyperammonemia using an oral glutamine challenge [62]. The rapid breakdown of glutamine by intestinal glutaminase leads to a brisk 2–3-fold elevation of blood ammonia. By using a glutamine oral challenge test with sensitive psychometric tests, an important phenomenon has been reported. This challenge basically does not alter psychometric performance (e.g., the digit symbol test) in most patients unless systemic inflammatory markers are raised. Whether this is mediated by the blood–brain barrier effects of inflammation or by some other mechanism, remains to be determined [63]. Binding of inflammatory cells or cytokines to cerebral endothelial cells allows it to bypass the normal exclusionary effect of the blood–brain barrier [64–66]. Whatever the mechanism, it is imperative to identify and treat infection as promptly as possible in the management of HE.

Overall concepts of the pathogenesis of hepatic encephalopathy

The literature on the possible mechanisms responsible for the pathogenesis of HE is enormous. Nonetheless, it is reasonable to propose multiple additive or synergistic processes that lead to HE [21]. Ammonia appears to be the key toxin involved in HE and a definitive connection between increased brain ammonia entry and cerebral edema has been established. Recent advances in nuclear magnetic resonance spectroscopy (H1-MRS) have allowed us to monitor alterations in brain chemistry during experimental induction of HE with ammonia elevations. Generally, increased intra-astrocytic glutamine levels are noted with reduced myoinositol levels. Astrocyte rather than neuronal edema has been demonstrated. Considerable edema in the white matter is also present. This usually low-grade cerebral edema in chronic liver disease is accentuated by hyponatremia, certain benzodiazepines, and other compounds [67]. Presumably, this major alteration in astrocyte cell function disrupts communication and/or the function of neuronal cells. An additional mechanism whereby swelling of the astrocyte may alter brain function is through the stimulation of neurosteroid production [68]. These compounds, rather like endogenous benzodiazepines, may enhance GABAergic neurotransmission. Peripheral benzodiazepine receptors (PBR) are expressed in astrocytes, and when upregulated by exposure to ammonia lead to increased neurosteroid production [69]. A whole array of other compounds may also be produced by PBR-upregulated astrocytes, which can lead to the activation of protein kinases and oxidative stress [70]. Ultimately, a very complex set of events are involved in the pathogenesis of HE. This brief overview deliberately does not comment much on other mechanisms proposed, which can be found in a number of excellent reviews by Butterworth, Cordoba, Haussinger, Norenberg, and their colleagues [70–75].

Diagnosis

Any change in mental status or prior performance in psychometric tests in patients with known or strongly suspected underlying cirrhosis should be considered to be due to hepatic encephalopathy unless proven otherwise.

Box 18.2 Concomitant causes of encephalopathy.

- Respiratory failure: hypoxia and hypercapnia
- Gross electrolyte abnormalities - potassium, magnesium, calcium
- Status epilepticus or postictal state
- Renal failure and uremia
- Cerebrovascular accident/stroke
- Hypoglycemia
- Central nervous system infections
- Intracerebral/intracranial hemorrhage
- Metabolic acidosis
- Drug intoxication
- Cerebral edema/intracranial hypertension
- Wenicke–Korsakoff syndrome
- Delirium tremens
- Pancreatic encephalopathy

Box 18.3 Causes of recurrent or intractable hepatic encephalopathy.

- Major portosystemic shunting
- Deep-seated abscess
- Occult medication use
- Underlying urea cycle disorder

Patients with decompensated cirrhosis are particularly prone to develop overt HE. However, advanced liver disease is also associated with other events (Box 18.2) that can cause changes in mental status. These need to be identified and treated, and technically the presence of other causes of encephalopathy makes it impossible to formally assign a diagnosis of HE. In reality often both the concomitant cause of encephalopathy and HE are diagnosed and treated at the same time. We have quite often encountered hypothyroidism occurring with HE [76].

As the term implies, to suspect HE one has to first identify the presence of underlying cirrhosis or, more rarely, portosystemic shunts without cirrhosis. Figure 18.9 illustrates the various clinical signs indicative of cirrhosis. When overt HE is encountered with well-preserved liver function (e.g., near-normal prothrombin time and albumin levels), one should look for large spontaneous portosystemic collaterals, a major septic focus, or occult intake of central nervous system active drugs (Box 18.3). Diabetes is reported to be associated with overt HE when liver function is still relatively well preserved. This may be related to motility disturbances in diabetics associated with small bowel bacterial overgrowth [77,78]. While these modulating factors may be encountered, most patients begin to experience bouts of overt HE once they develop more advanced cirrhosis(Child–Pugh class B and C). When biochemical evidence of loss of function of the liver is evident, then neurologic impairment is usually due to HE, especially when the classic signs of asterixis, confusion, and other prominent motor disturbances are detected. Box 18.4 shows the various tests employed for the diagnosis of hepatic encephalopathy .

Neurologic assessment of patients with cirrhosis

Asterixis

Asterixis is defined as a tremor of the wrist when it is held in dorsiflexion, sometimes resembling a bird flapping its wings. "Asterixis" is derived from the Greek *a* (not) and *sterixis* (fixed position). It mainly denotes failure to actively maintain posture or position. It was first described by Foley and Adams in 1949 [1]. The classic method of eliciting it is by dorsiflexion of the hand with the forearm and fingers extended. The postural lapse that occurs consists of a series of rapid, involuntary, flexion–extension movements of the wrist; this has been called the "hepatic flap" [4]. Other places where asterixis could be elicited are tongue protrusion, dorsiflexion of the foot, fist clenching, and forced eye closure. The pathogenesis of asterixis is thought to be due to the abnormal function of the supraspinal motor centers. It is classically seen in grade II HE on the West Haven scale. However, it can be seen in other encephalopathies from renal failure, congestive heart failure, respiratory failure, frontal lobe tumors, and hypokalemia.

Other neurologic findings

Hypertonia, hyperreflexia, extensor plantar reflexia, and even transient decerebrate posturing may occur [79]. Very few studies have been done on the prevalence of neurologic abnormalities in patients with HE. The signs that can be elicited can be classified for convenience into three main categories: motor and coordination abnormalities, signs of progressive cerebral dysfunction or dementia, and those seen in metabolic encephalopathy. The disruption of smooth pursuit of eye movement (SPEM) is the most common motor abnormality seen in these patients [80]. There is evidence that this sign persists after a patient has an episode of HE whilst in remission [81]. Other signs include nystagmus, asterixis, hyperreflexia, ataxic heel-to-shin, ataxic finger-to-nose, and dysdiadakokinesia (slow alternating hand movement).

Clinical scales for the assessment of overt HE

West Haven criteria

Initially called the portosystemic encephalopathy index, this was the first attempt at objectively assessing the degree of hepatic encephalopathy. The scale is a semiquantitative assessment of mental status and behavioral and neurologic function. It was devised by Professor Harold Conn in 1978 and has stood the test of time as it is still used in HE clinical trials [16,82,83]. The original scale has four grades ranging from grade I (trivial lack of awareness and euphoria) to grade IV (coma). In recent years, studies have shown that there is a lot of interobserver variability in assessing lower grades of HE, especially grade I [19]. In response to this, there were attempts to introduce objective scales that closely correlated with the different grades of the West Haven scale (see Table 18.2) [84]. Further studies are necessary to approve the widespread use of this version of the West Haven scale.

HESA (hepatic encephalopathy scoring algorithm)

In order to overcome the variability in assessment of lower grades of HE, this scale was devised by Hassanein et al. [85]. It incorporates simple neuropsychologic tests, along with clinical indicators for the classification of lower grades of HE (West Haven grade I/II). This scale was studied along with West Haven scale and Glasgow coma scale in a multicenter study that assessed the clinical utility of extracorporeal albumin dialysis as a treatment for HE [86]. It has shown early promise but, again, further studies are necessary for implementation of this scale in routine clinical use.

CHESS (clinical hepatic encephalopathy staging scale)

This scale was devised to simplify the characterization of HE into different stages. CHESS ranges from 0 to 9 depending on the subject's response to nine simple questions [87]. This has been shown to correlate well with the West Haven scale. Even though this scale has been used for lower grades of HE, it is not useful in the diagnosis of minimal HE.

Laboratory diagnosis

Laboratory testing adds limited value to diagnosing hepatic encephalopathy, especially in a cirrhotic patient with prior episodes of overt HE who presents with altered mental status. However, these tests can be judiciously deployed to rule out other causes of HE and the reason for precipitation of HE. There are four main aspects of laboratory testing (Box 18.5):

1 To confirm the presence of chronic liver disease.
2 To rule out other causes for metabolic/toxic encephalopathy.
3 To corroborate the diagnosis of HE.
4 To diagnose the cause for precipitation of HE.

Box 18.5 Laboratory testing for hepatic encephalopathy (HE).

Evidence for chronic liver disease
- Increased prothrombin time/INR
- Decreased serum albumin
- Pancytopenia/leucopenia/thrombocytopenia
- Hypergammaglobulinemia
- Hepatitis serology
- Autoimmune serology

Metabolic encephalopathies
- Hypoxia/hypercapnia:
  - Arterial blood gas
  - Clinical chemistry
  - Pulmonary evaluation
- Hypoglycemia:
  - Clinical chemistry
- Renal failure/azotemia:
  - Blood chemistry
  - Urine analysis
  - Renal imaging
- Hyponatremia
  - Blood chemistry
  - Urine analysis
  - Evaluate for chronic cardiac/renal/liver disease
- Diabetic coma (ketoacidosis/hyperosmolar):
  - Arterial blood gas
  - Clinical chemistry
  - Urine analysis

Toxic encephalopathy
- Alcohol:
  - Serum alcohol level
  - Serum tylenol/salicyate level
  - Blood/urine toxic screen
- Drugs (hypnotics, analgesics, heavy metals (lead/mercury/manganese)):
  - Serum alcohol level
  - Serum tylenol/salicyate level
  - Blood/urine toxic screen

Diagnosing HE
- Serum ammonia (arterial/venous)
- CSF glutamine
- Plasma branched chain amino acid/aromatic amino acid ratio

Precipitation of HE
- Gastrointestinal bleeding:
  - Complete blood count
  - Coagulation profile
  - Clinical chemistry
- Infection:
  - Complete blood count with differential count
  - Ascitic fluid studies
  - CSF studies
  - Microbiology studies: culture/Gram stain:
- Hypokalemia/alkalosis:
  - Clinical chemistry
- Acute hepatic injury:
  - Liver function tests
  - Coagulation profile
  - Toxic/metabolic/infectious/ischemic etiology workup
- Azotemia/diabetic coma:
  - Clinical chemistry
  - Arterial blood gas

CSF, cerebrospinal fluid; INR, international normalized ratio.

Serum ammonia

Altered mental status in a patient with chronic liver disease should be treated as HE unless proven otherwise. Hence, serum ammonia is not recommended routinely for the diagnosis of HE. However, it does help in very rare circumstances but for now is predominantly limited to use in the research setting. Also, a number of studies have shown a strong correlation between venous and arterial ammonia [8]. Box 18.6 depicts the appropriate way of testing for serum ammonia and Box 18.7 lists the most common causes for erroneous readings in serum ammonia levels.

Cerebrospinal fluid amino acids

In response to increased ammonia concentrations in the brain, glutamate is released from cellular stores and

Box 18.6 Serum ammonia testing.

- Blood should be collected from a stasis-free vein. Avoid clenching of fist or application of tourniquet, which can elevate ammonia levels due to release from skeletal muscle
- A lithium- or sodium heparin-containing vacutainer (green top vacutainer) should be used to collect blood. Heparin inhibits the release of ammonia from red cells
- Sample should be stored and transported in an ice bath within 20 minutes for assay

Box 18.7 Most common sources of laboratory error in ammonia assay.

- Prior exertional activity by patient (release of ammonia from skeletal muscle)
- Improper collection technique
- Delay in transportation
- Hemolysis or use of heparin lock during venipuncture

converted to glutamine, mainly in astrocytes. This amino acid is thought to spill over into the cerebrospinal fluid (CSF) causing increased concentrations. A number of experimental studies and postmortem human studies have demonstrated at least a two-fold rise in the CSF glutamine in subjects with HE [88]. The other amino acids that show a remarkable increase in HE are phenylalanine and tyrosine [89]. These biogenic amines are precursors of dopamine and norepinephrine, which could potentially alter monoaminergic function in the brain. The most predictable rise in amino acid level relating to the degree of neurologic deterioration was demonstrated by CSF alanine. It is thought to arise from the metabolism of glutamine, which incorporates into the Krebs cycle. These tests are currently employed only in research and have a long way before they have clinical applicability. Patients presenting with HE are likely to have coagulation defects, therefore lumbar puncture is not performed unless absolutely necessary.

Psychometric tests

Minimal HE is a neurocognitive disorder wherein patients have abnormal performance in specific psychometric tests. It is generally associated with cirrhosis but can be seen in early stages of fibrosis and portosystemic shunts. This condition, recognized in the 1970s, was previously known as subclinical HE based on the performance of patients on the trail making and other cognitive tests [82,90]. The most comprehensive effort to understand the various neurocognitive domains impaired in this condition was performed by Hamster et al. [91]. He subjected 96 cirrhotic and 163 healthy age-matched controls to more than 30 different psychometric tests to assess cognitive domains ranging from premorbid intelligence levels and verbal abilities to visuomotor function and coordination. Using statistical discriminant analysis it was found that the line tracing test, peg board, aiming and steadiness of motor performance scale, and digit symbol test could effectively differentiate cirrhotic and noncirrhoti patients. It was these early efforts that paved the way for further standardization in the testing methods for what is now called minimal HE. Figure 18.10

illustrates the proposed algorithm for the diagnosis of covert or minimal HE.

Paper and pencil tests

PHES (Psychometric Hepatic Encephalopathy Score)

This test battery was devised by Weissenborn, Schomerus et al. based on the findings from the Hamster study [15]. The PHES includes the following tests: the number connection test A (NCT A), number connection test B (NCT B), digit symbol test (DST), line tracing test (LTT), and serial dotting test (SDT). This battery was employed on a large group of healthy volunteers in Germany to devise age-matched normative data and was further validated by testing on nonalcoholic cirrhotic patients. The domains tested were motor speed and accuracy, visual perception, visuospatial orientation, visual construction, concentration, attention, and to a lesser extent memory. In the subsequent World Congress of Gastroenterology meeting in Vienna, 1998, the Consensus Group for Hepatic Encephalopathy endorsed this as the temporary "gold standard" test for the diagnosis of minimal HE [2]. Further studies have shown that age and education have some influence on tests like the NCT A and NCT B [92]. This battery initially gained a lot of popularity and Italy, Spain, Mexico, and Great Britain have developed local normative data for it. Limited availability and copyright issues, along with difficulties experienced in administering and scoring this test, curtailed its popularity in the United States [93].

RBANS (Repeatable Battery for Assessment of Neuropsychological Status)

This is an established battery for the assessment of dementia and other neurocognitive disorders [94]. It is a paper and pencil test with four alternate forms (A, B, C, and D) and takes about 20–30 minutes to administer. It has extensive normative databases across the ages 20–89 years in the United States [92]. Preliminary studies done on patients waiting for liver transplantation showed close correlation between the model for end-stage liver disease (MELD) score and performance in RBANS [95]. Its main drawback is the remarkable learning effect shown by patients when tested at close intervals, which limits its utility in assessing response to treatment.

Computerized psychometric tests

Over the last few years a number of computerized test batteries have been validated to diagnose minimal HE [93]. These testing systems aim to circumvent some of the main problems encountered with the paper and pencil tests: availability, issues with administering the test, and scoring. Most computerized tests are capable of generating age-matched results at the end of the testing session. These tests are available online and can be used free of charge or for a nominal fee. They also offer the convenience of being able to be administered in the outpatient setting. The most popular testing systems are the inhibitory control test (ICT) and cognitive drug research (CDR) test.

Inhibitory control test

This is an established test utilized mainly for determining deficits in attention and response inhibition in patients with attention deficit disorder, schizophrenia, and traumatic brain injury. Bajaj et al. validated this testing system for minimal HE diagnosis by comparing it with the standard psychometric test (a paper and pencil test) [96,97]. In this test the subject is shown several letters at 500 ms intervals on a computer screen. The subject is required to focus mainly on the X and Ys that are interspersed between these letters. They are instructed to respond (by pressing the space bar) when X is followed by Y or Y is followed by X, which is called "target," and to refrain from responding when X is followed by X or Y is followed by Y, which is called "lure." The subject has to go through six runs of 2 minutes each in addition to the training run at the beginning. They are graded based on their lure response, and more than five lures diagnoses minimal HE with 88% sensitivity. In the United States, this test has been mainly investigated and employed by a single investigator, Dr Bajaj, in two centers at Wisconsin and Virginia [98] (it is available online and can be downloaded free of charge from www.HEcme.TV). However, it did not perform consistently in Europe, making it less popular on the other side of the Atlantic [99].

Cognitive drug research test

This testing system was validated for the diagnosis of minimal HE by investigators in Newcastle, UK [100]. The CDR test is presented on a computer screen with patients responding with a "Yes/no" response box. The battery is composed of seven different tests. The scores are reported on a scale of performance in five different domains, which include power of attention, continuity of attention, quality of episodic memory, quality of working memory, and speed of memory. However, one of the limitations of this test is that patients need to undergo a practice session 1–7 days prior to the test date for familiarization.

Critical flicker fusion frequency test

Developed by Kircheis et al. in 2002 for the diagnosis of minimal HE, this is now a well-established neurophysiologic test based on the principle of hepatic retinopathy [101]. The Müller cells in the retina (which are glial cells)

are thought to undergo changes similar to the astrocytes in the brain. This is, at least in part, thought to change the perception of light frequency by the retina. The test involves showing a patient light pulses, initially at high frequencies of 60 Hz, and then progressively reducing them by 0.1 Hz/s. At these high frequencies the subject perceives this as a single stream of light, but the critical frequency is when they first perceive it as discrete light pulses. A critical frequency of less than 39 Hz diagnoses minimal HE with high sensitivity and specificity, and positively correlates with paper and pencil psychometric tests. This test can be administered in inpatient and outpatient settings and takes about 15 minutes in total. Binocular vision is a prerequisite for optimal performance in this test. It is not influenced by education or occupation and only slightly influenced by age. It is widely used in therapeutic trials in hepatic encephalopathy due to it is ability to demonstrate improvement without any learning effect [102–104]. Limited availability is the main reason for its lack of popularity in the United States.

Electroencephalogram

Electroencephalograms (EEGs) help us study the neurophysiologic status of patients with cirrhosis [105–107]. It is commonly used in research and clinical settings. In the former it is used for the following:

- To monitor the effects of treatment (dietary or pharmacologic), portosystemic shunt insertion, or surgery or liver transplantation.
- To objectively quantify the degree of physiologic changes in the brain and to study its correlation with other tests employed to diagnose minimal HE.

In the clinical setting it is most commonly used as a diagnostic tool in cirrhotic patients with severely impaired consciousness

Some of the common findings on EEG are:

- Generalized slowing of the background EEG activity, which is objectively quantifiable but can be seen in other metabolic encephalopathies.
- A decrease in the amplitude of the waves.
- The presence of triphasic waves and bursts of slow activity in the theta and delta range.

Some studies report a sensitivity of about 83–100% for diagnosing overt HE and up to about 40% sensitivity diagnosing minimal HE patients. However, these are largely dependent of the technique used.

Some newer techniques have evolved:

- ANESS (artificial neural network expert system software).
- SEDACA (short epoch, dominant activity, cluster analysis).

These have helped to overcome some drawbacks although EEG still remains largely used in the research setting.

Brain imaging

Increasingly over the last couple of decades, cerebral edema has been demonstrated by a variety of magnetic resonance imaging techniques of the brain (Table 18.4) [37]. This is mainly seen in the white matter and in all grades of hepatic encephalopathy. A computerized tomographic scan of the brain is done routinely in patients with altered mental status, to rule out concomitant causes like intracranial hemorrhage and space-occupying lesions.

Treatment

The treatment of HE has empirically evolved over the decades primarily from data based on clinical observation. The current standard of care for management of overt HE consists of four main strategies (Fig. 18.11): (i) supportive care for the patient with altered mental status; (ii) concomitant causes for encephalopathy are sought and treated if possible; (iii) precipitating factors for bouts of HE are identified and corrected promptly; and (iv) empirical treatment is provided for HE. Until recently lactulose was the only approved therapy for HE in the United States. Now an alternative agent, rifaximin, is available to treat certain types of patients with recurrent HE [108].

Supportive care

The nasogastric tube delivery of overly large amounts of lactulose has become widespread in the treatment of HE [18]. As a consequence, aspiration is a significant risk for patients being treated in intensive care units. Most intensivists electively intubate patients with severe HE (e.g., stage III or IV, West Haven scale), which is certainly justified when major upper gastrointestinal bleeding is also an issue. Another supportive issue is the provision of nutrition to the unconscious patient. Data now exist to show that adequate nasogastric feeding can be delivered to patients as they emerge from bouts of severe HE. Generally, however, nutrient delivery is compromised in the first few days of hospitalization because of the frequency of tests and the need to lavage the gut to clear it of blood.

Other causes of encephalopathy

The second strategy of major importance in the management of HE is making sure that no other cause of encephalopathy is present in the unconscious patient diagnosed with overt HE (see Box 18.2). There are a number of issues that arise from this strategic point. The first is that technically, as mentioned previously, if a comatose patient has severe hypoglycemia or shock they cannot be labeled as having HE since other causes of encephalopathy need to be absent to make the diagnosis. In reality, HE and other causes of encephalopathy can occur

Table 18.4 Magnetic resonance imaging (MRI) in hepatic encephalopathy (HE).

Imaging modality	T1-weighted imaging	H1-magnetic resonance spectroscopy	MTI[a]	FLAIR imaging[b]	DWI[c]
MRI abnormality	Bilateral, symmetric, high signal intensity in the substantia nigra and globus pallidus	Increase in intracellular glutamate/glutamine signal. Concomitant decrease in myoinositol, taurine, and choline signals	Low magnetization transfer ratios (about10%) seen diffusely in the brain in normal-appearing white matter. This is not accompanied by any abnormalities in T1 or T2 signal intensities in that region	Diffuse white matter signal intensities involving the hemispheric white matter and the corticospinal tract on T2-weighted imaging	Increase in mean diffusivity in hemispheric white matter
Correlation with clinical severity of HE	No	No	Not established	Not established	Yes, and correlates with serum ammonia levels
Resolution of changes following liver transplantation	Yes (may take up to 1 year)	Yes (takes a few months)	Yes	Yes	Yes

[a]Magnetization transfer imaging (MTI) refers to the transfer of longitudinal magnetization between protons in water molecules that have been restricted in motion, such as those in the nuclei (bound to proteins), to those protons that are freely mobile, such as those in the cytoplasm. Low magnetization transfer is indicative of brain structures that are able to exchange magnetization with surrounding structures relatively easily, such as cell destruction and brain edema.
[b]FLAIR (fluid inversion attenuated recovery) imaging is used to suppress the effects of cerebrospinal fluid on the image and to enhance periventricular lesions.
[c]Diffusion-weighted imaging (DWI) can locate the compartment where there is a collection of water (intracellular or extracellular).

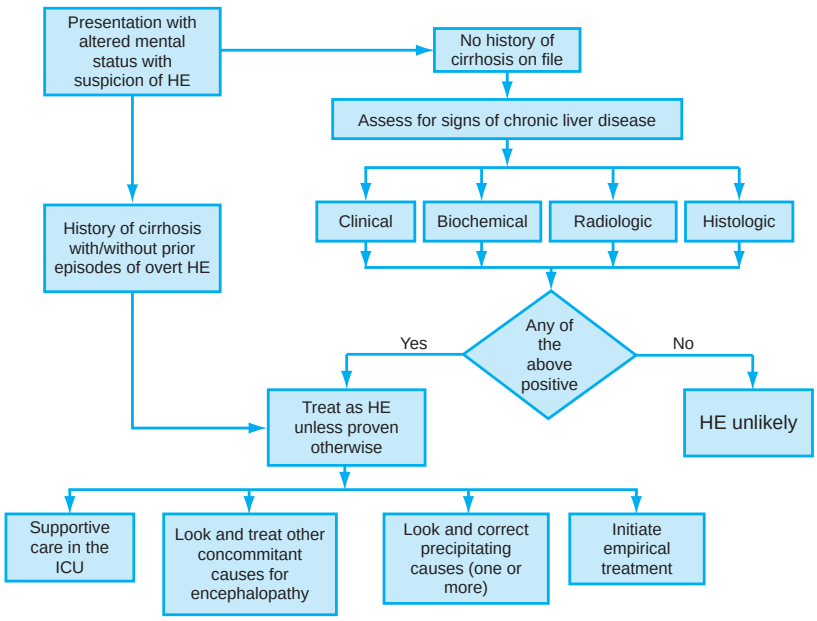

Figure 18.11 Algorithm for the management of hepatic encephalopathy (HE). ICU, intensive care unit.

simultaneously. Patients often will not recover unless these concomitant diseases are diagnosed and corrected. Vigilance is important in monitoring for the accidental induction of dehydration or other complication (e.g., hypomagnesaemia) of overly aggressive lactulose dosing.

Precipitating factors

The third strategy employed in the management of bouts of overt HE is extremely important. In advanced cirrhotic patients (Child–Pugh class C) most bouts of overt HE are precipitated by defined factors (Box 18.8). Prompt identification and correction of these factors is a very effective therapy for HE. Recovery rates of 80–90% have been reported with the correction of precipitating factors alone [109]. Because of overlap (e.g., lactulose used to clear gastrointestinal blood) it is sometimes difficult to know what actually reversed the HE episode. Complicating matters further, many patients have more than two simultaneous precipitating factors. These types of issues have made it very difficult to conduct randomized controlled trials in the treatment of overt HE. Multiple precipitating factors and additional concomitant causes of encephalopathy together make conducting a "controlled" trial well nigh impossible. In any event, seeking and treating precipitating factors is an effective treatment for overt HE. Patients with especially large spontaneous or surgically created portosystemic shunts tend to have more bouts of spontaneous HE [110].

Some additional comments are warranted on precipitating factors. One of the most dominant factors is likely sepsis. If a major focus of infection is not identified and treated successfully, recovery from bouts of HE can be very protracted or the patient may have recurrent bouts of overt HE [111]. When patients with cirrhosis develop severe HE, sepsis is the number one suspect. One issue with sepsis is the fact that it is capable of inducing encephalopathy on its own [59]. This is another example of the difficulties in managing HE.

Upper gastrointestinal bleeding is a frequent precipitant for bouts of HE. It has been proposed that the digestion of blood in the gut generates an undue amount of ammonia that precipitates HE. The absence of the essential amino acid isoleucine from hemoglobin may make it more ammoniogenic than other forms of protein [57,112].

Gut lavage and catharsis are employed to clear the gut of blood and empirically one sees patients recovering from overt HE with this form of therapy. Because lactulose is a laxative it is difficult to know whether its unique action or the resulting purgative effect is responsible for the observed recovery from bouts of HE. Regardless, gut cleansing is a main stay of therapy. If constipation or ileus is present, clearing blood from the gut might not be achievable until gut motility is improved. It has been suggested that gastrointestinal motility is reduced by HE itself, perhaps generating a self-perpetuating mechanism for bouts of HE. In the setting of constipation, bowel obstruction, or ileus, the rectal administration of lactulose has shown to be effective for treatment of overt HE [113].

Hyponatremia, based on a number of papers, is clearly capable of aggravating or precipitating HE too [114]. Hyponatremia adds to the cerebral edema already present in patients with advanced cirrhosis [67]. Whether hyponatremia is a precipitating factor or a true pathogenetic factor for HE has not been clarified.

Drug therapy

Box 18.9 lists most of the empirical therapies employed at one point or another for the treatment of HE. We are going to confine most of our comments to the two approved agents for the treatment of HE, lactulose and rifaximin. Box 18.10 lists various therapies that have been utilized for the prophylaxis of hepatic encephalopathies. Figures 18.9 and 18.11 outline two detailed algorithms to clearly map out the possible therapeutic approaches to be taken in managing patients with minimal and overt HE, respectively.

Box 18.8 Precipitating factors for hepatic encephalopathy.

- Sepsis
- Gastrointestinal hemorrhage
- Electrolyte abnormalities (hypokalemia/alkalosis)
- Dehydration
- Central nervous system active drugs
- Constipation
- Dietary protein overload
- Poor compliance with lactulose therapy
- Uremia
- Ileus or bowel obstruction
- Prior anesthesia
- Superimposed hepatitis
- Development of hepatocellular carcinoma
- Portal decompression procedure/transjugular intrahepatic portosystemic shunt placement

Box 18.9 Empirical therapies for hepatic encephalopathy treatment.

- Lactulose 15–30 mL PO two to three times a day titrated to two to three soft bowel movements
- Rifaximin 550 mg PO twice daily
- Neomycin 500 mg PO four times daily (caution in renal failure and in high doses)
- Metronidazole 250 mg PO four times daily (only for short-term use)
- Vancomycin 250 mg PO four times daily
- Sodium benzoate 5 g PO twice daily
- Flumazenil 1–3 mg intravenous (short-lasting therapy)

Box 18.10 Therapies for the prophylaxis of hepatic encephalopathy.

- Lactulose 15–30 mL PO two to three times a day titrated to two to three soft bowel movements
- Rifaximin 550 mg PO twice daily
- LOLA (L-ornithine L-aspartate) 6 g PO three times daily
- Sodium benzoate 5 g PO twice daily
- Bromocriptine 15–60 mg PO daily
- Zinc (zinc sulfate and zinc acetate) 600 mg PO daily
- Vegetable protein-based diet
- Branched chain amino acid-enriched diet

Lactulose

This nonabsorbed disaccharide has been used for over 40 years to treat HE [16,115]. Like other drugs developed that long ago, there are concerns regarding the adequacy of data in support of its efficacy. There is little doubt in most physicians minds that lactulose is an effective treatment for HE. However, the published data in support of lactulose treatment for overt HE is not convincing [116]. Unfortunately, lactulose began to be believed to be a therapy that ethically could not be withheld from patients with overt HE. In particular, once that belief arose in the human investigation review boards in the United States, paradoxically neither lactulose nor any other therapy could be compared to placebo. Essentially, lactulose based on its original approval by the US Food and Drug Administration (FDA) in 1977 has continued to be used nearly exclusively for the treatment of HE. Some data have now been published showing that lactulose was superior to placebo in the treatment of covert or minimal HE [116–118].

One concern about the lack of data in support of lactulose treatment of overt HE relates to the mechanism of action of this drug. A variety of mechanisms have been reported that should limit the generation of ammonia in the gut and its subsequent absorption [119]. However, it is probable that simple laxatives could have the same effects with less cost and side effects. In some parts of the world, lactulose is no longer used because of lack of evidence-based data. It should be feasible now to get permission to conduct placebo-controlled trials against lactulose and formally establish its true efficacy. It is our opinion, based on data generated in the treatment of minimal HE, that lactulose clearly does have efficacy in treating HE [120]. The real question is how much it reverses HE compared with cheaper laxatives.

Rifaximin

This minimally absorbed broad spectrum antibiotic had previously been used in multiple HE treatment trials in Europe [121–124]. However, as with lactulose therapy, no placebo-controlled trials were performed. Instead rifaximin was compared with a variety of other agents (lactulose, lactitol, and other antibiotics) and consistently displayed similar efficacy [125,126]. Most studies were not sufficiently powered to verify therapeutic equivalence and this may explain the lack of use of rifaximin in Europe.

The publication of a recent, large ($n = 298$) rifaximin trial in the United States has provided data that clearly indicate that rifaximin reduces recurrent HE episodes in patients at high risk for these events (58% reduction) [108]. The study essentially showed that the prevention of HE episodes was largely in patients who had had lactulose treatment failure; 91% of the enrolled patients continued to take lactulose even though two or more overt episodes had already occurred while on lactulose. This is not to say that lactulose is totally ineffective as a treatment to prevent recurrent episodes of HE. The particular population recruited into this study had hardly any identifiable precipitating factors for their bouts of overt HE. More specifically, we do not know how many or how soon HE episodes would occur if lactulose therapy had been discontinued. Clearly, this could be identified in future studies. However, in the interim we know that rifaximin is effective in reducing recurrent episodes of HE in patients where lactulose has failed to do this.

The FDA approved rifaximin use for maintaining HE remission after recovery from previous bouts of overt HE. Already, the questions being raised is whether rifaximin can be used for shortening episodes of existing overt HE. There is no indication for this use at this time, but it is worth noting that designing and conducting a randomized controlled trial in patients with advanced liver disease with overt HE is a major challenge.

Other forms of treatment

Neomycin has been used to treat HE since the 1950s [127]. As with other agents for the treatment of HE there is not an abundance of evidence in support of its efficacy. Indeed a very well-conducted trial by Strauss and colleagues in Brazil essentially showed neomycin to be no more effective than placebo [109]. However, before dismissing neomycin totally based on that study it is worth pointing out a few of its features. One major aspect of study design was that patients in both arms of the study (e.g., neomycin versus placebo) had precipitating factors identified and corrected. This was associated with a 80–90% reversal of HE in both arms. The vast majority of studies never identify or treat precipitating factors, which based on this study can correct HE episodes in 90% of patients. Sufficient to say neomycin may have efficacy in treating HE but its toxicity has largely ended its use. Typically, antibiotics with activity in HE treatment have activity against anaerobic bacterial species [128]. Neomycin

did not fit this profile but we now have an alternative mechanism for the action of neomycin. There is definite proof that it inhibits the intestinal mucosal enzyme glutaminase [129]. This particular enzyme is responsible for generating a large proportion of the blood ammonia contained in the portal vein. This may explain neomycin's apparent therapeutic effect in HE. Recently, it has been noted that differential gene inheritance for this glutaminase enzyme may modulate the expression of overt HE in patients [130]. More glutaminase inhibitor type drugs may be developed in the coming years.

Other antibiotics

Metronidazole [131], vancomycin [132], paramomycin [133], and some other antibiotics in various publications have been reported to reverse HE [124]. Possibly the major mechanism of action of antibiotics is exerted in the small intestine where bacterial overgrowth has been reported on a number of occasions [77]. It seems that intestinal motility reduction may play a role in small bowel bacterial overgrowth. One proposed advantage of rifaximin to treat small bowel bacterial overgrowth in cirrhotic patients and in other situations is its lack of a major effect on colonic bacterial flora. This should be formally proven but rifaximin is solubilized by bile salts in the small intestine and thus has very active antibiotic action. Once bile salts are reabsorbed across the intestinal wall, rifaximin is far less active and therefore does not suppress colonic flora to a major degree. Some action is still retained since rifaximin is known to have activity against *Clostridium difficile*. Future therapy in HE may use prokinetic and selected delivery antibiotics.

Other therapies

At the risk of omitting some interesting facts it is not feasible to address all the therapies ever applied to HE. The enthusiastic reader may want to delve into literature on urease immunization [134], colonic resection or bypass[135], arterialization of the portal vein stump [136], and other forms of therapy. Box 18.11 illustrates some important aspects of nutrition in patients with HE [137]. Because of their potential importance in the pathogenesis of HE, endogenous benzodiazepines are worth another brief mention [70,138]. Patients who have never taken benzodiazepine drugs are "awoken" by about 30% from severe HE by intravenous infusion of flumazenil. This phenomenon has been demonstrated in rat and rabbit models of HE. It has been argued that the "awakenings" from HE by flumazenil reflect benzodiazepine drug use in patients with HE. It is worth noting that animals, in which endogenous benzodiazepines have been found, do not have access to prescription drugs. In any event, when a 30% recovery from coma is reported from one short-acting drug it would seem prudent to see if responders could be maintained out of coma by further dosing. This was actually reported upon once but never followed up with a formal study [139].

Box 18.11 Nutrition in patients with cirrhosis.

- Daily intake is 30–35 kcal/kg body weight:
  - 50–60% carbohydrate
  - 20–30% proteins (1–1.5 g/kg body weight)
  - 10–20% fat
- In patients with hepatic encephalopathy:
  - There is little evidence for protein restriction
  - If protein intolerant then change to vegetable-based protein
  - Branched chain amino acid-enriched supplements
  - Supplement with probiotics and prebiotics as they have ammonia-lowering properties
- Frequent small meals (4–6 times) with a light snack (carbohydrate) before bed time
- Screen for vitamins (A, D, E, and K) and mineral deficiencies (zinc, calcium, and magnesium) and supplement accordingly

Liver transplantation

When medical therapy fails to preserve adequate liver function for survival, liver transplantation is required. At present, liver transplantation is not usually performed because of recurrent or intractable HE. Instead, the priority is given using primarily the MELD score which has no component of HE [140]. Exceptions for severe HE are not granted, instead patients have to wait for liver transplant until their MELD score is sufficiently high to merit this intervention. The modification of the MELD score with the addition of hyponatremia may hasten transplant in some patients, which seems appropriate as hyponatremia is known to aggravate cerebral edema in cirrhotic patients [141]. Nonetheless, patients with persistent or frequently recurrent HE rapidly lose their muscle mass and become less fit for survival after liver transplantation.

The development of even more effective treatments to prevent or significantly delay the onset of HE would clearly be a major advance. Alternatively, earlier transplantation for patients before bouts of overt HE occur may improve neurologic outcomes [39,40,95,142].

Future directions

The decision to temporarily endorse PHES as the gold standard for the diagnosis of minimal HE by the World Congress Consensus Group had an important impact on

HE research. It largely, but not entirely, encouraged a standardized battery of psychometric tests to be used by all investigators. This quickly led to multiple publications all over the world on ninimal HE and its effect on driving ability[143–145], health-related quality of life [117,146,147], and the future prediction of patients at risk for developing overt HE. Treatment trials for various agents to reverse minimal HE have already commenced [118,148]. Placebo-controlled randomized controlled trials can now be undertaken for patients with minimal HE. As noted on a number of occasions in this chapter, attempting to conduct treatment trials in patients with overt HE and quite advanced liver disease is fraught with many uncontrolled issues. These are largely not a factor in minimal/covert HE trials. As we pursue even better systems for the detection and quantification of minimal HE our ability to test drugs for treatment is enhanced. Truly a new era of therapeutics in HE has commenced.

We have until recently thought that overt HE is totally reversible. However, evidence is accumulating that this may not always be the case [98]. Indeed, a case can be made to intervene in the earliest stages of HE to prevent a loss of function in a number of domains of brain function. Liver transplantation outcomes in patients with bouts of overt HE have long been noted to demonstrate future reversal of all the effects of HE. This may eventually lead to transplantation being utilized earlier in the course of disease unless even more effective therapies can abolish the evolution from minimal to overt HE.

Finally, for a major paradigm shift to occur in the early detection of HE, i.e., minimal HE, a testing system needs to be developed available to all physicians.

Multiple choice questions

18.1 **A significant proportion of portal vein ammonia is generated by intestinal ammonia.**

a True.
b False.

18.2 **Hepatic encephalopathy (HE) primarily arises because of large portosystemic shunts.**

a True.
b False.

18.3 **Correction of precipitating factors for HE is effective therapy.**

a True.
b False.

18.4 **Prophylaxis with lactulose after transjugular intrahepatic portosystemic shunting has shown to reduce episodes of HE.**

a True.
b False.

18.5 **Decreased brain myoinositol levels on nuclear magnetic resonance spectroscopy support the presence of cerebral edema in HE.**

a True.
b False.

18.6 **The presence of minimal HE predicts the development of overt HE.**

a True.
b False.

18.7 **Blood ammonia level are useful for the diagnosis of HE.**

a True.
b False.

18.8 **Neomycin inhibits intestinal glutaminase activity.**

a True.
b False.

18.9 **Treatment of minimal HE is associated with improved driving ability.**

a True.
b False.

18.10 **Asterixis is highly specific for the diagnosis of HE:**

a True.
b False.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 19
Acute Liver Failure

Anne M. Larson
University of Texas Southwestern Medical Center, Dallas, TX, USA

Key concepts

- The syndrome of acute liver failure (ALF) is defined as an illness of less than 26 weeks' duration with coagulopathy (international normalized ratio ≥1.5) and any degree of hepatic encephalopathy in patients without preexisting liver disease or cirrhosis.
- There are many causes of ALF, which vary geographically and socioeconomically. Viral hepatitis remains the most common cause worldwide, while drug-induced ALF, particularly acetaminophen hepatotoxicity, predominates in the United States and many parts of Europe.
- The cause of ALF carries prognostic significance and directs specific treatment options where available.
- The clinical presentation of ALF is similar regardless of the cause. Depending upon the severity, it is associated with coagulopathy, thrombocytopenia, hemodynamic instability, acid–base disturbances, renal insufficiency, metabolic derangements, electrolyte imbalance, infection and sepsis, and hepatic encephalopathy associated with cerebral edema.
- Management of ALF is complicated and requires a multidisciplinary approach, including transplant hepatologists, transplant surgeons, intensive care physicians, nephrologists, and neurosurgeons.
- Spontaneous survival ranges from 20% to 70% depending upon the cause. With the advent of liver transplantation as a treatment option in this setting, overall survival rates have improved to ~60%.
- Several prognostic models have been developed in an attempt to predict who will require transplantation and who will survive. None of these models can predict outcome with absolute certainty, however.

Acute liver failure (ALF) is a devastating multiorgan syndrome characterized by sudden and severe hepatocellular dysfunction (jaundice, coagulopathy, and encephalopathy) which develops in previously healthy individuals. This catastrophic illness can swiftly progress to coma and can result in death from cerebral edema and multiorgan system failure. ALF is associated with a variety of causes, including drug-induced liver injury and viral hepatitis, although in as many as 20% of cases no etiology can be found (indeterminate ALF) [1]. It may also be the presenting feature in certain chronic liver diseases, including Wilson disease and autoimmune hepatitis.

The clinical syndrome of ALF is the same, however, regardless of the cause. Complications include coagulopathy, hepatic encephalopathy, cerebral edema, brainstem herniation, infection, circulatory instability, renal failure, pulmonary failure, electrolyte disturbances, and acid–base disorders. Mortality ranges from 30% to 100% [1]. Aggressive multidisciplinary management and the judicious use of emergent orthotopic liver transplantation (OLT) have improved overall patient survival. However many patients are not candidates for OLT or will die before an organ becomes available [2–4]. There is generally complete hepatic recovery if the patient survives without OLT (spontaneous survival).

Definitions

The syndrome of ALF was first described in the 1950s. Trey and Davidson in 1970 defined ALF as the onset of hepatic encephalopathy within 8 weeks of the first symptoms of illness in patients without preexisting liver disease [5]. ALF is described as a syndrome, rather than a specific disease, since it has multiple causes that vary in course and outcome. ALF is also variably called fulminant hepatic failure, fulminant liver failure, fulminant hepatic necrosis, or acute hepatic necrosis. The preferred terminology is acute liver failure or acute hepatic failure, since this encompasses all clinical presentations.

The clinical progression of ALF is a consequence of its etiology, predicting its eventual outcome. This fact has led some to suggest refinements to the basic definition [6,7]. O'Grady et al. proposed stratifying patients according to the time interval between the onset of jaundice and the development of encephalopathy into

hyperacute (<7 days), acute (8–28 days), and subacute (28 days to 6 months) [6]. This classification system is currently used in the United Kingdom. A subcommittee of the International Association for the Study of the Liver (IASL) proposed two categories: acute liver failure, that which develops within 4 weeks of the onset of illness, and subacute liver failure, that developing 4 weeks to 6 months after the onset of symptoms. However, others have questioned the prognostic significance of these classifications independent of the etiology of the syndrome.

In general, the syndrome of ALF is currently described as an illness of less than 26 weeks' duration with coagulopathy (international normalized ratio (INR) ≥1.5) and any degree of hepatic encephalopathy in patients without preexisting liver disease or cirrhosis. Exceptions to this include Wilson disease, vertically acquired hepatitis B virus (HBV) infection, autoimmune hepatitis, or hepatitis D virus (HDV) superinfection in patients with chronic HBV infection, all of which may present with ALF despite the presence of unrecognized underlying chronic liver disease or cirrhosis.

Epidemiology

Acute liver failure affects about 2,000–2,800 persons annually in the United States [8,9]. It has been estimated that ALF accounts for about 0.1% of all deaths in the United States (3.5 deaths per million population) and 6% of all liver-related deaths. In addition, 5–6% of all US liver transplants are performed for acute liver failure [8,9].

Studies in the United States in the 1960s suggested that up to two thirds of ALF cases were due to viral hepatitis, with about 23% secondary to drug-induced liver injury (DILI) [10]. From the 1970s to the early 1980s, HBV emerged as a predominant cause [11]. In an equal number of patients, a cause could not be found (indeterminate cases). Drug-induced liver injury occurred in <20% and acetaminophen-induced ALF was not seen [11]. Case reports began to appear in the 1980s linking acetaminophen to cases of ALF. A 1983 to 1995 series from the University of Pittsburgh revealed that acetaminophen toxicity had emerged during that era as the cause for 19% of ALF cases. The incidence of HBV had decreased to 18% and 44% of cases were indeterminate [12]. The US Acute Liver Failure Study Group (ALFSG) retrospectively reviewed the causes of ALF between 1994 and 1996, revealing a 20% incidence of acetaminophen-induced ALF and a further decline in viral hepatitis (17%) [13]. In 1997, the ALFSG began to prospectively collect ALF patient data. Data collected on the first 308 cases enrolled between 1998 and 2001 revealed that over 50% of cases of ALF in the United States were secondary to medications, including herbal preparations (39% acetaminophen, 13% idiosyncratic drug reactions) [1]. Of those with acetaminophen-induced ALF, overdose was unintentional in 48% and most were consuming the medication for pain relief [14]. In this series, viral

Data from the ALFSG (William Lee, personal communication).

hepatitis accounted for only 12% of cases and a cause could not be found in 17% (indeterminate ALF). Acetaminophen overdose is now the commonest cause of ALF in both the United Kingdom and United States [13].

The majority of ALFSG patients in the United States are women (67–73%) and Caucasian (74%); however this varies with etiology (Table 19.1) [1,13]. Regardless of race, the groups are similar with regard to gender, years of education, age at presentation, and current alcohol or injection drug use. Acetaminophen appears to be the more common etiology among whites (52% whites, 28% blacks, 20% Asians). Asians are more likely to have viral hepatitis-induced ALF (8% whites, 19% blacks, 26% Asians) and blacks and Asians more likely to have drug-induced ALF than whites. There is no significant difference in overall mortality rate between racial groups; however, the odds of receiving liver transplantation are greater among Asians and Hispanics (and similar between whites and blacks).

ALF is less common in the United Kingdom. In contrast to the US data, acetaminophen overdose is the commonest cause, accounting for up to 70–75% of cases [15,16]. Other drugs are responsible for 5% of cases of ALF and viral hepatitis accounts for <5%. Most acetaminophen overdoses in the United Kingdom follow attempts at deliberate self-harm, rather than unintentionally consuming too much product. Following a surge in acetaminophen-induced cases of ALF in the United Kingdom, legislation was passed in 1998 aimed at restricting the quantity of acetaminophen which could be purchased [17]. This resulted in a decrease of approximately 30% in the number of hospital admissions, number of liver transplant listings, and deaths from acetaminophen poisoning [18].

Etiology

The causes of ALF are many and vary both geographically and socioeconomically (Box 19.1). Viral hepatitis remains the commonest cause worldwide, while drug-induced ALF, particularly acetaminophen, predominates in the United States and many parts of Europe [1,13–15,19]. Despite advances in diagnostic techniques, an etiology cannot be found (indeterminate ALF) in up to 20% of cases.

Box 19.1 Etiologies of acute liver failure [324].

Viral
- Hepatitis A, B (±D), and E
- Hemorrhagic fever viruses
- Cytomegalovirus
- Herpes simplex viruses

Drugs/toxins
- Dose-related
  - Acetaminophen
  - Carbon tetrachloride
  - *Amanita* poisoning
  - *Bacillus cereus* emetic toxin
  - *Cyanobacteria microcystins*
- Idiosyncratic
  - Reye's syndrome (salicylic acid)
  - Herbal medications
  - Prescription medications (i.e., isoniazid, halothane, troglitazone, bromfenac)

Metabolic/genetic
- Galactosemia
- Fructose intolerance
- Tyrosinemia
- Neonatal iron storage disease
- Wilson disease
- α_1-Antitrypsin deficiency

Neoplastic
- Metastases: breast, melanoma, lung, lymphoma

Pregnancy-related
- Acute fatty liver of pregnancy
- HELLP syndrome (hemolysis, elevated liver function tests, low platelets)

Vascular
- Budd–Chiari syndrome
- Sinusoidal obstruction syndrome
- Ischemic (shock) liver

Miscellaneous
- Autoimmune hepatitis
- Heat stroke
- Primary graft nonfunction in liver transplant recipients

Indeterminate

Viral hepatitis

Viral hepatitis is the leading cause of ALF worldwide, although ALF occurs in <5% of all viral hepatitis infections [10,20]. HBV accounts for the majority of these cases. Those with underlying liver disease or those who are older when infected appear to be at greater risk of developing ALF due to acute viral hepatitis [21].

Hepatitis A virus

The majority of acute hepatitis A virus (HAV) infections in children and adolescents are anicteric and asymptomatic, with symptoms becoming increasingly prevalent with increasing age. Acute liver failure occurs in 0.2–0.4% of cases of acute HAV; those over 40 years of age and those with preexisting liver disease are at higher risk [20,21].

It has been reported that patients with chronic hepatitis C virus (HCV) infection who are superinfected with HAV also have a greater risk of developing ALF [22], although this finding is not universal [1,23,24]. HAV accounts for 4–8% of cases of ALF in the United States, 5% in the United Kingdom, and 4% in France [1,13,25]. Approximately 40% of the US population is now immune to HAV, and the incidence of acute HAV, development of ALF, and mortality has dramatically declined [26–28]. Outbreaks, however, continue to occur.

Hepatitis B virus

Acute liver failure develops in 0.1–1.2% of patients with HBV infection, and women appear to be more susceptible than men. The percentage of HBV-ALF reflects the underlying prevalence of HBV in a particular population. In general, HBV-ALF is relatively more common in Asian and eastern European countries and is seen less frequently in the west. Superinfection with HDV must also be considered as a risk factor for ALF in the setting of chronic HBV.

The diagnosis of acute HBV in the setting of ALF is confirmed by the presence of serum immunoglobulin M (IgM) antibodies to the HBV core (anti-HBc) antigen. The hepatitis B surface antigen (HBsAg) may be absent in as many as 55% of cases of HBV-ALF. There have also been reports of HBV-ALF in the absence of all serologic markers, but this has not been confirmed in other series [29,30]. HBV-ALF may also occur in the setting of immunosuppression or chemotherapy whose withdrawal leads to viral reactivation [31–33].

ALF following acute HBV infection is related to a massive immunologic attack on the HBV-infected hepatocytes. This same exaggerated immune response may also be responsible for the ALF seen in chronically HBV-infected patients following the abrupt withdrawal of corticosteroids or chemotherapy. HBV-ALF patients who have more rapid viral clearance carry a more favorable outcome compared with patients who remain HBsAg-positive (mortality 53% versus 83%, respectively) [19]. In addition, those who clear virus also have a better outcome following liver transplantation.

Hepatitis C virus

It is generally believed that isolated acute HCV infection rarely, if ever, leads to ALF. Evidence of HCV infection in the setting of ALF is either not seen, or infrequently found [29,34,35]. HCV has been reported, however, as a coinfection or superinfection in cases of HBV-ALF [22,29]. It is of note that studies from Japan and Taiwan have shown that up to half of patients with non-A, non-B ALF have evidence of HCV infection [36]. There is also a single center report from the United States that reported detection of HCV-RNA in 60% of non-A, non-B ALF patients [37]. However, the causal role of HCV in this setting has not been established.

Hepatitis D virus

Hepatitis D virus (formerly delta virus), a defective viral particle, requires the presence of HBV for its replication. HDV is relatively uncommon in the west, is seen predominantly among injection drug users, and is associated with <5% of all cases of acute HBV infection in the United States [38]. It is endemic in the Mediterranean, however, including southern Italy and parts of Africa. In patients with HBV-ALF, HDV is seen in up to 40% [38,39]. HBV-HDV-ALF is also more severe than HBV-ALF alone, with a higher mortality [38].

Hepatitis E virus

Acute hepatitis E virus (HEV) infection presents with clinical features similar to those seen with acute HAV infection [40]. HEV-ALF is uncommon in western countries [29,34,35]. However, it accounts for sporadic and major epidemics of viral hepatitis in underdeveloped nations (e.g., India, Pakistan, Mexico, Central Asia, Southeast Asia, Russia, North Africa) and travelers returning from these areas [34]. The presence of anti-HEV IgM antibodies confirms the diagnosis. HEV infection has been reported to have a higher mortality rate among pregnant women, although this finding remains controversial [40,41].

Other viruses

Infection with several other viruses can lead to the development of ALF, including herpes simplex virus (HSV) types 1, 2, and 6, varicella zoster virus (VZV), cytomegalovirus (CMV), Epstein–Barr virus (EBV), parvovirus B19, human herpes virus 6 (HHV-6), Dengue virus, and yellow fever virus [42–45]. These viruses generally cause ALF in the setting of immune compromise or pregnancy, but cases in immunocompetent individuals have also been reported [42,46–49].

Drug- and toxin-induced liver injury

Numerous medications, toxins, and herbal remedies have been associated with liver injury; however the development of ALF is less common. DILI is divided into two broad categories. *Intrinsic (direct) hepatotoxins* predictably and reproducibly cause a dose-dependent hepatocellular necrosis with a brief period between exposure to the drug and development of liver toxicity (latent period). This is consistent from person to person and among animal models. In most cases, it is the compound itself, or one of its metabolites, that leads to the liver injury. *Idiosyncratic hepatotoxicity* is unpredictable. There is no constant relationship between the dose and the occurrence or severity of hepatotoxicity. The latent period is variable and unpredictable, and animal models are not

consistently helpful. Idiosyncratic reactions present as either immune-mediated hypersensitivity or metabolic injury. While these reactions often occur within several weeks following initiation of the drug, they can occur after months to years of drug exposure or even after the drug has been discontinued.

Hepatotoxicity is the most common reason that medications and herbal products are removed from the market place (e.g., bromfenac, troglitazone), and many products have been associated with ALF [50–52]. DILI is the most frequent cause of ALF in the United States (>50% of cases) [1]. Acetaminophen is the most common offender (45–50% of all ALF cases) followed by idiosyncratic liver injury from other drugs and herbal products (11–15%) [1,14]. Those patients who develop ALF secondary to idiosyncratic drug toxicity carry a worse prognosis (25% survival) and a higher rate of liver transplantation (53%) than with many other causes of ALF [1].

Acetaminophen

Acetaminophen (*N*-acetyl-*p*-aminophenol or APAP), a mild non-narcotic analgesic and antipyretic agent, is widely used as a pain reliever and/or fever reducer. APAP was first introduced for prescription use in 1955, and subsequently approved by the US Food and Drug Administration (FDA) in 1960. APAP has been generally considered safe and effective when consumed as recommended (1–4 g/day). Its use has achieved great popularity, and it is available in hundreds of single ingredient and combination over-the-counter (OTC) products with over 1 billion tablets sold annually in the United States.

At supratherapeutic doses (generally >7–10 g/day), it is well documented that APAP causes severe or even fatal liver injury secondary to massive hepatic necrosis [14,53]. Hepatotoxicity has also been reported in patients taking therapeutic doses under certain conditions, such as chronic alcohol consumption or malnutrition [14,54–59]. It has recently been shown, however, that even normal individuals taking therapeutic doses of APAP can develop transient asymptomatic aminotransferase elevations [60,61]. This suggests that even at therapeutic dosing there may be some hepatotoxicity.

Metabolism

Following ingestion at therapeutic doses, about 2% of APAP is excreted in the urine unchanged [62,63]. Over 90% is metabolized via conjugation – two thirds via glucuronidation (urine diphosphate (UDP) glucuronosyltransferases) and one third through sulfation (sulfotransferases) [63]. The inactive nontoxic conjugates are largely excreted in the urine and bile. The remaining 5–9% undergoes oxidative conversion via several cytochromes (CYP1A2, CYP2A6, CYP2E1, CYP3A4) to the highly toxic metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI) [57, 63–65]. Cytochrome P450 2E1 (CYP2E1) conversion predominates, with minor contributions from CYP1A2, CYP2A6, and CYP3A4 [63]. NAPQI is a highly reactive two-electron species that can act as an electrophile or an oxidant. Normally, it is rapidly metabolized by conjugation to intracellular glutathione (GSH) forming a nontoxic APAP-GSH conjugate (3-(glutathione-*S*-yl)-APAP) [62,66]. Subsequent processing leads to its urinary excretion as mercapturic acid and cysteine conjugates [62,66]. APAP is also oxidized by myeloperoxidase and the peroxidase function of cyclooxygenase 1 (COX-1), the clinical significance of which is unknown.

Hepatotoxicity

Acetaminophen is an established dose-dependent hepatotoxin. Therapeutic doses of APAP result in small quantities of NAPQI that are easily detoxified by GSH. Excessive doses of APAP lead to the saturation of the glucuronic acid and/or sulfate pathways, shunting more APAP into the CYP system. Toxic doses are generally greater than 7–10 g/day in adults or 150 mg/kg in children, but there are reports of toxicity occurring with doses less than this [14,54,67,68]. Excessive CYP activation secondary to other medications or herbs may further drive APAP into the oxidative pathway, leading to increased free radical formation with the possibility of hepatocellular injury [69, 70]. Depletion of GSH stores via overdose, malnutrition, or alcohol ingestion results in the inability of the liver to detoxify many reactive metabolites and may increase the risk of APAP hepatotoxicity [57,59,71]. The importance of these latter mechanisms remains controversial [69,70,72].

The precise mechanism of hepatocyte death remains speculative. Glutathione stores within the liver are limited and may be depleted in an attempt to detoxify the increased NAPQI levels. When GSH stores are reduced by 70–80%, the detoxification capacity of the liver is exceeded and NAPQI accumulates, interacting with and destroying hepatocytes and other cells [62,73,74]. In the absence of GSH, covalent binding of NAPQI to the cysteine groups on hepatocyte macromolecules occurs, forming NAPQI–cysteine adducts [75–77]. This is the initial and irreversible step in the development of cell injury [62,78]. GSH depletion further contributes to cellular oxidant stress [79]. With NAPQI binding to critical cellular targets such as mitochondrial proteins, mitochondrial dysfunction and loss of cellular adenosine triphosphate (ATP) occurs [80,81]. Hepatocytes subsequently experience overall energy failure (cellular exhaustion). The ultimate result is alteration in calcium homeostasis, mitochondrial dysfunction with ATP depletion, DNA damage, and intracellular protein modification, leading to necrotic cell death [62,82].

Rodents models, however, suggest that the covalent binding of NAPQI to hepatic proteins in isolation does not cause hepatotoxicity. There is a growing body of evidence suggesting that inflammatory mediators (i.e., interferon γ (IFN-γ)) trigger the innate immune system, leading to an influx of natural killer/natural killer T cells, neutrophils, Kupffer cells, and macrophages that participate in the development and propagation of hepatocyte injury [83–86]. It has therefore been proposed that acetaminophen toxicity occurs in two phases: a metabolic phase and an oxidative phase.

Epidemiology

Acetaminophen hepatotoxicity usually is the direct result of acute deliberate self-poisoning (suicidal poisoning), accidental pediatric exposure, and repeated supratherapeutic ingestion (RSTI) [14,53,54,56,87,88]. In the 2006 Annual Report of the American Association of Poison Control Centers' National Poison Data System (NPDS), acetaminophen poisoning was mentioned in over 125,000 reports, of which over half were secondary to RSTI. Patients with RSTI often take combinations of products, generally for pain relief, each of which contains acetaminophen. Repeated supratherapeutic ingestion may lead to "accidental" or unintentional overdose [14,89–91]. Many of these patients are not aware that the products they are consuming may all contain acetaminophen [89–92].

The majority of patients with acetaminophen poisoning will recover without incident if treated early with the antidote *N*-acetylcysteine (NAC). Acute liver failure develops in only a few of these poisonings and death occurs in <1% of total exposures [93]. In the United Kingdom, the majority of cases of APAP overdose leading to ALF are secondary to intentional overdose (75%) with the deliberate intent to cause self-harm. Intentional overdose makes up a significant portion of APAP overdose in other western nations as well [14,87,88]. In the United States, however, unintentional (accidental) overdose makes up only about 50% of cases of APAP-ALF, with the remainder intentional [14,54].

Course of overdose

Acetaminophen-induced ALF follows a predictable course. Patients often have few signs or symptoms within the first 24 hours following an acute overdose (stage 1), but may develop nausea, vomiting, and malaise. Laboratory studies are usually normal during this period, and early symptoms may completely resolve. Clinical and laboratory evidence of hepatotoxicity appears from 24 to 72 hours after ingestion (stage 2). Patients may develop abdominal pain or liver tenderness and elevations in serum aminotransferases (aspartate aminotransferase (AST), alanine aminotransferase (ALT)), prothrombin time, and bilirubin. During stage 3 (72–96 hours), the most severe abnormalities occur – hepatic encephalopathy, coagulopathy, hyperbilirubinemia (median 4.5 mg/dL), renal dysfunction, and lactic acidosis. Marked aminotransferases elevations (median ~4,100 IU/L) are often seen and this degree of elevation is highly correlated with APAP poisoning [14,56]. During this stage, death most often occurs from cerebral herniation or from multiorgan system failure (MOSF). Once the signs of ALF (i.e., encephalopathy and coagulopathy) have developed, the risks of complications and death increase significantly, with overall mortality approaching 30% [1,14]. Patients who survive stage 3 enter the recovery phase, which is generally complete by 7–14 days after overdose. Hepatic recovery is generally complete, without development of chronic liver dysfunction. There appear to be no differences in presentation between intentional and unintentional overdose once the syndrome of ALF develops [14]. Acetaminophen-induced ALF has one of the best spontaneous survival rates (68%) and lowest rates of liver transplantation (6%) [14,54].

Mushroom poisoning

Amanita phalloides, responsible for the majority of mushroom poisoning deaths, is seen in areas where the mushroom is prevalent [94–99]. Two toxins are produced – phallotoxin and α-amanintin – and both are heat stable and not destroyed by cooking [95,100]. The phallotoxin causes damage to the enterocyte cell membrane [94]. The α-amanintin toxin (amatoxin) is dose dependent and responsible for hepatic injury by disrupting hepatocyte messenger RNA synthesis [94,95,100]. It is lethal at doses of as little as 0.1–0.3 mg/kg (50 g or two to three middle-sized mushrooms) [99].

Course of poisoning

Following ingestion, a 6–12-hour asymptomatic phase evolves into three clinical phases. The gastrointestinal phase (phase 1; 12–24 hours), consists of diarrhea, vomiting, and abdominal pain. During the hepatotoxic phase (phase 2: 24–48 hours) signs of liver damage occur and the disease may progress to the third clinical phase (4–7 days), during which ALF, hepatorenal syndrome, hemorrhage, convulsions, coma, and death occur [98]. Mortality approaches 10–30% [94,98,101,102].

Other direct hepatotoxins

Medications and chemicals that carry direct hepatotoxicity generally are recognized quickly and removed from use (i.e., carbon tetrachloride, chloroform, and tannic acid) [103]. Certain direct hepatotoxins have been allowed to remain in clinical use because their toxicity is well known and generally occurs only at high doses. Examples include APAP, iron sulfate, intravenous tetracycline,

and phosphorus. Environmental toxins may also lead to ALF, including *Bacillus cereus* toxin, aflatoxin, cyanobacterial toxins, and yellow phosphorus (used in rat poison and fireworks) [104,105].

Idiosyncratic hepatotoxins

Overall, reactions to individual drugs are rare, occurring in 1 : 1,000 to 1 : 100,000 patients who receive a given medication. However, idiosyncratic drug reactions account for up to 20% of ALF cases, depending upon the geographic location [13,19].

Idiosyncratic hepatotoxins are believed to cause injury to susceptible individuals at least in part through the formation of neoantigens (i.e., drug–protein adducts), which either act as direct immunologic targets or they themselves directly interrupt normal cellular function. Neoantigens that interact with the immune system may lead to a *hypersensitivity (immune-mediated)* type of liver injury. These reactions are often accompanied by clinical and histologic evidence of hypersensitivity (i.e., rash, fever, eosinophilic leukocytosis, eosinophilic or granulomatous hepatic inflammation with hepatocyte necrosis and cholestasis) [103]. This type of liver injury is seen with medications such as phenytoin, amoxicillin-clavulanate, erythromycin, sulfonamides, halothane, dapsone, diclofenac, carbamazepine, and sulindac [106]. *Metabolic* idiosyncratic reactions show no hypersensitivity and are likely due to aberrant drug metabolism in susceptible individuals, who probably produce toxic metabolites to a greater degree than others. These reactions can occur at any time during the course of drug ingestion and can even occur up to several weeks after drug discontinuation. Examples include isoniazid, ketoconazole, disulfiram, valproate, troglitazone, and amiodarone [107].

The use of herbal and natural medications has increased significantly over the last few decades. These products are often considered safe simply because they are "natural." Many products have been associated with severe liver injury and acute liver failure, including chaparral, germander, comfrey, pennyroyal oil, Jin Bu Huan, Chinese herbs, black cohosh, kava kava, and the weight loss product Herbalife® [50,108–116]. Recreational drugs have also been reported to cause severe hepatic injury, particularly ecstasy (3,4,-methyledioxymetamphetamine) and cocaine (benzoylmethylecgonine) [117–119].

Indeterminate causes

Indeterminate causes account for up to 20% of ALF cases depending upon the country [13,19]. Despite significant advances in diagnostic techniques, an etiology for the ALF cannot be found.

Other causes

Pregnancy-associated acute liver failure

Acute fatty liver of pregnancy (AFLP) and the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) are believed to represent a spectrum of the same disease process. ALF generally presents during the third trimester, but may rarely occur slightly earlier or shortly postpartum [120]. The incidence of AFLP ranges from one case per 7,000 to 20,000 deliveries, with no ethnic or geographic variation. Most women are young (16–39 years) primagravidas and hallmarks of preeclampsia (hypertension, proteinuria) may be present. The frequency of HELLP syndrome is about 1–2 per 1,000 pregnancies and it occurs in about 20% of women with severe preeclampsia. Ethnic variations exist, the risk being significantly higher in Caucasian and Chinese populations (relative risk of 2.2) when compared with East Indian populations. Risk is also higher in African-Americans when compared with Caucasians. The average maternal age of onset is about 25 years (14–40 years) with primagravidas constituting from 52% to 81%.

Fetal deficiencies in long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) have been identified, but are more commonly seen in the setting of AFLP [121,122]. The deficiencies in LCHAD may lead to poor processing of triglycerides and free fatty acids, which leads to the accumulation of medium- and long-chain fatty acids in the mother and deposition within the maternal hepatocytes. In addition, these patients develop increased vascular tone and platelet aggregation [123].

Patients with AFLP present with malaise, fatigue, anorexia, headache, right upper quadrant pain, nausea, vomiting, and occasionally pruritus. As the disease progresses, jaundice develops in nearly all patients. Within 1–2 weeks of symptom onset, and within days after the development of jaundice, patients may develop signs of ALF. Approximately 50% of cases will show evidence of preeclampsia (hypertension, proteinuria). Serum aminotransferases up to 1,000 IU/L and hyperbilirubinemia averaging 15 mg/dL are seen; however, bilirubin levels up to 30-40 mg/dL have been reported. Most HELLP syndrome patients will also present with abdominal pain, nausea, vomiting, and malaise; signs of preeclampsia are present in about 85% of cases. Serum aminotransferases and lactate dehydrogenase are usually less than 500 IU/L.

Clinical findings and laboratory studies suggest the diagnosis of AFLP or HELLP syndrome, and liver biopsy (the gold standard) is rarely needed. Histologically, the centrilobular and midzonal hepatocytes in AFLP are swollen with microvesicular fat globules. There may be sinusoidal compression but signs of hepatic necrosis and inflammation are often subtle. In the setting of the HELLP syndrome, there is often massive hepatic necrosis,

marked steatosis, and necrotic vessels with intravascular thrombi.

Autoimmune hepatitis

Autoimmune hepatitis (AIH), most commonly viewed as a chronic illness, can present acutely in about a quarter of patients – some presenting with ALF [124–126]. AIH-ALF generally occurs in patients with unrecognized preexisting disease, and AIH represents the cause in about 5–6% of all US cases of ALF [1,13]. The presentation is identical to other causes of ALF, and there are no classic signs to suggest AIH as the etiology [127]. Exclusion of all other causes must be undertaken. Serum autoimmune antibodies may be absent, and in this situation liver biopsy may be helpful in establishing the diagnosis [125].

Wilson disease

Wilson disease is an autosomal recessive disorder of copper metabolism, with a prevalence of about 1 : 30,000 and a carrier frequency of about 1 : 90 [128]. The gene, located on chromosome 13q14.3, encodes a copper-transporting P-type ATPase (*ATP7B*) whose role is that of biliary copper excretion, and it is therefore expressed predominantly within the liver. Mutations lead to decreased hepatic copper excretion and its subsequent accumulation, particularly within the liver, brain, kidneys, and cornea. Most patients with Wilson disease or Wilson disease-induced ALF (WD-ALF) will present between the first and fourth decades, although both younger and older presentations have been reported.

WD-ALF accounts for <5% of all ALF cases [1]. It is usually seen in the setting of previously undiagnosed Wilson disease-induced cirrhosis, is clinically similar to all other cases of ALF, and is therefore considered classic ALF despite the presence of preexisting liver disease. The diagnosis of WD-ALF is crucial because it carries a nearly 100% mortality without liver transplantation [13,129]. In chronic Wilson disease, the diagnosis is based upon a low serum ceruloplasmin, the presence of Kayser–Fleischer rings, elevated hepatic copper, and increased urinary copper excretion. Diagnosis in the setting of ALF is more difficult, however, because these usual diagnostic studies lack sensitivity and specificity. Kayser–Fleischer rings are absent in up to 50%. Measures of copper metabolism are also of limited value since elevated urinary copper and alterations in serum copper can be seen in ALF due to other causes [130]. Serum ceruloplasmin is normal in up to 15% of WD-ALF cases, and low ceruloplasmin levels can be seen in ALF from other causes. However, WD-ALF is often accompanied by a Coombs-negative hemolytic anemia, severe hyperbilirubinemia, moderate elevations in aminotransferases (<500 IU/L), and high serum and urinary copper concentration [129]. WD-ALF should be strongly considered in the setting of a normal to low serum alkaline phosphatase level, an alkaline phosphatase to total bilirubin ratio of <2.0, or an AST to ALT ratio of >2.0–3.0 [130–134].

Cardiovascular diseases

Hepatic hypoxia, due to decreased hepatic blood flow, can lead to acute hepatic necrosis and at times ALF [13]. The most common form of hypoxic liver injury is hypoxic hepatopathy ("shock liver") seen after episodes of systemic hypotension or a low blood flow state [135,136]. Clinically, serum aminotransferases rapidly increase, sometimes to over 10,000 IU/L, followed by rapid resolution. Shock liver may be accompanied by mild coagulopathy and occurs in about 1% of critically ill patients [135]. The prognosis depends upon the patient's underlying disease state, and shock liver per se is rarely fatal. Severe vascular obstruction is more likely to lead to ALF and death. These conditions include Budd–Chiari syndrome, sinusoidal obstruction syndrome (venoocclusive disease) due to medications or herbs, and malignancies involving the liver (i.e., lymphoma) [137–142].

Pathogenesis

When parenchymal damage is so severe that the liver is no longer able to meet the metabolic demands of the body, the syndrome of ALF develops [143]. Unfortunately, significant hepatic damage has already occurred by the time the patient presents to medical care. Histologically, the most common picture is one of confluent necrosis with cellular dropout and parenchymal collapse, which may be either zonal or nonzonal in distribution (Fig. 19.1). Following the inciting event (i.e., toxin, viral,

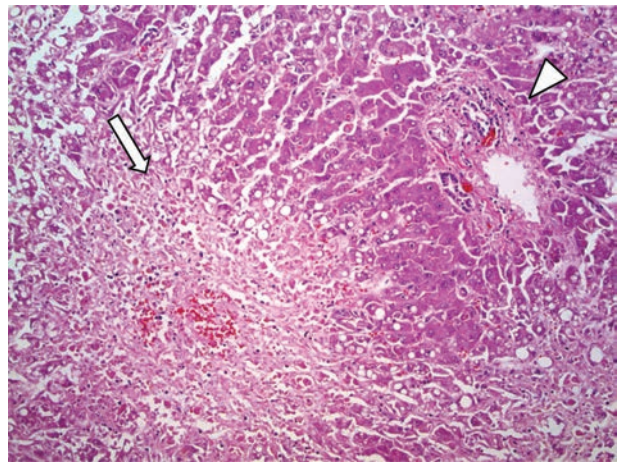

Figure 19.1 Hepatocellular injury secondary to acetaminophen hepatoxicity. The portal tract (arrowhead) shows very little injury and inflammation. There is marked centrilobular (zonal) necrosis, cellular loss, and parenchymal collapse (arrow). Original ×10. (Courtesy of Dr William M. Lee.)

ischemia), further injury may result from the activation of nonparenchymal cells within the liver and the release of cytokines. Other patterns of injury that may be seen in ALF include microvesicular steatosis (i.e., fatty liver of pregnancy, mitochondrial toxins, certain drugs) or malignant infiltration.

Depending upon the cause, one sees predominantly apoptosis (i.e., acetaminophen), necrosis (Wilson disease), or a combination of both [15,144,145]. Apoptosis is associated with nuclear shrinkage (pyknosis), followed by nuclear fragmentation, cytoplasmic shrinkage, and cell death. The cellular membrane is generally undisturbed, therefore minimal secondary inflammation is noted [143]. Apoptosis may be triggered either by the activation of hepatocyte receptors (extrinsic) or secondary to oxidative stress involving the mitochondria (intrinsic) [144]. Both the Fas ligand (FasL)/Fas receptor and tumor necrosis factor α (TNF-α)/TNF type I receptor apoptotic pathways have been implicated. Receptor activation triggers caspase cascades (cysteine proteases) leading to apoptosis and cellular death. The particular caspases activated depend upon the type of stimulus involved. Hepatocellular necrosis, on the other hand, is associated with the depletion of cellular ATP. This stress ultimately causes cellular swelling, cell lysis, and subsequent release of intracellular content resulting in secondary inflammation and further hepatocellular injury [5,144]. Cellular injury resulting in apoptosis may also precipitate necrosis if the mitochondria are severely damaged and ATP stores are sufficiently depleted [15,143]. Marked oxidative stress may also cause inhibition of the proapoptotic caspase cascade [15,144]. This may then result in progression from apoptotic cell death to necrosis [15,143,144]. Further products that mediate cellular death include antioxidants (i.e., glutathione), cellular nitric oxide, tyrosine kinases, transcription factors, pro- and anti-inflammatory cytokines, and chemokines [143].

The clinical result of this catastrophic injury is characterized by coagulopathy and hepatic encephalopathy, and is often associated with cerebral edema, hemodynamic changes, electrolyte disturbance, and renal failure. The exact relationship between hepatic injury and the syndrome of ALF is multifaceted, and our knowledge of the pathophysiology is limited by the lack of an adequate animal model of the disease.

Diagnosis

The early clinical features of ALF are nonspecific, including abdominal pain, fatigue, anorexia, malaise, and fever. This nonspecific phase often leads to significant delays in identification of the syndrome and the initiation of treatment. A high index of suspicion and recognition of the features characterizing the syndrome are crucial to a timely diagnosis. The presentation of ALF is similar regardless of the cause. Its hallmark is an altered mental status (hepatic encephalopathy) accompanied by jaundice and elevated serum aminotransferases and prothrombin time/INR in previously healthy individuals. The presence of moderate to severe hepatitis demands a careful mental status evaluation and measurement of the prothrombin time/INR. Family members and friends should be queried as to the presence of altered personality or mentation.

A careful history and physical examination will help establish ALF and suggest potential causes. Quickly identifying the specific etiology is vital to guide further management decisions, as several causes have specific treatments which may improve survival. One must pay particular attention to possible exposures (viral infections, drugs, or toxins). The details of dose ingested, amount and timing of last dose, duration of medication/herbal usage, and ingredients of nonprescription medications can be invaluable. An accurate history may be difficult or impossible to obtain from the encephalopathic patient; therefore family members or friends may be helpful in this setting.

A complete physical examination is a necessity, and mental status should be thoroughly and frequently assessed. A history of cirrhosis or the presence of its stigmata (i.e., spider angiomas, palmar erythema, or splenomegaly) suggests underlying chronic liver disease, which has a different course and prognosis. Abdominal tenderness may or may not be localized to the right upper quadrant. In the setting of infiltrative disease or hepatic outflow obstruction, hepatomegaly may be present. However, if there has been significant hepatocyte loss, the liver will not be palpable or percussable, which is an ominous prognostic sign. Jaundice may be absent until later in the course, particularly in the setting of microvesicular fatty injury. The initial laboratory evaluation should be extensive (Table 19.2) [146]. Markedly abnormal liver chemistries are usually seen on presentation, but may be normal early in the course of acetaminophen overdose. The arterial ammonia level may have prognostic implications, and an arterial blood gas and blood lactate can also help establish disease severity. Patients who present with a pH <7.3 often have a poor outcome, particularly in acetaminophen overdose, and immediate transfer to a transplant center should be considered [147].

The use of diagnostic liver biopsy remains controversial. Biopsy may be indicated if metastatic disease, lymphoma, or other infiltrative process is suspected. The presence of severe coagulopathy makes percutaneous biopsy impossible; therefore, tissue must be obtained via the transjugular route. It is rare, however, that a liver

Table 19.2 Laboratory evaluation in acute liver failure [146].

Test	Included tests
Serum chemistries	Sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphate, glucose, blood urea nitrogen, creatinine
Hepatic panel	AST, ALT, alkaline phosphatase, total bilirubin, albumin
Prothrombin time/INR	
Complete blood count	White blood cells, hemoglobin, hematocrit, platelets
Arterial blood gas	
Blood lactate level	
Acetaminophen level	
Toxicology screen	
Viral hepatitis serologies	Anti-HAV IgM, hepatitis B surface antigen, anti-HBc IgM, anti-HCV[a], anti-HEV (as indicated)
Autoimmune markers	Antinuclear antibody, antismooth muscle antibody, immunoglobulin G levels
Pregnancy test	
Ceruloplasmin level	If Wilson disease is suspected

[a] To identify underlying infection.
ALT, alanine aminotransferase; AST, aspartate aminotransferase; HAV, hepatitis A virus; HBc, hepatitis B core; HCV, hepatitis C virus; HEV, hepatitis E virus; IgM, immunoglobulin M; INR, international normalized ratio.

biopsy will help elucidate a diagnosis and the histologic findings do not generally alter the treatment course.

Clinical course and management

Patients suspected of having ALF should be swiftly evaluated for etiology and severity of liver injury. When the loss of hepatocyte mass becomes severe enough, hepatic function falls below a critical threshold. At this stage, multiorgan system failure is the rule, and death results from one of numerous complications [2,148]. The leading causes of death in ALF are cerebral edema with herniation and infection/sepsis [1,10,149].

Supportive measures

Immediate hospitalization is required for those with altered mental status and/or evidence of coagulopathy (prothrombin time prolonged by ≥4–6 seconds; INR ≥1.5), who by definition have ALF. ALF can progress rapidly from presentation to death, with patients worsening by the hour. Early transfer or direct admission to the intensive care unit (ICU) for more intense monitoring is essential. Transfer to a transplant center, if appropriate, should be initiated early in the course, as specialized centers with experience in managing ALF will optimize care. Strong consideration should be given to moving the patient to a specialized unit if the INR exceeds 2.0 or the patient develops grade 2 or higher encephalopathy [150]. The development of complications requires immediate and aggressive treatment. Management is complicated and requires a multidisciplinary approach, including transplant hepatologists, transplant surgeons, intensive care physicians and nurses, nephrologists, and neurosurgeons. This group will make an urgent assessment as to the need and suitability for liver transplantation and coordinate the complicated medical care necessary to ensure the best patient outcome.

Hepatic encephalopathy and cerebral edema

Hepatic encephalopathy (HE) is a reversible neuropsychiatric syndrome of metabolic disturbance and depressed consciousness that develops following liver failure. Symptoms range from subclinical alterations to deep coma. The complete pathophysiology of HE remains poorly understood and is likely multifactorial. Accumulation of toxins in ALF, particularly ammonia, in the cerebrospinal fluid (CSF) has been postulated as the predominant mechanism of HE [151–154]. Serum accumulation of ammonia is further exacerbated by renal failure and impaired skeletal muscle function [155]. In addition, the disturbance of central pathways (i.e., glutamatergic, serotonergic, noradrenegeric), activation of γ-aminobutyric acid (GABA) receptors, production of false neurotransmitters, and altered cerebral energy metabolism likely contribute [154]. Disruption of the blood–brain barrier allows toxins to more freely enter the CSF [151,155]. There is also loss of cerebral autoregulation, such that the brain is more susceptible to changes in peripheral blood pressure, which compromises cerebral perfusion [151]. The development of the systemic inflammatory response syndrome (SIRS) is associated with progression of HE in ALF, as the weakened blood–brain barrier allows an influx of inflammatory cytokines [156,157].

ALF-induced hepatic encephalopathy is differentiated from that of cirrhosis by the development of elevated intracranial pressure (ICP) and cerebral edema. Hyperammonemia is considered a critical factor in the development of cerebral edema and herniation [158]. Cerebral detoxification of ammonia occurs predominantly within the astrocytes, which convert the ammonia to glutamine [159]. Ammonia-induced inhibition of α-ketoglutarate dehydrogenase leads to lactate accumulation, decreased tricarboxylic acid (Krebs) cycle activity, less efficient production of phosphate compounds (e.g., ATP), and

ultimate swelling of the astrocytes [154,160,161]. Free radical formation within the astrocyte mitochondria further mediates cellular dysfunction [155,159]. Increasing evidence suggests that oxidative and nitrosative stress plays a significant role in the development of cerebral edema, although the precise cause is unclear [162]. There is a positive correlation between increases in brain ammonia and increased expression of heme oxygenase 1 (HO-1) and nitric oxide synthase (NOS) isoforms [162]. Both arterial ammonia and the partial pressure of ammonia (pNH_3) are independent predictors of intracranial hypertension. The pNH_3 correlates more closely with the clinical grade of HE than does the arterial ammonia [163]. In addition, the severity of multiorgan failure is also an independent predictor of intracranial hypertension in this setting [163].

Outcome worsens with increasing grades of HE – cerebral edema occurring in about 80% of patients who develop grade 4 HE [158,164]. The resultant increased intracranial hypertension compromises cerebral perfusion pressure (CPP), leading to ischemic brain damage or brainstem herniation, which accounts for up half of ALF mortality. Electroencephalographic monitoring shows slowing of cortical activity in some patients with advanced encephalopathy, and ALF patients may undergo subclinical epileptiform activity due to excessive central nervous system glutamate [165]. Survivors may suffer from long-term neurologic deficits.

Treatment of HE in the setting of cirrhosis involves decreasing the production and absorption of these toxins. However, in the setting of ALF, these measures are less effective. Lactulose, a nonabsorbable disaccharide, has never been shown to improve overall survival in ALF [166]. It may help prolong survival, however, and could be used in the setting of grade 1 and 2 HE [148,166]. The risk of aspiration increases as the patient becomes more encephalopathic, therefore oral lactulose should not be used in these patients unless they are intubated [148]. The nonabsorbable antibiotics (i.e., rifaximin, neomycin) have not been tested in this setting.

Simple therapeutic measures that can be performed on all patients to minimize intracranial hypertension include elevation of the head of the bed to 30° and minimizing patient stimulation. Elective mechanical ventilation with sedation and/or paralysis can prevent patient movement and its associated increases in ICP. Acute hyperventilation fails to reduce the number of episodes of cerebral edema, and it does not delay the onset of herniation [167].

The development of an increased ICP is an ominous sign. Physical examination changes occur only after significant cerebral edema has developed; therefore they are generally not helpful in the diagnosis of cerebral edema. Head computed tomography (CT) is insensitive in the early stages of encephalopathy, but is recommended once stage 3–4 HE develops to rule out concurrent pathology such as intracranial hemorrhage [148]. Advanced cerebral edema is associated with hyperventilation, systemic hypertension, pupillary abnormalities, decerebrate posturing, and ultimately uncal herniation and death. Arterial ammonia levels over 200 μg/dL have been strongly correlated with cerebral herniation and death [158]. Sustained ICPs of greater than 20 mmHg and CPPs of less than 50 mmHg for more than 2 hours are associated with irreversible brain injury [168].

ICP monitors may help to both diagnose intracranial hypertension and optimize its management, although their use remains contentious [168–171]. ICP monitors may be of significant value during the transplant operation, when fluctuations in ICP are common [172]. The placement of ICP monitors, however, carries risk in the patient with coagulopathy. Intracranial hemorrhage occurs in up to 10% of cases although fatality is rare. Nonrandomized trials have shown no survival advantage with ICP monitoring, and randomized controlled trials have not been performed [173].

ICP monitoring allows for more rapid recognition of fluctuations in ICP and potentially more rapid treatment [171]. Treatment is aimed at maintaining the CPP at >50 mmHg (the difference between the mean arterial pressure and the ICP), and the ICP at <20 mmHg [148,174,175]. If the CPP falls to <50 mmHg due to systemic hypotension, intravascular volume resuscitation and/or vasopressor support should be initiated. Mannitol (0.5 g/kg body weight) is the established first-line therapy in the setting of a sustained increased ICP (>20 mmHg), although its use may be limited in patients with concomitant renal failure [176,177]. Renal replacement therapy is required in this setting. Repeated mannitol dosing may be necessary. Other potential therapeutic measures proposed include thiopental or phenobarbital coma, phenytoin, and mild to moderate hypothermia (32–35°C) [157,165,169,178–181]. Small studies of hypothermia have shown promising results. Conflicting data exist regarding the use of prophylactic phenytoin [165,182]. Corticosteroids have no role in this setting [177].

Following transplantation, the elevated ICP and cerebral edema may persist for up to a day. It is therefore reasonable to maintain the therapies, including ICP monitoring, which were in place prior to and during the transplant, for at least 24 hours. As the patient awakens, these measures can be discontinued. If there is delayed graft function or primary nonfunction of the graft, these measures should be continued until hepatic recovery or retransplantation.

Hemodynamic abnormalities

Acute liver failure patients develop a hyperdynamic circulatory picture, characterized by splanchnic vasodilatation, low systemic and pulmonary vascular resistance,

elevated cardiac output, increased metabolic rate, and systemic hypotension. These changes are most likely due to circulating endotoxin, cytokines (interleukins 6 and 8), and tumor necrosis factor, and are often exacerbated by the decreased oral intake and dehydration that accompanied the prodromal illness [183]. Abnormal peripheral oxygen transport and utilization frequently leads to lactic acidosis [184]. Clinically, these findings can be difficult to distinguish from sepsis.

The ideal resuscitative strategy in this setting is unknown. In general, hypovolemia should be corrected to achieve an adequate cardiovascular filling pressure [148]. Vasopressors may be required, and are indicated if the mean arterial pressure is consistently <50 mmHg in the setting of normal intravascular volume. Norepinephrine is often the recommended vasopressor, although dopamine may have a more beneficial effect on peripheral oxygen delivery [148]. Overuse of norepinephrine may exacerbate cerebral hyperemia. Small studies evaluating the use of the vasopressin prodrug, terlipressin, have shown conflicting results [185,186]. Corticosteroid insufficiency may contribute to hypotension in this setting, but is much less common than seen in other illness.

Coagulopathy and thrombocytopenia

Intact hepatic function is critical to the synthesis of protein products that are involved in both coagulation and thrombolysis. Multiple factors contribute to the coagulopathy associated with ALF, including decreased hepatic synthesis of both procoagulant and anticoagulant factors and low-grade disseminated intravascular coagulation [187]. Although hemostatic alterations are common in ALF, spontaneous hemorrhage or clinically significant bleeding are very rare (<5–10%) [188,189].

Coagulopathy, as measured by the prothrombin time/INR, develops following decreased hepatic synthesis of factors 2, 5, 7, and 10 [190]. Since this group of factors is vitamin K dependent, concomitant vitamin K deficiency must be excluded. Lack of improvement in the INR after vitamin K replenishment indicates decreased hepatic reserve. The prothrombin time/INR is one of the most sensitive liver function tests available in the setting of ALF and mirrors the prognosis and course of disease [147,191]. The tendency to spontaneously bleed is low despite marked elevations in the prothrombin time/INR, therefore fresh frozen plasma (FFP) should be used only for active bleeding or when needed to perform invasive procedures [192]. Prophylactic administration of FFP is not necessary, may contribute to volume overload, may worsen cerebral edema, and hinders the prognostic evaluation of the patient. Recombinant factor VII may be used with caution under certain conditions, such as prior to an invasive procedure [193,194].

The coagulopathy of ALF is balanced by decreased hepatic production of the procoagulant factors protein C, protein S, and antithrombin III [188,190]. In addition, there appears to be upregulation of factor VIII. Hypofibrinogenemia develops due to decreased hepatic synthesis and increased catabolism and contributes to diffuse mucosal and wound oozing [195]. It can be corrected with the administration of cryoprecipitate – generally if the fibrinogen level is <100 mg/dL and bleeding is evident.

There is also both quantitative and qualitative platelet dysfunction. The platelet count declines progressively over the course of the illness; reaching a nadir of $<100{,}000 \times 10^9$/L in about 70% of ALF cases [187]. However, platelets rarely fall below $25{,}000 \times 10^9$/L or necessitate replacement [196].

Renal failure

Renal failure develops in up to 70% of ALF patients, particularly following acetaminophen overdose [197,198]. The cause is multifactorial, with contributions from direct medication nephrotoxicity (i.e., acetaminophen, nonsteroidal anti-inflammatories), depleted volume status from poor oral intake, hypotension secondary to the disease state itself, sepsis, and/or disseminated intravascular coagulation [197,199]. Hepatorenal syndrome may also contribute in the setting of high levels of renin and decreased renal blood flow [198,200]. The development of hepatorenal syndrome, however, does not appear to correlate with the severity of ALF [199,200]. The presence of SIRS predicts the development of renal dysfunction in nonacetaminophen-induced ALF [201].

Judicious intravenous fluid challenge should be attempted to exclude prerenal azotemia. Renal replacement therapy is often needed, particularly in the setting of acidosis, fluid overload, or cerebral edema requiring mannitol administration. Continuous forms (veno-veno hemodiafiltration) are preferred as they minimize circulatory and cerebral fluctuations in pressure [202].

Infection and sepsis

Distinguishing sepsis from ALF-induced hemodynamic changes can be difficult, given the fact that many infected ALF patients may not develop leukocytosis or fever. Immune system function is impaired, with decreased complement and opsonization and impaired innate immunity. The risk of developing infection is greater in the setting of subacute ALF and increases with increasing time in the ICU [203,204]. The grade of hepatic encephalopathy on admission (grade >2) or a SIRS score >1 are independent predictors of bacteremia (odds ratio 1.6 and 2.7, respectively) [205]. Clinical or culture evidence of bacterial infection is seen in up to 90% of cases. The most common sites of infection are pulmonary (47%), blood (26%), and urine (23%) [16]. Gram-negative

enteric bacteria (i.e., *Escherichia coli*) and staphylococcal or streptococcal species are the organisms usually identified. Bacterial infection is the cause of death in 10–37% of patients. Fungal infections, especially *Candida*, are seen in about 30%, occur later in the course of illness, particularly after the use of antibiotics or in the setting of renal dysfunction, and are often associated with bacterial infection [203]. The presence of infection worsens both HE and cerebral edema [156].

Infection can also trigger SIRS, thought to be the byproduct of multiple inflammatory pathways mediated by chemokine–cytokine responses. In acute liver failure, SIRS is linked to worsening hepatic encephalopathy, renal failure, adult respiratory distress syndrome, sepsis syndrome, and multiorgan system failure [12,156,201]. Prophylactic antibiotics have been shown to decrease the number of infections, but do not change the eventual outcome, and should be reserved for patients with advanced encephalopathy, renal failure, or awaiting transplantation [192]. Periodic surveillance cultures and frequent chest radiographs can help detect bacterial and fungal infections early. Proven infections should be vigorously treated.

Electrolyte and acid–base imbalance

Serum electrolyte abnormalities persist throughout the course of ALF. Decreased free water clearance is associated with renal sodium reabsorption and hyponatremia [206]. Serum and total body deficits of potassium follow. Hypophosphatemia, particularly common after acetaminophen overdose, is likely secondary to renal loss [207–210]. Mixed acid–base disturbances, including respiratory alkalosis and lactic acidosis, are common [184].

Pulmonary dysfunction

Acute lung injury can be seen in up to 40% of ALF patients, and significantly contributes to overall morbidity and mortality [211]. There is increased pulmonary vascular permeability, most likely secondary to endothelial damage, as well as structural alterations in the pulmonary vasculature [212]. Care should be taken with the use of protective ventilator strategies in the treatment of adult respiratory distress syndrome, as this may worsen cerebral edema.

Gastrointestinal bleeding

Acute liver failure patients are at increased risk of developing gastrointestinal bleeding. The use of intravenous antacids reduces both morbidity and mortality, and should be considered standard of care [148].

Hypoglycemia

Hepatic derangements lead to hypoglycemia in up to 45% of ALF patients. High serum levels of insulin are present. In addition, the liver is unable to mobilize glycogen and gluconeogenesis is impaired. Frequent glucose monitoring is required and intravenous dextrose may be necessary to maintain normoglycemia.

Nutrition

Early consideration should be given to complete caloric replacement. ALF patients have significant nutritional and metabolic needs, with energy requirements up to 60% over baseline [213]. Hepatic glucose metabolism (glycogen storage, gluconeogenesis) is disordered, and energy must come from other sources, leading to depletion of muscle and fat stores [214]. In addition, decreased hepatic production of insulin-like growth factor 1 further contributes to protein breakdown [215]. Enteral nutrition is preferred in this setting since this has been shown to maintain gut integrity with decreased rates of bacterial translocation and potential infection [216]. The caloric requirements of ALF patients are as high as 50 kcal/kg/day, with protein needs of over 1 g/kg/day.

Specific therapies

There are several etiologies of ALF that have specific therapies which have been shown to improve outcome in many cases.

Acetaminophen overdose

Diagnosis

Prompt recognition of APAP intoxication is imperative to the management and prevention of hepatocellular injury, liver failure, and death. Identifying patients who have intentionally taken substantial amounts of APAP is often less challenging than identifying those with an unintentional overdose. The history of the amount of APAP ingested in both cases, however, is often unreliable. Patients may be unwilling or unable to admit to the amount or timing of the overdose. The vague or symptom-free latent phase may further confuse the clinical picture. Careful attention must be paid to the type of product ingested, quantity of APAP used, intent of the ingestion (intentional, unintentional), pattern of ingestion (single dose, repeated dosing), and other medications, drugs, herbs, or toxins consumed.

Ideally, plasma APAP levels should be obtained between 4 and 24 hours following ingestion. A negative value does not preclude a significant ingestion and false-positive levels have been seen in patients with hyperbilirubinemia (>10 μg/mL) [217]. NAPQI–cysteine adducts are released into the circulation following hepatic injury and are detectable in both tissue and serum samples using high-pressure liquid chromatography

with electrochemical detection (HPLD-EC) assay [218]. These APAP–cysteine adducts persist for an average of 7 days and decline in parallel with aminotransferase levels [75]. Adducts can be detected even in the setting of negative serum APAP levels. Since measurement of serum NAPQI–cysteine adducts reliably identifies acetaminophen toxicity, they may be a useful diagnostic test for cases lacking historical data or other clinical information [75]. Unfortunately, their measurement is not routinely available in most centers.

There is no correlation between the dose of APAP reportedly ingested and the serum APAP concentration measured [219]. Nor is there a correlation between dose ingested and outcome [220]. The most widely accepted approach to determine the risk of hepatotoxicity following acute single time-point ingestion is to plot the serum APAP concentration on the Rumack-Matthew nomogram [72,93]. Patients whose APAP concentration exceeds the lowest plotted line post-ingestion have a probable risk of hepatotoxicity. Following development of the nomogram, the FDA required that a more conservative measure be used to account for errors in plasma assays and estimated ingestion time [72,93]. This lower "safety" line is 25% lower than the original and patients with levels above this line are considered to be at "possible risk" for hepatotoxicity. This is the nomogram that is most commonly used in the United States [93]. Treatment is recommended if serum levels of APAP exceed this concentration.

The nomogram was developed for single time-point overdoses. It cannot be used to accurately predict risk of hepatotoxicity if patients have taken multiple large doses over time, the precise time of ingestion is unknown, or patients have been taking an extended-release product. There have been attempts to develop treatment algorithms in these settings, but none are used routinely [221,222].

Treatment

Data supporting the use of most poisoning interventions in the setting of APAP overdose are weak. Activated charcoal may be effective if administered within 1–2 hours following an acute ingestion [223]. Hepatotoxicity can be greatly attenuated if the antidote, *N*-acetylcysteine (NAC; Mucomyst® or Acetadote®), can be administered within 24 hours following an acute overdose, regardless of the initial APAP concentration [93,224–228]. Although often given up to 72 hours following overdose, the usefulness of administration of NAC more than 24 hours after an acute overdose has not been consistently shown [226].

NAC is a glutathione precursor and was first used for the treatment of APAP poisoning in 1977. Its mechanism of action is likely three-fold. First, it increases glutathione stores, acts as a glutathione substitute that binds with NAPQI, and enhances sulfate conjugation [62,229–231]. Second, it also has anti-inflammatory and antioxidant effects mediated via cytokines [226,227,232–235]. In addition, it has inotropic, and vasodilating effects that may further benefit the patient [226,227,232,233].

Adverse events following infusion of intravenous NAC range from 0.2% to 21% and include nausea, flushing, rash, pruritus, bronchospasm, rhinorrhea, hemolysis, fevers, chills, angioedema, hypotension, and anaphylaxis [236–238]. Many of these side effects occur when the drug is used endotracheally as a mucolytic [238]. Most of the reactions are mild and resolve with discontinuation of the infusion; however, occasionally, patients will require further treatment (i.e., antihistamine or epinephrine), and rare deaths have been reported [236,237]. Slowing the infusion rate of the initial dose does not decrease drug efficacy or lower the incidence of adverse events.

It is generally recommended that NAC be administered to all patients with ALF secondary to APAP overdose. Evidence has suggested that even late administration of NAC (up to 72 hours) is beneficial to patients who develop APAP-ALF, and progression to stage 3 or 4 encephalopathy is decreased in those ALF patients who receive NAC [226,227,232,233]. Intravenous NAC is preferred because it decreases risk of aspiration, results in higher serum concentrations, and has been shown to be beneficial in this setting [226,239]. The loading dose consists of 150 mg/kg over 60 minutes, followed by 12.5 mg/kg over the next 4 hours, then 6.25 mg/kg/h thereafter. NAC is continued until the serum acetaminophen level is unmeasurable and there is clear evidence of improvement in hepatic function (improving encephalopathy and resolution of coagulopathy (INR <1.5)), liver transplantation, or death [226,227, 232,233]. It should be emphasized that the duration of therapy in this setting is dictated by the clinical outcome, rather than an arbitrary time limit.

Concern has been raised regarding the extended use of NAC in the setting of ALF [227]. Recent animal data have suggested that the prolonged use of NAC impairs liver regenerative capacity [240]. These findings have not been supported by others [241]. Therefore, the appropriate duration of NAC therapy in this setting remains uncertain.

Pregnancy-related acute liver failure

Acute fatty liver of pregnancy and the HELLP syndrome are medical and obstetric emergencies. Patients should be promptly admitted to a liver failure unit, since it is impossible to predict which patients will worsen. Following aggressive maternal care and stabilization, delivery should be attempted as soon as reasonably possible. With early diagnosis and management, the severity of disease and need for liver transplantation can be

minimized. Maternal mortality, historically up to 50%, can be lowered to 15% with early delivery. Fetal death occurs in 42–49% with only minimal improvement with early delivery (36%). Patients will slowly improve following delivery – full recovery often takes up to a month, and there are no hepatic sequelae. HELLP syndrome may be complicated by hepatic infarction or hepatic rupture.

Autoimmune hepatitis

It is well established that the treatment response to corticosteroids is the only predictor of outcome in the setting of chronic AIH. There are no prospective trials outlining the role of corticosteroid or immunosuppressant therapy in the setting of AIH-ALF; therefore, their use in this setting has not been firmly established [125,242,243]. AIH-ALF patients in the ALFSG study who were treated with corticosteroids had a higher rate of spontaneous recovery compared with those who were not treated. In general, AIH-ALF patients who worsen, or whose serum aminotransferases and bilirubin fail to improve within 2 weeks of initiating treatment, carry a 100% mortality without OLT [244].

Wilson disease

d-Penicillamine, trientene, and zinc are often ineffective in the setting of WD-ALF [245,246]. Plasmapheresis may help to bridge the patient to OLT, but itself carries no survival benefit [246,247]. Mortality approaches 100% so listing for transplant should be considered early in the course of disease [130,245].

Mushroom poisoning

Randomized controlled trials of therapy for *Amanita* poisoning do not exist. Severe cases often require transplantation. Silibinin (20–50 mg/kg/day) or penicillin G (250 mg/kg/day) may be effective if administered early following ingestion, although this remains controversial [98,248–252]. Overall mortality following *Amanita* poisoning ranges between 10% and 40% [13].

Hepatitis B virus

The usefulness of antiviral medications in the setting of HBV-ALF remains uncertain. Several small series using foscarnet, lamivudine, or entecavir have suggested benefit with rapid viral suppression. A small randomized trial using lamivudine in 71 patients failed to show any benefit [253]. A more recent randomized trial of 80 patients, however, showed that treatment of HBV-ALF patients with lamivudine therapy was an independent predictor of survival [254]. It is, therefore, probably reasonable to consider antiviral medication in this setting.

Herpes simplex virus

The diagnosis of HSV-induced ALF is often made late in the course of illness because characteristic vesicles are often absent. If HSV is suspected, intravenous aciclovir is both safe and has proven benefit [255]. Unless treatment is initiated early, HSV-induced ALF has a very poor prognosis [43,49].

Nonspecific therapies

Nonspecific therapies that have shown no benefit in the setting of ALF include corticosteroids, heparin, insulin and glucagon, and prostaglandin E1. Other therapies that have been evaluated show promise, but in general prospective randomized trials are lacking.

Drug-induced liver injury

There is currently no standard therapy in the setting of DILI except discontinuation of the offending agent. However, establishing causality in cases of idiosyncratic DILI remains challenging, particularly in the setting of ingestion of multiple products. Numerous medications have been implicated, but some of the more commonly reported offenders include antituberculous drugs, sulfonamides, phenytoin, antibiotics, and herbal and dietary supplements.

N-acetylcysteine for non-acetaminophen acute liver failure

A recent prospective, randomized, double-blind, placebo-controlled trial in the setting of ALF not due to acetaminophen showed a significant improvement in transplant-free survival in patients with early-stage encephalopathy (stage 1–2) who received NAC [256]. There was no difference in overall survival in the entire group (all stages of encephalopathy). Thus, NAC use early in the course of ALF may prevent progression to deeper encephalopathy with its associated complications. It has been suggested that in this setting NAC also exerts renal protective effects and is beneficial to the hemodynamics of multisystem organ failure.

Hypothermia

Mild to moderate hypothermia (33–35°C) has been shown to both delay progression of hepatic encephalopathy and consistently lower intracranial pressures, and thus decrease the likelihood of cerebral edema [157,257,258]. Hypothermia normalizes cerebral blood flow, attenuates increases in brain concentrations of ammonia, and decreases brain extracellular glutamate, as well as reducing brain levels of nitrites/nitrates [162,259]. Nitrite/nitrate reduction leads to a decrease in cellular oxidative/nitrosative stress, and could in part explain the

beneficial effects described when hypothermia is used in the management of ALF [181,257]. However, the clinical benefits of hypothermia remain to be confirmed in large randomized clinical trials, and complications of hypothermia itself remain a concern [259].

Liver assist therapies

The goal of liver assist therapies has been to either support the patient until the native liver has had time to recover, or to bridge the patient to liver transplantation. Liver support therapies can be broadly divided into either artificial or bioartificial. Artificial therapies provide detoxification support without the use of biologic (cellular) material. Bioartificial support systems utilize cellular material and, in theory, provide not only detoxification, but also assume some of the synthetic function of the failing liver.

Artificial liver support

There has to date been no evidence that any artificial therapy reliably reduces mortality in the setting of ALF. Plasmapheresis has been shown to decrease ammonia levels, improve cerebral blood flow, improve cerebral perfusion pressures, improve hepatic encephalopathy, and to improve systemic hemodynamic parameters. However, its benefit on survival remains unproven. The molecular absorbent recirculation system (MARS) was introduced in the 1990s and first used clinically in 1999 (Fig. 19.2) [260]. MARS is a two-circuit system, which allows albumin-bound toxins to be removed. The blood circuit, a high flux dialyzer, passes the patient's blood over an albumin impermeable membrane, allowing the efflux of small- to medium-sized molecular weight molecules. The secondary circuit, a low flux dialysis, comprised of exogenous human albumin dialysate, provides detoxification over adsorbent columns (an anion exchange resin and activated charcoal column) [261]. A meta-analysis of studies using MARS failed to show a significant survival benefit in ALF patients [262]. The Prometheus® albumin dialysis system was introduced clinically in 1999 [263]. This system uses a membrane that is permeable to albumin and albumin-bound proteins; therefore the secondary circuit utilizes the patient's own albumin for detoxification [264]. The system functions similarly to MARS, but appears to carry a greater risk of clotting [264]. There exist even fewer data on the survival benefit of this system.

Bioartificial support

Given the outcome data with artificial support systems, many experts believe the focus of artificial support for ALF should be cell-based. Bioartificial liver support would ideally incorporate human hepatocytes, which would provide both detoxification and synthetic functions of the liver (Fig. 19.3). The use of normal human hepatocytes is limited, however, by both their poor capacity to grow in vitro as well as their decreased biologic function when cultured [265]. Therefore, bioartificial liver support systems have utilized immortalized cell lines (C3A human hepatoblastoma) [266,267]. Using potentially oncogenic cells has raised safety concerns, although there have been no reports of cellular transmission in this setting. Porcine hepatocytes have also been utilized and are more readily available than human hepatocytes. Despite the lack of evidence that these cells may spread zoonotic disease, this concern remains.

Five systems have been tested clinically: HepatAssist® (Arbios, formerly Circe, Waltham, MA), extracorporeal liver support device (ELAD®, Vital Therapies, San Diego, CA), modular extracorporeal liver support system (MELS®, Charité, Berlin, Germany), bioartificial liver support system (BLSS®, Excorp Medical, Minneapolis, MN), and the Amsterdam Medical Center bioartificial liver (AMC-BAL®, AMC, Amsterdam) [268–272]. HepatAssist was the first cell-based liver assist device tested, and in a small randomized trial showed a survival advantage in patients with ALF and subacute liver failure [268]. Despite this, the FDA did not approve the device and

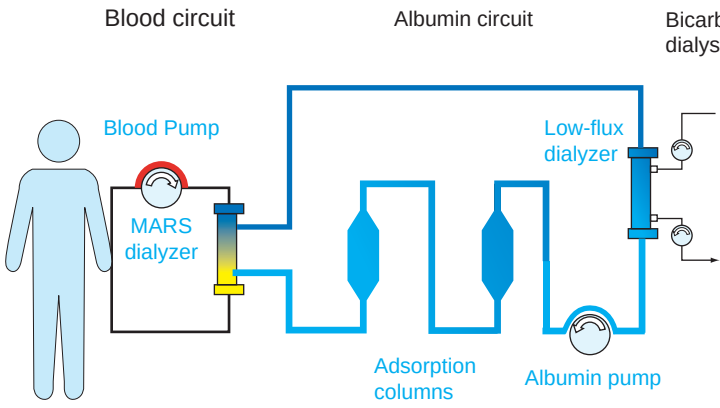

Figure 19.2 Schematic diagram of the molecular adsorbent recirculation system (MARS) circuit. (Reproduced from Mitzner et al. [325] with permission from Wiley-Blackwell.)

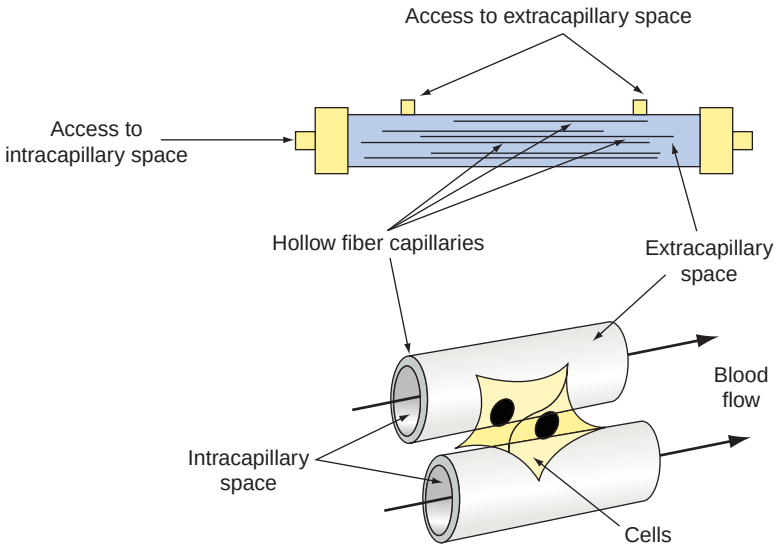

Figure 19.3 Diagram of a hollow fiber cartridge, on which the bioartificial liver (BAL) and extracorporeal liver assist device (ELAD) are based. The close-up view shows cells attached to the external surface of the hollow fibers. (Reproduced from Ellis et al. [326] with permission from Cambridge University Press.)

recommended further testing in patients with ALF. Small series using ELAD in the setting of ALF have suggested benefit, however there have been no large, randomized trials [267,273]. Phase I studies in small numbers of ALF patients have demonstrated safety and efficacy using MELS, BLSS, and AMC-BAL [270–272]. Larger scale data for these devices are lacking.

Liver transplantation

Advances in critical care medicine have improved the spontaneous survival in ALF patients from 10–20% to about 40% [1]. However, orthotopic liver transplantation remains the only treatment modality that improves survival in those who will not recover. With the advent of OLT as a treatment option in this setting, overall survival rates have further improved to ~60%. Thus, liver transplantation has been recommended for the treatment of ALF since the early 1980s. Candidacy for transplantation must be determined quickly, given the rapid pace of the syndrome. Acute liver failure is one of the very few conditions for which a patient can be listed as a United Network for Organ Sharing (UNOS) status 1A (urgent) patient in the United States and "super urgent" in the UK. Although about half of ALF patients undergo liver transplantation, ALF accounts for less than 10% of US transplants and approximately 11% in Europe [274].

Overall, the 1-year survival following OLT for ALF is less (60–80%) than that seen in patients who have been transplanted for chronic liver failure (80–90%) [1,3, 274,275]. The majority of these deaths occur in the first 2–3 months following the transplantation, usually due to neurologic complications or sepsis. However, by 1–4 years following transplantation this trend has reversed, and ALF patients have a better survival than those transplanted for chronic liver disease. Poorer outcomes are seen in centers performing less than 25 liver transplants per year and less than 20 split-liver grafts per year for those doing living donor liver transplantation [276].

In addition to whole-organ deceased donor liver transplantation, various others types of liver transplantation may be utilized depending on the situation: living donor liver transplants (LDLTs), incompatible ABO status transplants, and auxiliary liver transplants. In the setting of organ shortage, the risk of mortality while waiting for an organ must be weighed against the risk of complications or failure using an alternative graft.

Living donor liver transplant

The use of LDLT in this setting remains controversial [277–280]. Between January 1, 1988 and March 31, 2010, LDLTs accounted for approximately 2% of transplants for ALF (based on Organ Procurement and Transplantation Network (OPTN) data as of July 5, 2010). It is important to consider the need for an adequately sized graft for the recipient with sufficient residual mass for the donor. Grafts in excess of 40% of standard liver volume are necessary in the setting of ALF, and outcomes are better with a graft-to-recipient weight ratio greater than 0.8, with 1.0 (whole organ) being ideal [281]. LDLT is associated with potential recipient complications, such as biliary complications (in 15–65%) [282–284]. The graft is at risk of small-for-size syndrome. A graft of less than 40% of standard liver weight is at risk for the development of portal hypertension following reperfusion leading to sinusoidal damage and graft injury [285]. Nevertheless, right lobe LDLT improves survival of patients with acute liver failure, and the 1-year survival rate following LDLT is approximately 75% [280].

Unique ethical issues exist in the setting of LDLT. Given the urgent need for an organ in the setting of ALF, the donor evaluation must be compressed. This carries the risk of an incomplete evaluation and the possibility of donor coercion. The donor and transplant team must consider the fact that LDLT is associated with significant donor complications, including death in 0.2% [282,283]. In regions where cadaveric organs are not as readily available, the risk of the recipient's death while waiting for a cadaveric organ must be weighed against the risk to the living donor.

ABO-incompatible liver transplant

Although ABO identical grafts are preferable, ABO-compatible grafts (e.g., O graft, A recipient) have a comparable 1-year survival following OLT for ALF. Alternatively, ABO-incompatible grafts (e.g., A graft, B recipient) show less favorable outcome (30% 1-year graft survival). A Canadian group reported overall 5-year graft survival rates of 54–60% and 5-year patient survival rates of 61–77%, although the number of study subjects was small [286]. At present, survival of the graft is generally seen in up to 60% of ABO-incompatible transplants, likely related to intensive management (use of quadruple immunosuppression, plasmapheresis, splenectomy, methylprednisolone, or prostaglandin E1). Use of an ABO identical graft is still preferred.

Auxiliary liver transplant

Auxiliary OLT leaves the recipient's liver in place, using a partial left or right lobe from the donor which acts as temporary support for the recipient's injured liver. Ideally, in this setting, immunosuppression may be withdrawn following native liver recovery allowing the graft to atrophy naturally or it is surgically removed [287]. The partial graft is placed below the native liver (heterotopic auxiliary transplantation) or replaces a resected right or left native liver lobe (auxiliary partial liver transplantation). While easier to perform, implantation of the heterotopic graft onto the infrahepatic vena cava may lead to venous outflow obstruction, resulting in slower hepatocyte regeneration, presumably due to cytokine release from residual necrotic liver tissue. There is an increased incidence of primary graft nonfunction and portal vein thrombosis with heterotopic auxiliary transplantation compared with auxiliary partial or whole graft OLT. Unique complications may develop following auxiliary transplantation. Portal blood flow is partially diverted from the native liver to the graft, thus regeneration of the native liver may be impaired and graft function may be impaired. Moreover, due to the smaller mass of the transplanted liver, cerebral edema and neurologic dysfunction may continue to progress [287]. In addition, leaving the necrotic graft in situ following immunosuppression withdrawal may lead to the development of multisystem organ failure, or, over time, cirrhosis in the native liver [288,289].

The best outcomes with auxiliary transplantation are in young patients with hyperacute presentations due to a viral or autoimmune disorder [4,290]. Overall survival rate for auxiliary transplantation is reported to be between 60% and 65%, and immunosuppression has successfully been withdrawn in 65–85% of these patients by 1-year post-transplant [280,287,290,291].

Prognosis and prognostic models

It is critical to quickly and accurately identify those patients most likely to benefit from emergent OLT. To minimize the risk of unnecessarily committing individuals to lifelong immunosuppression, one must balance the desire to delay transplantation to allow for the potential of spontaneous recovery against the risk of death with that delay and the risk of the surgery itself. Of patients listed for transplantation, 37% will recover spontaneously without the need for OLT and it is estimated that as many as 20% of ALF patients may be transplanted needlessly. Once listed, a significant number of ALF patients will progress and die awaiting OLT. In the United Kingdom, ~30% of patients initially considered for OLT ultimately become untransplantable following the development of complications (i.e., cerebral edema, sepsis, hemodynamic abnormalities, multiorgan system failure) [292]. In the US ALFSG, 44% of patients were listed for OLT, yet only 25% of the entire cohort received a transplant. Additionally, many patients have medical or psychosocial contraindications to transplantation, including irreversible brain injury, underlying cardiovascular disease, infection/sepsis, alcohol or drug abuse, poorly controlled psychiatric disease, or inadequate family support [293]. Therefore, it is important to identify and even delist patients who are too ill to benefit from OLT.

It is, therefore, crucial that reliable predictive models of survival and need for liver transplantation be developed. Successfully predicting outcome would allow more judicious use of scarce organs and spare those who will ultimately recover anyway the necessity of transplantation and lifelong immunosuppression. The varying causes of ALF, with wide variability in patient survival, and the unpredictability of subsequent complications makes it very difficult to determine who will survive without OLT. There are at present no standardized criteria to predict who should be listed for OLT with ALF.

Clinical predictors

Clinical predictors of death may help determine which patients are more likely to die; however these are

generally unreliable. The degree of serum aminotransferase elevation and the rate of its recovery do not predict prognosis. In fact, improvement of aminotransferase levels in conjunction with worsening bilirubin, encephalopathy, and coagulopathy (INR) signals complete liver failure and is an ominous sign. The criteria most commonly used to exclude a patient from OLT vary between transplant centers but generally include: age older than 70 years, the presences of certain malignancies outside the liver, severe cardiac, lung, or multiple organ failure, severe infection, uncontrolled septic shock, and brain death.

Etiology

The etiology of ALF is one of the more important predictors of outcome [1]. In the past, mortality from ALF approached 100%. However, with the epidemiologic shift to more benign causes (e.g., acetaminophen), the advent of improved clinical management, and selected utilization of liver transplantation, the overall mortality now ranges between 30% and 40%. The lowest mortality is seen with ALF due to acetaminophen hepatotoxicity (~30%), hepatitis A virus infection (~50%), shock liver, and pregnancy-related ALF [1,14,25]. In contrast, the mortality for the remainder of causes is abysmal (80–100%) [1].

Multiorgan failure

The severity of multiorgan failure at the time of OLT is also a predictor of post-transplant survival. Decreased renal function is associated with worse spontaneous survival in non-APAP-induced liver injury. In a multivariate analysis of UNOS data (1988–2003), four risk factors predicting post-transplant survival were identified: pretransplant use of life support, recipient age >50 years, recipient body mass index $\geq 30\,kg/m^2$, and serum creatinine >2 mg/dL. If an individual had all of these risk factors, the 5-year post-transplant survival was only 44–47%. Whereas, if none of these features were present, the 5-year post-transplant survival was 82–83% [275].

Hepatic encephalopathy

Mortality rates also appear to correlate with the severity of hepatic encephalopathy, with 30% morality for those who reach grade 2 HE, 45–50% for grade 3 HE, and 80–90% for grade 4 HE [20]. Paradoxically, those with more rapid development of hepatic encephalopathy (i.e., acetaminophen induced) appear to have a better outcome compared with those with a longer interval between the development of symptoms and encephalopathy (i.e., DILI) [6,19,147].

Graft quality

The quality of the graft impacts post-transplant outcome [294]. Graft steatosis, reduced graft size, and ABO-incompatible grafts have all been shown in multivariate analyses to lead to decreased patient and graft survival [292,294]. Unfortunately, graft quality must be weighed against transplant urgency, since patients may deteriorate while waiting for optimal grafts, sometimes to the point when they are no longer feasible candidates. Suboptimal grafts may fail, however, leading to the need for retransplantation.

Prognostic models

Multiple prognostic models have been proposed to help determine the likelihood of spontaneous survival [7,147,156,191,295–302]. However, many of these models are methodologically flawed and subject to bias. In addition, many equate liver transplantation with death, which falsely elevates the positive predictive value of these prognostic systems [303,304].

King's College Hospital criteria

The most widely applied prognostic system is that using the King's College Hospital criteria (Kings criteria), developed from a retrospective cohort of nearly 600 patients (Table 19.3) [147,305]. The Kings criteria incorporate both the etiology of ALF and the clinical parameters of disease. When applied to ALF patients in the United Kingdom, these criteria have a positive predictive value for death from APAP-ALF of 84%, and 82% in all other causes, and a negative predictive value of 86% and 82%, respectively [147]. In a meta-analysis of studies using the Kings criteria, the pooled sensitivity and specificity were 69% and

Table 19.3 King's College Hospital criteria for predicting death or need for transplantation in acute liver failure (ALF) [147,305].

Acetaminophen ALF	Non-acetaminophen ALF
Strongly consider OLT listing if arterial lactate >3.5 mmol/L after early fluid resuscitation List for OLT if: pH <7.3 *or* Arterial lactate >3.0 mmol/L after adequate fluid resuscitation List for OLT if all three of the following occur within a 24-hour period: Presence of grade 3 or 4 hepatic encephalopathy INR >6.5 Creatinine >3.4 mg/dL	List for OLT if: INR >6.5 irrespective of degree of hepatic encephalopathy *or any three of the following*: Age <10 or >40 years Jaundice for >7 days before encephalopathy INR >3.5 Bilirubin >17 mg/dL *Or* Unfavorable etiology, such as: Wilson disease Idiosyncratic drug reaction Halothane Seronegative hepatitis

INR, international normalized ratio; OLT, orthotopic liver transplantation.

92%, respectively [304]. However, patients who do not meet these criteria may ultimately still require transplantation. In general, the predictive accuracy of these criteria appear to be less when applied to patients from other regions and countries [40,306–309]. Following the finding that the arterial lactate improved the sensitivity of the model in APAP-ALF, the Kings criteria have been recently refined [19,207,305].

Clichy criteria

The French Clichy criteria were developed in a cohort of patients with acute hepatitis B virus infection [297]. These criteria suggested that a serum factor V level of <20% in patients younger than 30 years or <30% in any patient with grade 3–4 HE has validity as a marker of mortality. The criteria predicted a poor outcome with a sensitivity and specificity of 86% and 76%, respectively [297,298,310]. Factor V level measurements are less readily available than the measures in the Kings criteria, meaning this prognostic model is not commonly utilized [306,310]. In addition, this model has not been validated in the non-HBV population.

Serum α-fetoprotein

Serum α-fetoprotein (AFP) is a marker of hepatocyte turnover, generally considered indicative of hepatocellular regeneration. No correlation is seen between the absolute AFP level and outcome in ALF [311]. However, an increasing AFP level is strongly associated with a favorable outcome [296,311]. In one study, on the day of peak ALT levels, AFP values were significantly higher in survivors than in nonsurvivors [312]. A threshold AFP of ≤3.9 μg/L 24 hours after the peak ALT identified nonsurvivors with a sensitivity of 100%, a specificity of 74%, a positive predictive value of 45%, and a negative predictive value of 100%. A second study showed that a rising level of AFP between day 1 and day 3 frequently indicated survival without transplantation (71%), whereas a decreasing level was seen in 80% of those who succumbed [311].

Gc-globulin

The Gc-globulin (group-specific component) scavenges monomeric actin and, together with gelsolin, constitutes the extracellular actin scavenger system. The level of Gc-globulin is markedly reduced in all forms of tissue injury. This marker has not been shown to reliably predict survival in those with APAP-induced ALF. In non-APAP-ALF, however, using a cutoff value of ≤80 mg/L, the Gc-globulin level carried a positive predictive value of 74% and a negative predictive value of 81% [296].

Arterial ammonia

An elevated arterial ammonia increases the risk of developing intracranial hypertension, and a level of >150 μmol/L predicts the development of intracranial hypertension with a sensitivity of 60% and a specificity of 84% [163]. Concentrations of >100–150 μmol/L have also been correlated with cerebral herniation [151, 152,158,313]. Patients with renal and circulatory insufficiency are at risk of intracranial hypertension at even lower ammonia levels [151].

Other models

The model for end-stage liver disease (MELD) score carries a specificity and sensitivity of <75% in predicting outcome in both APAP-ALF and non-APAP-ALF [151,314,315]. The acute physiology and chronic health evaluation (APACHE) scoring system is also ineffective in predicting who will survive without transplantation, since many patients who do not meet the severity criteria will ultimately die of subsequent complications. A factor V <10% has been shown to predict a poor outcome with a sensitivity of 91% and a specificity of 100%; while a factor VIII : V ratio of >30 similarly predicts outcome (91% sensitivity, 91% specificity) [295]. Persistently elevated phosphate levels may be associated with a poorer prognosis in the setting of acetaminophen-induced ALF [207,208]. A serum phosphate level >1.2 mmol/L on day 2 or 3 following APAP overdose carries a sensitivity of 89% and a specificity of 100% for poor outcome [208,209]. A liver volume of <1,000 mL on CT imaging is also associated with a high mortality rate [302]. Liver biopsy has also been proposed to determine the severity of liver damage, with greater than 70% hepatic necrosis associated with a transplant-free survival of <10% in one analysis [316]. However, there is a great degree of sampling error, and more recently a multivariate analysis of 97 consecutive patients showed that the amount of necrosis was not predictive of mortality [317].

Based upon the available data, the current prognostic scoring systems have not consistently demonstrated reliable accuracy in predicting outcome from ALF and the subsequent need for OLT. Therefore, the American Association for the Study of Liver Diseases does not recommend sole reliance on any one of these systems.

Outcomes

There are unique postoperative issues that plague ALF patients. Despite transplantation, elevated ICP and cerebral edema can persist for up to a day or more. In ALF patients who die post-OLT, as many as 13% succumbed to brain death [275]. Protective strategies, such as

continued ICP monitoring, may be helpful through this period of risk. Although renal function often improves dramatically, patients may require renal replacement therapy for many weeks post-OLT, particularly in the setting of APAP-ALF. This author and others have adopted immunosuppressive strategies that attempt to minimize nephrotoxic agents, such as calcineurin inhibitors, in this critical recovery period. Nearly one third of post-OLT deaths in this setting are from bacterial or fungal infections [275].

Long-term clinical outcomes in ALF patients have not been well described [318,319]. Life-altering complications that may occur include permanent neurologic injury secondary to cerebral edema or persistent or recurrent disease following recovery [318,319]. There exist very few data on long-term neurologic impairment and its consequences. Rapidly recurrent disease in the newly transplanted liver is generally less common. It has been noted in the setting of autoimmune hepatitis, acute HAV, and acute HBV infections [320,321].

Following spontaneous recovery, patients with psychiatric illness who had taken a deliberate APAP overdose are at risk of repeated overdoses [292]. However, risk of repeated overdose appears to be less common in this group if they have been transplanted, perhaps due to the intensity of postoperative care. In two series from the United Kingdom, APAP-ALF patients who underwent OLT showed similar long-term survival (median 5 years and 9 years) compared with patients transplanted for chronic liver disease [322,323]. Less than 5% of those transplanted for APAP overdose reattempted overdose. There was a worse 30-day mortality for the APAP-ALF patients, and a greater probability of post-OLT medical nonadherence and adverse events in those who had taken APAP for deliberate self-harm compared with both non-APAP-ALF patients and chronic liver disease patients [323].

Conclusions

ALF is a rare but rapidly fatal disorder leading to jaundice, coagulopathy, hepatic encephalopathy, and multisystem organ failure. Idiosyncratic drug-induced hepatotoxicity and acetaminophen overdose remain the most common causes identified in the United States. The early recognition of ALF requires a high index of suspicion and thorough evaluation. Despite improvements in care, these patients remain medically challenging and mortality is high. Early intervention is crucial, and involvement of an experienced multidisciplinary team and transfer to a specialty center will maximize survival. Cerebral edema with intracranial hypertension and infections remain the leading causes of death. Liver transplantation remains the treatment of choice in those who are not recovering and its use has markedly improved overall survival. Optimal prognostic survival models are lacking and many patients will ultimately die without transplantation.

Multiple choice questions

19.1 **The use of *N*-acetylcysteine (NAC) in the setting of acute liver failure (ALF) not due to acetaminophen has been shown to improve transplant-free survival if given prior to the development of stage 1–2 hepatic encephalopathy.**

a False.
b True.

19.2 **The most common cause of death in the setting of acute liver failure is which of the following?**

a Fungal infection.
b Cerebral edema and brainstem herniation.
c Electrolyte imbalance.
d Renal failure.

19.3 **The most common cause of ALF worldwide is which of the following?**

a Drug-induced liver injury.
b Viral hepatitis.
c Autoimmune hepatitis.
d Ischemic hepatitis.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

PART IV

Cholestatic Disorders

CHAPTER 20

Primary Sclerosing Cholangitis

Douglas L. Nguyen, Nicholas F. LaRusso, & Konstantinos N. Lazaridis

Center for Basic Research in Digestive Diseases, Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, MN, USA

Key concepts

- Primary sclerosing cholangitis (PSC) is a progressive, cholestatic liver disease that is characterized by diffuse chronic inflammation and fibrosis of the biliary tree.
- PSC affects primarily young to middle-aged men and is frequently associated with inflammatory bowel disease, most often chronic ulcerative colitis.
- The cause of PSC remains unknown, although the interaction between exogenous factors with the genetically predisposed individual is likely critical in disease pathogenesis.
- PSC patients are at increased risk for the development of cholangiocarcinoma and colon cancer.
- Currently, no medical therapy has been of proven benefit.
- Liver transplantation is the best available treatment option for patients with advanced PSC; however, the disease can recur in about 20% of recipients after successful transplantation.

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease of unknown etiology, characterized by diffuse inflammation and fibrosis of the biliary tree, resulting in ductal obliteration, biliary cirrhosis, and hepatic failure. PSC was first described by Delbet in 1924 [1]. Before the widespread availability of endoscopic retrograde cholangiopancreatography (ERCP) in the mid-1970s, PSC was considered a rare disease [2]. It remains unclear whether the prevalence of the disease has truly increased in recent decades or merely that an enhanced frequency of PSC diagnosis has occurred with the greater availability of ERCP and magnetic resonance cholangiopancreatography (MRCP). Though we have a better understanding of the natural course of PSC, the etiology for disease development and an effective medical therapy remain elusive.

Epidemiology

Two epidemiological studies from the United States and United Kingdom described the incidence and prevalence of PSC in the community setting. The first study from Olmsted county, Minnesota, estimated the age-adjusted incidence of PSC to be 0.9 per 100,000 individuals with point prevalence of 13.6 per 100,000 persons in 2000 [3]. Specifically, the age-adjusted incidence was 1.25 and 0.54 per 100,000 men and women, respectively. The estimated prevalence was 20.9 per 100,000 for males and 6.3 per 100,000 females [3]. Based on this study, it was projected that approximately 29,000 cases of PSC exist in the white US population. Moreover, the median age at PSC diagnosis was 40 years; 68% (15/22) of the patients were males and 73% (16/22) of the patients had concurrent IBD [3].

The second study from Swansea, Wales, reported an annual incidence of 0.91 per 100,000 and a point prevalence of 12.7 per 100,000 individuals [4]. The median age at PSC onset was 52 years, 62% (33/53) of the patients were men, and 62% (33/53) of the patients had coexisting IBD [4]. These two studies have shed light on the epidemiology of the disease, but additional population-based studies are required to better define the prevalence and natural history of PSC.

Pathogenesis

Although a number of avenues have been explored in the past three decades, the exact pathogenesis of PSC is unknown. A consensus pathogenesis postulates that PSC develops as the result of acquired exotoxins, infections,

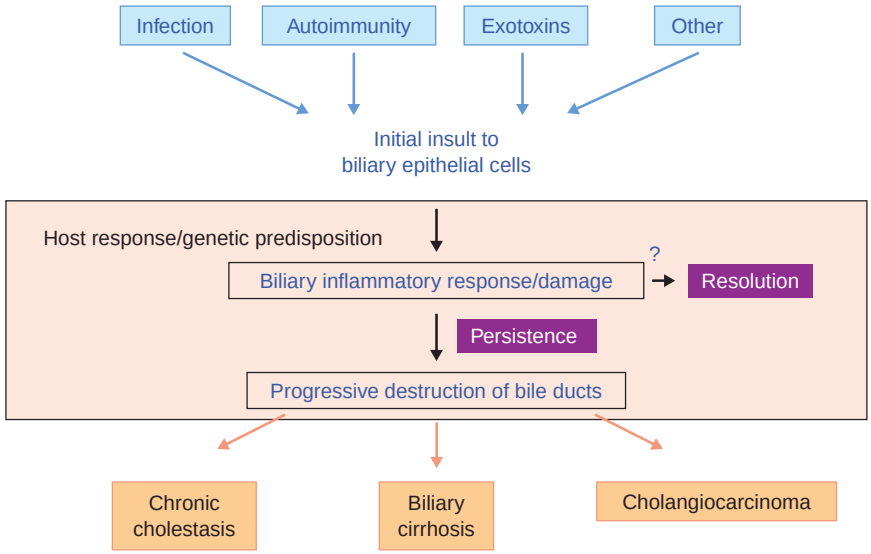

Figure 20.1 Proposed pathogenesis of primary sclerosing cholangitis.

or other agents interacting with predisposing host factors (Fig. 20.1). It is proposed that this interplay leads to an initial damage of cholangiocytes, the target epithelial cells that line the bile ducts. Subsequently, a biliary inflammatory response takes place but most individuals recover without consequences. Perhaps, the genetic predisposition of the host and other unknown mechanisms may contribute to persistance of inflammation of the bile ducts resulting in progressive biliary destruction, chronic cholestasis, biliary cirrhosis, and, in some cases, cholangiocarcinoma (Fig. 20.1).

Genetic factors

Prior studies have documented familial PSC cases and a significantly higher prevalence of PSC among first-degree relatives of affected patients [5,6], supporting the presence of inherited elements in disease pathogenesis. In addition, several case–control studies have demonstrated the genetic predisposition to PSC development by identifying genetic variants associated with patients compared to controls. Chapman et al. first reported the human leucocyte antigen B8 (HLA-B8) frequency to be significantly higher in patients with PSC (60%) compared with controls (25%) (P <0.001) [7]. Subsequently, Donaldson et al. demonstrated an association of PSC with the HLA-A1, -B8, -DR3 haplotype (40% in cases versus 12% in controls, P <0.0005) [8].

In recent years, genetic polymorphisms associated with susceptibility to PSC have been reported, including: (i) the promoter region of the tumor necrosis factor α (TNF-α) receptor [9]; (ii) stromelysin (i.e., matrix metalloproteinase 3) [10]; (iii) the *MICA* gene (i.e., major histocompatibility complex class I related MIC gene family) [11]; (iv) the CCR5-delta 32 mutation [12]; and (v) intracellular adhesion molecule 1 (ICAM-1) [13] (Table 20.1). From a theoretical standpoint, the variety of susceptibility genes interacting with environmental factors likely explain the heterogeneity of PSC phenotype as this relates to disease development, progression, and complications. It is expected that many genetic variants (i.e., susceptibility alleles) predispose to disease, each of which contribute a small effect on the PSC phenotype. To this end, large association (i.e., case–control) and familial studies are needed

Table 20.1 Susceptibility genes in primary sclerosing cholangitis.

Gene	Type	Variaton	Reference
TNF-α	Cytokine	G/A, substitution	Mitchell et al. 2001 [9]
Stromelysin	Matrix metalloproteinase	5A/6A alleles	Satsangi et al. 2001 [10]
MICA	MHC	*002/*008 alleles	Norris et al. 2001 [11]
CCR5-delta32	Chemokine	32 base pair deletion	Eri et al. 2004 [11]
ICAM-1	Adhesion molecule	K469E	Yang et al. 2004 [12]

CCR5, chemokine, CC motif receptor 5; ICAM-1, intracellular adhesion molecule 1; MICA, major histocompataibility complex class I-related MIC gene family; TNF-α, tumor necrosis factor α.

to better dissect the genetic susceptibility of PSC. Such results will aid in the development of novel diagnostic tools and intervening therapies.

Abnormalities in humoral and cellular immunity

Abnormalities of the humoral immune system in PSC include the presence of: (i) hypergammaglobulinemia, particularly elevated immunoglobulin M levels; (ii) circulating immune complexes; and (iii) activated complement [14]. Moreover, PSC patients have serum positivity for several autoantibodies including antineutrophil cytoplasmic antibodies (ANCA), anticardiolipin antibodies, and antinuclear antibodies (53%) [15]. In addition, the cellular immune system in PSC can be abnormal, as indicated by a decrease in the total number of circulating T cells due to a decline in CD8 (suppressor/cytotoxic cells) and an increase in circulating B cells. Furthermore, the documented aberrant expression of HLA class II antigens on the biliary epithelial cells may serve to target an immune response against the biliary cells [16,17], while the presence of ICAM-1, which serves as a ligand for the leukocyte function-associated antigen 1 (LFA-1), may help form connections between T lymphocytes and antigen-presenting cells. Indeed, increased levels of ICAM-1 have been found in both the bile duct epithelial cells and serum [17–19]. LFA-1 also appears to be overexpressed by intrahepatic lymphocytes, but this expression may simply be induced by proinflammatory cytokines [20]. Despite all these observations, the documented altered immune status may simply be an epiphenomenon and yet not linked directly to PSC pathogenesis.

Other proposed hypotheses of pathogenesis

Due to the strong clinical association between IBD and PSC, much interest has been paid to the potential role of an inflamed colon in causing the liver disease [21]. It was proposed that inflammation of the colon may increase the colonic permeability to various intraluminal products leading to liver injury. To this extent, bacteria or bacterial toxins have been considered but have not been convincingly demonstrated to play a pathogenetic role in PSC [22]. In addition, abnormal bile acids generated by bacterial action in the diseased colon and directly absorbed through the colonic mucosa into the portal system have been suggested as a possible etiology of PSC. Nevertheless, no direct evidence in support of this theory has been forthcoming.

In an animal model, inflammatory bacterial peptides led to portal inflammation and histologic changes suggestive of PSC [23,24]. In this model, a variety of agents were useful in blocking this response, including an inhibitor of TNF. However, when pentoxifylline, a TNF inhibitor, was used in patients with PSC, no clinical benefit was found [25]. Furthermore, the finding that PSC can develop in approximately 25% of patients without concurrent IBD, the lack of association between the severity of colonic inflammation and the likelihood of PSC development, and the fact that proctocolectomy for chronic ulcerative colitis (CUC) does not alter the natural history of PSC [26] speak against the role of the inflamed colon in the development of liver disease.

At present, there is no convincing evidence of a virus or other microorganism causing PSC. The usual hepatotrophic viruses (i.e., hepatitis A, B, and C virus) have been excluded. Cytomegalovirus can produce changes suggestive of PSC in patients with acquired immunodeficiency states, but in immunocompetent patients no evidence of cytomegalovirus infection has been found [27]. Reovirus type 3 was considered a possible causative agent but further work excluded it as an etiology for PSC [28].

Clinical features

Primary sclerosing cholangitis affects men almost twice as commonly as it does women and the average age at diagnosis is the early forties [3]. In the past two decades, a frequent clinical scenario of diagnosis includes asymptomatic patients who come to medical attention solely because of abnormal liver function tests. Physical examination may be unrevealing, but splenomegaly, hyperpigmentation, and skin excoriation can be found. Symtoms of advanced PSC such as jaundice, pruritus, fever, or portal hypertension on initial presentation are uncommon. Health-related quality of life is significantly impaired among patients with PSC relative to the healthy population [29,30].

PSC usually affects the entire biliary tree. Approximately 20% of patients have involvement of the intrahepatic bile ducts alone and 5% have disease involving the interlobular and septal bile ducts (i.e., small duct PSC) seen only on liver biopsy, while the ERCP is normal [31–34]. Up to 15% of patients can have involvement of the cystic duct and gallbladder [35]. Another clinical entity is the overlap syndrome, in which PSC and autoimmune hepatitis coexist and occurs in about 5% of adult patients [31–33]. Rarely, PSC can afflict children and in this population the disease will often have features of autoimmune hepatitis [36].

Natural history

Primary sclerosing cholangitis is usually a progressive disease. In a retrospective study with 174 PSC patients

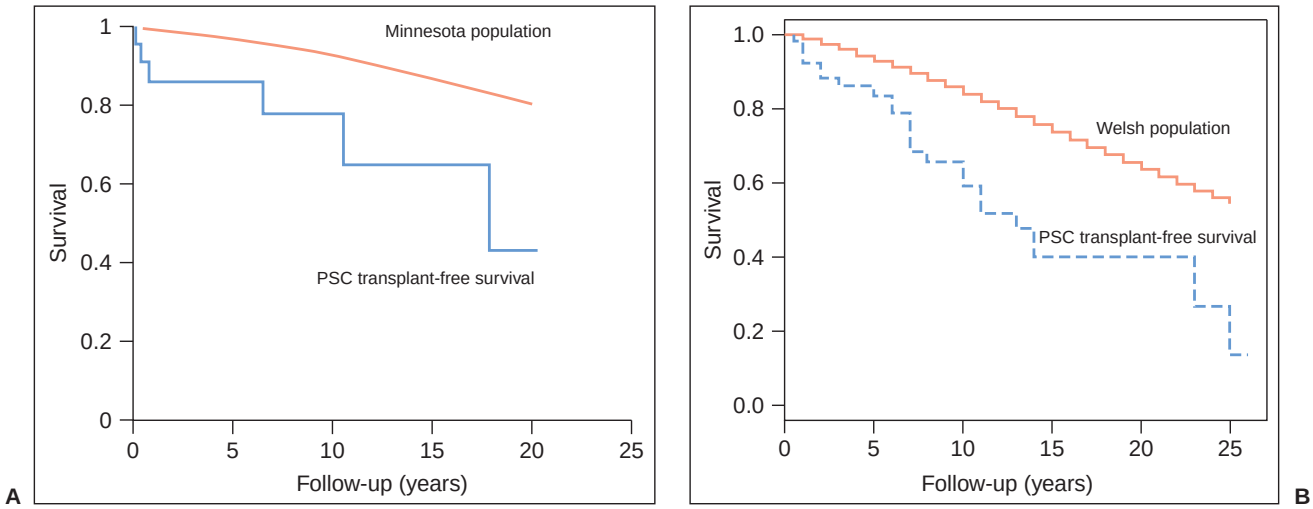

Figure 20.2 Transplant-free survival of primary sclerosing cholangitis (PSC) patients compard with age- and sex-matched population controls from the corresponding counties of Olmsted, Minnesota (A) and Swansea, Wales (B). (Reproduced from Bambha et al. [3] and Kingham et al. [4] with permission from Elsevier.)

from the United States, the median survival rate from the time of diagnosis was approximately 12 years, which was less than that for an age-matched population [37]. In another study from Norway, investigators estimated the median survival time of PSC patients to be 17 years [38,39].

Recent population-based epidemiologic data also reported that PSC is a progressive disease and shortens life expectancy. Studies from Olmsted County, Minnesota and Swansea, Wales indicated that the liver transplantation-free survival was 65% at 10 years after the diagnosis of PSC and significantly less than the age- and sex-matched populations (Fig. 20.2) [3,4].

Given these natural history studies, prognostic models have been developed to more accurately forecast an individual patient's disease progression, and thus define the best timing for liver transplantation. The variables for these prognostic models were created using Cox multivariable regression analysis [38,40–42]. The revised Mayo PSC natural history model employs five independent and reproducible parameters (age, total bilirubin, albumin, aspartate aminotransferase, and history of variceal bleeding) to estimate the survival of patients [40]. Recently, the model of end-stage liver disease (MELD) score has been widely used to prioritize liver transplantation in PSC patients with end-stage liver disease [43].

Small duct PSC is associated with a better long-term prognosis compared with large duct PSC [44]. In a comparative study, small duct PSC appeared to have significantly longer transplantation-free survival than large duct PSC, and cholangiocarcinoma did not seem to occur in patients with small duct PSC unless the disease progressed to large duct PSC. Small duct PSC can progress to large duct PSC over a course of approximately 7 years in an estimated 22.9% of cases [44,45]. Finally, secondary sclerosing cholangitis has a poorer long-term outcome when compared with PSC, with a signficantly shorter survival free of liver transplantation [46].

Associated diseases

The close association of PSC with IBD, particularly CUC, is now widely recognized. This association is found in 70–80% of patients with PSC. Crohn disease has been reported as the cause of colitis in 10–15% of patients with PSC [21,47]. There is no clear temporal association between the diagnosis of PSC and IBD, although the diagnosis of IBD is usually established before the liver disease is clinically apparent. Nevertheless, there are well-documented cases of IBD occurring years after the diagnosis of PSC. Additionally, patients can develop PSC many years after proctocolectomy for colitis [26]. In patients with PSC and colitis, the bowel disease is one of relatively quiescent disease. However, the risk of development of colon cancer in patients with coexisting PSC and CUC appears to be substantially greater than if patients did not have PSC. There has been no association between the severity of bowel disease and the severity of liver disease, and therapy for the bowel disease, including proctocolectomy, does not affect the liver disease [26].

Aside from IBD, a variety of diseases have been reported to occur with PSC (Box 20.1). It is unclear, however, whether these associations are true, and thus share a pathogenetic mechanism, or coexist by chance.

Box 20.1 Diseases associated with primary sclerosing cholangitis.

- Inflammatory bowel disease
- Autoimmune hepatitis
- Chronic pancreatitis
- Celiac disease
- Rheumatoid arthritis
- Retroperitoneal fibrosis
- Peyronie disease
- Riedel thyroiditis
- Bronchiectasis
- Sjögren disease
- Glomerulonephritis
- Systemic lupus erythematosus
- Pseudotumor of the orbit
- Vasculitis
- Autoimmune hemolytic anemia
- Immune thrombocytopenic purpura
- Angioimmunoblastic lymphadenopathy
- Histiocytosis X
- Cystic fibrosis
- Sarcoidosis
- Systemic mastocytosis
- Polymyositis
- Alopecia universalis
- Thymoma
- Ankylosing spondylitis

Laboratory findings

Biochemical testing

The biochemical findings of PSC patients are nonspecific. Nevertheless, chronic biochemical cholestasis is typically apparent. Alkaline phosphatase is the most commonly elevated liver enzyme although patients with well-documented PSC and normal alkaline phosphatase levels have occasionally been described [48]. Aminotransferase levels are frequently elevated, but the degree of elevation is only modest except in patients with overlap syndrome where levels can be markedly increased. Serum bilirubin is typically normal but in advanced disease can be very high.

Imaging studies

Visualization of the biliary tree is essential for establishing the diagnosis of PSC. ERCP has been the diagnostic procedure of choice, although MRCP is equally sensitive and specific for detection of the disease [49] and may be more cost effective [50–52]. A percutaneous transhepatic cholangiogram (PTC) can be used, but because of the frequently sclerotic intrahepatic biliary system gaining access via the percutaneous route can be challenging.

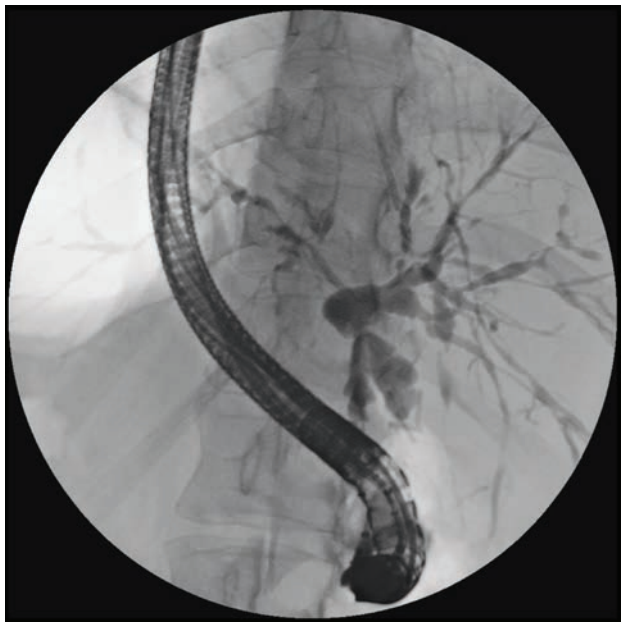

Figure 20.3 ERCP of a patient with primary sclerosing cholangitis. Extensive extrahepatic and intrahepatic biliary disease is evident.

Typical cholangiographic findings of PSC include multifocal stricturing and beading, usually involving both the intra- and extrahepatic biliary system (Fig. 20.3). Often the strictures are diffusely distributed, short in length, and annular. During cholangiography, the presence of polypoid masses should raise the suspicion of cholangiocarcinoma, although the diagnosis of the latter can be very difficult to establish.

Histology

Liver biopsy findings alone are generally nondiagnostic of PSC. The classic onion-skin fibrosis is seen in fewer than 10% of biopsy specimens, but when present is almost pathognomonic (Fig. 20.4) [53]. The histologic grading

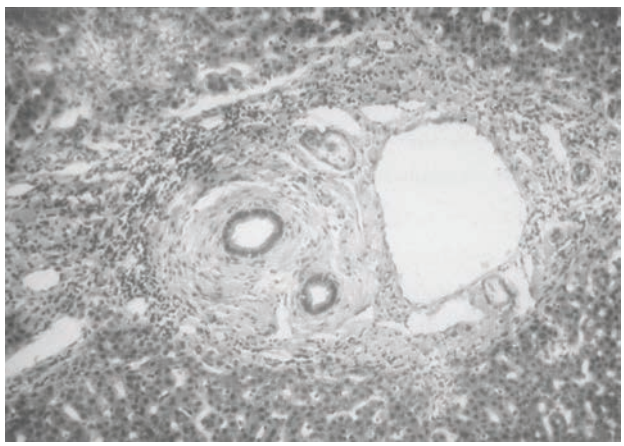

Figure 20.4 This characteristic onion-skin lesion is not typically found in liver biopsy specimens from patients with primary sclerosing cholangitis.

Box 20.2 Histologic staging of primary sclerosing cholangitis.

Portal stage (stage I)
- Portal edema, inflammation, ductal proliferation; abnormalities do not extend beyond the limiting plate

Periportal stage (stage II)
- Periportal fibrosis, inflammation with or without ductular proliferation; piecemeal necrosis may be present

Septal stage (stage III)
- Septal fibrosis or bridging necrosis can be identified

Cirrhotic stage (stage IV)
- Biliary cirrhosis

system, proposed by Ludwig et al. [53], has four stages: stage 1, portal; stage 2, periportal; stage 3, septal; and stage 4, cirrhosis (Box 20.2). Intrerestingly, the histologic changes seem to be quite variable in different segments of the same liver, and therefore histologic staging has been avoided as a component of current PSC survival models [38,40–42].

Diagnostic criteria and differential diagnosis

The current diagnostic criteria for PSC include: (i) typical cholangiographic abnormalities involving any part of the biliary tree; (ii) compatible clinical and biochemical findings (i.e., cholestasis for more than 6 months); and (iii) exclusion of other causes of secondary sclerosing cholangitis (Box 20.3). Liver biopsy has been used in the past to help confirm the diagnosis, although the specificity and sensitivity of the biopsy have come under question. Nevertheless, liver biopsy may be useful to diagnose small duct PSC in a patient with normal cholangiography and in the setting of a patient with overlap syndrome. The differential diagnosis of PSC is outlined in Box 20.3.

Finally, PSC predisposes to the development of colon cancer and cholangiocarcinoma (see below). Patients with PSC and CUC have a significantly greater risk of developing colon cancer compared with patients having CUC only [54]. Therefore, PSC patients should undergo surveillance colonoscopies annually.

Box 20.3 Diagnostic criteria for primary sclerosing cholangitis (PSC).
- Typical cholangiographic abnormalities involving any part of the biliary tree
- Compatible clinical (cholestatic symptoms, history of inflammatory bowel disease) and biochemical (2–3-fold increase in serum alkaline phosphatase level for longer than 6 months) findings
- Exclusion of identifiable causes of secondary sclerosing cholangitis:
  - AIDS (acquired immune deficiency syndrome) cholangiopathy
  - Bile duct neoplasm (unless diagnosis of PSC has been previously established)
  - Biliary tract surgery, trauma
  - Choledocholithiasis
  - Congenital abnormalities of biliary tract
  - Caustic sclerosing cholangitis
  - Ischemic stricturing of bile ducts
  - Toxicity or stricturing of bile ducts related to intra-arterial infusion of floxuridine

Management

The complications of PSC include: (i) advanced stage liver disease (i.e., portal hypertension, decompensated cirrhosis, and hepatic failure); (ii) chronic cholestasis; and (iii) the underlying disease (i.e., specific for PSC). The management of complications of portal hypertension, decompensated cirrhosis, and hepatic failure are discussed in Chapters 11, 12, and 33. The management of complications related to chronic cholestasis and those specific for PSC are discussed below.

Complications of chronic cholestasis

Pruritus

Although not common, pruritus can be disabling and associated with a diminished quality of life. The pathogenesis of pruritus in cholestasis is unknown, although endogenous opioids and retention of factors usually excreted in the bile have been considered [55,56]. The severity of the pruritus does not seem to parallel the severity of the liver disease, and pruritus may diminish as the liver disease progresses. Cholestyramine, antihistamines, rifampin, and opiate receptor antagonists have been used with varying results to treat patients with cholestatic pruritus [57,58]. The usual doses of these medications are shown in Box 20.4. It is important to remember that rifampin is associated with a reversible hepatotoxicity in 15% of cases. Therefore, it is important to monitor the liver function tests closely if this drug is used.

Box 20.4 Medications used for the management of pruritus.
- Ursodiol: 15–30 mg/kg/day orally
- Cholestyramine: 4 g 3–4 times per day orally
- Naltrexone: 50 mg/day orally
- Rifampin: 150–300 mg twice per day orally

Box 20.5 Vitamin replacement therapy for primary sclerosing cholangitis.

- Vitamin A: 25,000–50,000 units 2–3 times per week orally
- Vitamin D: 25,000–50,000 units 2–3 times per week orally
- Vitamin E: 100 units/day orally
- Vitamin K: 5–10 mg/day orally

Fat-soluble vitamin deficiency

Fat-soluble vitamin deficiency is relatively common among patients with PSC, particularly as the patient progresses towards liver transplantation [59]. Up to 40% of patients have vitamin A deficiency, and vitamin D and E deficiencies have been found among 14% and 2% of patients, respectively [59]. Vitamin K deficiency is uncommon. If this condition is suspected, a short trial of 10 mg water-soluble vitamin K can be considered. If the prothrombin time responds after a few doses, long-term therapy should be recommended. Vitamin E deficiency is rare and unfortunately once established can be very difficult to correct with replacement therapy. The usual fat-soluble doses of vitamin replacement therapy are shown in Box 20.5.

Metabolic bone disease

Metabolic bone disease, usually caused by osteoporosis rather than osteomalacia, is relatively common and an important complication among PSC patients [60]. The glucocorticoids used to treat the accompanying IBD aggravate osteoporosis. Unfortunately, there is no proven therapy that can help these patients. Use of estrogen replacement therapy by women can be considered, but it is not of proven benefit. Calcitonin does not appear to be useful to patients with osteoporosis associated with PBC, but it has not been tested in the treatment of PSC patients. Bisphosphonates have been used with varying results to treat patients with PBC, but have not been tested in the care of patients with PSC [61]. Patients with PSC and IBD, undergoing long-term glucocorticoid therapy for the latter, may benefit from the oral administration of vitamin D and calcium, particularly those with a bone density in the range of osteopenia or osteoporosis.

Steatorrhea

Steatorrhea can occur in patients with PSC secondary to a diminished delivery of bile acids to the intestine either from coexisting chronic pancreatitis or celiac disease. These conditions should be considered in the evaluation of patients with steatorrhea in the setting of PSC [62] before treatment is recommended. If steatorrhea in patients with PSC is primary, a low-fat diet and the substitution of medium-chain triglycerides for long-chain ones may be benificial.

Specific complications of primary sclerosing cholangitis

Gallstones, choledocholithiasis, and gallbladder polyps

Stones involving the gallbladder or bile ducts (i.e., choledocholithiasis) occur in approximately one third of patients with PSC. Chronic cholestasis predisposes to the formation of cholesterol gallstones and bile stasis, with bacterial cholangitis leading to the formation of pigment stones of the bile ducts. In PSC patients, choledocholithiasis may present with acute deterioration of liver function, worsening jaundice, or bacterial cholangitis if the bile duct becomes obstructed, but can be treated endoscopically once the diagnosis is established. Additionally, recent case series have reported a high incidence of adenocarcinoma in polypoid lesions of the gallbladder in PSC patients, even in polyps of less than 1 cm diameter, and elective cholecystectomy may be justified once these lesions are detected [63].

Biliary strictures

In the largest series to date, dominant biliary strictures occurred in only 7% of patients whose cases were followed for up to 10 years. These dominant strictures are usually in the extrahepatic biliary system and may be associated with jaundice, pruritus, or relapsing bacterial cholangitis. If any of these symptoms occur in PSC patients, cholangiography should be strongly considered. Any evidence of dominant stricture(s) requires brush cytologic specimens for standard cytology, fluorescence in situ hybridization (FISH), and digitized image analysis (DIA) to exclude cholangiocarcinoma (see below). Often, bile duct strictures can be dilated endoscopically with a balloon catheter. Short-term biliary stenting has been shown to improve the prognosis of liver disease in some studies, whereas others have shown that patients with biliary stents are at increased risk of complications [64]. Direct surgical intervention for biliary strictures is seldom used and may predispose patients to recurrent bacterial cholangitis because of the widely patent surgical anastomosis, and may make future liver transplantation more technically demanding.

Prophylaxis for bacterial cholangitis should be considered in the care of patients with PSC undergoing biliary manipulation. The Mayo Clinic experience suggests that PSC patients have a much higher risk for cholangitis than patients without PSC (4% versus 0.2%, $P < 0.0002$), while the risks for other complications of pancreatitis, perforation, and bleeding are similar in PSC and non-PSC patients [65]. Ciprofloxacin or other broad-spectrum antibiotics with high biliary excretion are frequently administered both immediately before and 1 or 2 days after the procedure.

Cholangiocarcinoma

Cholangiocarcinoma (CCA) is the most feared complication among patients with PSC. CCA may occur in 7–15% of patients with PSC at an annual incidence of 0.5–1% [66–69]. Interestingly, the development of CCA does not correlate with the severity of PSC. Chronic inflammation of the bile ducts and cholestasis are likely predisposing factors associated with the development of CCA in PSC. Smoking and the presence of IBD have been suggested as predisposing conditions although they remain controversial. The diagnosis of CCA in PSC patients can often be difficult to establish because it is not easy to differentiate between benign and malignant dominant biliary stricture(s). Furthermore, conventional imaging of computed tomography and ultrasound have poor sensitivity for the detection of CCA. A recent study suggested that dynamic positron emission tomography (PET) may be more useful for screening CCA compared with conventional modalities, but more studies are necessary to define the role and routine use of PET in PSC patients [70].

Serum markers for the early detection of CCA in PSC have not been helpful. As a screening test, carbohydrate antigen 19-9 (CA 19-9) does not appear to be sensitive enough, and the specificity is limited. For instance, CA 19-9 levels may be elevated due to bacterial cholangitis secondary to benign strictures, thus limiting the specificity of the test [71]. Nevertheless, in a patient with PSC, sudden and unexpected clinical deterioration – which is associated with a progressive elevation of alkaline phosphatase and serum CA 19-9 (>100 U/mL) – in the absence of bacterial cholangitis indicates a probable development of CCA.

New diagnostic methods such as DIA and FISH offer promise in evaluating bile duct lesions for cellular aneuploidy and chromosomal aberrations [71]. To perform DIA and FISH assays, bile duct brushings are collected at the time of ERCP or PTC. DIA allows DNA content quantification, assessment of chromatin distribution, and nuclear morphology. In one study, DIA was found to be significantly more sensitive (39.3%) than standard cytology (17.9%, $P = 0.014$) [72].

The biliary FISH assay uses fluorescently labeled DNA-based probes to detect chromosomal aberrations in brushings of bile duct cells. A FISH assay is declared positive when five or more cells display gains of two or more chromosomes, or ten or more cells demonstrate a gain of a single chromosome (Fig. 20.5) [71]. A recent study of nearly 500 patients demonstrated that the sensitivity of polysomy FISH for carcinoma (42.9%) was significantly higher than standard cytology (20.1%), while maintaining identical specificity (99.6%) ($P < 0.001$) [73]. Multivariable modeling using standard cytology and FISH findings, age, and PSC status may be used to estimate the probability of carcinoma in individual patients [73].

Overall, in a patient with PSC, the diagnosis of CCA is usually made by combining the clinical examination, biochemical results, and imaging procedures. In medical practice, it is not uncommon to make the diagnosis of CCA based on clinical grounds and imaging studies without tissue-proven evidence of tumor. Physicians who evaluate PSC patients should be highly suspicious for the development of CCA when these patients present with sudden clinical deterioration. Because we lack methods of

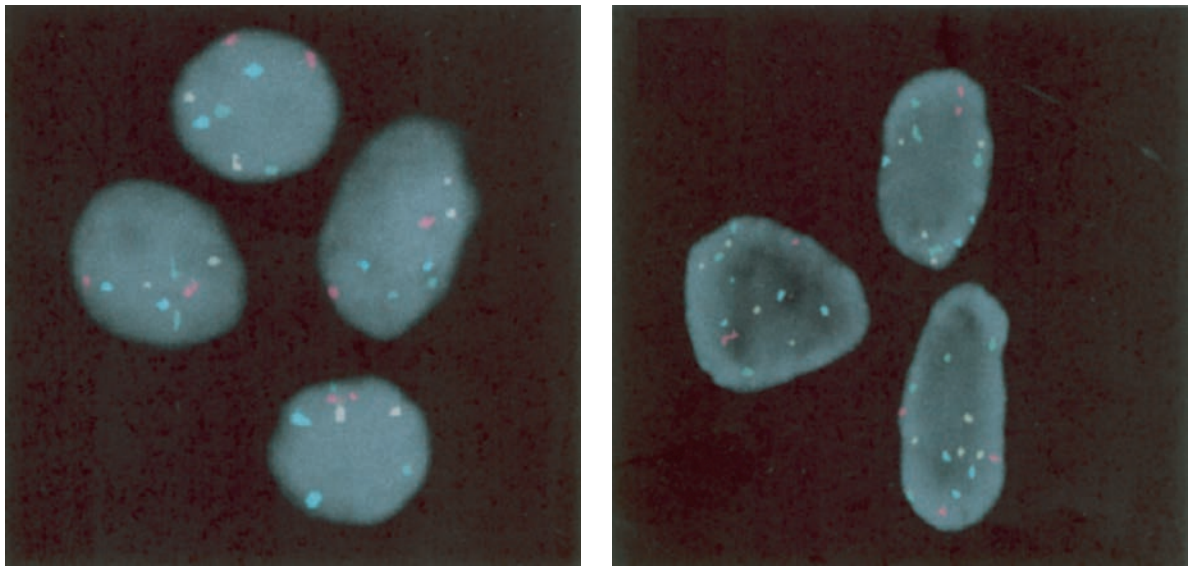

Figure 20.5 FISH of normal (A) and maligant (B) bile duct cells. Normal cells display duplicate color for each chromosomal probe while malignant cells reveal multiple gains of chromosomes (i.e., polysomy). (Reproduced from Lazaridis and Gores [71] with permission from Elsevier.)

early CCA detection in PSC, the outcome of these patients is poor. Nevertheless, early diagnosis of CCA in PSC can be successfully treated by liver transplantation in selected medical centers [74].

Peristomal varices

Peristomal varices can occur in patients with ileostomy after proctocolectomy for underlying IBD [75]. The bleeding of peristomal varices can be severe and refractory to local measures, including ileostomy revision and injection of sclerosants. A transjugular intrahepatic portosystemic shunt or portacaval shunt can be considered, although many of these patients with bleeding peristomal varices have severe underlying liver disease with portal hypertension and thus should be considered for liver transplantation.

Specific management

Medical therapy

A variety of drugs have been tested as therapeutic agents for PSC, but none have been found to be disease modifying. Randomized, placebo-controlled trials of penicillamine, colchicine, methotrexate, and ursodeoxycholic acid (UDCA) (13–15 mg/kg/day) have all been ineffective [76–80]. Small-scale studies using nicotine, pirfenidone, pentoxifylline, and budesonide have not demonstrated clinical benefit [25,81–84]. Pilot studies using high-dose UDCA (20–30 mg/kg/day) initially appeared to have improvement in survival probability, with trends toward Ludwig histologic stabilization/improvement [85,86]. Unfortunately, larger randomized, placebo-control trials failed to demonstrate an improvement in symptoms, quality of life, survival, and risk for cholangiocarcionoma with higher doses of UDCA [76,77]. Specifically, over the course of a 5-year longitudinal follow-up, patients randomized to the high-dose UDCA group had a greater than two-fold increased risk for serious adverse events, death, or transplantation compared with the placebo group [77]. Interestingly, UDCA has been shown to decrease the prevalence of colonic dysplasia in patients with PSC and CUC [78]. Nevertheless, we need prospective studies to confirm the chemopreventive effect of UDCA in patients with coexisting PSC and CUC before its implementation as routine prophylactic therapy.

Surgical therapy

Surgical therapy other than liver transplantation is seldom warranted for PSC. Biliary reconstruction has been suggested to be helpful [79], but this aggressive approach has not been validated in prospective controlled studies.

Liver transplantation
