Lipid droplets are composed of a hydrophobic core of triglycerides and lesser amounts of cholesterol esters surrounded by a phospholipid monolayer [276]. They form at the site of fatty acid acyl transferases in the ER in association with the cytoskeleton [277]. Droplets are associated with lipoprotein-like proteins known as PAT proteins which govern lipase activity and are themselves regulated by PPAR-γ agonists [278–282]. Their growth appears to occur predominantly by fusion [283]. Through the activity of the MTTP enzyme at the ER, droplets normally serve as a source for triglycerides in VLDL synthesis. Because oxidative injury to the droplet surface alters PAT protein expression, it is likely that secretion and fusion is disturbed in NASH [284]. Consistent with this, the smallest droplets in alcoholic steatohepatitis resemble precursors of VLDLs [285,286]. Autophagy of fat droplets ('lipophagy'), which forms an autophagosome (lysosome), appears to be a key compensatory and regulatory pathway [287]. Altered permeability of the lysosome mediated by free fatty acids is a trigger of cell death pathways (see below).

Endoplasmic reticulum dysfunction

Experimentally, small droplet accumulation is associated with the formation of cholesterol-rich "Apo-B crescents" at sites in the ER [288]. We speculate that this is directly related to dysfunction of the ER. The latter is evident in human NASH as the unfolded protein response ("ER stress"), which activates proinflammatory pathways such as interleukin 8, nuclear factor κB (NF-κB), and c-jun N-terminal kinase (JNK) [289,290]. Thus, impaired Apo-B100 interaction with lipid droplets at the ER provides a link between oxidative stress, droplet accumulation, altered VLDL secretion, the ER stress reaction, and activation of proinflammatory pathways [291–293].

Mitochondrial dysfunction and adenosine triphosphate homeostasis

An association between steatosis and diminished ATP was observed over 50 years ago and later confirmed using ^{31}P magnetic resonance spectroscopy in vivo [294,295]. The evolutionary history of the mitochondrion places it centrally in critical pathways including fatty acid synthesis and oxidation, oxidative-phosphorylation, and apoptosis signaling [296,297]. Morphologic abnormalities in NASH include enlargement and formation of crystalline arrays, which may represent phospholipid phase transitions (Fig. 32.14) [298]. It likely results from an impaired electron transport chain (in part due to uncoupling protein) [299,300] and accounts for the poor function of steatotic livers in transplantation due to ischemia [301, 302]. Whether or not fatty acid oxidation is decreased in NAFLD is unclear as a net increase in mitochondrial β-oxidation has been reported in NASH and in obesity [303,304]. Changes in permeability cause the release of cytochrome *c* and apoptosis signaling (see below). Mitochondrial cholesterol content may contribute to changes in permeability [305].

Cell death, fibrosis, and the ductal reaction

Cell death results from a combination of apoptosis signaling and focal necrosis resulting in a process best described as "necroapoptosis" or "apoptonecrosis" [306]. Excessive free fatty acids due to diminished fatty acid-binding protein [307] (and possibly to impaired fat droplet function) alter autophagosome permeability, leading to the release of cathepsins (lysosomal proteases), which then alter mitochondrial permeability, leading to the release of cytochrome *c* and activation of proapoptotic caspases [308–310]. Caspase 3 in particular causes fragmentation of keratin 18, possibly contributing to the formation of Mallory–Denk bodies and to the release of keratin 18 fragments detectable in serum [311,312]. Although apoptotic pathways are diffusely activated, necrosis appears to dominate histologically, possibly as a result of an ATP deficit, fat droplet accumulation, and cytoskeletal injury – all of which appear to contribute to cellular ballooning. Cell death stimulates inflammation and activation of hepatic stellate cells to produce collagen [313]. This process is mediated at least in part by activation of toll-like receptors [314]. Compensatory repair is characterized by increased activity of progenitor cells recognized as the "ductular reaction" in the portal tracts [315].

Cytochrome P450 and peroxisomal metabolism

Induction of cytochrome P450 2E1 (CYP2E1) has been described as a possible source of oxidative stress through microsomal ω-oxidation of fatty acids [316]. Expression of CYP2E1 is influenced by dietary fat and colocalizes to markers of lipid peroxidation [317]. Its role is uncertain as experimental overexpression of CYP2E1 is protective against oxidative injury and decreases apoptosis but increases the risk of necrosis induced by fatty acid

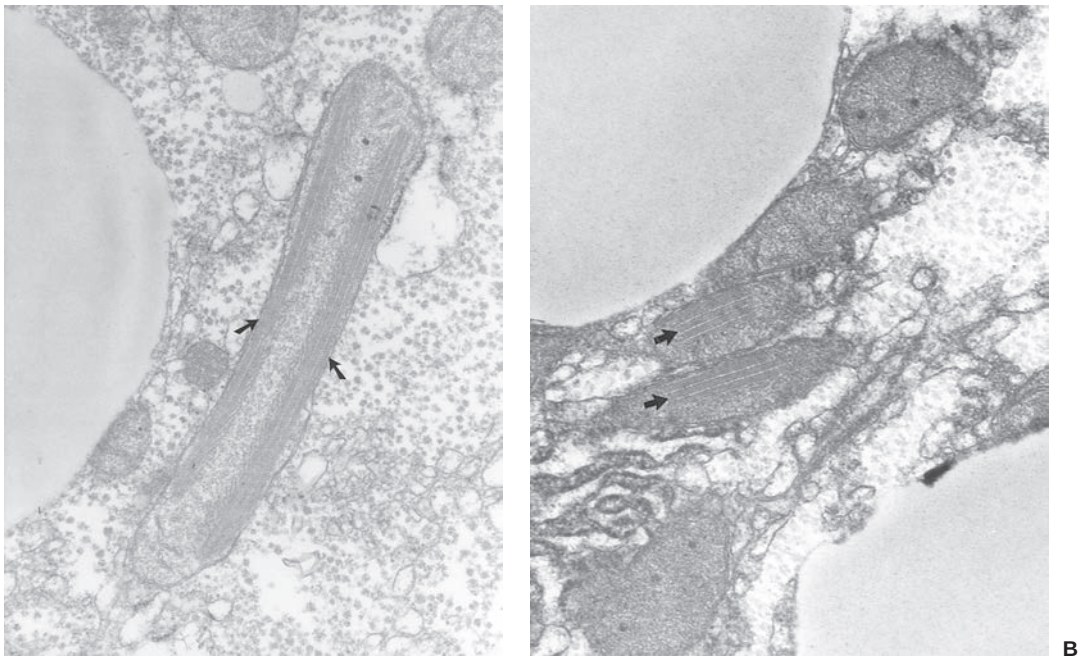

Figure 32.14 Deformed mitochondria with crystalline inclusions in nonalcoholic steatohepatitis. (A) An elongated mitochondrion with two bundles of parallel, crystalline structures (arrows) near a large fat droplet. (B) Two mitochondria cut tangentially showing crystalline inclusions (arrows) in an area of cytoplasm between two large fat droplets. Note the paucity of normal cristae.

exposure [318]. Peroxisomes are involved in numerous potentially relevant lipid-related metabolic pathways and morphologic abnormalities have been described in human fatty liver [319,320]. Although not well defined, it is possible that genetic abnormalities, nutritional abnormalities, or adaptive changes in the peroxisome may contribute in some patients.

Ballooned cells

Hepatocyte ballooning is a major histologic feature of NASH evident in all scoring systems, but a consensus definition has remained elusive [321–323]. Ballooning is conventionally defined at the light level based on hematoxylin and eosin (H&E) staining as cellular enlargement 1.5–2 times the normal diameter (normal up to 30 μm) with rarefied cytoplasm [324,325]. Recent advances have shown that ballooning is associated with injury to the cytoskeleton evident as diminished cytokeratin 8 and 18, the presence of Mallory–Denk bodies, and the detection of cytokeratin 18 fragments (M30), suggesting impairment of cell size regulation [326–328]. Further work has revealed an association between the accumulation of small and medium fat droplets and morphologic changes in the ER (Fig. 32.15) [15]. These studies show cytoskeletal injury also in smaller cells, suggesting that this pattern exists as a spectrum. Experimentally, abnormal keratin metabolism may also play a role in mitochondrial dysmorphology [329]. Correlation of injury to the cytoskeleton and serum keratin 18 (M30) fragment levels is emerging.

Systemic factors

Insulin resistance and systemic inflammatory changes

Although insulin resistance is neither sufficient nor essential for NAFLD (see above), it is present in the majority of NAFLD patients and is intertwined with disease pathogenesis. Iinsulin resistance (evident in adipose tissue, skeletal muscle, and liver) is mediated by lipid accumulation, free fatty acids, and altered mitochondrial metabolism [330–332]. Manifestations include decreased muscle utilization of glucose, mobilization of fatty acids from adipose tissue (lipolysis), and unrestrained hepatic glucose output. Biochemically, insulin resistance is characterized by a shift from tyrosine phosphorylation in the insulin receptor substrate to serine phosphorylation resulting in diminished insulin-stimulated activity in *metabolic pathways* (mediated by phosphatidylinositol 3-kinase (PI3-kinase), Akt, and mTOR) and *mitogenic pathways* (mediated by Ras, Raf, and mitogen-activated protein or MAP-kinase). Inflammatory changes in adipose tissue are characterized by ER stress and JNK activation, which stimulates the production of systemically active cytokines, which contribute to the shift from tyrosine to

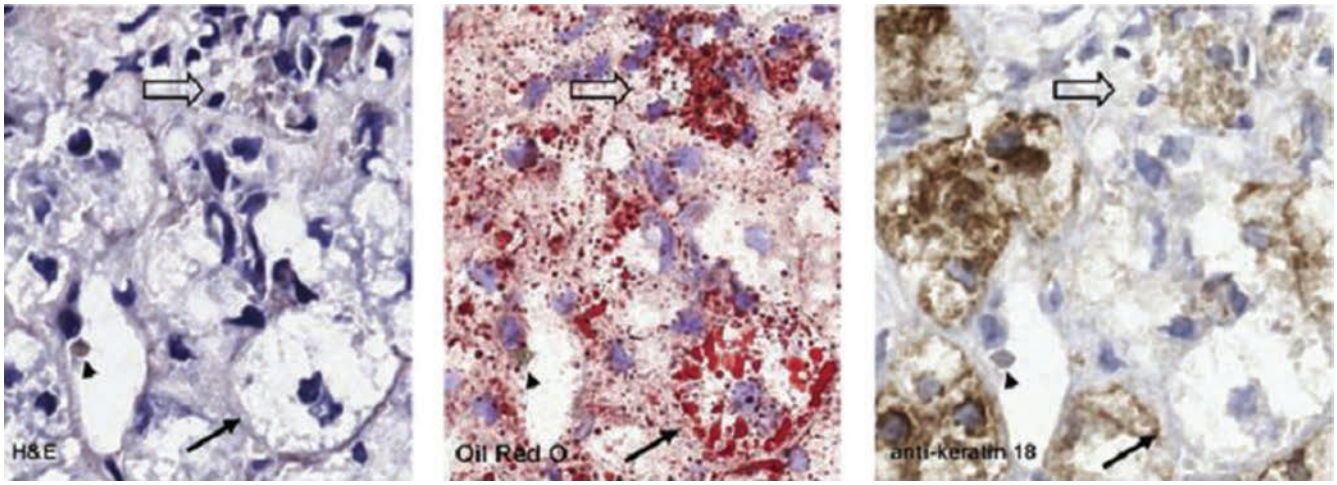

Figure 32.15 Relationship between cellular ballooning, small droplet fat accumulation, and cytoskeletal injury. Serial imaging of a frozen section using oil red O to accentuate the small lipid droplets in ballooned cells, in comparison to H&E and antikeratin 18 stains. The long arrow indicates a ballooned hepatocyte. The arrowhead indicates a landmark red blood cell in a central vein. The open arrow indicates a focus of necrosis with densely staining fat droplet remnants. (Reproduced from Caldwell et al. [15] with permission from Elsevier.)

serine phosphorylation [333,334]. Tumor necrosis factor α (TNF-α) and interleukins 6 and 8 act through their effects on a modulator of cytokine activity known as SOCS (suppressor of cytokine signaling) [335].

Adipocytokines and lipokines

Adipose-derived "adipokines" (adiponectin, leptin, resistin, visfatin) modulate insulin signaling. Adiponectin is the most abundant protein in the adipocyte and participates in glucose homeostasis via receptors in muscle (adipoR1) and liver (adipoR2) where it activates adenosine monophosphate (AMP) kinase and promotes fatty acid oxidation [336–338]. Depressed production of adiponectin has a prominent role in NAFLD and successful therapy is often associated with the recovery of normal levels. Recently, adipose-derived "lipokines," including C16:1n7-palmitoleate, have been proposed as additional systemic modulators of hepatic fat and insulin activity in skeletal muscle [339].

Other systemic changes

Alterations in small bowel permeability and associated bacterial overgrowth in NAFLD patients have been implicated in the activation of inflammatory mediators through exposure to substances such as endotoxin in portal blood [340,341]. The latter may partly explain the previously reported association between celiac disease and NAFLD due to increased gut permeability in celiac disease [342]. Whether or not systemic exposure to environmental pollutants such as bisphenol A significantly alters insulin resistance and manifestations of the metabolic syndrome remains controversial [343].

Energy homeostasis

Steatosis can be viewed as a component of integrated systems involved with energy (and thermoregulatory) homeostasis including the adrenergic system, the adipose organ, the thyroid axis, and insulin/glucagon signaling. While the insulin axis is the best characterized with regard to fatty liver, a broader understanding is helpful in understanding the disease. This is evident by the recently described presence of cold-activated brown adipose tissue in healthy men and its inverse relationship to obesity [344]. Factors governing these relations are unclear. Adrenergic modulation of hepatic inflammation has been demonstrated in animal models and may play a role in human fatty liver [345]. Liver fat metabolism in migratory Palmipedes may also be instructive (see above).

Other conditions associated with NAFLD/NASH ("secondary" NASH)

The foregoing has focused on what may be referred to as "primary" NAFLD associated with insulin resistance. Other conditions are sometimes referred to as "secondary" NAFLD (see Boxes 32.1 and 32.3) although overlapping risks often make the distinction less clear.

- *Jejunoileal bypass*. Historically, older forms of bariatric surgery played a role in the recognition of NAFLD/NASH due to a severe form of NASH following jejunoileal bypass [346]. Stimulation of TNF by bacterial overgrowth and endotoxin production, micronutrient deficiency, and rapid weight loss were conditions etiologically implicated. Modern forms of bariatric surgery

are much less likely to exacerbate NASH and may indeed ameliorate the condition (see below).

- *Medication-induced*. A number of medications have been implicated as causes of steatohepatitis. For some, including nifedipine, methotrexate, and tamoxifen, the association may be one of medication use in patients at risk for NASH and possible exacerbation of underlying disease [347–349]. Steatosis has been associated with exposure to anabolic steroids among body builders in the absence of obesity [350] and amiodarone has long been associated with phospholipidosis and steatohepatitis, although this seems less common now possibly due to lower dosing [351]. Acquired lipodystrophy, insulin resistance, and steatosis has been well described with therapy for human immunodeficiency virus (HIV) infection [352]. Obesity also appears to increase the risk of chemotherapy-associated steatohepatitis in colorectal cancer liver metastatic disease [353].
- *Parenteral nutrition, malnutrition, and celiac disease*. Liver disease, often with macro- and microvesicular steatosis, is a potentially severe side effect of total parenteral nutrition (TPN) [354,355]. Both the amount and composition of infused lipid appear to affect the expression of liver disease [356]. Choline deficiency may play a role in some patients. At the opposite end of the spectrum, steatosis in kwashiorkor results from impaired hepatic lipid export due to protein malnutrition (diminished apolipoprotein B) [357]. Celiac disease can be seen in up to 3–4% of NASH patients even in the absence of significant weight loss [358]. In this situation, celiac disease is postulated to exacerbate intrahepatic inflammation.
- *Solvents and industrial agents*. A variety of toxins have been implicated in the development of fatty liver diseases [359]. Better described agents include carbon tetrachloride (now rarely used), dimethylformamide, perchloro-ethylene, and more recently petrochemical derivatives [360]. These forms of steatohepatitis have been termed TASH (toxicant-associated steatohepatitis) and can also be seen with high exposures to vinyl chloride [361]. Although these conditions may be dissociated from insulin resistance, vinyl chloride exposure was associated with insulin resistance in the absence of obesity.
- *Wilson disease and other inherited metabolic diseases*. Macro- and microvesicular steatosis are well known features of Wilson disease [362]. It should be considered particularly with steatohepatitis in a younger individual. It is not known how often the carrier state for mutations in the copper-transporting ATPase gene could influence NASH [363]. Macrovesicular steatosis is seen in other inherited metabolic diseases, most of which present in childhood. These include glycogen storage diseases, galactosemia, tyrosinemia, heterozygous hypobetalipoproteinemia, and abetalipoproteinemia. The latter disorders involve impaired formation of VLDL due to decreased synthesis of apolipoprotein B [364,365]. Lipid storage diseases (cholesterol ester, Niemann–Pick, Tay–Sachs, and Gaucher disease) can have fatty infiltration of the liver with cholesterol esters, sphingolipids, phospholipids, sphingomyelin, gangliosides, or glucocerebrosides. Presentation in infancy (although not exclusively) and distribution in the reticuloendothelial cells distinguish the lipid storage disorders [366].

Obese, diabetic patients with newly discovered cirrhosis

The silent progression of NASH to cirrhosis has led increasingly to the incidental discovery of cirrhosis in patients with obesity and type 2 diabetes [367]. While therapy aimed at diabetes may ameliorate steatohepatitis in an early stage (see below), there is little knowledge on the effects of commonly employed medications such as aspirin and angiotensin-converting enzyme (ACE) inhibitors in the setting of NASH-related cirrhosis. However, it should be noted that portosystemic shunting results in the "hyperdynamic state" of cirrhosis, a hallmark of which is systemic vasodilatation and changes in renal hemodynamics. In this setting, ACE inhibitors and nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin may exacerbate fluid retention and ascites. Thus, treatment in these patients needs to include a reconsideration of conventional tenets of diabetes management. Another emerging area is that of overlapping atherosclerotic vascular disease and NASH cirrhosis (see section on natural history above). This situation increasingly results in the need for balancing anticoagulation strategies with portal hypertension-related bleeding risks.

Treatment

Overview of therapy: who should be treated

Patient selection and the relative risk–benefit of intervention remain some of the most challenging aspects of treating NAFLD. NASH carries the major risk for cirrhosis (relative to NNFL) and thus warrants stronger consideration for pharmacologic treatment (Table 32.3). However, there is consensus that dietary changes and exercise are cornerstones of initial intervention although variable compliance complicates the interpretation of pharmaceutical trials [368]. Most such studies account for weight loss and some for dietary changes but few account for physical conditioning, which can also influence the outcome. These variables likely explain the placebo effect

Table 32.3 Selected randomized, controlled trials of therapy for nonalcoholic steatohepatitis (NASH) with histologic end-points: key differences between active and control groups are shown in comments. Improvement in control groups (placebo effect) is seen consistently in pharmacologic studies and probably reflects voluntary lifestyle changes.

	N	*Agent*	Daily dose	Duration	Comments	Reference
Lifestyle modifications	25	Diet, exercise	Diet 25 kcal/kg IBW, jogging b.i.d.	3 months	Decreased steatosis compared to control group; mild improvement in inflammation, fibrosis; BMI decreased by 3 over study period in intervention group	Ueno et al. 1997 [388]
	53	Diet, exercise	25–30 kcal/kg, 45 min/day	24 months	Improvement in ALT, steatosis, inflammation, NAS. No additional benefit of adding vitamin E 600 IU/day or vitamin C	Nobil et al. 2008 [389]
	23	Exercise	Graded by effort	4 weeks	Significant reduction in visceral and especially liver fat even without weight loss	Johnson et al. 2009 [383]
	31	Diet, exercise	<1500 kcal, 200 min/week	48 weeks	Significant improvements in NAS, steatosis, inflammation, ballooning (weight loss 9.3% in lifestyle intervention group)	Promrat et al. 2010 [390]
Weight loss agents	50	Orlistat	360 mg	36 weeks	Vitamin E 800 IU/day in all patients. Improvement seen in multiple histologic parameters dependent on weight loss but independent of orlistat use	Harrison et al. 2009 [401]
Thiazolidinediones	20	Pioglitazone	30 mg	6 months	Improvement in steatosis and inflammation, no improvement in fibrosis	Sanyal 2004
	55	Pioglitazone	45 mg	6 months	Improvement in ALT, steatosis, inflammation; no significant improvement in fibrosis	Belfort et al. 2006 [431]
	74	Pioglitazone	45 mg	12 months	Improvement in ALT, ballooning, fibrosis; no improvement in steatosis	Aithal et al. 2008 [432]
	53	Rosiglitazone	8 mg	3 years	Improvement in ALT, steatosis; no significant improvement in inflammation, fibrosis	Ratziu et al. 2010 [435]
	163	Pioglitazone	30 mg	96 weeks	Improvement in ALT, steatosis, ballooning, inflammation, NAS, fibrosis	Sanyal et al. 2010 [419]
Cytoprotective agents	166	UDCA	13–15 mg/kg	24 months	Improvement in multiple parameters but no different than placebo	Lindor et al. 2004 [410]
	48	UDCA + vitamin E	12–15 mg/kg 800 IU/day	2 years	Improvement in AST, steatosis; no significant improvement in inflammation, fibrosis	Dufour et al. 2006 [412]
	185	UDCA	23–28 mg/kd	18 months	No improvement in steatosis, NAS, fibrosis	Leuschner et al. 2010 [411]
	74	Carnitine	2 g	24 weeks	Improvement in ALT, steatosis, ballooning, inflammation, NAS, fibrosis; placebo effect also observed	Malaguamera 2010
Antioxidants	45	Vitamins E and C	1000 IU 1000 mg	6 months	Slight improved fibrosis; no improvement in steatosis, inflammation	Harrison et al. 2003 [418]
	167	Vitamin E	800 IU	2 years	Improved ALT, steatosis, ballooning, inflammation, NAS	Sanyal et al. 2010 [419]
	55	Betaine	20 g	12 months	No improvement in ALT, steatosis, ballooning, inflammation, NAS, fibrosis	Abdelmalek et al. 2009 [424]
HMG-CoA reductase inhibitors	16	Simvastatin	40 mg	12 months	No improvement in ALT; no improvement in steatosis, ballooning, inflammation, NAS, or fibrosis	Nelson et al. 2009 [459]

ALT, alanine aminotransferase; BMI, body mass index; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; IBW, xxx; NAS, nonalcoholic fatty liver disease activity score; UDCA, ursodeoxycholic acid.

and sometimes the failure of agents in randomized controlled trials (RCTs) that appeared promising in pilot studies [369,370].

End-points of therapy

Because progression to cirrhosis carries a severe prognosis, the primary end-point of therapy remains improvement in histology, although sampling error is a potential problem which requires that studies report biopsy details (length and/or portal tracts). Surrogate markers for liver injury include serum aminotransferases, hepatic fat content by imaging techniques, and serologic markers of fibrosis such as collagen metabolites or cell injury such as keratin fragments (see above). Other measures include anthropometrics (weight, BMI, waist circumference), physical conditioning (VO_{2max} by ergometry), measures of insulin signaling, and adipocytokine/cytokine levels such as adiponectin, TNF-α, and TGF-β. Novel markers of histologic injury, especially in the research setting, include immunohistochemistry for oxidative cell injury, fat stains (oil red O), digital quantitative imaging for fibrosis, hepatocyte ultrastructure, and markers of stellate cell activation [371]. These parameters are used as surrogates for cell injury and thus for progression to cirrhosis. Although cirrhosis is an established prognositic indicator, ultimately any intervention will require translation into outcomes of liver-related morbidity and mortality; such studies will, however, require many years to accrue.

Initial intervention

Optimistically, diet modification and exercise can be accomplished in obese patients with success as high as 80% of patients achieving dietary goals and 36% achieving exercise goals [372]. Pessimistically, even intensive counseling to reduce fat intake (<30% of daily calories) and to engage in regular physical activity produces only a modest 5% sustained weight loss [373,374]. However, successful intervention can significantly reduce liver fat even with modest changes. In the Tuebingen Lifestyle Intervention Program (TULIP) study, the degree of physical deconditioning correlated both to baseline liver fat content and inversely to response to lifestyle intervention [375].

Exercise alone

The relative benefit of exercise *without* weight loss (i.e., the "fit fat") versus dietary weight loss has been explored in experimental and clinical NAFLD [376,377]. Exercise affects insulin signaling and calorie disposal through interactions with skeletal muscle substrate utilization, PPAR signaling, and mitochondrial metabolism [378–380]. Although the optimal "dose" remains to be determined, the most effective "conditioning" exercise is that which just passes beyond the lactate threshold – a level usually associated with some degree of discomfort [381,382]. Compared to a control group who received only stretching advice, a treated group who underwent 4 weeks of graded exercise (three 30–45-minute sessions per week at 50% baseline VO_{2peak} for 1 week, 60% for 1 week, and 70% for 2 weeks) had a 12% reduction in visceral fat and a 21% reduction in liver fat without overall weight loss [383]. It seems likely that the efficacy of this approach will depend on earlier intervention.

Dietary weight loss and exercise in adults and children

Diet *and* exercise-induced weight loss is effective in NAFLD although very rapid loss should be viewed cautiously [384,385]. Weight reduction through nutritional counseling is associated with improved aminotransferases and histology, usually in parallel to improved insulin signaling [386,387]. Significant improvement in aminotransferases and histology was seen in adults treated with diet (25 kcal/kg ideal body weight/day) and exercise (walking and jogging) for 3 months compared to a control group [388]. Similarly, improvement was seen in metabolic and histologic parameters (steatosis, inflammation, ballooning) after 2 years intervention in pediatric cases [389]. In another 2-year controlled trial in adults, lifestyle intervention resulted in 9% weight loss versus 0.2% in controls [390]. Seventy-two percent of the lifestyle intervention group versus 30% of controls had a reduction in the histologic score (NAS) by 3 or more or to ≤2 points post-treatment. Specific diet plans such as low carbohydrate diets [391] or reduced calorie diet may be less important than finding one that is sustainable.

Dietary composition (omega 3 fatty acids, fructose, and fast food)

Changes in dietary composition appear to be particularly important. Fast food hyperalimentation with two such meals per day for 4 weeks caused significant increases in aminotransferases and hepatic fat in a study of young healthy volunteers [392]. Elimination of this source of food could reasonably be expected to lead to improvement in these parameters. Dietary fats effect the composition of cell and organelle membranes, insulin sensitivity, gene regulation (PPARs), adipocyte differentiation, and prostaglandin metabolism (altered especially by the relative content of n6 versus n3 polyunsaturated fatty acids (PUFAs)) [393–395]. Although there has been concern regarding PUFAs in alcoholic steatohepatitis [396], animal and limited human studies of omega 3 (n3) supplements as EPA (eicosapentaenoic acid) and DHA (docosahexanoic acid) have been encouraging but are yet to be substantiated [397]. Cohort studies using food frequency questionnaires have indicated that concentrated fructose

sweeteners, especially in beverages such as soft drinks, are associated with increased fatty liver independent of metabolic syndrome and greater fibrosis in patients with NASH [398,399]. This may in part be attributable to the metabolism of concentrated fructose, which is particularly steatogenic [400].

Weight loss agents

Orlistat (tetrahydrolipostatin) decreases fat absorption by inhibiting lipase. In spite of several promising pilot studies, an RCT showed similar weight loss in both groups and improved insulin signaling and histology in subjects losing ≥9% body weight regardless of treatment with orlistat or not [401]. Less clear is the role of other weight loss agents such as sibutramine (a serotonin and norepinephrin reuptake inhibitor) and potential appetite modulators such as leptin, amylin, or the incretins (glucagon-like peptide 1, glucose-dependent insulinotropic polypeptide). Endocannabinoids such as rimonabant as weight loss agents are no longer under study to our knowledge due to concerns over side effects.

Weight reduction surgery

Gastric bypass, biliointestinal bypass, and gastric banding are effective in reducing weight, improving insulin resistance, and improving liver histology in NASH in selected patients [402–404]. Accepted indications include a BMI of >40 kg/m^2 (after failure of conventional weight loss measures) or a BMI of ≥35 kg/m^2 with a co-morbidity such as heart disease, diabetes mellitus, hyperlipidemia, or sleep apnea. NASH per se is not typically included as one of these co-morbidities although given the morbidity and mortality associated with steatohepatitis, this is likely to change. On the other hand, limitations of bariatric surgery include resource utilization, long-term effects, and application in patients with incidentally discovered cirrhosis. In the latter, mortality is increased at 4% and progressive liver dysfunction is seen in 12% [405]. In contrast, structured 5-year follow-up biopsies reveal only mild increased fibrosis in the majority of patients with initially early-stage fibrosis [406].

Ursodeoxcholic acid, L-carnitine, and other cytoprotective agents

The possible benefits of ursodeoxcholic acid (UCDA) include effects on mitochondrial membrane stability, blood flow, and immunomodulation [407]. Histologic and biochemical improvement were noted in pilot studies but the results from larger controlled trials have been variable [408,409]. In a 2-year RCT of 166 patients, both groups had similar improvement in aminotransferases and follow-up biopsy (available in only two thirds), consistent with a strong placebo [410]. Similar results were noted in an 18-month controlled trial of high-dose UDCA (23–28 mg/kg/day) in 185 patients where no significant differences were noted in multiple histologic parameters although improved inflammation approached significance [411]. On the other hand, combination therapy has been more promising: UDCA (12–15 mg/kg/day) and vitamin E (800 IU/day) for 2 years versus single or double placebo controls showed significant improvement in the NAS only in the group treated with combination therapy [412]. L-Carnitine at a dose of 1 g twice daily has been compared with placebo in a 24-week trial. Metabolic and histologic parameters improved in both groups but significantly more so in the carnitine-treated subjects [413]. Other potential cytoprotective agents include taurine, triacetyl uridine, pentoxifylline, and possibly probiotics through indirect mechanisms.

Antioxidants (vitamin E, betaine, and others)

Vitamin E refers to a family of tocopherols and tocotrienols that exhibit antioxidant activity. Available forms usually contain only α-tocopherol – whether other forms are more or less effective is uncertain [414]. Small and short-term human studies (mostly with α-tocopherol) have shown improvement in serologic markers of inflammation but variable histologic results and unclear differentiation from control groups [415–417]. However, a 6-month, placebo-controlled combination study (vitamin E 1,000 IU plus vitamin C 1,000 mg daily) showed improvement in fibrosis although no improvement in inflammation or necrosis was seen [418]. These results were supported in a recent 2-year controlled trial of 247 nondiabetic adults, comparing α-tocopherol (800 IU/day) with placebo and pioglitazone (see below) [419]. Although there were methodologic criticisms (histologic criteria and tocopherol metabolism), significantly greater improvement was seen in key parameters, including steatosis, inflammation, and ballooning, compared with placebo [420]. Toxicity has not been reported in these studies although there remains some theoretical concern regarding higher doses [421,422]. Betaine (trimethylglycine), a methyl donor, promotes conversion of phosphotidyl-ethanolamine to phosphotidylcholine and the export of fat as VLDL [423]. Steatosis was blunted in a 1-year, randomized, placebo-controlled trial but other metabolic and histologic parameters were unchanged compared with placebo [424]. Other potential agents, which to our knowledge have not been adequately studied, include silymarin (milk thistle extract), *N*-acetylcysteine (converted to glutathione in the liver), glycyrrhizin, and lazaroids (21-aminosteroids).

Antidiabetic agents

Insulin-sensitizing agents have emerged as the most studied form of pharmacologic therapy [425]. Most

adequately controlled studies have focused on the thiazolidinediones and metformin, while less is known about the effects of sulfonylureas, insulin, incretins, or agents such as acipimox (inhibits peripheral lipolysis), although the latter does not appear to lower hepatic fat with short-term exposure [426].

Thiazolidinediones

Thiazolidinediones (TZDs: rosiglitazone and pioglitazone) are ligands of PPAR-γ, a nuclear receptor normally activated by fatty acids that regulates gene expression of enzymes involved in lipid and glucose metabolism and which is usually expressed in adipose tissue, intestines, macrophages, and muscle. The receptor, the ligand, and a coactivator form a heterodimer with retinoid X receptor which binds to the response element of specific genes [427]. The most profound effect of TZDs is in adipocyte differentiation [428]. As a result, TZDs cause increased peripheral but decreased central adiposity [429]. A number of potentially relevant nonhypoglycemic effects are also reported [430].

The most consistent effects in human NASH studies have been improved aminotransferases, reduced hepatic steatosis and histologic inflammation, improved insulin signaling, a mild or zero impact on fibrosis even with extended therapy (up to 3 years in the FLIRT 2 study with rosiglitazone), and overall weight gain of several kilograms in most but not all patients (Fig. 32.16) [431–435]. Similar results have been seen with both pioglitazone and rosiglitazone although pioglitazone appears to be slightly more effective. A relapse of necroinflammation occurs after the discontinuation of therapy but can be ameliorated with sustained adherence to dietary changes and increased exercise [436,437]. Because PPAR-γ receptors are not highly expressed in human liver, the effects in NASH are likely to primarily involve indirect mechanisms [438]. In the largest study to date, although troubled by methodologic issues (see above), 47% of pioglitazone-treated patients versus 36% of vitamin E-treated patients and 21% of placebo-treated patients had resolution of steatohepatitis after 2 years of therapy [420].

Uncommon idiosyncratic hepatotoxicity led to the withdrawal of troglitazone (the first widely available TZD) [439]. Very rare hepatotoxicity has been reported with rosiglitazone and pioglitazone [440,441]. The effect of shifting fat stores on myocyte function, exercise tolerance, and endurance in these patients has not been adequately addressed. Other side effects of concern include possible precipitation of edema and congestive heart failure and osteoporosis [436,442]. However, of greatest concern is the risk of cardiovascular events in rosiglitazone-treated patients that appears to be related to changes in lipoprotein metabolism (much less evident or nonexistent with pioglitazone) [443,444].

Metformin

Metformin is an insulin-sensitizing, oral biguanide approved for use in type 2 diabetes in the United States since 1995 [445]. The biguanides exert changes in cellular bioenergetics, reduce hepatic glucose production, and increase peripheral glucose utilization [446]. A major site of action is the mitochondria and signaling is via AMP-activated protein kinase [447] – this pathway is similarly activated with exercise, suggesting that in some ways metformin simulates the effects of exercise on glucose transport. Lactic acidosis appears to be uncommon but caution is warranted in renal insufficiency [448]. Favorable studies in early rodent models, its mild side effect profile (especially the absence of weight gain), and early pilot data in humans sustained an interest in its use in NASH. However, conflicting data have led to the general impression that the agent is usually well tolerated in adult NASH but is not particularly effective in resolving histologic injury [449–452]. A large controlled pediatric study remains in progress.

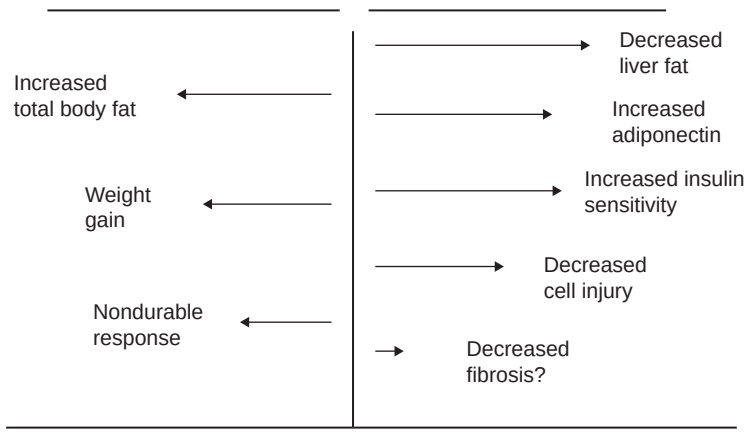

Figure 32.16 The relative effects of thiazolidinediones in nonalcoholic steatohepatitis. Limitations are shown to the left and potential benefits to the right. The length of the arrow indicates relative benefit.

Antihyperlipidemic agents (fibrates and statins)

Fibrates act on PPAR-α receptors located in the liver, heart, muscle, and kidney (normally activated by fatty acids) that stimulate fatty acid oxidation. Promising results with gemfibrozil were not recognized in a histology-based controlled trial of fenofibrate [453–454]. Whether there are differences between the agents is not known. Based on the natural history of NASH (an increased risk of cardiovascular death; see above), the lack of overt evidence of increased hepatic toxicity, and their efficacy in atherosclerosis, HMG-CoA reductase inhibitors or statins are widely prescribed in NASH patients and appear relatively safe [455]. However, the interaction of these agents and NAFLD/NASH is complex and presently not well explored [456]. Whether fibrosis is decreased or possibly increased is unclear from a long-term cohort study where mean fibrosis scores improved but the percentage of patients with advanced stage fibrosis appeared to increase [457]. Favorable therapeutic results in early pilot studies were not confirmed in a subsequent histology-based RCT [458,459].

Other agents (caspase inhibitors, adrenergics, and angiotensin receptor blockers)

Because of the role of apoptosis pathway activation (see above), a great deal of interest has centered on caspase inhibition as a possible therapeutic avenue in experimental models [460,461]. However, the effects on necrosis pathways, the relative risk–benefit with chronic therapy, and the costs of this approach are uncertain. The effects of the adrenergic system on NAFLD have also been explored and may offer an avenue of pharmacologic therapy [462,463]. Angiotensin receptor blockers may modulate fibrosis pathways and are also reported in an uncontrolled study in human NASH [464,465]. As evident from the foregoing discussion, controlled trials are needed to determine its efficacy.

Liver transplantation, disease recurrence, and donor organs

Although there is confusion in nomenclature between NASH-cirrhosis and many cases of cryptogenic cirrhosis, NASH as a designated indication for transplantation appears to be increasing in the Unted States. Whether this represents a true increase, or a greater acceptance of NASH as a cause of advanced cirrhosis, is unclear. Transplant eligibility is complicated by co-morbidities related to the metabolic syndrome [466,467]. Thus, many centers restrict candidacy by BMI (usually $<40\,kg/m^2$). Recurrent (and de novo) NAFLD and NASH after transplantation is reported and may be progressive (see Fig. 32.5) [216,468]. The relative risks of different immunosuppression regimens is not clearly established although weight gain is predictive. Compared with other causes, overall long-term post-transplant survival for NASH-cirrhosis is similar, although early survival is diminished in those with an age over 60 years, BMI $\geq 30\,kg/m^2$, and diabetes [469–471]. Steatosis in donor livers is associated with poor graft function likely due to disturbed ATP homeostasis [472]. This problem is magnified in living-related donation where accurate diagnosis of steatosis in a partial donor is essential.

A number of randomized controlled pharmacologic trials have been reported. The thiazolidinediones (TZDs) are the best studied group of agents. The most consistent effects of the TZDs are reduction of steatosis, inflammation, and ballooning, but they have a limited effect on fibrosis and increased body weight due to peripheral adipose accumulation in many but not all patients. Weight gain and vascular risk with some agents limits the application of the TZDs. Higher dose vitamin E, possibly in combination with cytoprotective agents, appears promising but requires further study and carries concerns of long-term safety.

The natural history of NAFLD and NASH has come into much sharper focus. From histologic studies using paired biopsies over time, inflammation appears to be a key predictor of progression to advanced fibrosis seen in about 15% of cases over about 5–10 years. Patients with histologic NASH compared with those with non-NASH fatty liver have significantly diminished survival. Leading causes of death are cardiovascular disease, nonhepatic cancers, and cirrhosis-related disease. The dominant pattern in a given patient is difficult to predict and it is increasingly apparent that many patients develop coronary disease in the setting of cirrhosis, presenting the clinician with complex challenges.

These studies have established significant ethnic variation and familial risk in the prevalence of NAFLD and elucidated the complex relationships between

obesity, insulin resistance, and fatty liver within these groups. Much of the variation is conferred by a gene product called PNPLA3 (adiponutrin) which is a lipase that appears to be especially active in the endoplasmic reticulum.

Key histologic parameters have been combined into a widely utilized composite score (the NASH activity score or NAS) which facilitates assessment of therapeutic interventions and comparison between different studies. Interobserver variation in the criteria of ballooning has been problematic. It now appears that these cells are depleted of keratin 8 and 18 and contain small fat droplets as well as dilated endoplasmic reticulum – features that may lend themselves to more refined scoring.

Maheshwari A, Thuluvath PJ. Cryptogenic cirrhosis and NAFLD: are they related? *Am J Gastroenterol* 2006;101:664–8.

Cryptogenic cirrhosis remains a common diagnostic problem. The potential for NASH to progress to a late stage of characterized by cirrhosis with loss of steatosis was first noted 20 years ago. Subsequently, a number of studies compiled and compared in this work confirmed that in most regions of the world, NASH is the most common cause of cryptogenic cirrhosis usually in association with prior obesity and diabetes although other causes are recognized such as silent autoimmune hepatitis.

These studies have demonstrated key pathologic mechanisms of cell injury in NAFLD/NASH. Lipid accumulation results from both increased de novo synthesis from carbohydrate substrate and uptake of nonesterified fatty acids from peripheral fat lipolysis. Impaired apo-B function contributes to lipid accumulation by insufficient VLDL secretion relative to the total fat content of the liver. Lysosomal recycling of accumulated small fat droplets is regulated through a process called lipophagy. Caspase activation results from the effects of fatty acids on lysosomal and mitochondrial permeability and results in fragmentation of the elements of the cytoskeleton including keratin 18 fragments.

Ueno T, Sugawara H, Sujaku K, et al. Therapeutic effects of restricted diet and exercise in obese patients with fatty liver. *J Hepatol* 1997;27:103–7.

These studies have clearly demonstrated histologic improvement of NASH with conservative measures of exercise and dietary changes. Exercise alone (without net weight loss) also diminishes liver fat. Such voluntary lifestyle changes constitute the most important intervention but are successful in only about 20–30%. Outcomes are enhanced with more structured programs. Voluntary adoption introduces a confounding variable into pharmacologic studies which is challenging but essential to account for.

Multiple choice questions

32.1 NASH (nonalcoholic steatohepatitis) is the more severe form of NAFLD (nonalcoholic fatty liver disease). It is present in about one third of patients with NAFLD. Which of the following is true about NASH?

a Steatosis exceeds 5–10% liver triglyceride by weight (estimated by light microscopic appearance)
b NASH progresses to cirrhosis in 15–20% of patients.
c NASH is characterized histologically by inflammation, cellular ballooning, and fibrosis, usually beginning as perisinusoidal fibrosis.
d NASH currently requires biopsy to confirm and stage.
e All of the above.
f None of the above.

32.2 The treatment of NAFLD is evolving. Exercise and dietary changes are cornerstones. Pharmacologic therapy has been primarily aimed at NASH because of its greater risk of progression. Which of the following is correct?

a Thiazolidinediones (pioglitazone) are the only agents approved for treating NASH.
b Vitamin E and other antioxidants have been uniformly ineffective in treating NASH.
c Exercise (with or without weight loss) can reduce liver fat.
d Statin agents have been shown to ameliorate NASH in randomized controlled trials.
e All of the above.
f None of the above.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

PART VIII

Vascular Diseases of the Liver

CHAPTER 33
Vascular Diseases of the Liver

Ranjeeta Bahirwani, Mark A. Rosen, & Thomas W. Faust

Division of Gastroenterology, Department of Internal Medicine, The University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Key concepts

- Budd–Chiari syndrome occurs as a consequence of thrombotic occlusion of hepatic venous outflow.
- Hypercoagulable states account for most cases of Budd–Chiari syndrome. Anticoagulation is the mainstay of medical management.
- Webs and membranes in the inferior vena cava develop from prior thrombosis and represent the most common subtype of Budd–Chiari syndrome in the Far East.
- Acute or subacute Budd–Chiari syndrome may present with abdominal pain, hepatomegaly, and ascites, whereas symptoms and signs of portal hypertension are prominent with chronic disease.
- Doppler ultrasonography is a useful noninvasive screening test for Budd–Chiari syndrome. Contrast-enhanced computed tomography and magnetic resonance imaging can also demonstrate hepatic vein occlusion and associated parenchymal abnormalities secondary to venous outflow obstruction. Venography and liver biopsy remain the gold standards for diagnosis.
- Angioplasty and thrombolysis may be of benefit in highly selected cases. Decompressive surgery and transjugular intrahepatic portosystemic shunting (TIPS) are often reserved for progressive liver disease despite medical management. Liver transplantation may be performed for patients with decompensated cirrhosis or acute liver failure.
- Hereditary hemorrhagic telangiectasia, also known as Rendu–Osler–Weber syndrome, is a multisystemic vascular disorder that may involve the liver.
- Peliosis hepatis is characterized by blood-filled cystic lesions in the hepatic parenchyma, which may occur in the setting of immunosuppression or human immunodeficiency virus (HIV) infection. *Bartonella henselae* is the cause of bacillary peliosis hepatis in patients with HIV infection.

Budd–Chiari syndrome and related disorders

Etiology

The most frequent causes of venous obstruction are prothrombotic disorders, particularly myeloproliferative diseases (Box 33.1) [1]. In one of the largest series, 45% of patients with Budd–Chiari syndrome had polycythemia rubra vera and 9% were diagnosed with essential thrombocythemia [2]. Occult myeloproliferative states, demonstrated by spontaneous endogenous erythroid colony formation in the absence of erythropoietin stimulation, are also common [3]. An increasing number of thrombotic disorders have been associated with Budd–Chiari syndrome [4–6]. In over 25% of cases, more than one thrombophilic state may be present [6]. Careful, systematic evaluation for prothrombotic disorders has lowered the proportion of cases labeled as idiopathic to less than 10% [3,6]. Factor V Leiden mutation is the most frequent cause of hereditary thrombophilia and is thought to be the second most common cause of thrombotic occlusion of the hepatic veins and vena cava [4–9]. Other hypercoagulable states associated with Budd–Chiari syndrome include antiphospholipid antibody syndrome, paroxysmal nocturnal hemoglobinuria, prothrombin G mutation, methylene-tetrahydrofolate reductase mutation, antithrombin III deficiency, and deficiencies of protein C and protein S [6,7,10–15]. Patients who are pregnant or are taking oral contraceptives and develop Budd–Chiari syndrome usually also have an underlying thrombophilic state [4–9].

Local compression by adjacent tumor, abscess, or inflammation may lead to a secondary Budd–Chiari syndrome. Neoplasms associated with outflow obstruction include primary hepatocellular, renal, adrenal, pulmonary, pancreatic, and gastric carcinomas [16–19]. Benign and malignant vascular neoplasms arising within the hepatic veins or vena cava (e.g., cavernous hemangiomas, leiomyomas, and leiomyosarcomas) have also been associated with Budd–Chiari syndrome [20–22].

Box 33.1 Etiology of Budd–Chiari syndrome.[a]

Myeloproliferative disorders
- Polycythemia rubra vera
- Essential thrombocytosis
- Occult myeloproliferative disorders

Local compression
- Neoplasms
- Infection

Systemic diseases
- Behçet's disease
- Inflammatory bowel disease
- Sarcoidosis
- Idiopathic

Other hypercoagulable states
- Factor V Leiden mutation
- Prothrombin G20210A gene mutation
- Antiphospholipid antibody syndrome
- Methylene-tetrahydrofolate reductase mutation
- Paroxysmal nocturnal hemoglobinuria
- Protein C and S deficiency
- Antithrombin III deficiency
- Oral contraceptives
- Pregnancy

[a] Frequently more than one condition may be present.

Other rare causes of hepatic venous outflow obstruction have been identified. Bacterial, viral, and parasitic infections, collagen vascular diseases, and inflammatory bowel disease may all also result in venous occlusion [23–28].

Inferior vena cava thrombosis

Budd–Chiari syndrome includes thrombosis anywhere along the hepatic venous outflow tract. It has been proposed that obstruction principally affecting the inferior vena cava should be termed *obliterative hepatocavopathy* [29]. Primary inferior vena cava thrombosis appears to be more common in India, China, Japan, Nepal, and South Africa for unclear reasons. Compared to classic Budd–Chiari syndrome, obliterative hepatocavopathy is more often considered idiopathic [29–31]. It has also been found in association with hepatocellular carcinoma [29–31]. However, systematic investigation frequently reveals an underlying thrombophilic state [30,32]. The obstruction results from caval webs or membranes, which may also involve the ostia of the hepatic veins. Although the lesions were formerly thought to be congenital, it is now recognized that they represent the transformation of inferior vena cava thrombosis [29,33]. Widespread acceptance of obliterative hepatocavopathy as a distinct entity has not occurred because its etiology, prognosis, and management are similar to those of classic Budd–Chiari syndrome (Box 33.2) [34].

Box 33.2 Budd–Chiari syndrome subtypes and sinusoidal obstruction syndrome.

Classic Budd–Chiari syndrome
- Thrombosis principally of hepatic veins
- More common in western countries
- Thrombophilic state most common etiology

Obliterative hepatocavopathy
- Webs and membranes (representing prior thrombosis) in inferior vena cava
- More common in China, Nepal, India, Japan, and South Africa
- Thrombophilic state, idiopathic and hepatocellular cancer common

Sinusoidal obstruction syndrome
- Nonthrombotic fibrosis of hepatic sinusoids and small intrahepatic veins
- Almost exclusively seen in the setting of bone marrow transplantation
- Mainly caused by conditioning chemotherapy

Occlusion of the terminal hepatic venules (sinusoidal obstruction syndrome)

Sinusoidal obstruction syndrome (previously called venoocclusive disease) refers to obstruction of the hepatic sinusoids or small intrahepatic veins. In contradistinction to Budd–Chiari syndrome, occlusion is not thrombotic but results from fibroobliterative endophlebitis (Box 33.2). Occasionally, Budd–Chiari syndrome may involve only small intrahepatic veins. Sparing of the large hepatic veins can be seen with allergic phlebitis, granulomatous disease, paroxysmal nocturnal hemoglobinuria, and other thrombophilic states [6,34]. Distinction from sinusoidal obstruction syndrome can generally be accomplished by recognition of etiology and in some cases by demonstration of clots. Outside the setting of bone marrow transplantation, the two conditions may be indistinguishable.

Initial reports of sinusoidal obstruction syndrome were attributed to ingestion of herbal teas containing large quantities of pyrrolizidine alkaloids [35,36]. Today, sinusoidal obstruction syndrome is seen almost exclusively in the setting of bone marrow transplantation. Hepatotoxic agents, particularly certain chemotherapeutic conditioning regimens, account for most cases (Box 33.2). Recipients of liver and renal allografts and patients exposed to azathioprine are also at risk for developing sinusoidal obstruction syndrome. Other rare conditions associated with sinusoidal obstruction syndrome include vitamin A toxicity, arsenic poisoning, exposure to insecticides, administration of 6-thioguanine, intra-arterial 5-fluoro-2′-deoxyuridine, and a combination of norethisterone with conditioning chemotherapeutic agents [35,37–40].

Pathology

Hepatic venous outflow obstruction is caused by thrombotic occlusion of the terminal hepatic venules, hepatic veins, or inferior vena cava. Generally, the disease is silent if only one hepatic vein is occluded. Obstruction may manifest as fibrous cord remnants of hepatic veins, short-length stenoses, membranes, webs, or occlusions of the hepatic venous ostia [10,29,33,41]. In acute Budd–Chiari syndrome, the liver appears enlarged, smooth, and red-purple because of congestion. In chronic disease, direct outflow from the caudate lobe to the inferior vena cava may compensate for venous outflow obstruction of the major hepatic veins, resulting in caudate lobe hypertrophy with atrophy and cirrhosis of the remaining segments [42]. In some cases caudate lobe hypertrophy may obstruct the intrahepatic portion of the inferior vena cava.

Histologic changes may be uneven and result in liver biopsy sampling errors. Centrilobular congestion and sinusoidal dilatation are seen with acute obstruction, whereas atrophy, necrosis, and centrizonal hepatocyte dropout with extension to periportal regions are associated with severe injury. Venous stasis and congestion lead to hypoxic damage and oxidative injury to hepatocytes [43,44]. In chronic disease, there is complete obliteration of the central veins associated with centrilobular fibrosis that may culminate in cirrhosis [45,46]. Periportal fibrosis may be more prominent if branches of the portal vein are concomitantly thrombosed because of stasis [47]. Large, regenerative nodules are also commonly reported in areas exposed to a compensatory increase in arterial blood flow [43,47].

Clinical presentation

About two thirds of patients with Budd–Chiari syndrome are women, with the onset of symptoms usually in the late thirties [2]. Clinical presentation is variable and depends on the extent and rate of outflow obstruction, as well as the development of collaterals (Box 33.3) [10]. Presentation may range from an asymptomatic state to fulminant hepatic failure, or to cirrhosis with complications of portal hypertension [7,48,49]. More than 85% of patients have hepatomegaly and ascites, whereas esophagogastric varices and splenomegaly may be seen in 40–60% of individuals [48]. The presence of dilated subcutaneous veins over the body and trunk are more often associated with inferior vena cava obstruction [29]. Acute obstruction is commonly accompanied by right upper quadrant abdominal pain, nausea, vomiting, hepatomegaly, and ascites [48]. Jaundice and splenomegaly may be present with acute occlusion but are usually mild. Rarely, massive hepatocellular necrosis with acute hepatic failure may follow rapid and complete occlusion of all major hepatic veins [48]. A subacute presentation of less than 6 months is characterized by vague right upper quadrant discomfort, hepatomegaly, mild to moderate ascites, and splenomegaly [48,49]. Jaundice is either absent or mild. Chronic Budd–Chiari syndrome of greater than 6 months' duration generally presents with progressive ascites. It may also be accompanied by other complications of portal hypertension, such as bleeding varices, encephalopathy, coagulopathy, renal insufficiency, fatigue, and muscle wasting [10,48,49]. Generally, cirrhosis is found only in patients with chronic disease. However, the demonstration of cirrhosis in biopsy specimens taken from patients with acute outflow tract obstruction provides an argument that the current classification system leaves room for improvement [50].

Box 33.3 Clinical manifestations of Budd–Chiari syndrome.

- Right upper quadrant pain
- Hepatomegaly
- Ascites
- Splenomegaly (rare)
- Jaundice
- Acute liver failure (rare)
- Weight gain
- Nausea and vomiting
- Pleural effusions
- Lower-extremity edema
- Complications of portal hypertension

Diagnostic evaluation

Laboratory investigation

Standard laboratory investigation is rarely helpful in patients with Budd–Chiari syndrome. Nonspecific mild transaminase level elevation can be seen in 25–50% of patients but does not aid in establishing the diagnosis [16]. Transaminase values over 1,000 IU/L are possible in acute outflow obstruction or hepatic failure, especially if there is accompanying portal vein thrombosis [16]. Serum bilirubin and alkaline phosphatase levels and prothrombin time are usually normal or mildly elevated and are also not specific [16,51]. Ascitic fluid analysis is consistent with portal hypertension. Myeloproliferative and thrombotic disorders are common. Therefore, systematic, comprehensive evaluation for hypercoagulable disorders should be undertaken. The following tests should be performed: plasma clotting factors and inhibitors, factor V Leiden factor mutation, prothrombin G gene analysis, antiphospholipid antibodies and lupus anticoagulant, flow cytometry for paroxysmal nocturnal hemoglobinuria, blood smear analysis, and in select cases determination of total red cell mass, bone marrow biopsy, and

measurement of serum erythropoietin levels [34]. Caution must be exercised in the interpretation of protein C, protein S, and antithrombin III abnormalities because compromised hepatic synthetic function may provide alternative explanations.

Medical imaging

Doppler ultrasonography allows for noninvasive evaluation of the hepatic veins, inferior vena cava, and portal vein. In experienced hands the sensitivity of ultrasonography for detecting venous obstruction approaches 85–95% [7,10,52]. Real-time evaluation of acute venous occlusion reveals enlarged, stenotic, or tortuous hepatic veins, whereas the major hepatic veins of patients with chronic disease may not be seen [52,53]. Intrahepatic venous-to-venous spiderweb collaterals and/or the presence of intrahepatic or subcapsular hepatic venous collaterals are highly suggestive of Budd–Chiari syndrome [34,52]. Ultrasonography may also show caval compression by a hypertrophied caudate lobe or obstruction of the vena cava by thrombus, tumor, or membranes [52,53]. Visualization of a caudate vein is over 90% specific for Budd–Chiari syndrome, although only 50% sensitive [54]. The addition of Doppler to conventional ultrasonography increases sensitivity. Doppler is effective for evaluating not only the perihepatic vascular anatomy but also the direction of blood flow and site of obstruction. Loss of the normal triphasic wave variation in the vena cava or hepatic veins has a sensitivity of 88% for occlusion [55].

Computed tomography (CT) scan and magnetic resonance imaging (MRI) are complementary investigations to Doppler ultrasonography [56–58]. Abnormalities seen may include nonvisualization of vessels or obstruction by thrombus [52,53,59,60]. Acute thrombus may be demonstrated as an expanded nonenhancing vein (Fig. 33.1), whereas more chronic changes are suggested when vessels are narrowed or not visualized.

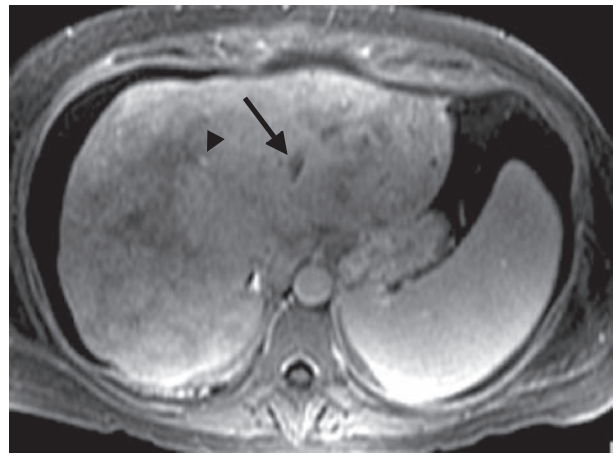

Figure 33.1 Gadolinium-enhanced magnetic resonance imaging of a 67-year-old woman with Budd–Chiari syndrome and acute hepatic decompensation. Delayed postgadolinium images demonstrate expanded nonenhancing left hepatic vein (arrow), representing acute thrombus. A narrowed but enhancing middle hepatic vein is also shown (arrowhead). Vessel narrowing suggests prior thrombosis with recanlization. Portal vein thrombus and ascites were also present. The patient decompensated and underwent transplantation. Explant pathology confirmed acute left hepatic vein thrombus. The middle and right hepatic veins with chronic thrombotic changes and recanalization were also demonstrated.

A "mosaic" pattern of abnormal parenchymal enhancement (Fig. 33.2), representing the effects of relative venous outflow obstruction, is commonly seen in contrast-enhanced CT and MRI. This pattern is not specific for Budd–Chiari syndrome and can also be seen in severe right-sided heart failure. In cases of chronic venous outflow obstruction, parenchymal changes of nodular regeneration (including macroregenerative nodules) and cirrhosis may ensue (Fig. 33.3) [53,55,60,61]. When portal hypertension develops, characteristic imaging findings (e.g., splenomegaly, ascites, collateral vessels) are often depicted as well.

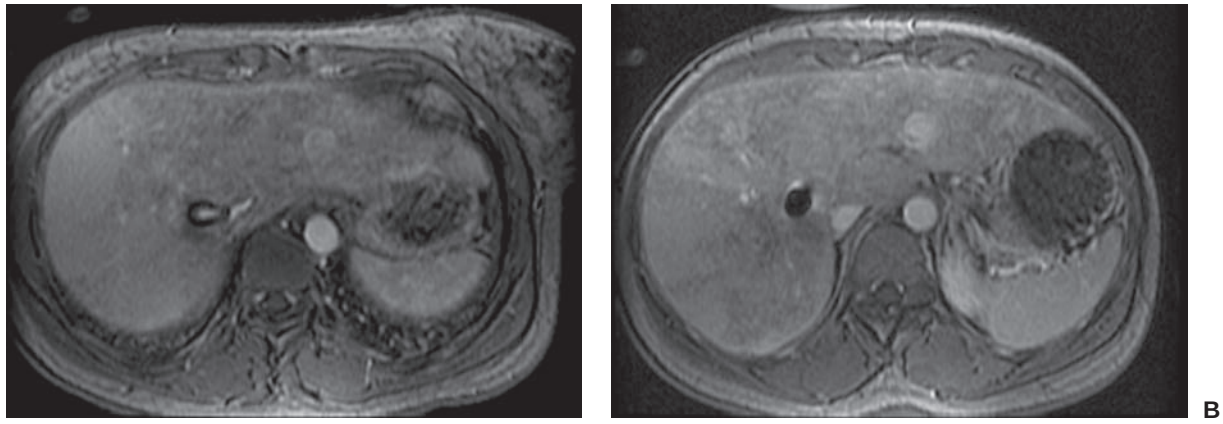

Figure 33.2 Gadolinium-enhanced magnetic resonance imaging (MRI) of a 57-year-old woman with chronic Budd–Chiari syndrome and a prior transjugular intrahepatic portosystemic shunt. The MRI demonstrates heterogeneous (mosaic) enhancement in the left lobe (A) and portions of the right lobe (B).

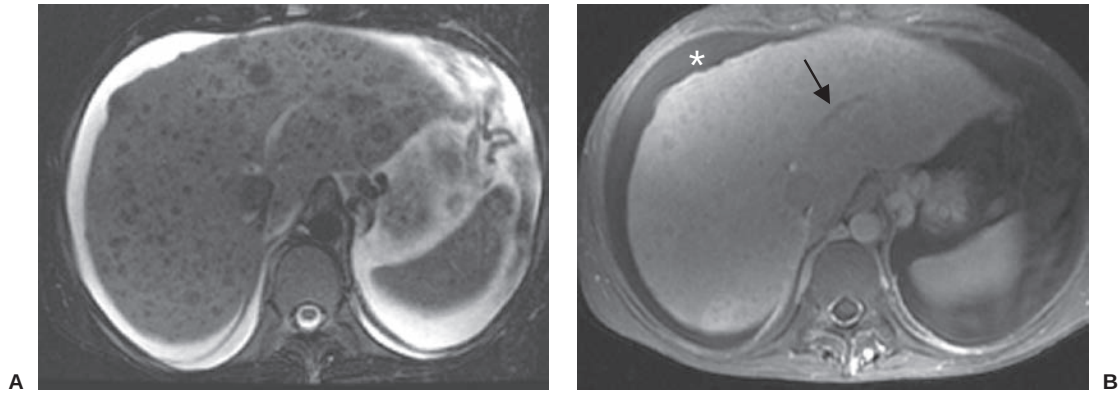

Figure 33.3 Magnetic resonance imaging of the liver of a 31-year-old man with longstanding Budd–Chiari syndrome. (A) In the T2-weighted image, liver parenchyma is abnormally edematous, with signal intensity elevation (comparable to that of the spleen). Multiple regenerative nodules characteristic of longstanding Budd–Chiari syndrome are hypointense to the edematous liver parenchyma. (B) In the postgadolinium image, nodular enhancement heterogeneity is shown. A portion of the thrombosed left hepatic vein is demonstrated (arrow); ascites is also seen (asterisk).

Venography remains the standard of reference for diagnosis and is key to planning optimal therapy. Typical venographic findings include narrowed, irregular hepatic veins with or without occlusive thrombi. Thrombi may be found either at the junction of the hepatic veins with the cava or just distal to the venous orifices [16,51]. The replacement of hepatic veins with the classic "spider-web" appearance, intrahepatic collaterals, and recanalized veins can also be appreciated [16,51,55,62]. Angiographic assessment of the vena cava provides important information about the location and extent of obstruction, as well as its amenability to angioplasty and stenting [16,51,62]. Both catheter-based and magnetic resonance venography can be used to depict stenoses or webs of the inferior vena cava (Fig. 33.4). Local installation of thrombolytics may be performed at the time of venography in patients with fresh clots (less than 3–4 weeks) [63]. Liver biopsy may also be obtained at the time of catheter venography. Furthermore, pressure measurements obtained at the time of venography can provide useful information before surgical decompression [16,51,62].

Liver biopsy

Although not mandatory, liver biopsy is complementary to medical imaging and clinical patient assessment. Generally, the diagnosis can be established by medical imaging. In select patients, biopsy may be required to distinguish Budd–Chiari syndrome from sinusoidal obstruction syndrome or cirrhosis from other causes. Biopsy specimens may establish the presence of fibrosis and cirrhosis and may also grade the severity of hepatocellular necrosis. However, caution should be used when interpreting results because sampling error is common. Bilobar biopsy may provide a higher diagnostic yield [62]. However, it is not clear whether results from liver biopsy determine the prognosis [64,65]. In a multivariate

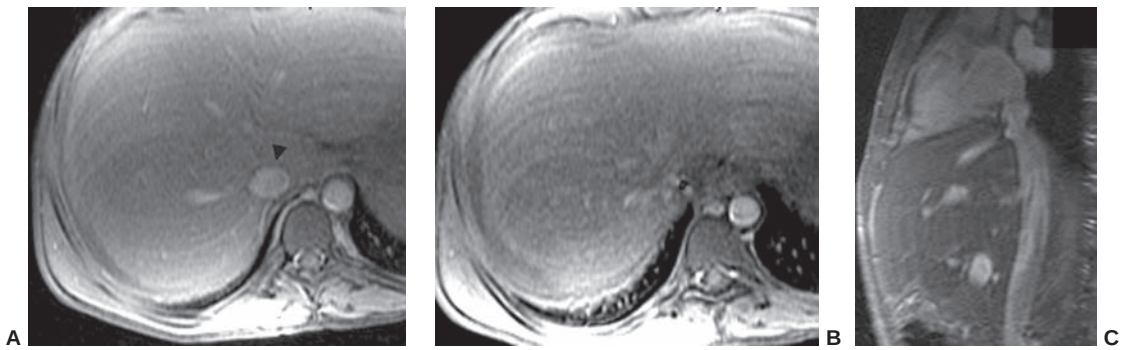

Figure 33.4 Cardiac-gated bright blood (cine) vascular imaging 2 cm below (A) and at (B) the level of the hepatic vein confluence of a 20-year-old man with lower extremity swelling and liver dysfunction showing (A) a patent inferior vena cava (IVC) with flow (arrowhead), and (B) a narrowed IVC. Dark areas within the IVC lumen represent turbulent (nonlaminar) flow. A cavogram (not shown) demonstrated IVC stenosis with thrombus, severely narrowing the lumen with a large pressure gradient. Angioplasty relieved both the lower extremity symptoms and the hepatic abnormalities. (C) Repeat cine magnetic resonance imaging in the sagittal plane after angioplasty demonstrating a patent IVC with mild structuring at the site of prior stenosis.

analysis, age, Child–Pugh score, responsiveness to diuretics, and creatinine were predictive of survival, whereas data from carefully documented biopsies were not [65].

Management

In the absence of prospective natural history studies of untreated and unselected patients and randomized, controlled trials of treatment options, firm management recommendations cannot be made; however, some general principles have emerged. Anticoagulation is recommended for most patients. Thrombolytics may be of benefit in acute thrombosis. Angioplasty with or without stenting may be considered for focal obstruction. If symptoms are progressive despite medical therapy, decompressive therapy with transjugular intrahepatic portosystemic shunting (TIPS) or surgical shunting is advised. Some investigators recommend decompressive procedures early in the course or if extensive necrosis is seen on liver biopsy. Generally, liver transplantation is reserved for acute liver failure or decompensated cirrhosis.

Medical therapy

Early series demonstrated poor survival in untreated Budd–Chiari syndrome; most patients died within 3 years of diagnosis [16,51]. More recent studies show an improvement in survival. In one study, 5-year survival was 50% before 1985 and 75% afterwards [65]. Widespread adoption of anticoagulation with warfarin is thought to be the cause of this improved trend. It seems prudent to recommend anticoagulation even in the absence of an identifiable prothrombotic state. It is possible that in some patients with myeloproliferative disorders, hydroxyurea and aspirin may be more appropriate [66]. Patients with ascites should be placed on a low-sodium diet and diuretics. Responsiveness to such measures is an independent predictor of survival [65]. For ascites uncontrolled after anticoagulation and medical therapy, decompressive therapy is recommended.

In carefully selected patients with clots no older than 3 or 4 weeks, the prompt administration of thrombolytics (e.g., streptokinase, urokinase, or recombinant tissue plasminogen activator) has been effectively used to dissolve thrombi and relieve hepatic congestion [63,67]. Thrombolysis may be more effective when thrombolytics are administered locally into the hepatic vein and combined with angioplasty with or without stenting [63].

Interventional radiology

Percutaneous transluminal balloon angioplasty has been used to treat focal stenoses of the inferior vena cava and/or hepatic vein [68]. Although excellent short-term results are achievable, sustained patency rates of only 50% are seen at 2 years [69]. Wire-, laser-, or needle-assisted angioplasty is appropriate for stenoses refractory to standard techniques [70]. For salvage of failed angioplasty or as primary therapy for focal stenoses, percutaneous intraluminal stenting is an option [10,69,70]. More than 80% of stents remain patent 3 years after placement, with good control of symptoms [10,71]. Stenting has also been used to treat intrahepatic inferior vena cava obstruction caused by compression from caudate lobe hypertrophy, which would otherwise preclude portacaval shunting. After stenting, portacaval shunting has been successfully performed [72].

TIPS is being increasingly used as an alternative to decompressive surgical procedures because it is less invasive and does not carry the high perioperative mortality associated with surgical shunting. TIPS may have a role as a bridge to transplantation for patients with end-stage liver disease and ascites refractory to diuretics and sodium restriction [73–75] or in patients who present with fulminant hepatic failure [73–76]. The use of TIPS has been reported after progressive, symptomatic liver disease and ascites despite anticoagulation and medical therapy with successful control of symptoms, improvement of Child–Pugh class, and good 5-year survival without liver transplantation (74%) [50]. Survival after TIPS compares favorably with historical controls from surgical series. Shunt dysfunction often develops over time because of thrombotic occlusion. Therefore, surveillance with ultrasonography or angiography and chronic anticoagulation are recommended [50,76]. The introduction of polytetrafluoroethylene-coated stents may dramatically reduce TIPS thrombosis. In one study, only 33% of patients with covered stents experienced dysfunction after TIPS within 1 year of the procedure, compared to 87% of patients with bare stents [77].

Surgical decompression

There is currently a divergence of opinion about whether surgical decompressive procedures should be offered early in the course of Budd–Chiari syndrome or should be reserved for patients who have progressive symptomatic disease despite medical therapy. One approach emphasizes the role of liver biopsy in determining which patients should undergo early surgical shunting. Anticoagulation alone is recommended if biopsy reveals only centrilobular congestion and sinusoidal dilatation, whereas surgery is reserved for those with hepatocyte necrosis [78]. A second strategy advocates early surgical decompression, regardless of biopsy findings. Presumably, early relief of hepatic congestion may prevent ongoing necrosis and fibrosis. Such a strategy is supported by recent studies that found carefully collected data from liver biopsy to be not predictive of prognosis [64, 65]. Furthermore, in one retrospective study after adjustment for case severity, surgical shunting was associated with improved outcomes [64]. If biopsy does not predict

outcome, but performance of a surgical shunt does, then perhaps early surgery is preferable. However, caution must be exercised because no rigorous prospective study has been performed to test this strategy.

A third treatment approach has been increasingly used. Patients are first treated medically with anticoagulation and diuretics if ascites is present. If symptoms and serum tests of hepatic synthetic function do not improve within days for subacute Budd–Chiari syndrome and within weeks for slower presentations, then decompressive shunting is advised [2]. Similar treatment strategies using TIPS in place of surgical decompression have achieved excellent results [50]. Success with TIPS has led to recommendations that decompressive surgery be relegated to third-line therapy. Moreover, surgical decompression is associated with high perioperative mortality (5–30%) and cannot be safely performed for patients with Child–Pugh class B or C cirrhosis [10,34,50]. A therapeutic algorithm is depicted in Fig. 33.5.

A variety of portosystemic shunts are available to relieve sinusoidal hypertension of Budd–Chiari syndrome. Side-to-side portacaval shunts have been successfully used to convert the portal vein into an outflow tract [7,16,58,79]. A pressure gradient of more than 10 mmHg between the portal vein and the inferior vena cava is required for adequate shunt flow. For patients with compression of the intrahepatic portion of the inferior vena cava by a hypertrophic caudate lobe, inferior vena cava shunting may not be possible. Mesocaval shunts between the superior mesenteric vein and vena cava provide effective portal decompression for these patients [16,78]. As with the side-to-side approach, caval pressure must be considerably lower than portal pressure. Shunt thrombosis remains a problem for 20–55% of patients who receive mesocaval shunts [7]. Other shunts have been described, including splenocaval, cavoatrial, hepaticoatrial, and mesojugular shunts [80]. Interposition synthetic grafts are also occasionally used. Finally, transatrial membranotomy with finger fracture or excision may be effective for patients with fenestrated membranes [81,82].

Liver transplantation

Liver transplantation is the preferred treatment for patients with Budd–Chiari syndrome and either acute liver failure or decompensated cirrhosis [7,62,79,83]. Patients with significant liver disease who decompensate after receiving decompressive shunts or those with shunt failure may be rescued with transplantation [81]. Excellent 5-year patient and graft survival have been achieved, with rates similar to those for patients undergoing

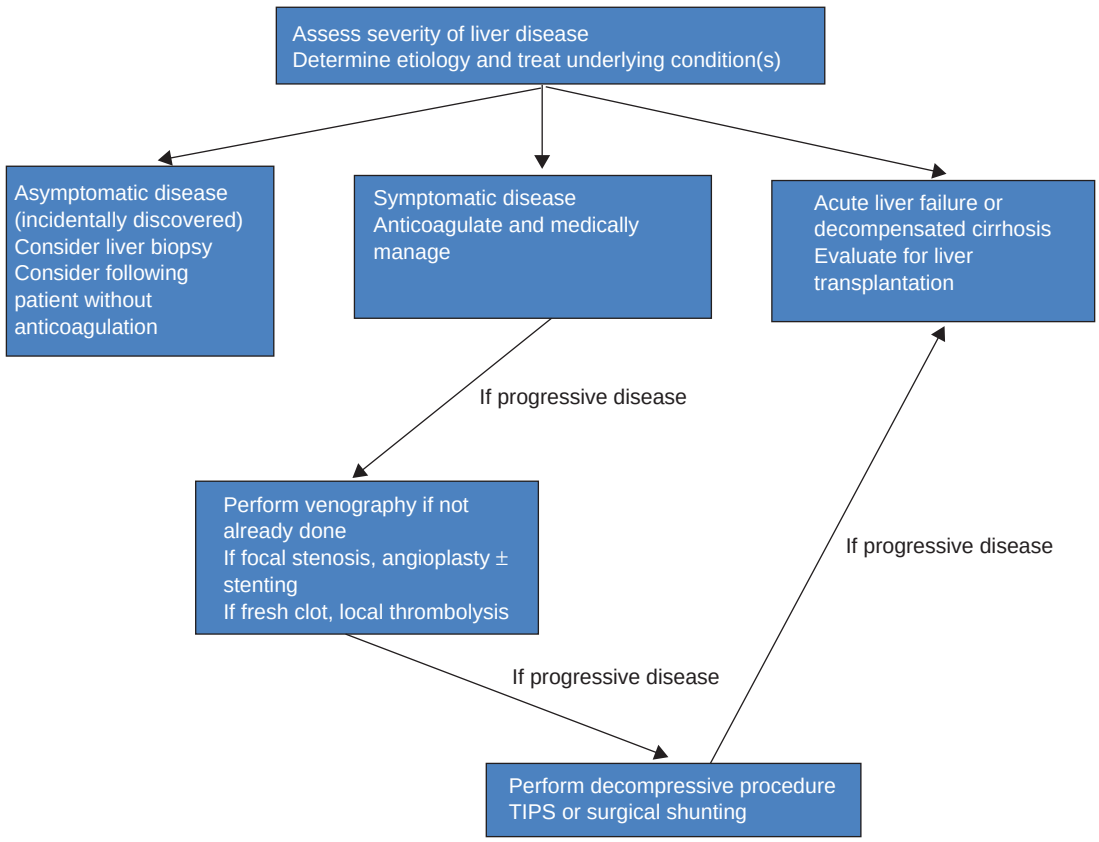

Figure 33.5 Proposed algorithm for the management of Budd–Chiari syndrome. TIPS, transjugular intrahepatic portosystemic shunting.

transplantation for other diseases [84]. Transplantation is curative for protein C, protein S, and antithrombin III deficiency. All patients should receive indefinite anticoagulation for hypercoagulable states not curable by liver replacement [83]. Aspirin and hydroxyurea effectively reduce platelet aggregation and number, respectively, and may be appropriate for preventing recurrent thrombosis after transplantation in patients with underlying myeloproliferative disorders [66,85]. Patient selection is critical because individuals with short life expectancies due to underlying medical conditions are not appropriate for transplantation. However, most underlying myeloproliferative and other disorders associated with Budd–Chiari syndrome have near normal 10-year life expectancies, which should not preclude transplantation [84].

Liver involvement in hereditary hemorrhagic telangiectasia

Hereditary hemorrhagic telangiectasia (HHT), also known as Rendu–Osler–Weber syndrome, is a multisystemic vascular disorder that variably affects the liver. The Curacao criteria require the presence of three of the four following criteria for definitive diagnosis: recurrent and spontaneous epistaxis, multiple mucocutaneous telangiectasias, visceral arteriovenous malformations, and diagnosis of HHT in a first-degree relative [86]. The disease is autosomal dominant and exhibits age-dependent penetrance. Identification of endoglin (*ENG*) and activin receptor-like kinase 1 (*ALK-1*) gene mutations have allowed subclassification of HHT into types 1 and 2 [87]. Both *ENG* and *ALK-1* encode membrane glycoproteins expressed on vascular endothelial cells involved in vascular remodeling [87]. Patients affected with HHT1 tend to have *ENG* mutations and are more likely to have pulmonary arteriovenous malformations. HHT2 is associated with *ALK-1* mutations and is often clinically milder and more commonly associated with hepatic involvement. Additionally, mutations in the *MADH4* gene (encoding SMAD 4 protein) have been identified in individuals with combined juvenile poylposis and HHT syndrome [88].

Retrospective studies suggested radiologic evidence for hepatic involvement in only 8–30% of patients with HHT [89]. However, a more recent prospective study using multiphasic helical CT scans demonstrated hepatic vascular abnormalities, including arterioportal shunts, arteriosystemic shunts, telangiectasias, vascular masses, and parenchymal perfusion disorders, in up to 74% of 70 serial patients with HHT [90]. Hepatic vascular abnormalities may be visualized with Doppler ultrasonography, CT angiography (Fig. 33.6), direct catheter angiography, or magnetic resonance angiography [91]. Using contrast-enhanced CT or catheter angiography as the gold standard, sensitive and specific sonographic criteria for HHT have been defined. These include a dilated common hepatic artery (>7 mm) and the presence of intrahepatic hypervascularization on Doppler evaluation [92]. Therefore, absence of these findings on a sonographic study may obviate the need for additional imaging. Furthermore, screening for hepatic involvement in HHT is not generally required because most hepatic lesions remain asymptomatic and do not require treatment [90].

There are several possible symptomatic presentations of HHT with hepatic involvement (Table 33.1). High-output cardiac failure presenting with dyspnea and edema may be related to extensive hepatic artery to hepatic vein shunting [93]. Portal hypertension resulting from shunting between the hepatic artery and portal vein may present with ascites or variceal hemorrhage [93]. Hepatic encephalopathy may develop in the presence of portal vein to hepatic vein shunting [93]. Finally, cholestasis and biliary abnormalities may result from

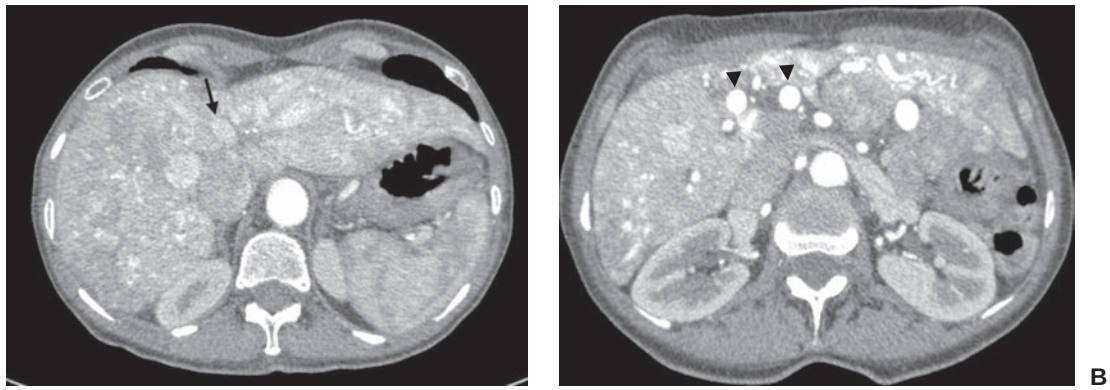

Figure 33.6 Contrast-enhanced computed tomography scan in a female patient with hereditary hemorrhagic telaniectasia and hepatic involvement. (A) Heterogeneous hypervascularity of the liver parenchyma in the upper liver. Hepatic veins are markedly dilated (arrow). (B) At the level of the porta hepatis, the dilated tortuous proper hepatic artery is shown (arrowheads).

Table 33.1 Hepatic involvement of hereditary hemorrhagic telangiectasia: clinical presentations.

Clinical presentation	Type of shunting
High-output cardiac failure	Hepatic artery to hepatic vein
Dyspnea	Hepatic artery to hepatic vein
Edema	Hepatic artery to hepatic vein
Portal hypertension	Hepatic artery to portal vein
Ascites	Hepatic artery to portal vein
Variceal bleeding	Hepatic artery to portal vein
Hepatic encephalopathy	Portal vein to hepatic vein
Biliary abnormalities	Hepatic artery to hepatic vein
Cholestasis	Hepatic artery to hepatic vein
Cholangitis	Hepatic artery to hepatic vein

ischemic injury related to hepatic artery to hepatic vein shunting [93]. Symptomatic disease can often be managed conservatively. Hepatic arterial embolization of vascular lesions was initially used with some success, but more recent reports have highlighted the high mortality rates associated with postembolization hepatic and biliary necrosis [94]. Hepatic arterial embolization can no longer be recommended for the treatment of hepatic HHT. Liver transplantation has been successfully performed despite technical difficulties with vascular reorganization [95].

Peliosis hepatis

Peliosis hepatis is characterized by blood-filled cystic cavities in the hepatic parenchyma lined by hepatocytes or endothelial cells [96]. Similar lesions may also develop in the spleen. Peliosis has been well described in immunosuppressed patients, including those with human immunodeficiency virus (HIV) infection, tuberculosis, and cancer, and after solid organ transplantation [97,98]. Medications associated with peliosis hepatis include anabolic and androgenic steroids, azathioprine, and cyclosporine [98].

Bartonella henselae, associated with catscratch disease, is the causative agent of bacillary peliosis hepatis in patients with HIV infection [97]. Exposure to cat bites, scratches, and fleas are risk factors for the acquisition of *B. henselae* [97]. This fastidious Gram-negative bacillus has a granular and purple appearance on a Warthin–Starry stain of affected hepatic specimens [96]. Infection with the bacteria may also be demonstrated by blood culture, serologies, and polymerase chain reaction-based tests, although no single test is reliable. Some patients with bacillary peliosis hepatis also develop bacillary angiomatosis, characterized by vascular lesions affecting the skin (most commonly red or purple papules), lymph nodes, bones, and central nervous system.

Imaging reports of peliosis hepatis are largely limited to isolated case reports [99]. On sonography, vague areas of slightly decreased heterogeneous echotexture have been described. On unenhanced CT scan, irregular areas of low attenuation are shown. On MRI, lesions are usually of low-signal intensity on T1-weighted imaging and high-signal intensity on T2-weighted imaging. However, appearance on MRI may vary if lesions are complicated by hemorrhage, with variable T1 brightening. On both CT scans and MRI, dynamic contrast enhancement demonstrates an early central enhancement, with gradual centripetal fill-in. This pattern is distinct from that of other vascular liver lesions, including hemangioma, adenoma, and focal nodular hyperplasia, and may be the key to diagnosis.

Peliosis hepatis is often an incidental finding. Among patients with HIV infection, fever, lymphadenopathy, anemia, elevated alkaline phosphatase level, and lower CD4 counts are more common in affected patients than in controls [100]. Treatment of bacillary peliosis hepatis consists of several months of administration of erythromycin (500 mg four times daily) or an alternative macrolide. Nonbacillary peliosis is best treated by stopping the offending medication or addressing the underlying etiology.

Conclusions

Budd–Chiari syndrome is an uncommon disease associated with thrombotic obstruction of the terminal hepatic venules, hepatic veins, vena cava, and/or right atrium. Sinusoidal congestion and centrilobular necrosis occur as a consequence of venous outflow obstruction and can lead to fibrosis and cirrhosis. Most patients present with chronic signs and symptoms of portal hypertension, although some may present subacutely or even acutely. Doppler sonography is an excellent screening test for evaluating the patency of the major hepatic veins and vena cava. CT scans and MRI are complementary studies. Venography remains the standard of reference for the diagnosis of venous occlusion and may either show the classic spider web appearance of hepatic vein obstruction or demonstrate intrahepatic or subcapsular collaterals. Liver biopsy and pressure measurements made during venography may also guide treatment selection.

Rigorous studies are not available to derive definitive treatment algorithms. Generally, anticoagulation is offered to all patients. Diuretics and a low-sodium diet are prescribed for those with ascites. If symptoms and hepatic synthetic dysfunction do not resolve after medical therapy, then decompressive procedures are offered.

Some investigators recommend the performance of surgical shunting or TIPS early in the course of disease. Thrombolytic therapy may be useful for acute thrombosis. Angioplasty with or without stenting may treat focal stenoses. TIPS can effectively decompress hepatic sinusoids with symptomatic improvement. Surgical shunting has been used successfully for those with adequate hepatic reserve, although perioperative mortality can be high. Liver transplantation is preferred for patients with acute liver failure or decompensated cirrhosis. Survival after transplantation is similar to that of patients undergoing transplantation for cirrhosis due to other causes.

HHT is characterized by epistaxis, mucocutaneous telangiectasias, and visceral arteriovenous malformations. Patients with hepatic lesions are generally asymptomatic; possible symptoms include high-output cardiac failure, complications of portal hypertension, hepatic encephalopathy, and symptoms related to cholestasis. Management is most often conservative, and hepatic arterial embolization has been associated with unacceptably high mortality.

Peliosis hepatis is often an incidental finding. Characteristic blood-filled cystic cavities may occur in the setting of immunosuppression or HIV infection. *Bartonella henselae* is the cause of bacillary peliosis hepatis in patients with HIV infection. Generally, treatment consists of addressing the underlying cause of immunosuppression or treating *Bartonella* infection.

Deleve LD, Valla DC, Garcia-Tsao G. Vascular disorders of the liver. AASLD Practice Guidelines. *Hepatology* 2009;5:1729–64.
An excellent overview of vascular disorders of the liver with guidelines by the American Association for the Study of Liver Diseases.

Denniger MH, **Chait Y**, **Casadevall N, et al.** Cause of portal or hepatic venous thrombosis in adults: the role of multiple concurrent factors. *Hepatology* 2000;31:587–91.
The authors suggest that the occurrence of multiple prothrombotic disorders is more common than expected. Evaluation for hypercoagulable states in patients with hepatic or portal venous occlusion is recommended.

Garcia-Tsao G, **Korzenik JR**, **Young L, et al.** Liver disease in patients with hereditary hemorrhagic telangiectasia. *N Engl J Med* 2000;343:931–6.
The authors describe and categorize symptomatic presentations in 19 patients with hereditary hemorrhagic telangiectasia involving the liver.

Janssen HL, **Garcia-Pagan JC**, **Elias E, et al.** European Group for the Study of Vascular Disorders of the Liver. Budd–Chiari syndrome: a review by an expert panel. *J Hepatol* 2003;38:364–71.
The authors discuss difficulties with nomenclature. They emphasize that in the absence of rigorous studies, aggressive early treatment can not currently be advised.

Klein AS, **Molmenti EP.** Surgical treatment of Budd–Chiari syndrome. *Liver Transpl* 2003;9:891–6.
A comprehensive review of surgical decompressive techniques. Patient selection and success with various procedures are discussed.

Koehler JE, **Sanchez MA**, **Garrido CS, et al.** Molecular epidemiology of *Bartonella* infections in patients with bacillary angiomatosis-peliosis. *N Engl J Med* 1997;337:1876–83.
This case–control study used molecular techniques to show that bacillary peliosis hepatis is associated exclusively with Bartonella henselae. Epidemiologic links to cat and flea exposures were identified.

Murad SD, **Valla DC**, **de Groen PC, et al.** Determinants of survival and the effect of portosystemic shunting in patients with Budd–Chiari syndrome. *Hepatology* 2004;39:500–8.
The authors present a large retrospective series of patients with Budd–Chiari syndrome (n = 237). On multivariate analysis encephalopathy, ascites, prothrombin time, and bilirubin were the only independent predictors of survival. Portosystemic shunting showed a trend towards improved survival in a select group of patients.

Okuda K. Inferior vena cava thrombosis at its hepatic portion (obliterative hepatocavopathy). *Semin Liver Dis* 2002;22:15–16.
Okuda proposes that inferior vena cava obstruction, characterized by webs and membranes, and typically seen in Nepal, South Africa, China, India, and Japan, should be considered a distinct disease from classic Budd–Chiari syndrome. He proposes a new term, obliterative hepatocavopathy.

Multiple choice questions

33.1 Which of the following is the most common prothrombotic disorder leading to Budd–Chiari syndrome?

a Polycythemia vera.
b Factor V Leiden.
c Antiphospholipid antibody syndrome.
d Paroxysmal nocturnal hemoglobinuria.
e Protein C deficiency.

33.2 Imaging findings in Budd–Chiari syndrome include all of the following except which one?

a Hepatomegaly.
b Caudate lobe hypertrophy.
c Ascites.
d Inferior vena cava obstruction by the caudate lobe.
e Cystic lesions in the liver.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 34

The Liver in Circulatory Failure

Santiago J. Munoz[1,2], *Jonathan M. Fenkel*[3], *& Kiley Kolb*[1]

[1]Department of Medicine and [2]Division of Abdominal Organ Transplantation, Temple University Hospital and School of Medicine, Philadelphia, PA, USA
[3]Division of Gastroenterology and Hepatology, Thomas Jefferson University, Philadelphia, PA, USA

Key concepts

- The hepatic artery and portal vein provide a dual blood supply that makes the liver comparatively resistant to ischemic injury.
- Nonetheless, during acute and severe arterial hypotension, shock, or hemodynamic instability, hepatic perfusion may become compromised resulting in ischemic hepatic injury.
- Zone 3 of the hepatic lobule is the most susceptible to ischemic damage, but in severe cases the histology may reveal extension of the hepatocellular necrosis into zone 2 and even periportal areas.
- There is a spectrum of severity of ischemic hepatic injury. However, it is an uncommon cause of acute (fulminant) liver failure. In typical cases, serum aminotransferases rapidly increase within a few days, followed by an equally prompt decline after the inciting hypotensive episode is resolved.
- Passive congestion of the liver caused by heart failure results in abnormal serum aminotransferases and may include elevated serum bilirubin and coagulopathy. Ascites may be a presenting feature of passive hepatic congestion, even in the absence of cirrhosis. Chronic, severe, passive hepatic congestion may lead to hepatic fibrosis and a characteristic form of cirrhosis ("cardiac cirrhosis") with complications that include hepatocellular carcinoma.
- Cirrhotic preexisting to the ischemic injury may be particularly susceptible to ischemia, and acute-on-chronic liver failure may follow after severe hypotension or shock.
- The unique circulatory abnormalities of the Budd–Chiari syndrome include hepatocellular necrosis due to venous outflow obstruction. In severe Budd–Chiari syndrome with associated portal vein thrombosis, extensive hepatocellular necrosis with liver failure may result from the inability of the portal vein to serve as a secondary compensatory outflow tract from the liver.
- Hepatic arterial occlusion may result in ischemic cholangiopathy due to the exclusive arterial blood supply of the biliary ductal system. This may lead to biliary strictures developing long after the occlusive episode.
- Hepatic infarction may also result from occlusion of the main hepatic artery, particularly in the early postoperative period following liver transplantation.

The liver is abundantly perfused with blood from both the portal vein and hepatic artery. This dual blood supply mixes within the hepatic sinusoids and subsequently exits the liver through the three major hepatic veins. The dual blood supply dampens the effect of arterial hypotension or decreased cardiac output on the total hepatic blood flow. Nonetheless, marked and/or prolonged decreases in cardiac output or shock may lead to ischemic hepatic injury. Heart failure associated with arterial hypotension primarily affects arterial blood flow and oxygen delivery to the liver. If severe, this can lead to hepatocellular necrosis and prominent, at times towering, elevation in serum levels of liver-derived aminotransferases. Acute hepatic ischemic injury frequently occurs without affecting hepatic function or causing permanent liver damage. Less severe but chronic hepatic ischemia may exhibit mild to moderate elevations of aminotransferase levels but may lead to progressive hepatic fibrosis. Acute or chronic congestive heart causes elevated pressures in the vena cava and hepatic veins leading to passive hepatic congestion, ascites formation, and eventually the development of cirrhosis. Hepatic injury caused by circulatory failure may exhibit a broad array of biochemical, histologic, and pathophysiologic features.

This chapter discusses liver injury related to acute ischemia, passive hepatic congestion, ischemic cholangiopathy, hepatic infarction, obstruction to the venous outflow of the liver, and heatstroke. Liver cells may also be injured, as reflected by abnormal liver chemistries, by many other disorders affecting hepatic blood flow such as immunologic diseases and vasculitides, which are discussed in other chapters.

Anatomy and physiology of hepatic blood flow

The hepatic vascular anatomy and physiology of hepatic blood flow is reviewed in detail elsewhere. Certain aspects relevant to circulatory failure are summarized below.

About two thirds of the dual blood supply of the liver enters the organ through the main portal vein. The portal blood is a low-pressure system that contains nutrients absorbed from the intestine, including glucose, amino acids, water-soluble vitamins, and triglycerides; it has a relatively low oxygen content [1]. The remaining one third of the blood flow is derived from the hepatic artery. In contrast, hepatic arterial blood supplies about one third of the hepatic blood flow and is an oxygen-rich high-pressure system. More than half of the oxygen delivered to the liver is supplied by the hepatic artery blood flow, which is also the only blood supply for the entire biliary ductal system. The liver, including the biliary ductal system, is susceptible to ischemic injury due to a reduction in hepatic arterial blood flow. A comparable decrease in portal blood flow is less likely to cause ischemic injury to the liver. Inadvertent ligation of hepatic arterial branches during surgery or the embolization of hepatic arterial branches for treatment of hepatocellular carcinoma (HCC) may lead to hepatic infarction of the segment(s) supplied by the occluded vessel. Arterial hypotension may also result in partial or widespread hepatic infarction. Patients with portal vein thrombosis, in which the only hepatic blood supply is through the hepatic artery, are particularly susceptible to ischemic hepatic injury following a disruption in hepatic arterial blood flow. This may occur after chemoembolization of HCC or simply with hypotension.

The functional unit of the liver is the hepatic acinus or lobule, a roughly pentagonal-shaped structure with a single central hepatic vein flanked by several portal tracts (Fig. 34.1). Each portal triad contains a small branch of the hepatic artery, portal vein, and one or two bile ducts. Sheets of hepatocytes, one to two cells thick and lined by hepatic sinusoids, extend between the portal triads and central vein. Both the portal and hepatic arterial blood enters the hepatic acinus through the portal tracts (zone 1 of the hepatic acinus in the Rappaport classification) and mixes within the hepatic sinusoids [2]. This admixed portal and arterial blood then flows to the center of the acinus (Rappaport zone 3), and ultimately exits the liver through the major hepatic veins. Therefore, zone 1 of the hepatic acinus contains oxygen- and nutrient-rich blood, and as blood flows through the sinusoids distally, it is progressively depleted of these components. Conversely, the zone 3 pericentral area receives less oxygen, and is more susceptible to ischemic injury.

The portal blood flowing into the liver is a low pressure and relatively slow system, minimally affected by changes in systemic arterial blood pressure. In contrast, the hepatic arterial blood flow is a high-pressure system closely regulated to maintain a constant total hepatic blood flow (the sum of arterial and portal blood flows) [3]. Adenosine, a potent vasodilator of arterial smooth muscle cells, regulates hepatic arterial blood flow via local synthesis of nitric oxide. As portal blood flow increases, portal triad adenosine levels become diluted, leading to constriction of the hepatic arterioles and a decline in arterial blood flow [4,5]. The response of hepatic

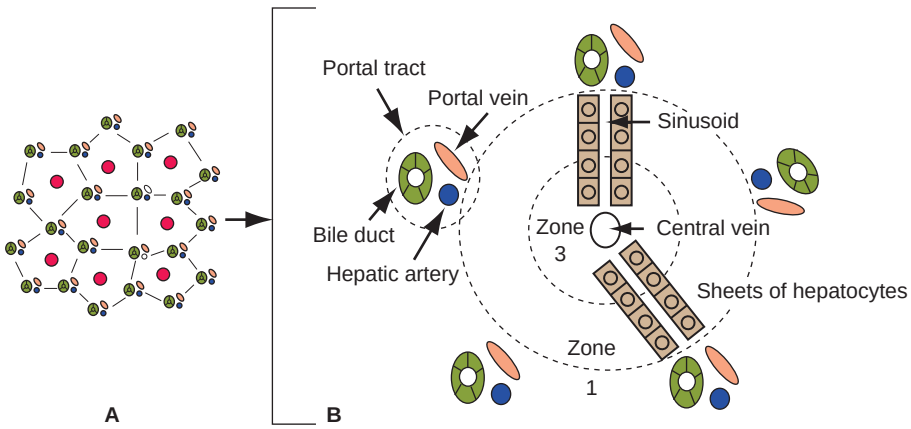

Figure 34.1 (A) A section of liver. The functional subunit of the liver is the hepatic lobule or acinus, a roughly pentagonal-shaped structure with a central vein in the center and portal triads at each corner. Each portal triad is shared by several hepatic lobules. (B) A hepatic lobule or acinus. Each portal triad contains a branch of the hepatic artery, portal vein, and bile duct. Sheets of hepatocytes extend between the central vein and portal triads at the edges of the lobule. Hepatic arterial and portal venous blood enters the acinus through the portal triad and then flows through hepatic sinusoids to the central vein. Zone 1 of the lobule lies at the periphery of the hepatic acinus (outer dashed circle). Zone 3 of the lobule lies in the center of the acinus (inner dashed circle).

arterial smooth muscle to adenosine is not impaired in patients with cirrhosis.

Ischemic hepatic injury

Ischemic hepatic injury, previously termed ischemic hepatitis, is caused by reduced oxygen delivery leading to hepatocellular dysfunction and necrosis [6–10]. This form of hepatic injury is most often seen in the setting of severe arterial hypotension leading to global hepatic hypoperfusion. The most common causes of ischemic hepatic injury are shown on Box 34.1. Events that cause abrupt and severe acute reductions in cardiac output (for instance, massive myocardial infarction, pulmonary embolus, or congestive heart failure) are common causes of ischemic hepatic injury. Hypovolemia from exsanguinating hemorrhage, dehydration, heatstroke, sepsis, or hypoxia associated with respiratory failure may also result in ischemic injury of the liver. The term *shock liver* is sometimes utilized when hepatic ischemic injury develops in the setting of severe hemodynamic instability.

Pathophysiology

The histologic hallmark of ischemic hepatic injury is zone 3 hepatocellular necrosis with little or no inflammatory response. In more severe cases, extensive lobular collapse may be observed (Figs 34.2 and 34.3). Fibrosis is absent unless there is chronic congestion or hypoxia, or an underlying unrelated chronic liver disease. Features of both acute passive congestion and ischemic hepatic injury may be simultaneously present in patients with congestive heart failure experiencing episodic reductions in cardiac output and hypotension. Ischemic hepatic injury often resolves spontaneously following correction of the initial ischemic insult, with hepatocyte regeneration, and a return to normal histology and liver function. However, in patients with chronic passive congestion and fibrosis, these abnormalities remain after resolution of the ischemic hepatic injury.

Box 34.1 Causes of ischemic hepatic injury.

Arterial hypotension

- Cardiac failure:
  - Myocardial infarction
  - Pulmonary embolus
  - Exacerbation of congestive heart failure
  - Cor pulmonale
  - Pericardial tamponade
- Hypovolemia:
  - Hemorrhage
  - Dehydration
  - Extensive burns
- Miscellaneous:
  - Septic shock
  - Heatstroke
  - Sickle cell crisis

Hypoxia

- Acute respiratory failure
- Acute exacerbation of chronic respiratory disease
- Obstructive sleep apnea

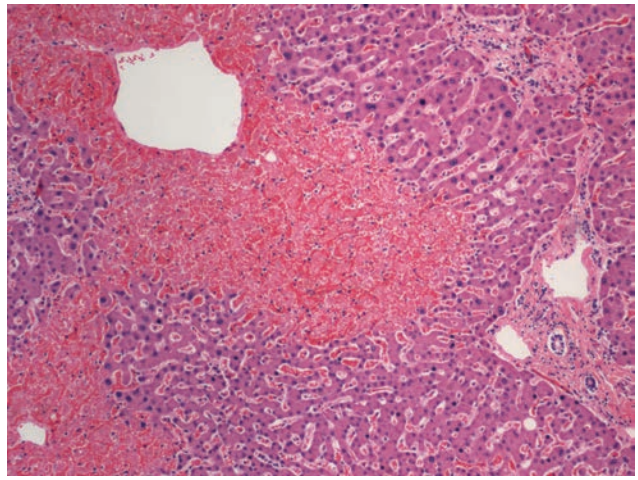

Figure 34.2 The liver in congestive hepatopathy. Zones 3 and 2 show sinusoidal congestion with necrosis of the hepatocytes; in contrast, periportal sinusoids and hepatocytes are spared. Hematoxylin and eosin (H&E), original ×100.

Clinical features

Most patients with ischemic hepatic injury do not develop signs or symptoms of liver disease such as jaundice, ascites, or encephalopathy, but exhibit changes confined to the liver biochemistries (see below). Patients with ischemic hepatic injury often have changes in mental status but this is rarely due to fulminant liver failure as a

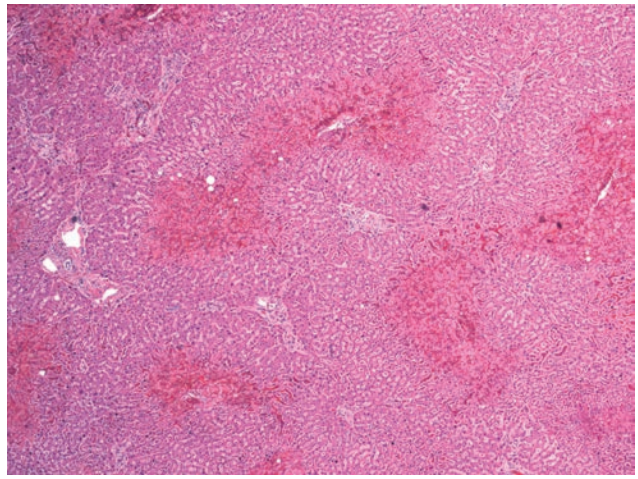

Figure 34.3 Zonal distribution of sinusoidal congestion and necrosis of hepatocytes in congestive heart failure. H&E, original ×40.

result of the ischemia. In a large prospective series, acute liver failure due to ischemic hepatic injury represented a very small proportion of cases (6%) [11]. Thus, true hepatic encephalopathy and associated hyperammonemia is uncommon in ischemic hepatic injury. In most cases, it is likely that the mental changes are related to the acute hypotensive event and hemodynamic derangements leading to cerebral hypoperfusion.

An abrupt elevation in serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) is the biochemical hallmark of ischemic hepatic injury. These enzymes, released from ischemic hepatocellular necrosis, generally peak 1–3 days following the ischemic insult (for instance, an episode of severe hypotension (Figs 34.2 and 34.3)). Patients with ischemic hepatic ischemic injury are often hospitalized and/or acutely ill. Given the greater abundance of ALT in hepatocytes, this aminotransferase generally exhibits higher serum levels than AST. When AST is the dominant aminotransferase elevation following ischemia, additional sources (extrahepatic) of AST and organ damage should be suspected, such as muscle, cardiac, brain, or hemolysis. In fact, ischemic hepatic injury is frequently associated with hypoxic or hypotensive injury to other organs, particularly the kidneys, as reflected by a rise in serum creatinine and other signs of acute kidney injury. Serum aminotransferase levels typically peak in the range of 500 to 5,000 IU/L and the values often rapidly improve and return to normal within a few days provided the initial hypotensive event has resolved. Serum bilirubin level may remain normal or begin to rise 2–5 days after the elevation of aminotransferases, peaking 5–10 days after the maximum rise in aminotransferase levels (Fig. 34.4). The extent of serum bilirubin elevation is quite variable as it depends not only on the severity of the inciting event but also on the use of blood transfusions for resuscitation, associated hemolysis, and the presence of any underlying chronic liver disease. Serum alkaline phosphates may remain normal or increase to a moderate extent. The prothrombin time, expressed as the international normalized ratio (INR), generally remains normal, but in severe ischemic hepatic injury mild to moderate prolongation in INR may be observed. Serum ammonia is often elevated in these gravely ill patients with multiorgan failure but it is generally associated with a hypercatabolic state rather than acute hepatic failure.

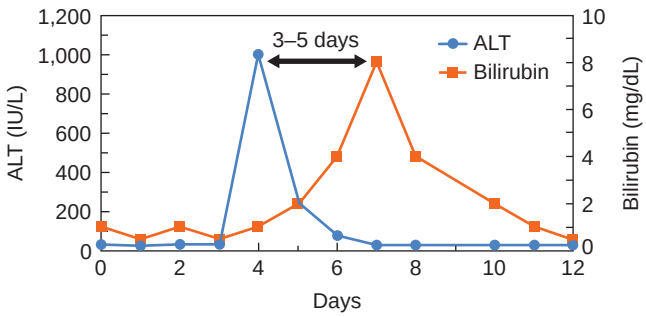

Figure 34.4 Pattern of serum alanine aminotransferase (ALT) and bilirubin level variation in patients with ischemic hepatitis. There is an abrupt and marked rise in serum aspartate aminotransferase (AST) (not shown) and ALT levels to values of 200–1,000 IU/L. This is followed by a delayed rise in serum bilirubin level, which usually reaches a maximum 3–5 days after the peak in serum AST and ALT levels.

The rapid rise in serum aminotranferase levels brings up the differential diagnosis of acute viral or nonviral hepatitis. However, the abrupt rise and fall in AST and ALT levels typical of ischemic hepatic injury is highly uncommon in acute viral hepatitis. Furthermore, in the later, aminotransferase levels gradually return to normal over several weeks rather than days. The systemic viremic syndrome (nausea, vomiting, anorexia, malaise, low-grade fever, and/or right upper quadrant discomfort), is absent in patients with hepatic ischemic injury. Nonetheless, acute hepatitis A, B, and C virus should be routinely excluded in patients with rapidly raising aminotransferases by the corresponding serologies. Inadvertent acetaminophen overdose is also an important differential diagnosis to keep in mind; the medical history and careful review of administered medications are key elements to identify this etiology. In the appropriate setting, causes of nonviral acute hepatitis such as Wilson disease and autoimmune hepatitis should be screened for as well.

The hypotensive event leading to hepatic ischemic injury is often readily apparent, but occasionally a transient or inapparent hypotensive event may lead to hepatic ischemia presenting as acute liver injury of unclear etiology. This scenario may be seen in patients with cirrhosis in whom hepatic blood flow is more dependent on hepatic arterial flow than under normal circumstances. Ischemic hepatic injury superimposed on cirrhosis may lead to lesser aminotransferase elevations and to an acute-on-chronic episode of liver failure associated with a mortality greater than 60% (see below). Likewise, in patients with chronic right or left heart failure, the liver is also more sensitive to changes in hepatic arterial blood flow caused by systemic arterial hypotension. Ischemic hepatic injury may occur in patients with hypoxic conditions including acute respiratory failure, decompensated chronic obstructive pulmonary disease (COPD), or sleep apnea in the absence of arterial hypotension [6–10].

The severity and prognosis of ischemic hepatic injury is related to the precipitating hypotensive or hypoxic event. If the episode of hypotension and/or hypoxia is brief and promptly reversed, the hepatic ischemic damage fully and rapidly resolves in most cases. In contrast, if hypotension is extremely severe or persistent, the ischemic hepatic injury eventually becomes part of irreversible multiorgan failure. Patients with chronic congestive heart

failure associated with passive hepatic congestion or cirrhosis are at risk of developing liver failure due to episodic hypotension or hypoxia.

The management of ischemic hepatic injury consists of restoring hepatic blood perfusion by promptly and effectively correcting the arterial hypotension and hypoxia. No specific drugs or agents promoting hepatic recovery from ischemia are available.

Hepatic ischemia in the patient with cirrhosis

The circulatory system is compromised in patients with cirrhosis in parallel with the severity of the liver dysfunction. A hyperdynamic circulatory state with relative arterial hypotension, peripheral arterial vasodilatation, and pooling of blood in the mesenteric splanchnic territory are characteristic of advanced cirrhosis. To compensate for the increased intrahepatic resistance to portal vein inflow, there is often enlargement of the hepatic artery with a resulting greater proportion of arterial blood flow to the liver. This may lead to increased susceptibility of the cirrhotic liver to changes in systemic arterial blood pressure [12,13]. Thus, sepsis, general anesthesia, dehydration, hemorrhage, and other hypovolemic states may be followed by decompensation of the cirrhosis in a previously well-compensated patient. This is one of the mechanisms involved in the development of acute-on-chronic liver failure (AOCLF). Maintenance of adequate hepatic perfusion is, therefore, of paramount importance in preventing ischemic injury to the cirrhotic liver. The prevention of hepatic ischemic injury is important in patients with cirrhosis undergoing surgery under general anesthesia, in whom efforts should be made to avoid intraoperative arterial hypotension. Certain therapeutic agents such as β-blockers are commonly used in cirrhosis in the prophylaxis of esophagogastric variceal hemorrhage [14]. However, these agents may induce a decrease in cardiac output and additional hypotension, which may be deleterious in the setting of cirrhosis. For instance, β-blockers may not be safe in patients with the hepatorenal syndrome [15]. Moreover, a recent study found an increased mortality of patients with refractory ascites who were concomitantly treated with β-blockers [16]. Further work is necessary to ascertain the safety of hemodynamic active therapeutic agents in patients with cirrhosis.

Hepatic infarction

Hepatic infarction refers to a focal area of ischemic injury caused by a disruption in blood flow to a specific branch of the hepatic artery. Less often, a hepatic infarct can originate from hepatic or portal vein compromise. Unlike the lesions observed in ischemic hepatic injury, hepatic infarction is not usually reversible. Fortunately, the liver's dual blood supply makes this condition uncommon as the hepatocytes can augment their portal venous oxygen extraction during periods of hepatic arterial ischemia. However, the diagnosis of hepatic infarction may be on the rise as the result of more frequent use of computed tomography (CT) scans after interventional abdominal procedures.

Hepatic infarction generally occurs in three settings: iatrogenic injury, particularly after surgical or vascular interventions; secondary to a predisposing underlying disease; or related to an acute vascular event. The most common etiologies are detailed in Box 34.2.

Hepatic artery thrombosis complicates 2–6% of all liver transplants, and may result in hepatic infarction within the liver allograft [17]. Local ablative therapies for HCC and other liver lesions are risk factors for hepatic infarction, with an estimated incidence of 1.8% in patients undergoing radiofrequency ablation and 0.15% in patients after chemoembolization for HCC [18,19]. It occurs postoperatively in approximately 1% of all pancreaticobiliary surgeries, typically as a result of hepatic artery injury during lymph node dissection, inadvertent right hepatic artery ligation, or prolonged clamp time on the hepatic artery. Hepatic artery injury, particularly right hepatic artery, can also occur during cholecystectomy. Hepatic infarction has also been reported in

Box 34.2 Common etiologies for hepatic infarction.

Iatrogenic
- Liver transplantation
- Pancreaticobiliary surgery
- Cholecystectomy
- Embolization in acute GI bleeding
- Local ablative therapies for liver masses
- TIPS placement

Underlying disease
- Systemic lupus erythematosus
- Hypercoagulable states
- Polycythemia vera
- Vasculitis
- Sickle cell disease
- Hepatocellular carcinoma

Acute vascular injury
- Aortic dissection
- Septic emboli
- Cocaine
- Preeclampsia/HELLP syndrome in pregnancy
- Necrotizing pancreatitis

GI, gastrointestinal; HELLP, hemolysis, elevated liver enzymes, and low platelets; TIPS, transjugular intrahepatic portosystemic shunt.

association with embolization for acute gastrointestinal hemorrhage, aortic dissection, septic emboli, systemic lupus erythematosus, sickle cell disease, preeclampsia, and the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) with or without coexisting antiphospholipid antibody syndrome, thrombotic angiitis, polyarteritis nodosa, necrotizing pancreatitis, and cocaine-induced hepatic artery vasospasm.

While most hepatic infarctions are the result of hepatic arterial impairment, they can also rarely occur in the setting of hepatic venous disease such as HCC itself invading the hepatic veins causing severe congestion and subsequent ischemia, or in combination with portal vein thrombosis in polycythemia vera and other procoagulative conditions. Hepatic infarction has also been reported in the Budd–Chiari syndrome and after transjugular intrahepatic portosystemic shunt (TIPS) placement [20–23].

The diagnosis of a large hepatic infarction should be suspected in patients with increasing serum aminotransferases, right upper quadrant abdominal pain, fever, nausea, vomiting, right shoulder pain following abdominal interventional procedures, or the presence of risk factors detailed above. Some patients may be asymptomatic and diagnosed incidentally during a postoperative CT scan or imaging for another condition. Serum aminotransferases may rise to the 500–1000 IU/L range and leukocytosis is also common. Acute liver failure may develop if the infarct is large, or if a major arterial branch is involved. A CT scan typically identifies hepatic infarction as a low attenuation, segmental lesion, which is often peripheral and wedge-shaped, but may also be rounded or oval. The shape can evolve over time to be more rounded or to contain liquefaction. Contrast images may discover the culprit vessel, as well, or detect infarcts in other organs suggestive of embolic disease. More than 30% of patients have more than one site of infarction on CT scan at presentation. Ultrasound is excellent to examine for hepatic artery thrombosis, but not very sensitive in distinguishing infarctions. Magnetic resonance imaging (MRI) can also be used to detect infarction, on which it will have low T1 signal intensity and may show increased T2 signal intensity. An involved vessel may also be seen on MRI or magnetic resonance angiography. The diagnosis can be made clinically with confirmatory imaging. A liver biopsy is not necessary unless the diagnosis is not evident or the patient has an ambiguous clinical presentation. If a liver biopsy is performed, areas of coagulative necrosis involving all three zones of the hepatic lobule surrounded by inflammation may be observed. This lesion is then itself surrounded by a zone of partial necrosis. The involvement of all three zones is characteristically different from the histologic pattern of ischemic hepatic injury, which is typically limited to zone 3.

The management of hepatic infarction is usually supportive. Infarcted areas heal over time with scar formation and parenchymal atrophy. Prostaglandin E1, hemodialysis, corticosteroids, and plasma exchange have all been tried in the acute setting with some presumed success, albeit this evidence is limited to a few case reports. Since abscess formation is common in large infarcted areas, broad spectrum systemic antibiotics may be used empirically. The presence of gas inside the infarct on CT is highly suspicious for abscess formation. Needle aspiration and drainage should be performed in situations where abscess is suspected and antibiotics initiated without delay until cultures return. For patients in whom the etiology of hepatic infarction is obvious, i.e., postsurgery or postembolization, no further workup is necessary after the patient has recovered. In patients with systemic disorders such as antiphospholipid antibody syndrome or polycythemia vera, treatment specific to those disorders should be implemented as well. In post-liver transplant recipients, retransplantation may be necessary if the infarction is extensive and occurs soon after transplantation. Retransplantation improves short-term survival, and 5-year survival is similar to patients who underwent a single liver transplant. In patients whose etiology for hepatic infarction remains obscure, a hypercoagulable state evaluation and infectious workup to exclude septic emboli are recommended.

Congestive hepatopathy

Hepatic congestion develops in patients with significant and persistent elevations in hepatic veins and right atrial pressure caused by heart failure [24–27]. The main etiologies of heart disease leading to heart failure and hepatic congestion are shown in Box 34.3. The elevated intracardiac pressures lead to increased central venous pressure, which is transmitted to the hepatic veins, into the central veins of the hepatic acinus, and ultimately into the hepatic sinusoids. Congestive hepatopathy causes characteristic histologic changes (Figs 34.3 and 34.5).

Box 34.3 Causes of congestive hepatopathy.

- Tricuspid insufficiency
- Myocardial infarction
- Pulmonary hypertension
- Cor pulmonale
- Mitral stenosis
- Constrictive pericarditis
- Pericardial tamponade
- Pulmonary embolus
- Congenital heart disease

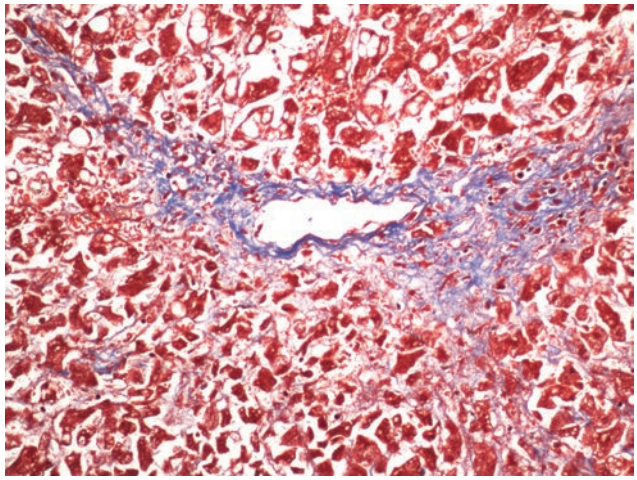

Figure 34.5 Perivenular (zone 3) fibrosis in a patient with prolonged hepatic congestion due to chronic congestive heart failure. Masson trichrome stain, original ×200. (Courtesy of Dr Rebecca Thomas, Director of Pathology and Clinical Laboratories, Temple University Hospital and School of Medicine.)

Chronic hepatic congestion ultimately leads to hepatic fibrosis, including bridging fibrosis and eventually "cardiac" cirrhosis [24–26]. In contrast to cirrhosis resulting from chronic active hepatitis, the bridges of fibrosis in cardiac cirrhosis connect the central veins to other central veins. In some cases, exuberant regeneration of the periportal hepatocytes may lead to the formation of noncirrhotic nodules known as nodular regenerative hyperplasia.

Prolonged passive congestion may lead to sinusoidal fibrosis, which may impair oxygen delivery to zone 3 hepatocytes, increasing their susceptibility to hypoxic injury. Furthermore, the elevated venous pressure causes enlargement of the sinusoidal fenestrae. In the setting of hepatic congestion, the passage of protein-rich fluid into the subendothelial space of Disse may cause the formation of ascites, yielding a low serum–ascites albumin gradient (SAAG) in the absence of portal hypertension. Once fibrosis and cardiac cirrhosis develop, the ascites protein content diminishes and the SAAG may increase above 1.0.

Patients with congestive hepatopathy may be asymptomatic and have only mild abnormalities in serum liver biochemical tests, including total and indirect bilirubin, and a modestly prolonged INR. In severe cases, right upper quadrant pain or discomfort and new-onset ascites may occur. Occasionally, the evidence of heart failure may not be obvious and the patient may be initially thought to have ascites due to cryptogenic cirrhosis.

The classic physical findings of right heart failure and congestive hepatopathy include jugular venous distension, pulsatile hepatomegaly, and hepatojugular reflex. Hepatic ultrasonography may reveal echogenic hepatomegaly. Enlarged hepatic veins and a reversal of flow may be detected by Doppler ultrasonography. CT scans and MRI may show a heterogeneous appearance of the liver consistent with the characteristic "nutmeg" macroscopic aspect of the congested liver.

If a liver biopsy is obtained because of diagnostic doubts, the transjugular route is preferred since the hepatic venous pressure gradient (HVPG) can be simultaneously determined to ascertain the role of the passive congestion, the existence of cirrhosis, and/or an independent liver disorder.

The management of congestive hepatopathy consists of therapy of the underlying congestive heart failure, which in turns depends on its specific etiology. Successful control of the heart failure improves the liver biochemical abnormalities and helps with ascites resolution. Prudent use of diuretics and occasional paracentesis may be necessary for symptomatic therapy of severe ascites. In contrast to noncardiac cirrhosis, the use of TIPS is contraindicated in the management of ascites caused by congestive hepatopathy. The increased preload on the heart brought about by TIPS installation may be excessive for these patients with heart failure. Patients with congestive hepatopathy may be unusually sensitive to warfarin (Coumadin®) and the INR may increase substantially on very low doses of warfarin. Additionally, the slower hepatic drug metabolism in congestive hepatopathy may lead to higher therapeutic drug levels and a lower threshold for toxicity.

The prognosis of patients with congestive hepatopathy is related to the severity of the underlying cardiac disease [24].

Hepatic outflow obstruction

Hepatic venous outflow obstruction may result in significant histologic changes and liver injury as a result of impaired drainage of blood from the liver [22,23,28,29]. Venoocclusive disease (sinusoidal obstruction syndrome, SOS) and the Budd–Chiari syndrome are examples of conditions limiting the hepatic venous outflow. SOS was initially described in a patient who ingested a drink that contained pyrrolizidine alkaloids. However, SOS may also develop in patients soon after hematopoietic stem cell transplantation, or after chemotherapy, abdominal radiotherapy, and liver or kidney transplantation. Common presenting symptoms include tender hepatomegaly, ascites, weight gain, and jaundice. The mechanism of injury is direct toxicity to the sinusoidal endothelial cells and loss of fenestration of the endothelial cell membrane. This damage allows red blood cells to penetrate into the space of Disse allowing the sinusoidal lining cells to slough and embolize downstream, obstructing sinusoidal blood flow. Early histologic changes include damage to the sinusoidal endothelial cell predominantly in the perivenular area (zone 3 of the liver acinus).

Subendothelial edema leads to sinusoidal congestion and hepatocellular necrosis. The endothelial injury to both the sinusoids and small hepatic venules may cause activation of the coagulation cascade and the formation of thrombi. These abnormalties cause an intrahepatic form of postsinusoidal portal hypertension and the clinical manifestations of hepatomegaly, weight gain, and ascites. Progression of venular collagen deposition ensues, ultimately leading to widespread hepatic fibrosis [22,23,28,29].

In the Budd–Chiari syndrome there is thrombotic or nonthrombotic hepatic outflow obstruction at the level of the hepatic venules, large hepatic veins, or the inferior vena cava at the junction of the right atrium [22]. Decompression via a "spider web" of collateral veins around the area of obstruction facilitates the diagnosis by a typical appeareance on the hepatic venogram. The caudate lobe outflow is often not involved by the occlusive process, given its veins directly drain into the inferior retrohepatic vena cava. Sinusoidal congestion, portal vein hypertension, and reduced portal vein flow are the hemodynamic consequences of hepatic vein outflow obstruction. Indeed, a patent portal vein in Budd–Chiari syndrome may show a reversal of flow (away from the liver: hepatofugal) and may become the outflow tract from the liver. In cases of severe prothrombotic diathesis, the portal vein may also become occluded. The absence of any outflow tract leads to a particularly severe form of Budd–Chiari syndrome, with marked elevation of the serum aminotransferases and often acute liver failure.

Ischemic cholangiopathy

In contrast to the dual blood supply of the liver parenchyma, the biliary ductal system receives its entire blood supply through the hepatic artery alone [30]. The bile ducts are, in fact, the intended target of approximately 50% of the blood flowing through the hepatic artery. As such, the bile ducts are susceptible to ischemic injury (termed ischemic cholangiopathy (IC)) if the hepatic arterial flow is compromised [31,32]. This can occur in the setting of ischemic hepatic injury but, more commonly, it occurs as an isolated phenomenon and spares the parenchymal liver cells.

Understanding the anatomy of the biliary arterial supply helps to predict where IC is most likely to occur. The intrahepatic branches of the hepatic artery course nearby the ducts, terminating in the peribiliary plexus (PBP). This plexus is composed of an inner capillary layer and an outer vascular layer, which is intimately connected to the intrahepatic portal venules. The PBP is responsible for the blood supply to the proximal and mid common bile duct (CBD), the biliary hilum, as well as smaller bile duct branches. Thus, an ischemic condition of the PBP may preferentially cause IC of the mid to proximal CBD, biliary hilum, and intrahepatic bile duct branches. The distal CBD, however, may be spared, as it receives substantial blood supply from small branches off the gastroduodenal artery.

Box 34.4 Common conditions associated with isolated ischemic cholangiopathy.

- Liver transplantation (particularly DCD grafts)
- Gallbladder or biliary tract surgery
- Transarterial chemotherapy or chemoembolization
- Abdominal radiation therapy
- AIDS cholangiopathy

AIDS, acquired immune deficiency syndrome; DCD, donor after cardiac death.

The transplanted liver is more susceptible to IC than the native liver as transcapsular peripheral arteries are severed during the transplantation procedure, reducing the ability to utilize collateral blood flow.

Isolated IC is often iatrogenic. It commonly occurs after liver transplantation, particularly in recipients of organs procured after cardiac death where the incidence may be greater than 30%. Common conditions associated with isolated IC are outlined in Box 34.4. Other conditions implicated in IC include polyarteritis nodosa, hypercoagulable states such as paroxysmal nocturnal hemoglobinuria, atherosclerosis, cholesterol crystal embolization after cardiac catheterization, sickle cell disease, and hereditary hemorrhagic telangiectasia.

In post-liver transplant recipients, IC is the most common cause of nonanastomotic biliary strictures [33–35]. Early hepatic artery thrombosis can cause severe stricturing and some patients may eventually require retransplantation. Prolonged cold ischemia time, reperfusion injury, cytomegalovirus infection, and rejection all predispose patients to IC by increasing the likelihood of PBP damage. Approximately one third of liver recipients who develop IC may require retransplantation. The use of a transcystic tube and histidine tryptophan ketoglutarate preservation solution may decrease the risk of nonanastomotic biliary strictures in transplanted patients.

Patients with IC may present with symptoms of biliary obstruction including jaundice, dark urine, abdominal pain, and pruritus. Some patients are asymptomatic but have abnormal liver biochemical tests with a subsequent discovery of a new biliary stricture – the hallmark lesion of IC. A cholestatic biochemical pattern is typical. The most common location for an IC-related biliary stricture is in the mid CBD, followed by the hilum, and then the intrahepatic bile ducts. Less frequently, hepatic abscess or cholangitis may lead to the diagnosis of IC. Secondary sclerosing cholangitis can develop in intensive care patients with secondary bacteremia and biliary cast formation, leading to high morbidity.

Liver biopsy is generally not helpful in IC. The injury occurs in the medium to large ducts, while biopsy typically examines more peripheral, smaller branches of the bile ducts. When histology is available, the pathology is often consistent with biliary obstruction, including bile ductular proliferation, portal tract edema, and mixed inflammatory infiltrates. In more severe cases, hepatocellular ballooning and necrosis may be present, along with Kupffer cell hyperplasia and hypertrophy.

Patients suspected of having IC should have imaging to help confirm the diagnosis and treat the stricture. One must consider the etiology of the IC and the management of IC separately from an imaging standpoint. To determine the etiology, the first test should be a duplex ultrasound of the liver, which can effectively detect hepatic artery thrombosis. In suspected cases of hepatic artery thrombosis not confirmed by ultrasound, CT angiography or conventional angiography can be diagnostic. If the patient is nontransplant, has no hepatic artery thrombosis, and there is no obvious cause from the patient history for the IC, a hypercoagulable workup, human immunodeficiency virus (HIV) testing, and vasculitis workup are reasonable next steps.

Treatment depends on the inciting etiology. If hepatic artery thrombosis occurs in the first month after transplant, urgent retransplantation is often necessary. For hepatic artery thrombosis occurring later after transplantation, revascularization procedures including thrombolysis, thrombectomy, stent placement, or surgical repair may be required. The available data are mixed as to whether revascularization improves graft or patient survival [33–35].

The management of IC is generally based on the stricture(s) location. Cholangiography, either by magnetic resonance cholangiopancreatography (MRCP) or percutaneous cholangiogram, should be used to precisely determine the site of stricture and define the anatomy. The strictures can be long and often multiple, resembling primary sclerosing cholangitis or cholangiocarcinoma. Endoscopic retrograde cholangiopancreatography (ERCP) can provide long-term successful stricture management in 50–75% of post-transplant cases via the extraction of debris/casts, dilatation, and stent placement. Insufficient data exist regarding the success of endoscopic management of IC-related strictures in nontransplant patients. Surgical revision creating a Roux limb is an option for refractory strictures.

Heat stroke and the liver

Heat stroke is the most severe form of heat-related illness, with a mortality of 20–60%. The diagnosis is suspected when neurologic changes develop in the setting of an elevated core body temperature (>40°C) and is associated with multisystem organ dysfunction including disseminated intravascular coagulation. The two main variants of heat stroke include exertional heat stroke (EHS) and classic heat stroke (CHS), the latter typically occurring as a result of environmental exposure. The liver is frequently involved in heat stroke, ranging from moderately abnormal liver biochemical tests to the fully developed syndrome of acute (fulminant) liver failure, which occurs in 5–12% of cases [36–39].

The pathophysiology of liver injury in heat stroke is multifactorial. The three major pathways include: (i) a hyperthermia-induced increase in metabolic demands, causing a relatively hypoxic state with circulatory dysfunction; (ii) direct cytotoxic injury from excessive heat; and (iii) activation of systemic inflammatory mediators leading to endothelial cell activation and cytokine release. Arterial hypotension that occurs as part of the multiorgan dysfunction may also cause ischemic hepatic injury.

Macroscopically, the liver in heat stroke has a yellow-brown appearance, with conflicting descriptions of density. Histologically, the presence of extensive centrilobular (zone 3) necrosis without compensatory bile duct proliferation should suggest heat-related liver injury. Microvesicular steatosis is characteristically present in the remaining viable hepatocytes. The distribution of these changes is predominantly centrilobular (zone 3), suggestive of acute hypoxia. Acute nondestructive cholangitis may also be present in up to 20% cases. Histologic changes reverse completely within 4–5 weeks in those who recover.

Serum aminotransferases can be markedly elevated, reaching peak levels 24–48 hours after the development of heat stroke. They are often higher in EHS than CHS, and may reach levels greater than 25 times the upper limit of normal. Whereas aminotransferase recovery is rapid in ischemic hepatic injury, in heat stroke the serum aminotransferases may remain elevated for an average of 2 weeks. Alkaline phosphatase and serum bilirubin are usually not significantly altered, except in severe and fatal cases, where cholestasis can be present. In addition to hyperbilirubinemia, severe hypophosphatemia (<0.5 mmol/L) may be associated with acute liver failure. Lactate and lactate dehydrogenase are frequently significantly elevated in EHS, as well as, but less often, in CHS.

Patients with chronic liver disease may be more susceptible to heat stroke. Alcohol abuse, poor physical conditioning, psychiatric conditions, and diuretic use have all been associated with lowering the threshold for developing heat stroke.

Treatment is mainly supportive. Over half of patients who develop acute liver failure from heat stroke will spontaneously recover. Others may progress to death without urgent liver transplantation. Transplantation, however, is not an option for every patient with acute

liver failure; irreversible neurologic injury and sepsis associated with heat stroke may preclude transplantation. There are four reports of patients with heat stroke-induced acute liver failure undergoing liver transplantation, including one allograft from a living donor. However, only one recipient survived 1 year after liver transplantation, underscoring the severity of heat-related liver injury. At present, conservative intensive medical management remains the standard of care. Considerable scrutiny should be used when determining liver transplant candidacy for a patient with acute liver failure due to heat stroke [39].

Multiple choice questions

34.1 **An abrupt raise in serum aminotransferases with a peak at 1–3 days and a subsequent rapid decline is characteristic of which of the following?**

- **a** Acute viral hepatitis.
- **b** Passive hepatic congestion.
- **c** Budd–Chiari syndrome.
- **d** Acute hepatic ischemic injury.
- **e** Portal vein thrombosis.

34.2 **The following therapeutic modalities for hepatocellular carcinoma are considered risk factor for hepatic infarction, except for which of the following?**

- **a** Radioembolization with yttrium-90.
- **b** Conventional transarterial chemoembolization (TACE).
- **c** Segmental or lobar hepatic resection.
- **d** Sorafenib chemotherapy.
- **e** Radiofrequency ablation.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

PART IX

Benign and Malignant Tumors; Cystic Disorders

CHAPTER 35

Benign Tumors, Nodules, and Cystic Diseases of the Liver

Adrian M. Di Bisceglie & Alex S. Befeler

Division of Gastroenterology and Hepatology, Saint Louis University Liver Center, Saint Louis University School of Medicine, St Louis, MO, USA

Key concepts

- Hepatocellular adenoma is a rare benign neoplasm of the liver, often related to the use of oral contraceptives, that may be complicated by rupture, hemorrhage, and, rarely, development of malignancy.
- Hemangioma of the liver is the second most common benign focal hepatic lesion (simple cyst being the most common one) and the most common *solid* hepatic tumor (1–7.4% of the normal population). It is rarely of significant clinical consequence.
- Dysplastic nodules are defined as a nodular region of hepatocytes that are macroscopically different from surrounding cirrhotic nodules and have a significant risk of developing into hepatocellular carcinoma
- Focal nodular hyperplasia (FNH) is a benign tumor-like lesion of the liver considered to be hyperplastic rather than neoplastic in origin. This lesion is related to an abnormal blood supply and is rarely of clinical significance.
- There is rarely an indication for a surgical intervention in patients with a hemangioma, FNH, or most other benign solid lesions.
- Nodular regenerative hyperplasia is defined by hepatocellular nodules that are distributed throughout the liver in the absence of fibrous septae between the nodules. This condition is often associated with systemic diseases and is complicated by portal hypertension.
- Polycystic liver disease (PCLD) is an inherited disease in which multiple cysts develop within the parenchyma of the liver and produce disease from direct mechanical effects of the cysts.
- PCLD is often associated with other related diseases, such as autosomal dominant polycystic kidney disease, whereas the rarer congenital hepatic fibrosis and choledochal cysts may occur in association with autosomal recessive polycystic kidney disease.
- PCLD is usually asymptomatic but can be complicated by the development of abdominal pain, portal hypertension, hepatic venous outflow obstruction, obstructive jaundice, and cyst infection.
- Cystadenoma is a benign tumor of the liver that is hypothesized to arise from congenital defects of the bile ducts or gallbladder. This condition carries a high risk of development of malignancy.
- Echinococcal cysts are related to infection with the parasites *Echinococcus granulosus* and *E. multilocularis* and may affect many organs, including the liver.

Benign focal lesions of the liver are identified with increasing frequency because of the common use of imaging studies of the abdomen. They represent a relatively common reason for referral to the hepatologist or gastroenterologist. Most benign lesions are detected incidentally by imaging studies performed for unrelated reasons. Many of the lesions that present as a focal liver mass are true neoplasms, while others result from reactive proliferation of different cells.

Benign tumors

In general, benign tumors of the liver may arise from hepatocytes, bile duct epithelium, the supporting mesenchymal tissue, or a combination of two or more of these (Box 35.1). In addition to true neoplastic conditions of the liver, a variety of nodular diseases may occur that resemble, and must therefore be differentiated from, tumors.

Although most patients with benign hepatic tumors are asymptomatic, a minority may present with symptoms that may be local or systemic. In these patients, the relationship between the symptoms and the hepatic lesions may be difficult to correlate, and additional evaluation is necessary to rule out other causes for the patients' complaints. In most cases patients with benign hepatic lesions have no preexisting liver disease, and the finding of a coexisting chronic liver disease such as cirrhosis, chronic hepatitis B or C, or hemochromatosis should raise a suspicion for a malignant tumor. A conclusive diagnosis of a focal hepatic lesion is essential because it may represent a primary or secondary malignancy, which may require immediate treatment. In addition, some benign lesions carry specific risks such as rupture, bleeding, malignant

- Nodular regenerative hyperplasia
- Mesenchymal hamartoma
- Microhamartoma (von Meyenburg complex)
- Inflammatory pseudotumor
- Focal fatty change
- Pseudolipoma
- Macroregenerative nodule

transformation, consumptive coagulopathy, and disseminated intravascular coagulation. Often the clinical presentation provides important clues to a specific diagnosis and suggests whether the tumor is benign or malignant. Still, in many cases the clinical information and the first imaging study are nondiagnostic and the clinician must choose additional studies from an ever-increasing number of available options. Despite continuing advancement in sensitivity and accuracy, imaging studies fail to yield conclusive diagnosis in a sizable number of patients, and in these cases histopathologic assessment is necessary to characterize the lesion. A tissue sample may be obtained by an ultrasonography or computed tomography (CT)-guided percutaneous liver biopsy or by a laparoscopic liver biopsy. Histopathologic evaluation remains essential in the clinical management of a significant number of tumors or masses in the liver; possible exceptions include hemangioma, focal nodular hyperplasia (FNH), and focal fatty change, which may be unequivocally diagnosed by imaging studies. Unfortunately, in some benign lesions (e.g., hemangioma and hepatic adenoma) liver biopsy carries a high risk of bleeding and is therefore contraindicated. A fundamental knowledge of the various lesions and their characteristic features should help in the differential diagnosis.

Benign tumors of epithelial origin

Hepatocellular adenoma

Epidemiology and risk factors

Hepatocellular adenoma, also termed *liver cell adenoma*, *hepatic adenoma*, or *telangiectatic adenoma* is a benign tumor of epithelial origin occurring primarily in women of childbearing age. It is considerably less common than hemangioma or FNH, occurring in less than 0.004% of the population at risk. Adenomas may be solitary or multiple and may reach more than 20 cm in size. Hepatocellular adenoma has a very strong association with the oral contraceptive pill (OCP) and other estrogens, though it may rarely occur in the absence of exogenous estrogens and in men. The annual incidence in long-term users of OCPs is to 3–4 per 100,000 compared to 1–1.3 per million in nonusers [1]. The use of OCPs with high hormonal potency, use for more than 5 years, and age over 30 years may further increase the risk [1,2]. However, in 10% of patients diagnosed with hepatocellular adenoma, the exposure to OCPs may be as short as 6–12 months [3]. Other risk factors for hepatocellular adenomas include anabolic-androgen steroids and familial polyposis coli [4,5].

Hepatocellular adenomas (typically multiple lesions) are commonly encountered in association with type I and III glycogen storage diseases [6]; the incidence is 22–75% in type I and 25% in type III [6]. In sharp contrast to hepatocellular adenomas in general, which show a strong female preponderance, those associated with glycogen storage disease show a male predominance [6]. Furthermore, adenomas associated with glycogen storage diseases develop before the age of 20 years.

A condition in which more than ten lesions are present has been termed *liver adenomatosis* [7]. This condition has been reported in men and women in the absence of OCP use or glycogen storage disease [7–9]. It may not be an independent entity and maybe related to germline mutations in hepatocyte nuclear factor 1α (HNF-1α) [8,9]. It is also seen in adenomas with somatic mutations of HNF-1α (see below).

Pathogenesis and genotype/phenotype classification

The pathogenesis of hepatocellular adenoma is still unclear. Hepatocellular adenomas are a heterogeneous group of monoclonal tumors. The strong association with the OCP and pregnancy suggests a possible trophic effect of estrogen on this tumor [10]. Furthermore, regression of adenomas after discontinuation of OCPs is well documented [10,11]. More recently, a genotypic and phenotypic classification for hepatocellular adenoma has been

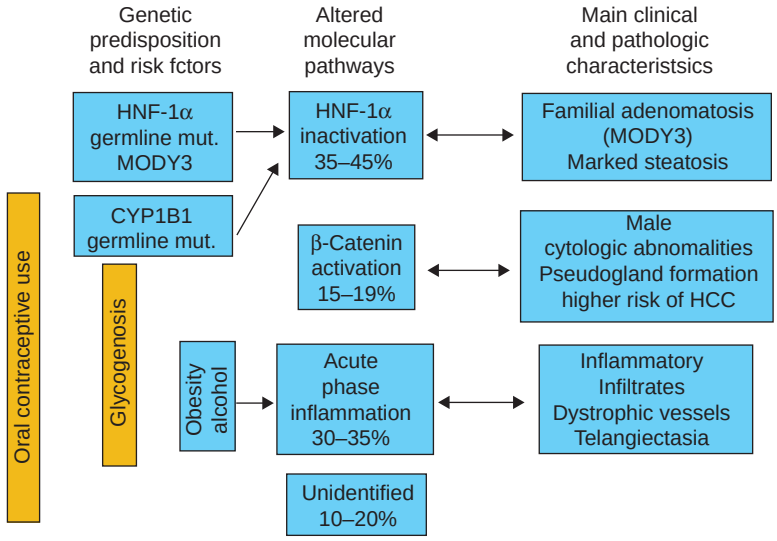

Figure 35.1 Pathogenesis and classification of hepatocellular adenoma. HCC, hepataocellular carcinoma; HNF-1α, hepatocyte nuclear factor 1α; MODY3, mature-onset diabetes of the young. (Adapted from Rebouissou et al. [280] with permission from Elsevier.)

proposed by the Bordeaux group that subdivides hepatocellular adenomas into four groups (Fig. 35.1) [12,13].

Hepatocyte nuclear factor 1α inactivated group

The HNF-1α inactivated group is characterized by biallelic inactivation of the tumor suppressor gene *HNF1A* and represents about 35% of cases [8,13]. HNF-1α is implicated in the regulation of gene expression in the liver associated with hepatocyte differentiation and liver development [8]. Most (approximately 85%) of the mutations in *HNF1A* are somatic, athough heterozygous germline mutations can occur [8]. The germline mutations are associated with mature-onset diabetes of the young (MODY3), which is an autosomal dominant form of nonketotic diabetes mellitus that usually presents before the age of 25 years. Germline mutations are also associated with a family history of adenomatosis, a syndrome in which there are multiple adenomas, usually more than ten [9].

Grossly, the tumors have irregular lobulated borders with multiple small foci of hepatocellular adenomas surrounding the main tumor mass [12,13]. Pathologically, the adenomas have marked steatosis and a lack of cytologic abnormalities or inflammation [8,12,13]. HNF-1α inactivated hepatocellular adenomas can be recognized on immunohistochemistry by a lack of liver fatty acid-binding protein (LFABP) staining in the tumor compared with the surrounding liver [12]. LFABP is positively regulated by HNF-1α.

Beta-catenin mutations

Beta-catenin mutations are present in about 10% of hepatocellular adenomas and define a separate group for those hepatocellular adenomas that do not have features of the inflammatory group (see below) [13]. β-Catenin is a key molecule in the Wnt signaling pathway and can lead activation of genes that lead to cell proliferation and a variety of cancers including about a third of hepatocellular carcinomas [13].

The hepatocellular adenomas usually have pseudoglandular formation and cytologic abnormalities that may make it difficult to distinguish them histologically from well-differentiated hepatocellular carcinoma [13]. These tumors lack steatosis. β-Catenin staining can be demonstrated by immunohistochemistry, but it is usually patchy and unreliable so staining for glutamine synthetase, an enzyme upregulated by β-catenin, is preferred [13]. These adenomas are more likely to occur in male patients and are associated with male hormone ingestion, glycogen storage disease, and familial adenomatous polyposis [13, 14]. Most importantly, this group is responsible for most of the risk of developing hepatocellular carcinoma from hepatocellular adenoma.

Inflammatory hepatocellular adenoma

Inflammatory hepatocellular adenomas represent about 50% of all hepatic adenomas and include what was previously called telangiectatic focal nodular hyperplasia [12,13,15]. The patients have an inflammatory syndrome with elevated serum C-reative protein (CRP) and often are obese. Inflammatory hepatocellular adenomas appear to have activation of the interleukin 6 (IL6) inflammatory signaling pathway, including signal transducer and activator of transcription 3 (STAT3) [16]. In 60% this activation is due to a mutation in gp130, a co-receptor for IL6 [16].

The tumors have focal inflammatory infiltrates, sinusoidal dilatations, and thick-walled isolated arteries

[12,13]. There can be a variable amount of tumor steatosis, peliosis, and hemorrhage. Inflammatory hepatocellular adenomas can be classified by immunohistochemical staining for the inflammatory proteins, serum amyloid A (SAA), and CRP in the tumor hepatocytes, but not in the surrounding liver [12,13]. About 10% of inflammatory hepatocellular adenomas have a β-catenin mutation and thus are at increased risk for transformation into hepatocellular carcinoma.

Hepatocellular adenomas without genetic or phenotype markers (unclassified)

The tumors in this group represent 5% of hepatocellular adenomas and have no evidence of mutations in *HFNF1A* or β-catenin and have no inflammatory infiltrates [13].

Pathology

Hepatocellular adenoma is usually a large, well-circumscribed, yellow to light-brown tumor. It arises in an otherwise normal liver and a complete or partial capsule is frequently present, although it may occasionally be absent. It is typically solitary but may be multiple, and it ranges in size from 1 to 30 cm [17–19]. Adenomas tend to be larger in women taking OCPs. They occur more commonly in the right lobe and are usually subcapsular, projecting slightly from the surface. Occasionally, they may be pedunculated. Foci of central hemorrhage or necrosis are frequently observed.

Microscopically, this tumor is composed of cells closely resembling normal hepatocytes. They are arranged in plates separated by sinusoids, which may be focally dilated, particularly in the inflammatory group. The plates may be slightly thicker than those in normal liver tissues (more than two cells). β-Catenin mutated hepatocellular adenoma may have a relatively increased nuclear : cytoplasmic ratio, resembling well-differentiated hepatocellular carcinoma (HCC). They may also contain bile-containing acinar structures. A variety of cytoplasmic changes and inclusions can be seen, including Mallory hyaline, lipofuscin, and giant mitochondria. Typically, there are few or no portal tracts or central veins within the adenoma [17–19]. Vascular elements, particularly thick-walled arteries and arterioles, are seen at the periphery of the tumor [17–19]. Peliosis hepatis may also be seen, particularly in the inflammatory group [12].

An absence of Kupffer cells was initially reported in hepatocellular adenoma; however, studies using immunoperoxidase staining for lysozyme demonstrated the presence of Kupffer cells in variable numbers within the adenoma [18,19]. Nevertheless, hepatocellular adenomas usually do not demonstrate the uptake of ^{99m}Tc-sulfur colloid, which is typically taken up by Kupffer cells.

Adenomas are perfused predominantly by peripheral arterial feeders that are unaccompanied by bile ducts. The arterial perfusion and their hypervascular nature, with dilated sinusoids and poor connective tissue support, may explain their tendency to bleed. A percutaneous needle liver biopsy theoretically carries an increased risk of bleeding, but can be performed safely.

Clinical manifestations and complications

Hepatocellular adenoma may present in different ways, and there are conflicting numbers in the literature with regard to the frequency of each type of presentation. In most series, patients presented with abdominal symptoms, usually pain or discomfort in the epigastrium or right upper quadrant [12,14,20]. Typical, the patient is a woman between 20 and 50 years who has a history of more than 5 years of OCP use [21]. More recently, the tumor commonly may be detected as an incidental finding on abdominal imaging study or at surgery. These tend to be the smaller adenomas and are less likely to be associated with OCPs. Presentation can be with severe pain and associated with hypotension in the setting of an acute hemorrhage or rupture [12,14,20]. Liver chemistries are usually normal although serum alkaline phosphatase and γ-glutamyl transpeptidase may be elevated, particularly in patients with bleeding or rupture [14,22].

The general risk of bleeding and rupture appears to be more likely in the inflammatory group and in those patients taking OCPs [12,14,20]. Bleeding is generally limited to larger adenomas, usually >5 cm in diameter [12, 14,20]. Mortality may be as high as 6%, but in more recent series is rare [12,14,20,23].

Malignant transformation of hepatocellular adenoma into carcinoma is uncommon but well documented. Unfortunately, there are no observational studies addressing the risk over time of an adenoma transforming into HCC. Most surgical resection series contain 5–8% of cases with associated HCC [12,14,20]. Size is a good predictor of malignancy risk with virtually all reported HCCs occurring in adenomas >5 cm. Multiple adenomas do not appear to confer additional risk of malignancy above the risk associated with size [14]. Transformation from adenoma to carcinoma may occur despite the discontinuation of OCPs [24]. β-Catenin mutations are associated with most HCCs [12,13]. The risk of malignant transformation appears to be significantly higher in men regardless of a β-catenin mutation [12,13]. An enlarging lesion, local or systemic symptoms, progressive abnormalities in liver chemistries, and rising blood levels of α-fetoprotein may all be signs of transformation to HCC.

Imaging studies

- *Ultrasonography* is nonspecific, often showing a well-demarcated mass with smooth borders and variable

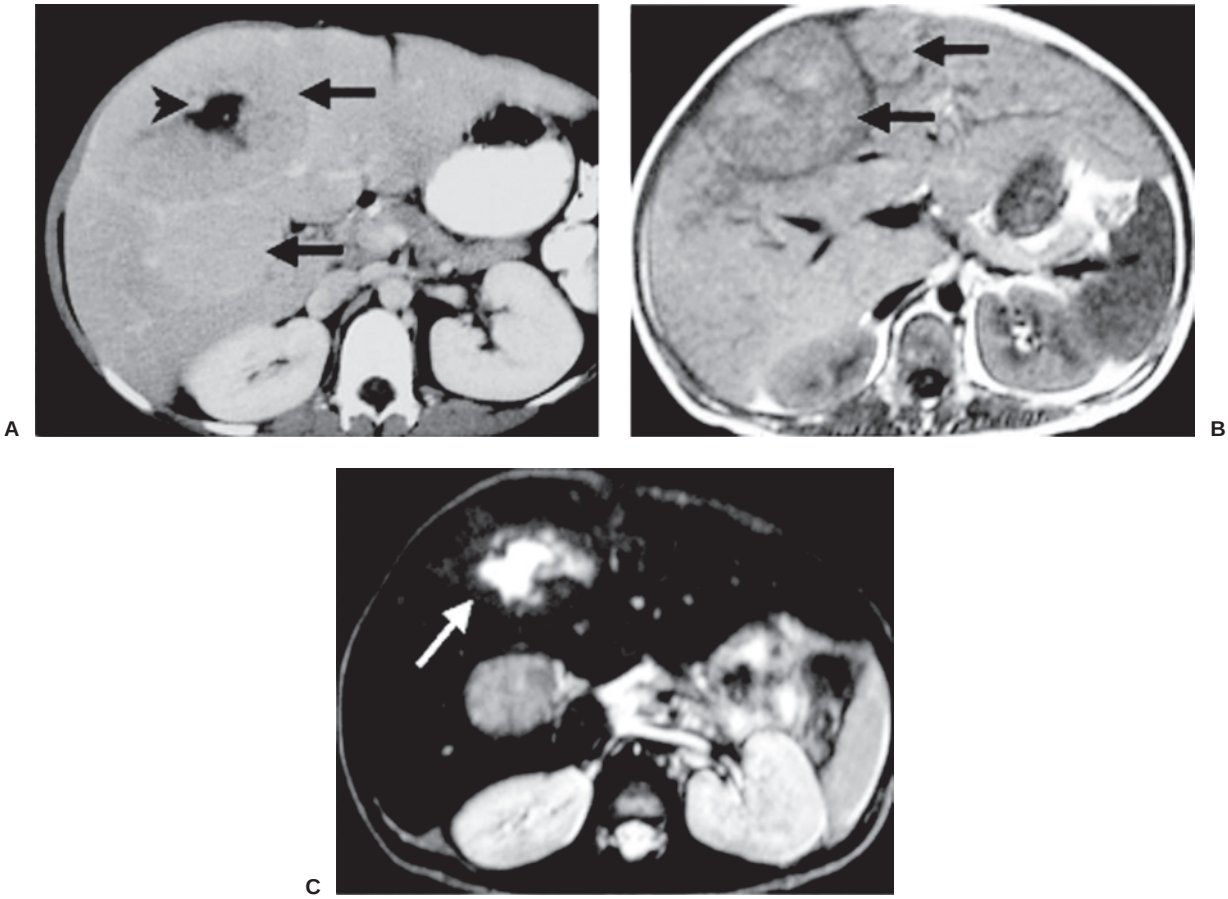

Figure 35.2 Hepatocellular adenoma. (A) Abdominal CT scan shows two well-circumscribed mass lesions in the right-hepatic lobe (arrows). The anterior lesion shows central necrosis (arrowhead). (B) Abdominal MRI (T1-weighted image) of the same patient shows two lesions with slightly decreased intensity and well-defined low-intensity capsule (arrows), which are suggestive of hepatocellular adenoma. (C) T2-weighted image shows a central high signal intensity (arrow), which is consistent with central hemorrhage.

echogenicity [25]. Color and power Doppler and particularly ultrasound with contrast may show vascular flow from the periphery to the center of the lesion (centripetal filling), though these findings are not diagnostic [26].

- *CT scanning* does not provide a diagnostic picture either, although findings on multiphasic contrast-enhanced CT scans can help in suggesting the diagnosis (Fig. 35.2A) [26]. On precontrast images, the adenoma appears as a hypo- or isodense mass, which may show high-density areas, consistent with intratumoral hemorrhage [26]. After contrast injection, in the arterial phase, the mass may show irregular enhancement with areas of normal, increased, and decreased density, which is characteristic for hepatocellular adenoma [27]. In the portal-venous phase, enhancement fades, becomes more uniform, and may be slightly hyperintense to isointense to the surrounding liver. There can be peripheral enhancement due to feeding vessels. On delayed imaging there can be "washout" similar to that seen with hepatocellular carcinoma (Fig. 35.2A) [26]. In the setting of an acute hemorrhage, the center may be hyperdense in the arterial phase. In the presence of an old hemorrhage, the center usually remains hypodense after contrast injection, making the differential diagnosis from a central scar difficult.
- *Magnetic resonance imaging* (MRI) shows a well-demarcated lesion that on T1-weighted images may show a mildly hypointense to mildly hyperintense signal (Fig. 35.2B) [26]. T2-weighted images show an isointense to slightly hyperintense signal that may be heterogenous because of areas of bleeding. Central necrosis typically appears as low signal intensity on T2-weighted images, whereas a recent hemorrhage may show increased signal on T1 images (Fig. 35.2C). Gadolinium (Gd) enhancement is similar to the pattern described for CT with arterial phase blush followed by a rapid fading in the venous and delayed phases to hypointensity or isointensity, with persistence of an enhancing rim related to the capsule. MRI can

identified HNF-1α mutated hepatocellular adenoma with reasonable reliability by demonstrating the combination of diffuse signal dropout on T1-weighted chemical shift due to steatosis, an isointense to slightly hyperintense signal on T2-weighted images, and moderate arterial enhancement without persistent enhancement in portal-venous and delayed phases [28]. Inflammatory hepatocellular adenoma show an absent to slight signal dropout on chemical shift, a marked hyperintense signal on T2, particularly on the edges from sinusoidal dilatations, and strong arterial enhancement with persisting enhancement in the portal-venous and delayed phases [28].

Hepatocyte-selective contrast agents such as Gd-BOPTA (gadobenate dimeglumine) have been shown to improve the differentiation between FNH and adenoma. This contrast agent is selectively taken up by functioning hepatocytes and excreted into the bile. It results in prolonged enhancement of the liver parenchyma. More than 1 hour after contrast injection, almost all FNH lesions appear hyper- or isointense, whereas almost all hepatocellular adenomas are hypointense [26].

- *^{99m}Tc-sulfur colloid scintigraphy* may be helpful in the diagnosis of hepatocellular adenoma because it typically shows no uptake of the colloid due to decreased activity of Kupffer cells within the adenoma. This is in contrast to FNH, which shows normal to increased uptake [26].

Diagnosis

In the setting of a person without liver disease or a prior history of cancer, the main differential diagnosis of a mass in the liver is usually between hepatocellular adenoma and FNH. There are no completely reliable radiologic features for the diagnosis of hepatocellular adenoma though some enhancement patterns are suggestive. FNH can be reliably diagnosed, thereby removing hepatocellular adenoma from the differential. A tentative diagnosis of hepatocellular adenoma is usually made in the setting of women aged 20–50 years, with a history of OCP use, and a typical-appearing focal hepatic lesion or lesions. Although there is considerable overlap in the radiologic features of hepatocellular adenoma and HCC, the latter is usually associated with a background of chronic liver disease, usually with evidence of cirrhosis. In patients with chronic hepatitis B or cirrhosis, any suspicious focal lesion with radiologic features consistent with both HCC and adenoma should be regarded as HCC until proved otherwise. High or increasing serum levels of α-fetoprotein, significant increase in nodule size, abnormal hepatic biochemical test results, and involvement of the portal vein are highly suggestive of HCC. Despite the advances in imaging modalities, the diagnosis often remains uncertain and histologic examination may be necessary. In hepatocellular adenoma, a percutaneous needle liver biopsy may carry an increased but acceptable risk of bleeding, which can be potentially mitigated by a laparoscopic biopsy with direct hemostasis. Historically, needle biopsies have often been nondiagnostic and pathologic review of resected nodules may be needed for definitive diagnosis, though new immunohistochemical staining has improved diagnostic ability. Liver biopsy can reliably categorize hepatic nodules into definite HCC or high-risk hepatocellular adenomas and metastatic lesions. Hepatocellular adenoma is sometimes difficult to differentiate from FNH. The two conditions are compared in Table 35.1.

Management

Classically, surgical treatment is recommended, if possible based on anatomic location of the lesions and comorbidities to avoid the risks of rupture, hemorrhage, and malignant transformation [29]. More modern series advocate that asymptomatic hepatocellular adenoma that are smaller than 4 or 5 cm in size are unlikely to rupture and bleed and, therefore, should not be resected, but should be followed by periodic imaging studies [12,14,20]. The interval and duration of imaging has not been clearly defined although one group recommends follow-up through menopause [12]. Blood α-fetoprotein levels are often followed, although there is scarce

Table 35.1 Comparison of hepatocellular adenoma and focal nodular hyperplasia.

Feature	Adenoma	Focal nodular hyperplasia
Sex	Female	Female
Oral contraceptive use	Strong association	Questionable
Symptoms	Occasional	Rare
Multiple	12–30%	Approximately 30%
Central arterial scar	No	Yes
Treatment	Resection	Resection only if symptomatic

Adapted from Rodes and Sherlock [279] with permission.

evidence to support the efficacy of this approach [6]. The development of symptoms, increasing size of the nodule, unexplained liver chemistry abnormalities, or rising α-fetoprotein levels should raise the suspicion of malignant transformation and should prompt a surgical intervention to remove the lesion. The data for this approach are stronger for hepatocellular adenoma with imaging and/or biopsy features of the HNF-1α mutated group than for the inflammatory and unclassified group. There are no prospective studies to confirm these recommendations, but there is long-term follow-up in a number of patients with residual hepatocellular adenoma after resection with only rare growth of the tumors requiring treatment [12,14]. Hepatocellular adenoma in men and with β-catenin mutations regardless of size should be resected because of the risk of HCC [12,14,20]. Some have recommended a period of observation after OCPs have been discontinued to assess whether the tumor size decreases or disappears [12]. However, there are rare reports of cancer occurring even in adenomas that have decreased in size or disappeared after the discontinuation of OCPs [24]. The risk : benefit ratio should be assessed for every case and the final decision should be made on an individual basis.

Surgical approaches for hepatocellular adenoma have included enucleation, resection, and liver transplantation. Enucleation is associated with less blood loss and preservation of normal liver tissue [30]. Both resection and enucleation are performed laparoscopically in many centers with excellent results, when technically feasible [12,14,20]. Almost all solitary lesions can be completely resected, but there is often residual hepatocellular adenoma if there were multiple lesions [12,14,20]. The mortality of an elective surgery is about 1%, but it increases to 5–8% for emergency resection [12,14,20,30,31]. Arterial embolization has been used to control bleeding, converting a high-risk emergency resection surgery into a low-risk elective case [14,20]. Embolization can also reduce the tumor size preoperatively, or relieve symptoms in patients with inoperable tumors [20,32–34]. Radiofrequency ablation (RFA) can also be used for small tumors [35]. There is only limited long-term follow-up of patients with hepatocellular adenoma having RFA and embolization as primary treatment for their hepatocellular adenomas.

In rare patients with multiple adenomas, orthotopic liver transplantation (OLT) may be the only way to remove all the lesions, though transplantation is generally reserved for patients with glycogen storage disease [6,36,37]. In type I glycogen storage disease, OLT also corrects the metabolic defect [36,37].

Generally, pregnancy should be avoided to prevent the risk of rapid tumor growth, rupture, and bleeding [38]. One series did have several successful pregnancies with occasional tumor growth but no cases of hemorrhage or rupture in women with a prior incomplete resection [14]. Women who have had hepatocellular adenoma, whether resected or not, should avoid the use of OCPs permanently. In patients with glycogen storage disease, pregnancy is probably safe. In the few reports of patients with glycogen storage disease and hepatocellular adenomas who became pregnant, there was no change in the size or number of the adenomas [39]. This observation supports the notion that the pathogenesis of hepatocellular adenoma in patients with glycogen storage disease may be different from that of adenomas occurring in healthy individuals.

Hepatocellular carcinoma

Hepatocellular carcinoma is a malignant neoplasm of hepatocytes and is described in Chapter 36. HCC has been described as occurring in association with several of the nodular lesions described earlier, including nodular regenerative hyperplasia (NRH), dysplastic nodules, hepatocellular adenoma, and FNH. The link between HCC and NRH or FNH probably involves compromise of blood supply to the liver because of the presence of the malignant tumor, which causes direct pressure or microvascular invasion, whereas dysplastic nodules and adenoma may give rise to HCC.

Intrahepatic bile duct adenoma

Intrahepatic bile duct adenoma is a rare non-neoplastic focal lesion that is usually discovered incidentally. Most cases are reported in men older than 40 years. Typically, it is a solitary subcapsular lesion measuring 0.5–2 cm in size [40]. Microscopically, it consists of numerous, uniform, normal appearing bile duct-like structures that are surrounded by a small amount of fibrous stroma. This lesion is occasionally confused with cholangiocarcinoma or metastatic adenocarcinoma on frozen sections. The distinction should be made by the absence of nuclear hyperchromasia, mitotic activity, and vascular invasion. Bile duct adenoma has also been referred to as peribiliary gland hamartoma [41].

Benign tumors of mesenchymal origin

Hemangioma

Epidemiology

Hemangioma is the most common benign *solid* lesion of the liver. The reported prevalence at autopsy ranges from 0.4% to 7.4% [42]. Among the benign focal hepatic lesions, it is second in prevalence only to simple cysts. Hemangiomas are most often found incidentally and have no major clinical implications. They are more prevalent in women and in the right hepatic lobe; the sex ratio is between 4 : 1 and 6 : 1. Hemangiomas may present at any age but are most common between the third and fifth

decades and rare in young children. There is some controversy about the term *cavernous hemangioma*. Whereas some authors use it as a general name for hemangiomas, others use it to describe a stage of development of the lesion [43].

Pathogenesis

Hepatic hemangiomas are congenital vascular malformations. They enlarge by ectasia rather than hyperplasia or hypertrophy and are considered to be hamartomas [44]. They compress, rather than infiltrate, the surrounding liver parenchyma, which results in a dissectible plane between the hemangioma and liver tissue. There is an ongoing controversy about the role of estrogen in their growth. Although most researchers found no association [45], some have reported growth or initial symptoms during pregnancy or in women receiving OCPs [46–48]. These reports suggest that although hemangiomas are unrelated to estrogens in most women, they may play a role in individual cases.

Pathology

On gross examination the hemangioma appears as a dark purple, compressible, spongy lesion (Fig. 35.3A, B) that may replace considerable portions of liver parenchyma (Fig. 35.3C, D). On microscopic examination, a hemangioma is typically composed of multiple vascular spaces of varying sizes, which are lined by a single layer of endothelial cells and are separated by fibrous septa (Fig. 35.3D). Intraluminal thrombi may be present and may lead to local calcifications. Nevertheless, biopsy is usually unnecessary and may be associated with significant morbidity because of bleeding.

Clinical manifestations

In most cases, hemangiomas are small and asymptomatic. Infrequently, they may grow to a large size, causing pressure or the displacement of adjacent structures. Hemangiomas larger than 4 cm in size have been referred to as *giant hemangiomas* [49]. Large hemangiomas are uncommon; however, they are more likely to cause symptoms. The most common complaints are of abdominal pain or discomfort; while early satiety, nausea, and vomiting may also occur [50,51]. Pain may be intermittent and is likely due to distension of the liver capsule or pressure on adjacent structures. Severe sudden pain may be caused by infarction, necrosis, or bleeding into the hemangioma. Other rare manifestations related to giant hemangiomas include gastric obstruction, obstructive jaundice [52], and symptoms resembling polymyalgia rheumatica [53]. The

(C) A cut surface of a giant hemangioma occupying a large part of the right and left lobes. (D) Histologic examination exhibits numerous dilated vascular channels with thickened, acellular fibrous septa. (Courtesy of Dr P. A. Bejarano, Department of Pathology, University of Miami School of Medicine.)

relationship between symptoms and the hemangioma may be difficult to ascertain, and in many cases other causes are discovered, such as peptic ulcer, gastroesophageal reflux disease (GERD), hernias of the abdominal wall, or tumors of the gastrointestinal tact. In one series of 87 patients with hepatic hemangiomas, 54% of patients were ultimately found to have other causes for their symptoms [54]. In these cases, symptoms may resolve after treatment of the concomitant illness and therapy for the hemangioma is not required.

Physical examination is usually unremarkable. Occasionally, there is abdominal tenderness over the right upper quadrant and a palpable mass may be encountered. Rarely, a bruit may be heard over a large hemangioma.

Hepatic biochemical tests are usually normal and are therefore of little help in the diagnosis of hepatic hemangioma. On rare occasions, serum aminotransferases or alkaline phosphatase level may be mildly elevated. Serum levels of α-fetoprotein and carcinoembryogenic antigen (CEA) are invariably normal.

Complications and natural history

Spontaneous bleeding into a hemangioma, although extremely rare, has been reported [51]. This complication typically presents with abdominal pain in the right upper quadrant and declining hematocrit, in the absence of trauma. The diagnosis is usually made on an abdominal CT scan and in some cases treatment is the removal of the hemangioma by lobectomy or enucleation. Thrombosis within a hemangioma may also present with right abdominal pain and occasionally with fever and an increase of the erythrocyte sedimentation rate [52]. Spontaneous rupture of hepatic hemangiomas is exceedingly rare [54]; however, there are several reports of the rupture of giant hemangiomas of the right lobe after abdominal trauma [55]. A few patients have presented with obstructive jaundice due to pressure on the bile ducts [52,56] or portal hypertension due to pressure on the portal vein [57]. Hemangiomas have rarely been reported to grow rapidly during pregnancy, and after the use of estrogens; however, the effect of pregnancy and estrogens on growth is inconsistent. Rarely, patients with giant hemangiomas may develop consumption coagulopathy within the hemangioma and may present with evidence of disseminated intravascular coagulation (DIC), the so-called Kasabach–Merritt syndrome [46,51,58], which typically occurs in infants. The pathogenesis is likely platelet trapping in the hemangioma that leads to activation of the clotting cascade and consumption of both platelet and clotting factors.

Despite rare reports of complications, the long-term clinical course of most hepatic hemangiomas is benign [59], and most patients will never experience symptoms. When followed up for periods of 15–20 years, most patients remained asymptomatic and showed no significant changes in quality of life [44,60]. In one of the largest series, 158 hemangiomas in 123 subjects were followed up for 12–60 months. No complications were observed during the follow-up period. Only one patient developed new symptoms, and only one hemangioma showed a significant change in size [61].

Imaging studies

- The typical *ultrasonographic* appearance of a hemangioma is of an echogenic, well-demarcated homogenous lesion with well-defined borders, although approximately 20–30% of patients may present with an atypical sonographic appearance. Posterior acoustic enhancement is a common feature. Doppler does not usually detect flow within the hemangioma because of the slow blood flow [62]. Larger hemangiomas are more heterogenous and occasionally contain central fibrosis due to a previous hemorrhage. These usually require further imaging studies. A characteristic radiographic feature of hemangiomas with contrast-enhanced imaging is slow centripetal filling of the lesion by the contrast agent. This may be demonstrated by dynamic CT imaging, contrast-enhanced harmonic ultrasonography or multiphasic MRI [63,64].
- *Dynamic CT scans* offer a few advantages over ultrasonography in the diagnosis of hepatic hemangioma and are often performed to verify the diagnosis suggested by the ultrasonography. On CT prior to the administration of intravenous contrast, the typical appearance is that of a well-defined hypodense lesion (Fig. 35.4). Serial images in the arterial phase of contrast administration show early peripheral enhancement with subsequent progressive globular centripetal filling [65]. Globular enhancement in the arterial phase represents venous lakes within the hemangioma and may be seen in 94% of large lesions. It usually takes about 3 minutes for complete opacification of the lesion to occur; however, it may take 10–15 minutes to complete opacification, and in many patients the center of the lesion may remain hypodense because of a central hemorrhage or fibrosis [66]. Smaller lesions generally fill more rapidly and larger lesions are more likely to show slower central filling. Large hemangiomas (>4 cm) typically develop central areas that fail to fill in on the delayed enhanced images. The center of the hemangioma is more likely to remain hypodense as the size increases. The contrast agent classically remains within the hemangioma for a long time (as long as 60 minutes) after the injection. Occasionally, calcifications may be seen within a large hemangioma. The diagnostic sensitivity and specificity of dynamic CT scan are more than 90% in lesions larger than 2 cm in size, but are significantly lower in smaller lesions [66,67].

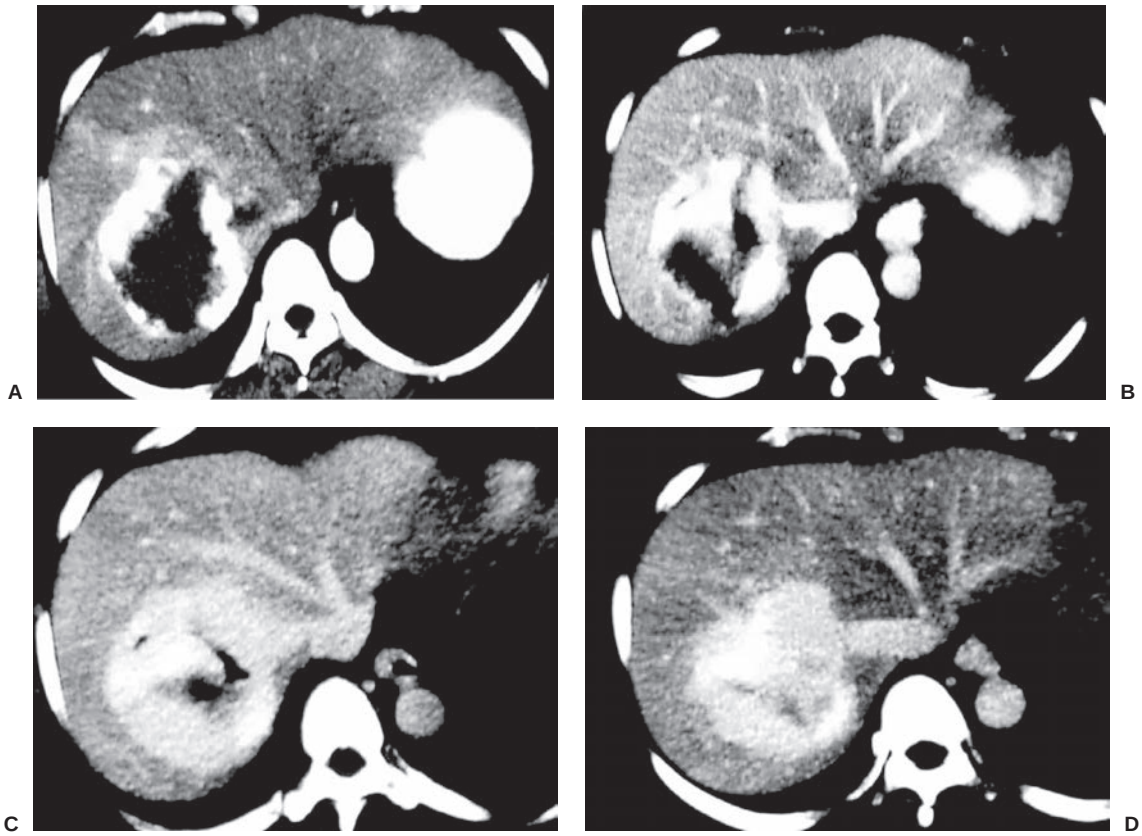

Figure 35.4 Hepatic hemangioma. Dynamic, contrast-enhanced computed tomography (CT) scan demonstrates globular peripheral enhancement with gradual diffusion of the contrast from the periphery to the center of the lesion: (A) 40 seconds, (B) 60 seconds, (C) 90 seconds, and (D) 120 seconds after intravenous contrast injection.

- *MRI* shows a high degree of sensitivity and specificity (both >90%) in the diagnosis of hemangioma and is generally considered to be superior to CT scan for this purpose [68,69]. It has a special value for the diagnosis of hemangiomas smaller than 2 cm in size and in patients with contraindications to the use of iodine-based intravenous contrast. A hemangioma usually appears as a well-circumscribed lesion that shows a moderately elevated signal on T2-weighted images and a low signal on T1-weighted images. The increased signal on T2-weighted images is typically less intense than that demonstrated by a simple cyst. Similar to the findings on CT scan, contrast enhancement with gadolinium shows a centripetal nodular filling on the arterial phase, which is considered by many to be a pathognomonic finding. Venous and delayed phases show progressive enlargement and coalescence of the peripheral nodules with variable degree of central filling.
- *^{99m}Tc-pertechnetate-labeled red blood cell (^{99m}Tc-RBC) pool scintigraphy* may occasionally be helpful in controversial cases, but the use of this technique is decreasing in most medical centers. It typically shows initial hypoperfusion during the arterial flow phase followed by a gradual increase in the isotope in the lesion, which peaks at 30–50 minutes after the injection. Delayed images usually show retention of the tracer, which is typical of hemangioma. ^{99m}Tc-RBC scan has low sensitivity for lesions smaller than 2 cm in size. Single photon emission computed tomography (SPECT) using ^{99m}Tc-RBC has been shown to increase the resolution of planar scintigraphy [70] and has a clear advantage over ultrasonography in differentiating large hepatic hemangiomas from other solid masses [71]. The sensitivity and specificity of ^{99m}Tc-RBC SPECT may be as high as 90–97% in lesions larger than 2 cm in size, which is close to the accuracy of MRI, but the specificity may decrease to 50% in lesions with mixed echoic pattern. ^{99m}Tc-RBC SPECT is best used to clarify a doubtful lesion on CT or to confirm a suspected hemangioma seen as a hyperechoic lesion on ultrasonography.
- *Plain X rays* of the abdomen may show calcification within a hemangioma but are otherwise of little value.
- *Catheter angiography* is rarely used for the diagnosis of hepatic hemangioma. The contrast injected into the common hepatic artery rapidly fills the vascular spaces, creating a "starry night" appearance in the early phase and vascular lakes in later phases, which remain opacified beyond the venous phase (>40 seconds) [72]. The

borders may be irregular but are well defined, and the feeding vessels are typically displaced and curled at the margins of the lesion. Arteriovenous shunting is typically absent and its presence should raise suspicions of HCC. Still, hepatic hemangiomas may show atypical features mimicking HCC such as early fading after arterial enhancement [73], arteriovenous shunting [74], and centrifugal rather than centripetal enhancement pattern [75].

Discrepancy in different imaging studies should therefore warrant further follow-up and evaluation. A combination of ultrasonography, contrast-enhanced CT scan, and ^{99m}Tc-RBC scintigraphy was shown in one study to have a sensitivity of 86%, specificity of 100%, and accuracy of 91% in differentiating hepatic hemangioma from FNH and adenoma in 437 patients [76].

Management

Because most hemangiomas are asymptomatic, rarely enlarge in size or rupture, and have no malignant potential, surgical intervention is rarely indicated. When the diagnosis of hemangioma is conclusive, observation is sufficient and the rare risk of rupture should not be considered as an indication for surgery. Surgical therapy is indicated only in patients with severe symptoms, complications, or inconclusive diagnoses that cannot be resolved with imaging studies. Biopsy should be avoided because of a high risk of bleeding [77]. Overall, surgical resection is indicated in about 2% of diagnosed hemangiomas. This percentage may increase considerably in referral centers because of selection bias. The most common cause for surgical intervention in patients with hemangiomas is the presence of symptoms. The causative relationship between the hemangioma and symptoms should be confirmed and additional tests should be considered to rule out other potential causes such as gastroesophageal reflux disease, peptic ulcer, or gallstones. When symptoms are clearly related to the hemangioma, resolution may be observed in as many as 96% of the patients after surgical treatment. Another major reason for surgery is to exclude the presence of malignancy. In one case series from the Memorial Sloan–Kettering Cancer Center, suspicion or inability to exclude malignancy was the indication in 36% of the patients subjected to surgery [51]. The surgical mortality in experienced centers is zero or nearly zero [51,54,78,79]. Nevertheless, even in specialized centers the frequency of postoperative complications may be as high as 25% [51]. Enucleation is the preferred approach by many groups because it allows the resection of large hemangiomas with less blood loss and preservation of more hepatic parenchyma compared with resection. Enucleation is performed using the interface between the hemangioma and the surrounding normal liver tissue [51,76,80]. Laparoscopy is currently used as the procedure of choice in many centers when the diagnosis is well established.

Although surgical resection remains the main definitive treatment for symptomatic hemangioma, other less effective options are occasionally used. Transarterial embolization has been used for symptomatic lesions [48,49], acute bleeding [81], and consumption coagulopathy [82]. However, there are few data on its long-term efficacy, and the procedure may have to be repeated or may lead to liver abscesses [83]. Transarterial embolization was used preoperatively to decrease blood supply to the hemangioma and improve the safety of the surgery [82]. Hepatic artery ligation [51], radiation therapy [46,84], radiofrequency ablation [85], and liver transplantation [86,87] have been used on rare occasions for unresectable giant hemangiomas. Recurrence has been described after surgical, intra-arterial, and radiation therapy [47,83].

Infantile hemangioendothelioma

Infantile hemangioendothelioma is a tumor derived from vascular endothelial cells, which is the most common benign hepatic tumor in children. It accounts for approximately 12% of all childhood hepatic tumors and for more than 50% of benign tumors of the liver diagnosed in infancy and childhood [88]. It can be solitary (55% of patients) or multiple (45% of patients) and may vary in size from a few millimeters to more than 20 cm. More than 90% are diagnosed before the age of 6 years. The typical presentation is of hepatomegaly, hemangiomas of the skin, and heart failure resulting from massive arteriovenous shunting [89]. In addition to heart failure, this tumor may cause consumption coagulopathy (Kasabach–Merritt syndrome) and obstructive jaundice [90].

Although well circumscribed, this tumor is not encapsulated and often has scattered calcifications. Microscopically, this tumor consists of multiple small vessels lined by plump endothelial cells and surrounded by fibrous stroma. Two types of infantile hemangioendotheliomas exist. The more common, type I, has a prominent endothelium closely related to the portal tract and tends to displace, rather than infiltrate, the liver parenchyma. It consists of small vascular channels lined by flattened or rounded endothelial cells with rare mitotic figures. Extramedullary hematopoiesis may occasionally be seen. Type II lesions are composed of tortuous vascular channels, with endothelial cells proliferating into the adjacent hepatic tissue. They exhibit larger, irregular channels lined by pleomorphic endothelial cells. Differentiation of type II hemangioendothelioma and rare malignant angiosarcoma may be difficult. In many cases, infantile hemangioendothelioma is associated with extrahepatic hemangiomas that may be found in the skin, lung, lymph nodes, pancreas, retroperitoneum, and bone. The most frequently involved site is the skin, where single

or multiple lesions may be present. Other associated abnormalities include atrial septal defect, patent ductus arteriosus, myelomeningocele, renal agenesis, and absent common bile duct [90]. Rarely, infantile hemangioendothelioma may undergo transformation to angiosarcoma [91].

The diagnosis is suggested when an infant presents with an enlarged liver, congestive heart failure, and cutaneous hemangiomas.

Ultrasonography usually shows hepatomegaly and solitary or multiple hepatic lesions, which may vary from anechoic to hyperechoic. The unenhanced CT scan demonstrates the lesion as a well-defined hypoattenuating mass, occasionally with calcifications. After contrast injection, the lesion may show enhancement resembling hemangioma and may become isodense on delayed images. Angiography shows dilated, irregular vascular lakes that commonly persist beyond the venous phase. ^{99m}Tc-sulfur colloid scintigraphy shows the lesion as a cold spot because of a lack of Kupffer cells within the tumor.

The prognosis of this lesion is dependent on its size and its effect on the heart function. Spontaneous regression is frequent but death may occur within the first 6 months of life because of cardiac failure or replacement of the normal hepatic parenchyma [92]. The prognosis is usually good if heart failure is managed successfully.

Treatment is dictated by tumor-related symptoms produced by tumor size. Management of congestive heart failure may be sufficient in some cases. If symptoms are not relieved, treatment should be aimed at decreasing the tumor size. Several studies have confirmed the success of steroid therapy [93]. However, failure of some tumors to respond to steroids has led to the use of other drugs such as cyclophosphamide [94] and interferon α2a [95]. Other treatments include hepatic artery ligation, transcatheter endovascular embolization, and radiation therapy [96–98]. Liver transplant is increasingly recognized as a viable treatment modality for infantile hemangioendothelioma when other treatments fail [99].

Epithelioid hemangioendothelioma

This tumor of low-grade malignant potential also has a vascular origin and occurs more frequently in adults. It may spread extensively within the liver and may metastasize beyond the liver.

Mesenchymal hamartoma

Mesenchymal hamartoma is a rare, slow-growing tumor of childhood that comprises approximately 5% of pediatric liver tumors. It has a male predominance and is diagnosed in most cases before the age of 3 years [100, 101], although it has been reported in adults [102]. The tumor is usually a solitary, large (average size of 16 cm), well-demarcated mass with a predilection for the right hepatic lobe. The cut surface shows multiple cysts separated by solid, pink-tan areas. The solid portions have a mixture of hepatic cells and mesenchymal cells with vascular proliferation and bile duct-like structures. The cystic spaces are filled with fluid or solid gelatinous material. The islands of hepatocytes within the mesenchymal stroma may show reactive and regenerative changes. Most patients present with abdominal enlargement or an abdominal mass. Few have pain or respiratory distress. Ultrasonography and CT demonstrate a large tumor, with central cystic changes showing internal septations [100]. Angiography reveals a hypovascular or avascular lesion. It is important to differentiate this tumor from embryonal sarcoma because both may demonstrate loose edematous myxoid stroma. In most cases of embryonal sarcoma, the cellularity of the tumor is readily evident, and the neoplastic cells show distinctive cytologic features of highly malignant cells. Resection is recommended when the tumor is large and compresses adjacent abdominal organs. It is curative in most cases. Simultaneous involvement of the liver by mesenchymal hamartoma and infantile hemangioendothelioma requiring liver transplantation has been reported [103].

Benign lipomatous tumors and tumor-like lesions

Focal fatty change

Focal fatty change is a localized area of steatosis that can sometimes be misinterpreted on imaging studies as a neoplastic growth. It is usually an ill-defined area that may be single or multiple. Multiple areas of fatty change may mimic metastatic disease on imaging studies. Focal fatty change is associated with alcoholism, obesity, malnutrition, total parenteral nutrition, corticosteroid treatment, cytotoxic chemotherapy, acquired immunodeficiency syndrome (AIDS), hypertriglyceridemia, and diabetes mellitus. Hepatic biochemical tests may be normal or mildly abnormal.

Ultrasonography shows a hyperechoic area with ill-defined borders. On CT scan, focal fatty change appears as a hypodense area, which is usually sharply demarcated without mass effect on the hepatic or portal veins [104]. The demonstration of normal-caliber vessels coursing through the hypodense lesion on CT scan is characteristic [105] and can help in distinguishing this lesion from primary or metastatic malignancy. MRI shows increased intensity on T1-weighted images. This finding is characteristic for focal fatty change, appearing in 100% of cases compared with less than 4% of other benign tumors. The differential diagnosis of a hyperintense focal hepatic lesion on T1-weighted images includes hemorrhage,

malignant melanoma, and iron or copper overload [106]. Fat-suppressed T1-weighted images may be helpful in identifying fatty infiltration because the hyperdense area typically becomes hypodense in a fat-containing lesion [106]. ^{99m}Tc-sulfur colloid scintigraphy shows no focal lesion; however, areas of steatosis show retention of ^{133}Xe [107]. Biopsy is diagnostic but not always required. Microscopically, the lesion shows macrovesicular fatty change within the lesion, which is indistinguishable from other forms of steatosis.

The treatment of focal fatty change is directed against the underlying disease. Resolution has been described after weight loss and abstinence from alcohol [108]. Occasionally, the focal absence of fat in a liver that is otherwise fatty may also give the appearance of a tumorous lesion.

Angiomyolipoma

Angiomyolipoma is a rare, benign, lipomatous tumor resembling the more common renal angiomyolipoma. It is usually solitary, ranging in size from 0.3 to more than 20 cm. It is typically asymptomatic and is detected as an incidental finding between the second and eighth decades, predominantly in women [109,110]. It is composed of variable proportions of adipose tissue and smooth muscle with thick-walled blood vessels. Tumors with extensive extramedullary hematopoiesis have been termed myelolipoma or angiomyelolipoma [111].

Angiomyelolipoma is a homogenous well-circumscribed tumor that is highly echogenic on ultrasonography. On enhanced CT scan, the density measurements are characteristic of fat (–2 to –115 Hounsfield units) [112]; MRI is also diagnostic. The prognosis is usually excellent. Budd–Chiari syndrome related to compression of the hepatic veins by angiomyelolipoma has been described [113]. Malignant transformation has not been reported. For symptomatic lesions or lesions in which the diagnosis cannot be confirmed, resection is the treatment of choice [109].

Pseudolipoma

Pseudolipoma is a small encapsulated lesion located on the capsular surface of the liver or immediately under the capsule. It consists of mature lipocytes and is presumed to originate from adherent epiploic appendices that became detached. Fat necrosis and calcifications may occur. The importance of this rare and asymptomatic lesion lies in its differential diagnosis from primary or metastatic tumors. There are no clear predisposing factors [114].

Inflammatory pseudotumor

Inflammatory pseudotumor of the liver is a rare benign condition presenting as a localized parenchymal mass. It is considered by some to be secondary to an infectious process [115], although the exact pathogenesis remains unclear, and few microscopic studies of hepatic tissue have disclosed pathogenic microorganisms. An association with extrahepatic infectious conditions and with Crohn disease [116,117] has been reported in a few patients. The lesion may be solitary or multiple and its size ranges from 1 to 25 cm. It is usually well circumscribed and may be encapsulated. It affects patients at any age and has a predilection for men with a male : female ratio of 3 : 1 to 8 : 1.

Patients usually present with fever, abdominal pain, and malaise. Jaundice and weight loss may occur. Elevated sedimentation rate, leukocytosis, and mildly abnormal hepatic biochemical tests are common. Ultrasonography reveals a heterogeneous lesion that may show a mosaic pattern. CT scan shows an irregular, clearly demarcated heterogeneous mass that is typically hypodense compared with surrounding liver parenchyma.

The differential diagnosis includes pyogenic hepatic abscess, as well as malignant and metastatic tumors. Needle liver biopsy is usually needed to establish the diagnosis. Histologically, the mass is composed of fibrous tissue and myofibroblasts and infiltrated by dense mixed inflammatory infiltrate with numerous plasma cells. Vascular invasion can sometimes be seen, and phlebitis may be present.

The prognosis of hepatic inflammatory pseudotumor is usually favorable. The lesion may regress and disappear spontaneously within a few weeks to months [118–120]. In a few cases antibiotic treatment was used and was followed by complete resolution. Response to steroids has also been reported. In some cases the lesion was treated successfully by local resection [120], but surgical removal is unnecessary in most patients. When the diagnosis is unequivocal, observation is the treatment of choice [118–120].

Other tumors of the liver

A variety of other very rare tumors of mesenchymal or mixed origin may occur in the liver, including fibroma, lymphangioma, benign mesenchymoma, and tertatoma.

Nodular diseases of the liver

In addition to the benign tumorous lesions of the liver described above, a series of nodular conditions may also affect the liver and need to be distinguished from neoplasms, benign or malignant. The classification and terminology of nodular diseases of the liver is somewhat confusing because different terms have been applied to the same type of lesion. In an attempt to standardize the terminology, the International Working Party proposed a new nomenclature, which has been widely adopted by pathologists [121]. However, this terminology does

not always lend itself to everyday clinical use, and the following discussion represents an attempt to combine this new standard terminology with the clinical features of hepatic nodules. A key factor to considering in discussing nodular conditions of the liver is whether or not they are associated with cirrhosis.

Hepatocellular nodular lesions with cirrhosis

The definition of cirrhosis has three components based on gross or microscopic pathologic findings: (i) nodules of regenerating hepatocytes; (ii) bands of fibrosis that surround these nodules; and (iiic) the process by which this occurs, which is diffuse throughout the liver. Many of the other forms of nodules described later are differentiated from cirrhosis by not meeting one of these three criteria. Cirrhosis is usually classified on the basis of morphologic findings as being *micronodular*, *macronodular*, or *mixed*. These terms refer to the size of the nodules of regenerating hepatocytes that are present. Therefore, in micronodular cirrhosis, the nodules are usually 2–3 mm in diameter. This pattern is characteristic of the cirrhosis caused by alcohol and hemochromatosis, whereas most other causes of cirrhosis result in macronodular or mixed macronodular and micronodular cirrhosis, in which the nodules typically range between 3 and 10 mm in diameter.

Dysplastic nodules

Among cirrhotic nodules, some stand out as being unusual on gross or microscopic examination. Therefore, dysplastic nodules are defined as a nodular region of hepatocytes at least 1 mm in diameter with dysplasia but without definite criteria of malignancy. For nodules larger than 10 mm, the term *macroregenerative nodule* (MRN) has been applied. Although the International Working Party abandoned it, this term may still have some value because clinicians and radiologists often encounter large regenerative nodules that seem to have a propensity to become malignant. Synonyms for this lesion include large regenerative nodule and adenomatous hyperplasia.

In two series of cases, investigators examined the incidence of MRNs in liver explants. Ferrell et al. [122] examined 110 sequentially explanted cirrhotic livers and found that 19 of them (17.3%) had nodules between 0.8 and 3.5 cm in diameter (Fig. 35.5). Ten livers had more than one nodule, and a total of 40 nodules were detected. Twelve of the nodules were HCC and 28 were MRNs. Theise et al. [123] examined 44 explanted livers and identified 48 MRNs larger than 1 cm in diameter in 11 livers. Both these studies showed a close association between MRNs and HCC in the same liver (Fig. 35.5).

There is debate about the origin of dysplastic nodules. It was thought that they are simply "overgrown" cirrhotic nodules. The observation that nearly all dysplastic nodules contain intact portal triads implies that these lesions are not derived from regenerating nodules but rather that they may represent the growth of nodules of transformed hepatocytes [124].

Dysplastic nodules rarely result in any clinical symptoms. Patients may have clinical features associated with cirrhosis, or the nodules may be detected radiographically if they are large enough, usually as an incidental finding. Nodules larger than 1 cm in diameter can be detected with either ultrasonographic examination or sensitive CT or MRI techniques. Unfortunately, large dysplastic nodules cannot be differentiated reliably from HCC by radiographic means; therefore, they present a challenge to the clinician caring for the patient. Biopsy of such nodules can be performed with CT or ultrasonographic guidance to rule out HCC, but if cancer is not present in the specimen, the possibility that the correct portion of the lesion has not been sampled cannot be excluded. Table 35.2 shows the high rate of development of malignant growth within large dysplastic nodules, ranging between 24% and 45% over a period of several years [125–128].

It may be difficult to distinguish dysplastic nodules from well-differentiated HCC. Their radiographic features are similar and even their histologic features may overlap and be difficult to distinguish, particularly on small needle biopsy specimens (Table 35.3) [17].

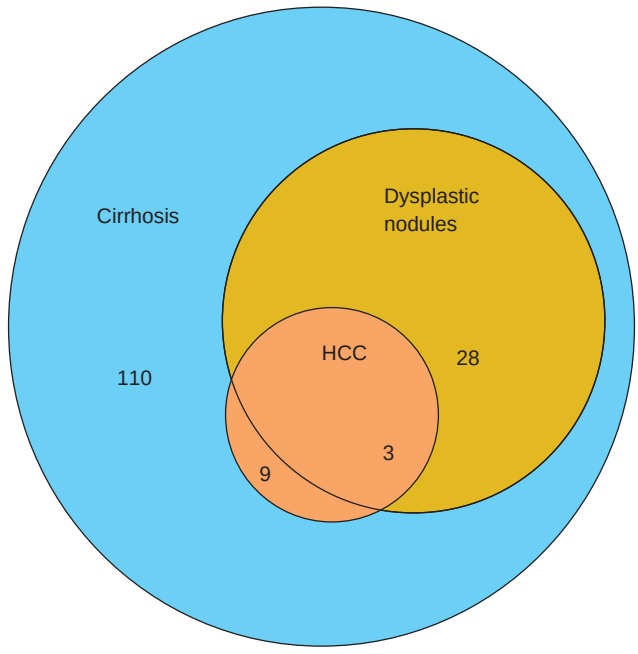

Figure 35.5 Dysplastic nodules and hepatocellular carcinoma (HCC) found in cirrhotic livers at the time of transplantation. (Data from Ferrell et al. [122].)

Table 35.2 Outcome of radiographically identified dysplastic nodules.

Number of nodules	Outcome of nodules			Reference
	Disappeared, *n* (%)	Hepatocellular carcinoma, *n* (%)	Unchanged, *n* (%)

Macroregenerative nodules

There is ongoing discussion about the characterization and classification of hepatocellular nodules found in the cirrhotic liver. An improvement of imaging techniques has led to the frequent detection of focal lesions in cirrhotic livers, many of which are benign nodules with various degrees of atypia. They may occur in cirrhotic livers of any cause. Several groups have suggested nomenclatures and diagnostic criteria to describe these lesions; however, none of these is used consistently [129]. Terms such as regenerative nodules, MRNs, adenomatous hyperplastic nodules, dysplastic nodules, atypical adenomatous hyperplastic nodules, and borderline nodules [129–132] have been suggested by different authors to describe what is believed to be different stages of the same lesion.

An MRN is typically larger than 1.0 cm. MRNs may be seen in less than 2% of cases of acute massive necrosis and in 14–21% of patients with cirrhosis [133]. The expanding nodule typically compresses the surrounding liver tissue. It may be solitary but many livers contain multiple MRNs. It is separated from the rest of the liver parenchyma by fibrous connective tissue. Needle biopsy specimens from these lesions are commonly classified as benign, but in some cases they may demonstrate varying degrees of atypia and occasionally foci of overt HCC. The characteristic histologic findings of MRN include normal thin plates of hepatocytes (two cells thick) and a lack of cytologic atypia (normal nuclear : cytoplasmic ratio). The nodule may include multiple portal areas. Larger hepatocytes may be seen and are considered an acceptable finding as long as the normal nuclear : cytoplasmic ratio is maintained.

MRNs have been classified according to the degree of atypia into type I and type II [134]. Type I MRN shows no cell atypia and is probably an ordinary adenomatous hyperplasia, whereas type II MRN represents atypical adenomatous hyperplasia, which is probably a true precursor of HCC [134]. The clonality of MRNs suggests that at least some of them are neoplastic and probably premalignant [132]. The incidence of progression to malignancy is still unclear; however, some authors recommend

Table 35.3 Differential diagnosis of well-differentiated hepatocellular carcinoma (HCC) from benign hepatocellular nodules.

	HCC	Adenoma	Dyspastic nodule
Cirrhosis in surrounding liver	80%	0%	100%
Portal areas	Absent	Absent	Present
Growth patterns	Trabecular	Sheet-like	Two-cell thick plates
	Pseduoglandular	Nodule-in-nodule	Compact
N : C ratio	High	Low	Low
Nuclear pleomorhism	Present/absent	Absent	Absent
Nucleoli	Frequent	Absent	Absent
Mitoses	Occasional	Absent	Absent
Vascular invasion	Frequent	Absent	Absent

treating atypical (type II) MRN in a patient with cirrhosis as a malignant lesion [135]. In a study of 307 patients with cirrhosis, multivariate analysis showed dysplasia to be the most important independent risk factor for the development of HCC [136].

Imaging studies may be suggestive of MRN, although they may not be sufficient to establish the diagnosis or distinguish MRN from HCC. On T1-weighted MRI, MRNs are typically isointense to slightly hyperintense compared with the surrounding hepatic parenchyma. On T2-weighted images the lesions are hypointense. In contrast, HCC has variable diminished signal intensity on T1, becomes hyperintense on T2, and enhances during the arterial phase of gadolinium injection. HCC also has a characteristic capsule of low signal intensity [68], which is typically absent in MRNs. Magnetic resonance angiography usually shows sparse arterial supply in MRN. Uniform arterial opacification is seen without neovascularity. The transition of MRN to dysplastic nodule and subsequently to HCC is associated with vascular proliferation within the nodule and preferential blood supply from branches of the hepatic artery [68,137].

Hepatocellular nodular lesions without cirrhosis

Nodular regenerative hyperplasia

Nodular regenerative hyperplasia is defined by hepatocellular nodules distributed throughout the liver in the absence of fibrous septae between the nodules. Most reports have been of single cases or small series of cases. A recent autopsy study showed that NRH was present in 2.6% of 2,500 consecutive autopsies. NRH has been reported to occur in children and even in fetal liver. Familial occurrence has been documented. NRH has been described in association with a variety of hepatic and systemic diseases (Box 35.2) but appears to be a nonspecific tissue adaptation to heterogeneous distribution of blood flow rather than a distinct disease entity. What many of these conditions appear to have in common is the disturbance of blood flow to the liver, which can involve the portal vein (through thrombosis), the hepatic artery (with arteritis), and the hepatic outflow tract (as in the Budd–Chiari syndrome and congestive heart failure). Even some of the drugs associated with NRH probably act through their effect on blood vessels. For example, azathioprine may cause signs and symptoms that resemble those of venoocclusive disease, and the use of this agent is causally linked with NRH. It seems that insufficient blood supply to portions of the liver, caused by conditions such as portal-venous thrombosis, leads to atrophy of the parenchyma, with compensatory hyperplasia occurring in areas with adequate blood supply.

Box 35.2 Conditions associated with nodular regenerative hyperplasia.

- Vascular diseases:
  - Budd–Chiari syndrome
  - Portal-venous thrombosis
- Drugs and toxins:
  - Azathioprine
  - Thorotrast
  - Toxic oil syndrome
  - Thioguanine
- Collagen vascular disease:
  - Systemic lupus erythematosus
  - Scleroderma
  - Mixed connective tissue disease
  - Rheumatoid arthritis
  - Felty syndrome
- Polymyalgia rheumatica
- Antiphospholipid antibody syndrome
- Other liver diseases:
  - Primary biliary cirrhosis
  - After liver transplantation
  - Metastases from pancreatic cancer
  - Hepatocellular carcinoma
- Neoplastic conditions:
  - Myeloproliferative disorders
  - After bone marrow transplantation
  - Non-Hodgkin lymphoma
  - Castleman disease
- Immunodeficiency syndromes:
  - HIV infection
  - Common variable immunodeficiency
- Miscellaneous:
  - Primary pulmonary hypertension
  - Glomerulonephritis
  - Behçet disease
  - Schnitzler syndrome
  - Diabetes mellitus
  - Congestive heart failure
- Idiopathic:
  - Sporadic
  - Familial

HIV, human immunodeficiency virus.

At gross examination of the liver, there is diffuse fine nodularity of the liver approximately 1–2 mm in diameter. Microscopic examination shows that the normal architecture has been replaced with monoacinar regenerative nodules, which often contain portal tracts [138]. The nodules are surrounded by compressed liver cell plates rather than fibrosis, and dilated sinusoids may be seen adjacent to nodules (Fig. 35.6). Although the nodularity may be visible with hematoxylin and eosin stain, it is best seen with a reticulin stain, which shows thick cell plates

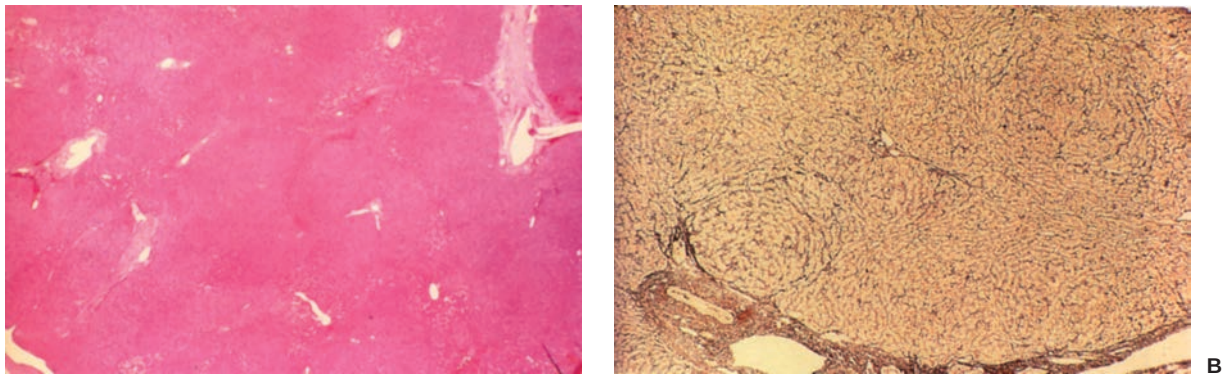

Figure 35.6 (A) Photomicrograph of the liver shows nodules of nodular regenerative hyperplasia without surrounding fibrosis. Hematoxylin and eosin (H&E). (B) Nodular regenerative hyperplasia. Reticulin stain. (Courtesy of Dr Elizabeth M. Brunt.)

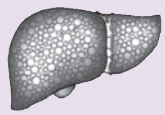
within the nodule and compressed plates surrounding the nodule.

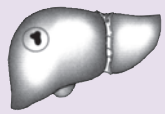
The clinical features of NRH are variable, and many patients have no symptoms. Patients range widely in age, although NRH is rare among children. Patients often have a history of another medical illness, which was presumably a predisposing factor for NRH. The main clinical consequence of NRH is portal hypertension, which manifests as splenomegaly and gastroesophageal varices. Ascites is uncommon because in most patients the hepatic synthetic function is preserved and, therefore, serum albumin levels are normal. Serum aminotransferase levels are characteristically normal, as are bilirubin values, although alkaline phosphatase levels are usually moderately elevated [139]. Therapy is directed at removing the causative agent if possible and controlling portal hypertension. Patients with NRH who experience bleeding from varices usually tolerate this well because hepatic synthetic function is preserved. Surgical shunting or transjugular intrahepatic portosystemic shunt (TIPS) is rarely indicated, and the varices can often be controlled with injection, sclerotherapy, or endoscopic banding. Patients with NRH have mistakenly undergone liver transplantation because they were thought to have cirrhosis, and they have done well.

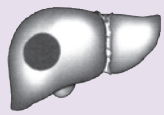
Unusual forms of nodular regenerative hyperplasia

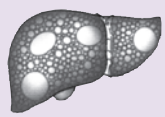
Felty syndrome is a rare complication of rheumatoid arthritis consisting of leukopenia and splenomegaly [140]. Leukopenia may be associated with sn increased risk of bacterial infection. The splenomegaly is thought to be caused by portal hypertension. Most biopsy specimens of the liver from patients with Felty syndrome show NRH, although a small proportion show only portal fibrosis or sinusoidal lymphocytosis. Felty syndrome carries an increased risk of non-Hodgkin lymphoma [141].

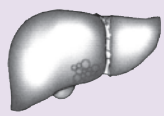
Partial nodular transformation











Partial nodular transformation (PNT) of the liver is a rare entity characterized by the formation of large hepatocellular nodules without marked fibrosis, particularly at the hepatic hilum or around large portal areas. It does not meet the criteria of cirrhosis because the condition is not diffuse and the nodules are not surrounded by fibrosis. It is similar to NRH, except that the nodules of NRH are diffuse throughout the liver and are usually much smaller (Table 35.4). PNT usually occurs as an isolated condition but has been reported in association with vascular abnormalities such as persistent ductus venosus, portal-venous thrombosis, and portal-venous emboli of HCC [142–144]. The pathogenesis is uncertain, but it has been suggested that PNT may represent a variant of NRH in which localized obstruction of blood flow causes the formation of localized hepatic nodules [141]. Because these nodules occur predominantly in or near the hepatic hilum, PNT often leads to presinusoidal portal hypertension.

PNT has been found in both adults and children. Patients usually have features of portal hypertension, such as bleeding from gastroesophageal varices and ascites. If the nodules are large enough, hepatomegaly resulting from portal hypertension may be present with splenomegaly. Serum aminotransferase activity is typically within the normal range. The diagnosis of PNT is often made only at autopsy or surgery, but it can be made with needle biopsy of the liver. No characteristic radiographic features of PNT have been described. Because PNT is such a rare condition, there are no specific treatment guidelines other than a recommendation for symptomatic management.

Focal nodular hyperplasia

Focal nodular hyperplasia is a benign, tumor-like lesion of the liver considered to be hyperplastic in origin rather than neoplastic. The exact frequency is not known, but

Table 35.4 Nodular diseases of the liver.

	Lesion	Size	Single/multiple	Common underlying causes	Comment
Nodular regenerative hyperplasia		Usually <1 cm	Multiple	Immunologic disorders (e.g., rheumatoid arthritis) Myeloproliferative disorders	Pathogenesis related to portal venopathy and decreased blood flow; usually presents with portal hypertension
Focal nodular hyperplasia		Usually <5 cm	Single	None recognized	Often an incidental finding
Hepatocellular adenoma		May be very large	Usually single; occasionally multiple	Estrogen use	Requires resection because of risk of rupture or hemorrhage
Hepatocellular carcinoma		May be very large	Often multiple	Cirrhosis Chronic viral hepatitis	Probably arises from within dysplastic nodules
Partial nodular transformation		1–5 cm	Multiple but localized to perihilar area	None recognized	Rare entity; presents with portal hypertension

large series of cases have been reported. FNH occurs predominantly in women but has also been found in men and children. It rarely causes clinical complications, but its importance lies mainly in being differentiated from hepatocellular adenoma and HCC. FNH classically occurs in noncirrhotic liver, but a recent report suggests that similar lesions may be seen in cirrhosis as well [145]. In most cases, it is an incidental finding on abdominal imaging or surgery performed for unrelated reasons.

Pathogenesis

Focal nodular hyperplasia is considered to be hyperplastic rather than neoplastic in origin, although its exact pathogenesis remains a matter of controversy. It typically occurs in the background of a healthy liver. It is believed by many to be a hyperplastic response to a preexisting vascular anomaly in the location of the lesion. According to this theory, the initial injury may be arterial malformation, which leads to increased arterial blood flow to a specific region compared to the adjacent parenchyma, which in turn leads to high sinusoidal pressure, resulting in hepatocellular hyperperfusion. This may be followed by local angiogenesis, leading to hyperplasia and causing the typical arterial branching in the center of the FNH [146].

FNH typically occurs in isolation but may be associated with other liver diseases such as Budd–Chiari syndrome, pulmonary hypertension, primary sclerosing cholangitis, hemochromatosis, echinococcal cyst, and agenesis of the portal vein. Because of the female preponderance of this condition (female : male ratio approximately 8 : 1), a link with oral contraceptive use has been postulated. However, Mathieu et al. [147], in a study in which the subjects were 216 women with FNH, examined tumors in patients taking oral contraceptives and those not taking these agents. The investigators found that neither the size nor the number of FNH lesions was influenced by oral contraceptive use. A more recent study identified an odds ratio of 2.8 for using oral contraceptives at any point of time among patients with FNH compared with controls [148]. FNH may be associated with other vascular conditions affecting the liver, such as hemangioma and hereditary hemorrhagic telangiectasia [149,150].

A recent report of FNH diagnosed in the same hepatic segment in identical twins supports the theory of a congenital anomaly being an initial event in the pathogenesis of this lesion, at least in some patients [151]. Most FNHs are supplied by a single artery, which is typically enlarged. In contrast to the usual situation, this artery is

not accompanied by a portal vein or a bile duct. Although some reports suggested that FNH may be a clonal lesion on the basis of a uniform pattern of X-chromosome inactivation, others have shown it to be of a clear polyclonal nature [152,153].

Pathology

The typical macroscopic appearance is of a firm, nodular mass with a dense central stellate scar and radiating fibrous septa that divide the lesion into lobules of various size (Fig. 35.7A–C) [154,155]. The lesion is sharply demarcated from the surrounding liver tissue but has no true capsule. The central scar is clearly seen macroscopically in approximately 50% of the cases [154]; however, in some of the cases it is absent and the fibrous septa may be poorly developed. The lesion is light brown or yellowish gray and usually occupies a superficial position. The average size is 5 cm and the lesion uncommonly exceeds 10 cm in diameter. Occasionally, it is exophytic or pedunculated. Larger lesions may have foci of hemorrhage or necrosis. FNH is solitary in most cases and is located in the right lobe more often than in the left [154]. Two or more lesions are encountered in approximately 20% of patients and a distinct minority may have more than five lesions [154–157]. The size may range from 1 mm to more than 20 cm but most (64%) are smaller than 5 cm in diameter [154].

In a study of 168 patients with FNH, investigators examined the gross and microscopic pathologic features of this condition [155]. In 76% of patients, the mass was solitary and more often located in the right lobe than in the left. In 21% of patients, between two and five nodules were found, whereas in the other 3% of cases between 15 and 30 nodules were detected. The lesions ranged in size from 1 mm to 19 cm in diameter. In total, 64% of masses were smaller than 5 cm in diameter. A central scar was visible on gross examination of 138 of 305 lesions (45%), and a large vascular pedicle was found in the periphery of 22 lesions (7%) (Fig. 35.7). Microscopic examination showed that all the lesions consisted of nodular hyperplastic parenchyma, partially or completely surrounded by fibrous septae. Additional changes such as periodic acid–Schiff-positive globules and Mallory hyaline were sometimes found in hepatocytes within the lesion. A central scar was found on light microscopic examination of 153 lesions, and the lesions always contained malformed blood vessels of varying caliber. Histologic cholestasis was found in 36 cases, and some patients had hepatocellular steatosis. Portal tracts and terminal hepatic venules were not present.

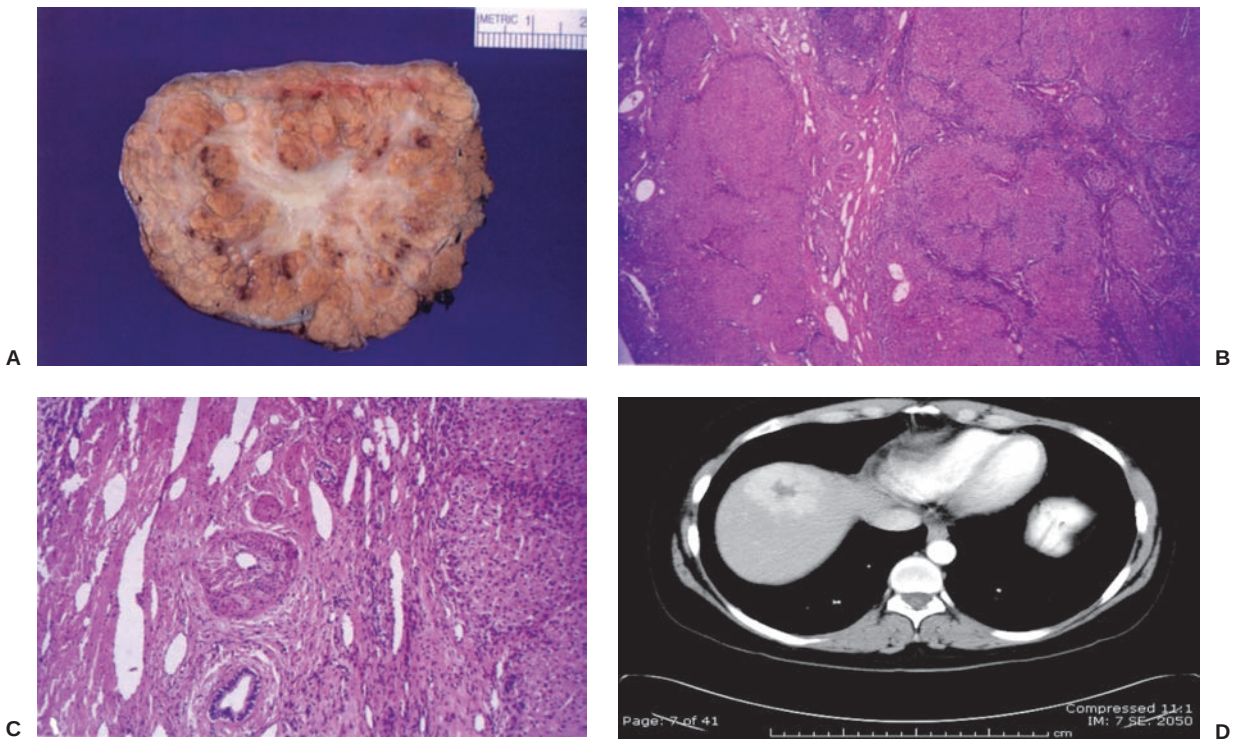

Figure 35.7 (A) Macroscopic appearance of resected focal nodular hyperplasia. The typical central scar is evident. (B) Photomicrograph of focal nodular hyperplasia shows regenerating nodules of hepatocytes surrounding a central core that contains abnormal blood vessels and a bile duct. (C) Focal nodular hyperplasia with an abnormal, thick-walled artery adjacent to the center of the lesion. (D) Dynamic computed tomography scan of the liver showing focal nodular hyperplasia. Note hypervascular area in right lobe of the liver with a darker, central stellate scar. (A–C, Courtesy of Dr Elizabeth M. Brunt.)

Clinical manifestations and natural history

In most cases FNH is asymptomatic and detected incidentally on imaging studies performed for unrelated reasons or during surgery. Hepatic biochemical tests are typically normal and the serum level of α-fetoprotein is not elevated. Abdominal discomfort may be the presenting symptom in a minority of patients [158]. Abdominal pain is rare and should prompt an evaluation for other causes. Some patients may present with hepatomegaly, abdominal mass, or abdominal tenderness but most (approximately 85%) will have normal findings in the physical examination [159]. Sudden abdominal pain may be related to rupture or bleeding that is distinctly rare [160]. Fibrolamellar HCC may be mistaken for FNH [161] or may occur in the same liver [162]. However, malignant transformation has not been unequivocally described in FNH, and there is no evidence that FNH it is a precursor of HCC or fibrolamellar carcinoma.

The prognosis of patients with FNH is almost invariably excellent. Most patients remain asymptomatic and exhibit no significant changes in lesion size over time [163]. Occasionally, FNH may regress [90,164] and only a small minority (<10%) may show some increase in size [76]. Any significant increase in size should therefore prompt an evaluation for another diagnosis such as HCC or fibrolamellar carcinoma.

Diagnosis

Because these lesions are usually clinically silent, radiographic imaging is a key tool in the evaluation of hepatic lesions and the diagnosis of FNH is often made by certain characteristic radiographic features. In most imaging studies, the typical appearance of FNH is related to the characteristic central scar, the hypervascularity, and the distinctive arterial blood supply, which begins in the center of the lesion with peripheral ramification in a spoke wheel pattern [165]. Other lesions in the differential diagnosis that may have similar radiographic features include hepatocellular adenoma and fibrolamellar carcinoma, although FNH is by far the most frequent of these conditons.

- *Standard ultrasonography* is highly sensitive but nonspecific for the diagnosis of FNH. It usually demonstrates the lesion as a well-demarcated nodular mass but is frequently nondiagnostic [163,166]. Ultrasonography detects the central scar in approximately 20% of cases [165,167,168], although the addition of Doppler imaging may reveal arterial signals within the lesion in other cases [169].
- *Contrast-enhanced harmonic sonography* has recently been demonstrated to show the typical spoke wheel pattern of the central arteries during the vascular phase in more than 90% of individuals with FNH [170]. In addition, it produces a typical pronounced enhancement during the hepatic arterial phase and the early portal-venous phase that may help differentiate it from hepatic adenoma [171]. This technique, which is based on the injection of a microbubble contrast agent, has been used for various focal liver lesions and may be a promising modality for the diagnosis of FNH.
- *CT scan* should always be used in the multiphase contrast-enhanced mode for the evaluation of a possible FNH. The enhancement pattern may be helpful in suggesting the diagnosis or ruling it out [172]. On precontrast images, FNH can be hypodense or isodense to the surrounding normal liver parenchyma. It is typically hyperdense on arterial phase images (20–30 seconds after contrast injection), becoming less prominent on portal-venous phase images (70–90 seconds), and may become completely isodense [168,173]. A central scar is seen in 43–60% of cases on imaging [174]. It is typically hypodense on the precontrast and arterial phase, becoming hyperdense on the portal-venous phase [173, 175]. Occasionally, FNH may show imaging characteristics suggestive of a primary or metastatic malignancy. These may include the absence of a central scar, rapid washout, calcifications, or the presence of a capsule. The use of three-dimensional volume-rendered CT angiography (CTA) may demonstrate the characteristic anomalous feeding artery and may be helpful in distinguishing FNH from other lesions [176]. Calcifications have been reported in 1.4% of 295 patients with FNH [161]. This finding raises the suspicion of fibrolamellar carcinoma and usually mandates a surgical exploration to rule out this diagnosis.
- *MRI* usually shows FNH as a homogenous lesion that is isointense to mildly hypointense on T1-weighted images and isointense to slightly hyperintense on T2-weighted images. The margins are usually not well defined and the central scar may be identified by T2-weighted images in approximately 50% of cases [159, 173,177,178]. On gadolinium-enhanced imaging, the lesion shows an early homogenous enhancement in the arterial phase and becomes isointense or slightly hyperintense compared to the surrounding liver in the venous and delayed phases. The central scar shows slowly progressive enhancement, which becomes maximal on delayed images. This characteristic appearance may differentiate FNH from malignant vascular tumors [179] and has a sensitivity of 70–80% and specificity of 98% in lesions that are larger than 2 cm in size. Another distinguishing feature on gadolinium-enhanced images is the lack of capsule enhancement that is commonly seen in adenomas and HCCs. Small FNH (<1 to 2 cm) may appear more uniform in enhancement and the central scar may not be perceived.

- *Three-dimensional gadolinium-enhanced MR angiography* may increase the accuracy of the test for the diagnosis of FNH by demonstrating the characteristic vessels radiating from the center to the periphery of the lesion (the so-called star sign) [180]. The use of liver-specific MRI contrast agents (i.e., reticuloendothelial and hepatobiliary agents) offers greater lesion-to-liver contrast than the conventional extracellular contrast agent, gadolinium chelate, which has a nonspecific distribution [68, 181]. These agents may be helpful in a small fraction of cases that remain ambiguous. The administration of superparamagnetic iron oxide (SPIO) particles, which undergo phagocytosis by Kupffer cells, may help distinguish benign from malignant lesions [182]. Recently, the use of the hepatocyte-selective contrast agent gadobenate-dimeglumine (Gd-BOPTA) has been shown to improve the differentiation between FNH and adenoma with a sensitivity of 80% and specificity of more than 96% [174,183,184].
- *^{99m}Tc-sulfur colloid scintigraphy* is currently used less commonly by most centers for the diagnosis of FNH. FNH takes up ^{99m}Tc-sulfur colloid at the same or greater rate compared with the surrounding liver parenchyma in 50–70% of patients. Hyperconcentration of the colloid by the lesion is uncommon (approximately 7%) but is considered typical of FNH because of the highly active Kupffer cells within the lesion [164,185]. Nevertheless, the reliability of this modality is poor in lesions smaller than 3–4 cm in size. and this technology has largely been replaced by spiral CT and MRI. Positron emission tomography (PET) scans using ^{18}F-fluorodeoxyglucose (1^{8}F-FDG) has been shown to be helpful for the differentiation of FNH from liver metastases in patients with cancer [186].

Although the diagnosis of FNH can be made by the examination of a needle biopsy specimen of the liver, this approach is less than ideal because of sampling error. Needle biopsy samples only a small portion of the lesion. The specimen may contain only a group of hepatocytes that cannot be reliably differentiated from hepatocellular adenoma. Furthermore, the presence of fibrous septae within the lesion may give the appearance of cirrhosis (referred to as pseudocirrhosis). Therefore, if the results of radiographic studies are convincing and the patient has no symptoms, no further testing is needed. However, if there is uncertainty about the diagnosis, surgical resection or large surgical biopsy may be needed for accurate diagnosis of FNH. A recent study suggests that the application of a rigorous scoring system to liver biopsy specimens can aid in the accurate diagnosis of FNH [187].

Management

Focal nodular hyperplasia rarely results in clinically important consequences or complications. Specifically, the risk of bleeding or rupture is very low, as is the risk of the development of malignant changes. Few longitudinal studies have been done, but in one small series of 18 cases of FNH, the volume remained stable in six, decreased in ten, and increased in two [188]. Usually, no specific treatment is needed, but surgical resection is curative if the patient has symptoms. Resection is often performed in cases of diagnostic uncertainty.

When surgery is indicated, wedge resection and enucleation are generally the recommended approaches [76,189]. In many cases, they can be performed laparoscopically with excellent results because the lesions tend to be smaller and peripheral. In patients with a large FNH, a segmental resection or a formal lobectomy may be required. Angiographic embolization and hepatic artery ligation are alternative approaches for unresectable lesions [190].

Unusual forms of focal nodular hyperplasia

The International Working Party has designated multiple FNH syndrome as a distinct syndrome consisting of two or more FNH lesions in association with hemangioma of the liver, vascular malformations of the central nervous system, or tumors of meningeal or astrocytic origin [121]. Of course, FNH is multiple in approximately 30% of cases, but most of these do not have the other features associated with this syndrome.

Nguyen et al. [154] found that approximately 20% of cases of FNH are *nonclassic*. This term refers to lesions lacking some of the typical histologic features, such as malformed vessels, a central scar, or abnormal nodular architecture. Notwithstanding these histologic differences, these cases were clinically identical to those with classic features.

Another variant of FNH is the telangiectatic form, which differs from typical lesions by the absence of a central scar and lack of architectural nodular distortion. Instead, there is sinusoidal prominence with associated hepatic plate atrophy. Telangietactic FNH is more likely to be monoclonal in origin than is classic FNH and is more likely to be multiple and perhaps even more likely to result in hemorrhage than typical FNH, making it more like adenoma [191]. Recently, it has been suggested that telangiectatic FNH may be closer to hepatic adenoma and should be referred to as *telangiectatic hepatocellular adenoma* [17].

Clinical approach to a focal solid lesion of the liver

Focal solid hepatic lesions often represent a diagnostic challenge and frequently mandate an extensive evaluation and a multidisciplinary approach. Although there is a wide spectrum of conditions that needs to be considered when a focal lesion is detected in the liver, most

lesions fall into a relatively small group of entities. The clinician must decide at an early stage whether the lesion is malignant or benign, whether a biopsy is indicated, and whether surgical intervention is required. In dealing with a patient with an unknown solid hepatic lesion, it is critical to determine whether the patient has underlying liver disease, and in particular whether cirrhosis is present. This involves serologic testing for various causes of liver disease and may even need liver biopsy away from the area of concern. If cirrhosis is present, HCC or dysplastic nodules are very likely to be found, whereas if there is no significant liver disease, FNH or adenoma should be considered. Imaging techniques have improved dramatically over the last decade and often allow excellent characterization of nodular lesions.

A detailed history should be obtained and should include questions about the history of cancer and previous use of OCPs, androgens, and anabolic steroids. The specific approach may vary according to the type of presentation, demographics of the patient, and medical history. The diagnostic approach in a young, asymptomatic, previously healthy woman should focus on the differential diagnosis of hemangioma, FNH, and adenoma. A history of prolonged treatment with OCPs will point toward a diagnosis of hepatocellular adenoma. In contrast, when the patient has a history of cancer, a focal hepatic lesion will often be a metastasis. In the presence of cirrhosis or chronic hepatitis B virus (HBV) infection, a focal solid lesion should be regarded as HCC until proved otherwise. A history of primary sclerosing cholangitis should point toward intrahepatic cholangiocarcinoma.

Presenting symptoms such as abdominal pain, weight loss, and malaise should raise the suspicion of malignancy. It should be remembered that most patients with benign hepatic lesions are asymptomatic, and the relationship between the symptoms and the focal lesion should be corroborated. Physical findings such as ascites, firm nodular liver, or splenomegaly should suggest the presence of a chronic liver disease and should point toward HCC. Hepatic biochemical tests are typically normal in patients with benign hepatic lesions, and a significant abnormality should raise the suspicion of a neoplastic lesion, a complication such as hemorrhage (usually in an adenoma), or an underlying liver disease. Tumor marker levels are also normal and are unhelpful in making the distinction between benign tumors. Nevertheless, any abnormality in tumor marker should prompt an evaluation for malignancy.

Imaging studies are commonly helpful in distinguishing between focal hepatic lesions (Fig. 35.8), but the differential diagnosis may be challenging because many of the lesions have overlapping radiographic features [68,192].

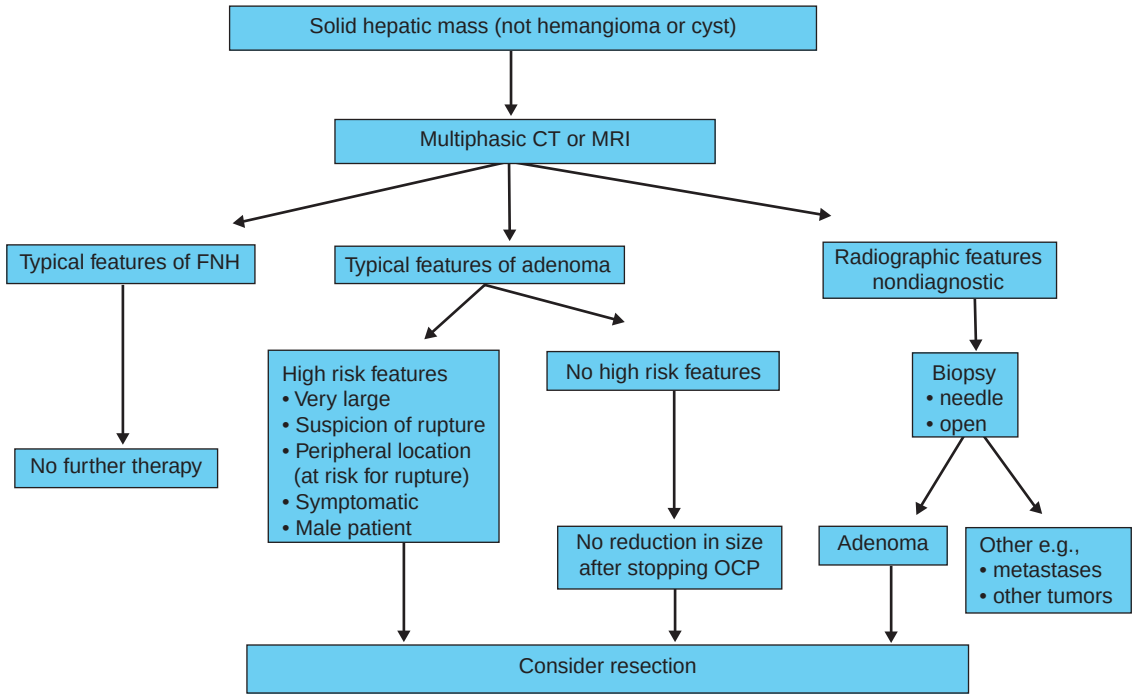

Figure 35.8 Algorithm for evaluation and management an incidental hepatic mass in patient without cirrhosis. Such masses may have been identified incidentally because of an imaging study being done for some other reason. Occassionally the mass itself may cause symptoms leading its discovery. Ultrasound examination may be used initially to assess for features of either hemangioma or cysts. CT, computed tomography; FNH, focal nodular hyperplasia; MRI, magnetic resonance imaging; OCP oral contraceptive pill.

Although ultrasonography is an excellent modality for the initial detection of lesions and for determining a solid versus cystic lesion, the sonographic appearance of a solid liver mass is often nonspecific and many patients will require additional hepatic imaging. CT is a reliable and easily reproducible method for the evaluation of focal hepatic lesions. It allows the characterization of lesions as small as 1.5 cm in size and may also help in the evaluation of the entire abdomen for signs of cirrhosis, portal hypertension, or malignancy [174]. Multiphasic CT scans using up-to-date equipment are capable of showing the vascularity of hepatic tumors and nodules in great detail. In a patient with cirrhosis or chronic HBV infection and a solid lesion, arterial enhancement on dynamic CT scan strongly supports the diagnosis of HCC [193]. When a hemangioma is suspected, triphasic dynamic CT with late images should be performed. A dynamic CT scan may conclusively establish the diagnosis of a hemangioma and, occasionally, FNH without any further workup [194].

However, the greatest advances appear to have occurred with MRI. Recent studies have demonstrated accurate differentiation of FNH from hepatic adenoma using contrast-enhanced MRI, or the distinction between adenoma or HCC and "nonsurgical" lesions such as FNH or regenerative nodules, although Krinsky and Israel found that dysplastic and nondysplastic nodules still cannot be separated [195–197].

Tagged RBC scan (^{99m}Tc-RBC pool scintigraphy) may be helpful in questionable hemangiomas, although gadolinium-enhanced MRI is superior to tagged RBC scan in most cases. ^{99m}Tc-RBC scan with SPECT is highly sensitive in hemangiomas larger than 2 cm in size and may be used to confirm the diagnosis. ^{99m}Tc-sulfur colloid scintigraphy is usually not helpful for the differential diagnosis of focal hepatic lesions, but it may assist in distinguishing between FNH and adenoma. If no focal defect is seen or if the uptake is increased, FNH should be suspected. In contrast, decreased uptake is more consistent with an adenoma.

In cases of uncertainty or when malignancy is suspected, a liver biopsy may be considered. A percutaneous liver biopsy is generally safe. The accuracy and safety of ultrasonography-guided biopsy of these lesions has been documented [198]. However percutaneous biopsy may be hazardous in hemangiomas and should be avoided when these tumors are suspected, or when imaging studies indicate hypervascularity. In these cases, laparoscopic liver biopsy may be considered as it has the advantage of hemostasis under direct vision.

In a minority of patients, an accurate diagnosis cannot be established despite histopathologic examination because of sampling error or inadequate sample size. In these cases, resection may be indicated. Similarly, persistent symptoms, increasing levels of tumor markers, or evidence of tumor growth are indications for a surgical resection, regardless of the diagnosis. Benign hepatic lesions accounted for 5% of hepatic resections in a recent database review in the United States [199]. Resection of benign lesions is performed laparoscopically in many centers with excellent results.

Cystic diseases of the liver

Cystic diseases of the liver represent three groups of hepatic disorders that share the clinical feature of abnormal fluid-filled spaces in the liver and biliary tree (Fig. 35.9). The first and largest group is fibrocystic diseases of the liver and biliary tree. They are related hepatic disorders characterized by overgrowth of biliary epithelium leading to the production of fluid-filled dilated spaces, the formation of portal fibrosis, and the development of embryonic ductal plate malformations. The lesions result from malformations in different portions of the developing biliary tree and include polycystic liver disease (PCLD), simple hepatic cysts, congenital hepatic fibrosis (CHF), von Meyenburg complexes, and choledochal cysts (Table 35.5). The second group of disorders results from congenital defects of the embryonic foregut and includes ciliated foregut cyst, cystadenoma, and cystadenocarcinoma. The last group of disorders mimic the other cystic liver diseases and result from infection with the parasites *Echinococcus granulosus* or *E. multilocularis.*

Fibrocystic liver disease

Polycystic liver disease

Polycystic liver disease is a rare disease in which multiple cysts develop within the parenchyma of the liver. It is generally defined as the presence of four or more thin-walled cysts within the hepatic parenchyma because simple hepatic cysts are commonly characterized by one, two, or three cysts [200]. PCLD occurs both in association with autosomal dominant polycystic kidney disease (ADPKD) and in isolation (Fig. 35.10).

Epidemiology and course of disease

The true prevalence of PCLD is not known. Results in autopsy series suggest that the prevalence ranges from 0.05% to 0.13% [201,202]. The prevalence of multiple liver cysts in patients with ADPKD is 45–68% [202]. Cyst prevalence in ADPKD increases from approximately 24% in the third decade of life to 80% in the sixth decade of life [203]. The association of PCLD with ADPKD occurs in 16–93% of patients [204,205]. This range is wide because the prevalence of PCLD in ADPKD depends on age and the amount of renal dysfunction [206].

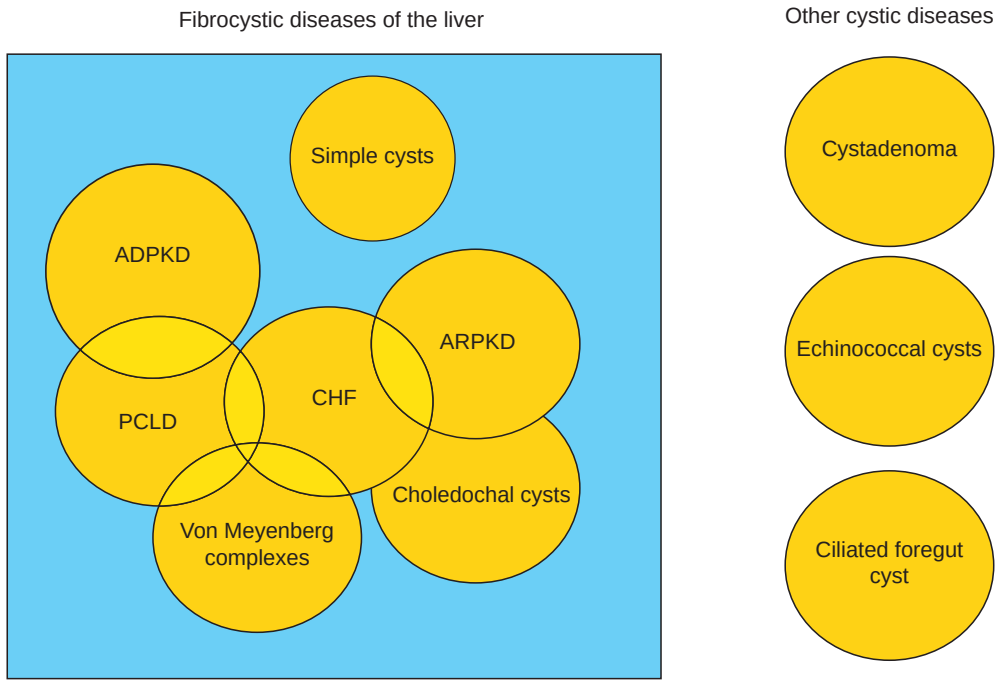

Figure 35.9 Interrelation between cystic diseases of the liver. ADPKD, autosomal dominant polycystic kidney disease; ARPKD, autosomal recessive polycystic kidney disease; CHF, congenital hepatic fibrosis; PCLD, polycystic liver disease.

When occurring with ADPKD, cysts generally begin to form in the liver after the onset of puberty. Although the proportion of men and women with liver cysts and ADPKD is the same, women tend to have both more and larger cysts [207]. Cyst formation is thought to be associated with estrogen exposure because the number and size of cysts correlate with the number of pregnancies, use of oral contraceptives, and use of female hormone replacement therapy [207]. Clinically relevant polycystic disease also correlates with advancing age, severity of renal cystic disease, and presence of renal dysfunction [206].

There are few published data on the frequency of symptomatic PCLD associated with ADPKD. Descriptions of symptomatic complications of PCLD are most often published in the form of case reports or reports of small series of patients over the course of many years. Most authors indicate that PCLD is predominantly a silent disease. The frequency of symptoms may be increasing because of the success of hemodialysis and renal transplantation – larger numbers of older patients with renal insufficiency are likely to have more and larger cysts within the liver. One report indicated that as much as 10% of the mortality among patients with ADPKD who undergo hemodialysis may be related to PCLD [208].

There is even less understanding of the epidemiology and course of isolated PCLD. Reports of old autopsy and surgical series suggest that multiple hepatic cysts may be present in the absence of renal cysts in as many as 50% of all patients with multiple hepatic cysts [209]. This is probably an overestimation. Results of a more recent autopsy series suggested that only 7% of patients with PCLD did not have associated renal cysts [202]. Several kindreds of patients have been found to have multiple cysts in their livers and no evidence of ADPKD [201, 210–212]. Similar to ADPKD-associated PCLD, isolated PCLD is more severe in women and more severe disease is associated with pregnancy [213]. Many patients are likely asymptomatic with clinically silent disease [213]. Because these series represent small numbers of patients, there is no clear understanding of the clinical course of isolated PCLD.

Table 35.5 Bile duct segment associated with fibrocystic disease of the liver and biliary tract.

Fibrocystic disease	Associated bile duct
Choledochal cysts	Common hepatic
Caroli disease	Segmental area
Congenital hepatic fibrosis	Interlobular
Polycystic liver disease	Intralobular
Simple cysts	Intralobular

Genetics and molecular pathogenesis

Autosomal dominant polycystic kidney disease is one of the most common genetic defects, with a disease

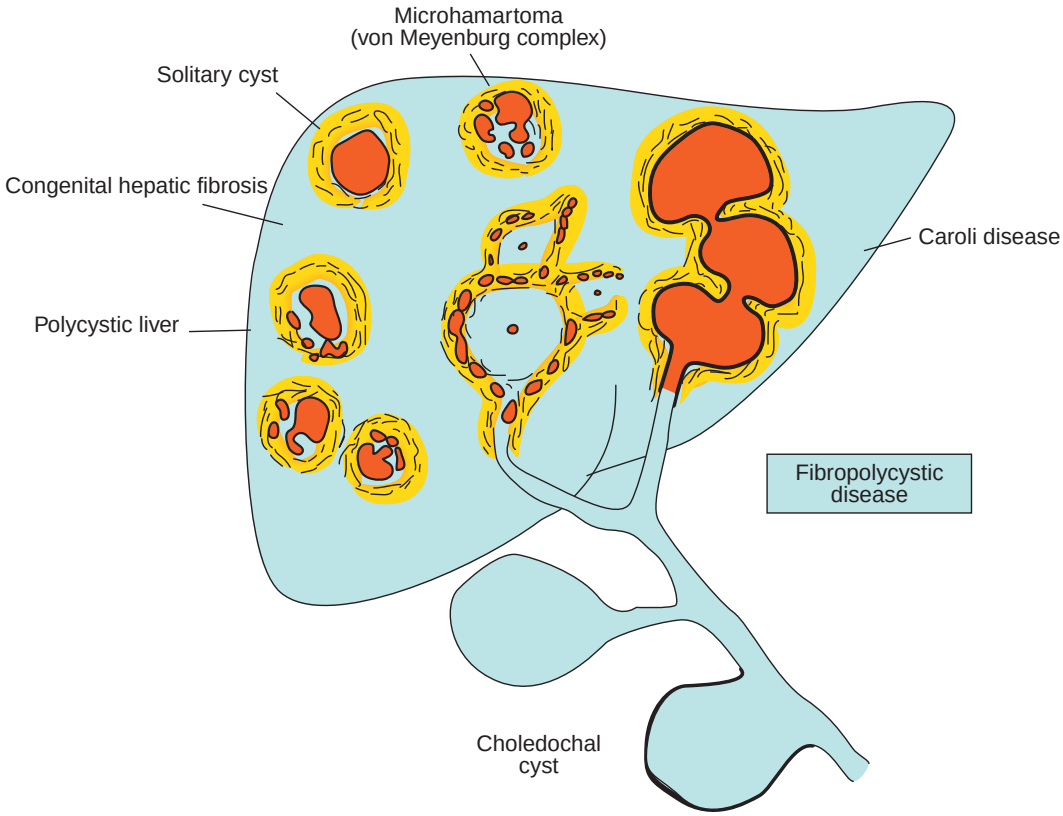

Figure 35.10 Diagram showing the relations between the fibrocystic diseases of the liver and biliary tract. (Courtesy of Dr Jay H. Lefkowitch.)

frequency of 1 : 1,000 in the white population [214]. There are two genes associated with ADPKD – *PKD-1* and *PKD-2* [215]. *PKD-1* is located on the short arm of chromosome 16 and is responsible for approximately 85% of cases of ADPKD [215]. *PKD-2* is located on the long arm of chromosome 4 and is responsible for about 15% of ADPKD [216]. There are numerous mutations known for the *PKD-1* and *PKD-2* genes. The gene products, polycystin-1 and polycystin-2, are transmembranous glycoproteins that are thought to be involved in cell–cell and cell–matrix interactions, cell cycle control, calcium ion regulation, and Wnt signaling [217]. Polycystin-1 appears to interact with a G protein signaling pathway that modulates calcium channels [216]. Polycystin-2 is an integral membrane protein with the characteristics of a cation channel [216]. Polycystin-1 and polycystin-2 complex in the cell membrane and localize in the primary cilium [216]. The primary cilium is a microtubule-based cellular structure found on the luminal surface of epithelium, including biliary and renal tubular epithelium, which acts as a flow sensor and regulates Ca^{2+} influx. Loss of flow sensing has been hypothesized to lead to dedifferentiation, cell proliferation, and loss of restriction in tubule size, resulting in cyst formation [218]. There is also evidence that the cysts contain high numbers of receptors for estrogen and insulin growth factor 1 [219]. Cultured human cyst cells proliferate in response to estrogen and insulin growth factor 1, which may explain the higher prevalence of symptomatic disease in women [219]. One potential mechanism for cyst lining cell proliferation is a reduction in microRNA 15a, a modulator of Cdc25A, a cell cycle regulator [198]. Proliferation of cyst epithelium has also been linked to the cyclic adenosine monophosphate (cAMP)-mediated activation of the mitogen-activated protein kinase/extracellular regulated kinase pathway and mammalian target of rapamycin (mTOR) pathway [213]. Cyst fluid secretion appears to be controlled by a cAMP-dependent pathway [213]. Changes in cell adhesion mediated by matrix metalloproteins also seem to be important for cell growth [213]. Neovascularization mediated by a number of factors is likely important for cyst growth [213]. Although the genetic inheritance pattern is autosomal dominant, a cellular recessive two-hit model has been proposed. A germline mutation in *PKD-1* or *PKD-2* is not sufficient to produce disease, but a second somatic mutation in the functional *PKD* gene triggers monoclonally derived cyst formation [220,221].

Recent progress has been made in understanding the genetic basis of isolated PCLD. Reynolds et al. studied two large kindreds with autosomal dominant isolated PCLD and showed linkage to a putative causative gene on the long arm of chromosome 19 [212]. Drenth et al. and Li et al. identified that mutations in *PRKCSH* are responsible for some cases of isolated PCLD [222,223]. PRKCSH has been previously identified as protein kinase C substrate 80K-H, but the function of the protein product, hepatocystin, is unclear. Hepatocystin can function as the noncatalytic β-subunit of glucosidase II, which plays a major role in the regulation of proper folding and maturation of glycoproteins. PKD-1 and PKD-2 are glycoproteins, so it has been proposed that mechanistically there could be a link between ADPKD-associated PCLD and isolated PCLD if defective glycosylation from mutant glucosidase II results in improper functioning of polycystins [223,224]. There is a preliminary report that mutations in translocation protein SEC63 are associated with isolated PCLD in persons who have normal PRKCSH [224]. SEC63 is also involved in the processing of integral and secreted proteins as a part of the multicomponent translocation involved in protein translocation [224]. A similar two-hit model of ADPKD-associated PCLD has been proposed for isolated PCLD.

Pathology

The fluid-filled cysts of PCLD are usually scattered throughout the liver, although they can be present in only one lobe (Fig. 35.11). The cysts vary in size from less than 1 cm to more than 10 cm in diameter and cause massive enlargement of the liver. Microscopically, the cysts are close to or actually within the portal tracts [225]. The cyst cavities are lined by flat or cuboidal epithelium, the presence of which is often associated with biliary microhamartoma [226]. Fluid within the cysts is consistent with the bile salt-independent fraction of bile and increases with secretin stimulation. Therefore, the cysts are lined

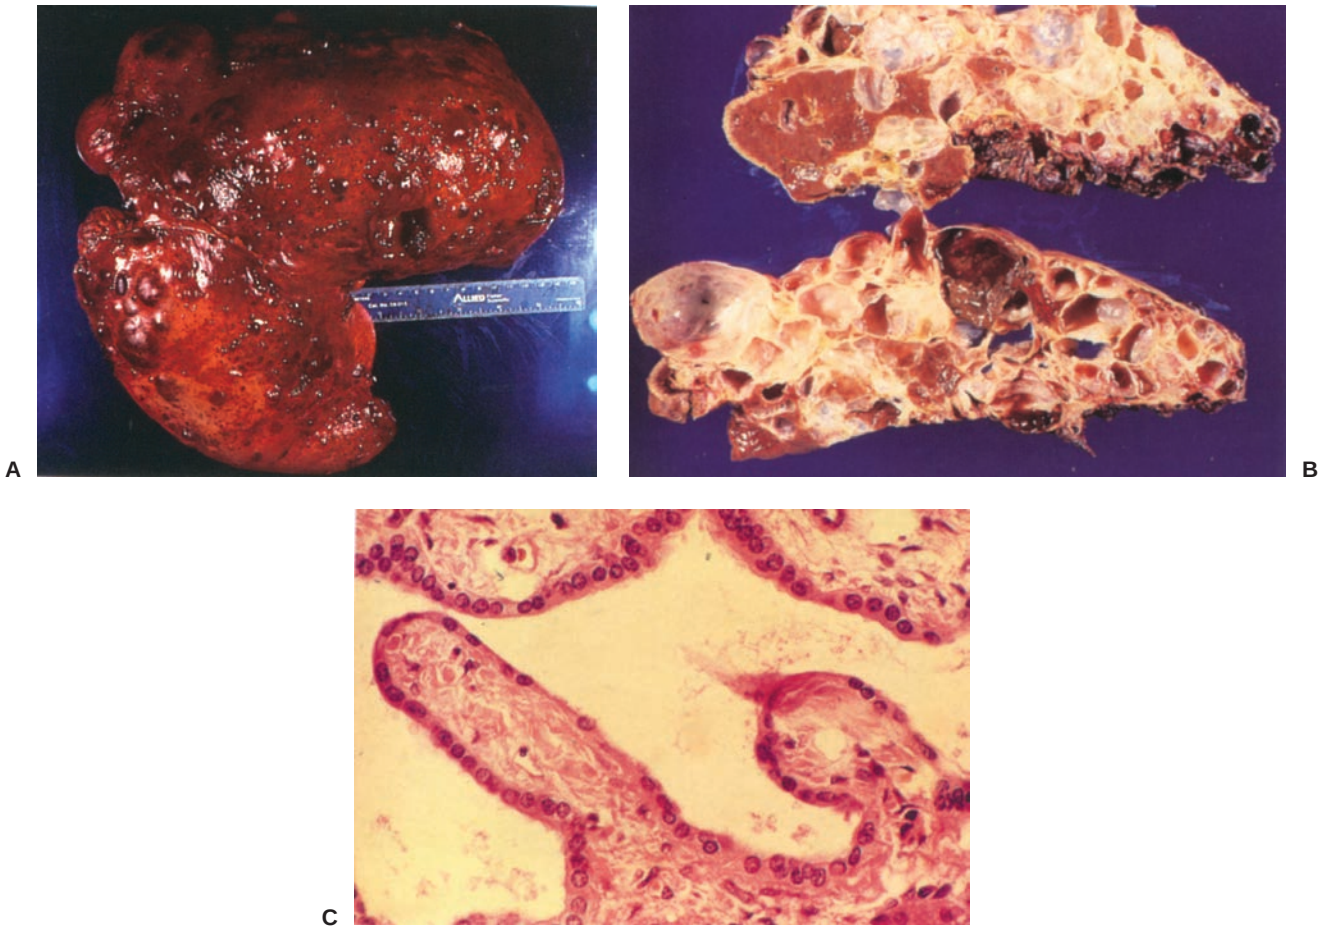

Figure 35.11 (A) Polycystic liver with massive enlargement of the liver. (B) Cut surface of a portion of a polycystic liver containing numerous cyst pockets. (C) Photomicrograph of polycystic liver stained with H&E showing cuboidal cyst lining. (B, C, courtesy of Dr Elizabeth M. Brunt.)

with biliary-type epithelium [227] and are hypothesized to form from the dilatation of biliary microhamartomata [203,226]. During their development the cysts become disconnected from the biliary tract [226]. It is not clear whether the biliary microhamartomata are congenital or develop as the patient ages [226].

Clinical features

The symptoms of isolated and ADPKD-associated PCLD are most often caused by the mechanical effects of the enlarged cystic liver. Most cases are asymptomatic [213]. Some cases of PCLD may manifest as vague abdominal fullness or a palpable abdominal mass. Patients who underwent surgical intervention have been reported to have the following symptoms: abdominal pain, abdominal distension, early satiety, fatigue, orthopnea, jaundice, ascites, and variceal bleeding [228]. The right upper quadrant pain and shortness of breath experienced by patients with both PCLD and ADPKD correlate with larger liver volumes and not with kidney volume [229]. Patients generally have preserved hepatic function on the basis of galactose elimination capacity and antipyrine clearance [229]. Total hepatocyte volume remains normal, according to calculations of hepatic mass from CT images (Fig. 35.12) [227]. Results of liver function tests are either normal or show a cholestatic pattern with usually mild elevations in alkaline phosphatase and total bilirubin levels. Serum albumin levels can be mildly depressed and prothrombin time elevated because of poor nutrition [213,228].

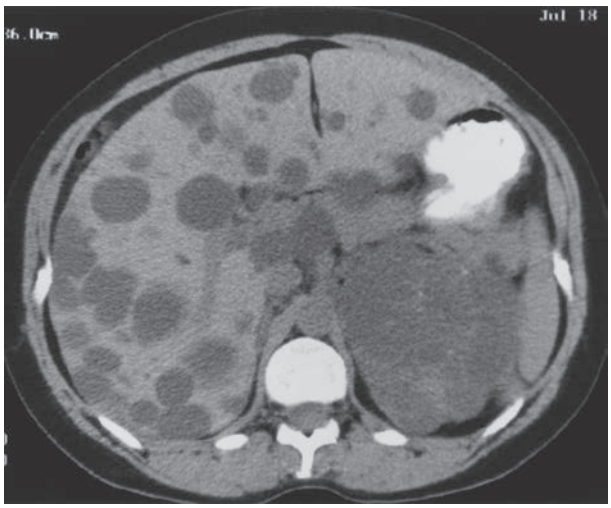

Figure 35.12 Abdominal computed tomography scan shows diffuse cystic involvement by polycystic liver disease involves obliteration of varices by means of repeated band ligation. Pharmacologic intervention with β-blockers or somatostatin analogs can also be attempted. TIPS is generally technically unfeasible because of the large cysts. Surgical debulking of the cysts can lead to relief of venous outflow tract obstruction and, therefore, of portal hypertension in some patients [62]. Surgical portocaval shunts can be helpful. Liver transplantation can be considered in cases of refractory disease.

Complications

The development of portal hypertension in PCLD is rare. There are 19 case reports of variceal bleeding related to PCLD in the literature [230]. The pathophysiology of the development of varices is not clear. Some patients seem to have hepatic venous and/or inferior vena caval obstruction from direct compression of the cysts. Others may have associated CHF. Treatment involves obliteration of varices by means of repeated band ligation. Pharmacologic intervention with β-blockers or somatostatin analogs can also be attempted. TIPS is generally technically unfeasible because of the cysts. Surgical debulking of the cysts can lead to relief of venous outflow tract obstruction and, therefore, of portal hypertension in some patients [228]. Surgical portocaval shunts can be helpful. Liver transplantation can be considered for refractory cases.

Hepatic venous outflow tract obstruction has been reported in small case series [231]. These patients have a history of PCLD and new development of ascites. Hepatic function is usually preserved, and the ascitic fluid has a high protein content. Findings on CT or MRI may suggest hepatic venous outflow tract obstruction, which can be confirmed with hepatic venography. Abdominal surgery may precipitate hepatic venous outflow tract obstruction. If there is no evidence of thrombus in the hepatic veins or vena cava, percutaneous or surgical treatment can be directed at the obstructing cyst. If thrombosis of vessels or the presence of multiple small cysts is the cause, surgical portosystemic shunting or liver transplantation should be considered. Transplantation should probably be reserved for patients with evidence of hepatic decompensation. Patients should be screened for hypercoagulable states with the appropriate laboratory studies.

Obstructive jaundice is a rare complication of PCLD, being described only in case reports. It results from direct obstruction of the biliary tree by a cyst. Endoscopic retrograde cholangiopancreatography (ERCP) is helpful to rule out other causes of biliary obstruction and to help identify the culprit cyst, usually with the aid of an abdominal CT scan [232]. Therapy can be with percutaneous drainage and sclerosis or with surgery.

Infection of hepatic cysts is a rare complication of PCLD. It occurs in 1–3% of patients with PCLD and ADPKD and appears to be more common in patients with renal failure [208]. Most patients have fever and right upper quadrant abdominal or right flank pain [208]. Leukocytosis or left shift is usually present, but results of liver function tests have a cholestatic pattern in

fewer than one half of patients [208]. Imaging with CT, ultrasonography, or MRI usually shows either a thickened cyst wall or different density of the cyst fluid [208]. If there is doubt, an indium leukocyte scan appears to be more sensitive than a gallium scan in the diagnosis of cyst infection [208]. Results of the culture of cyst fluid are almost always positive for single bacterial organisms, suggesting a hematogenous route of infection [208]. Treatment is with percutaneous or surgical drainage and intravenous broad-spectrum antibiotics.

Both ADPKD-associated PCLD and isolated PCLD are associated with the development of intracranial aneurysms [233,234]. Autopsy series show that 20% of patients with ADPKD have associated intracranial aneurysms [234]. Screening for aneurysms is probably prudent before considering anticoagulation or surgical therapy.

Management

The method of management of liver cysts depends on the size, number, and location of the cysts and on the clinical manifestations. Surgical therapy is generally reserved for patients with significant clinical symptoms that alter performance status given the relatively high morbidity and potential of mortality [228]. Surgical options include both open and laparoscopic fenestration (deroofing) of the cyst, hepatic resection and cyst fenestration, and OLT. Percutaneous drainage has no role in treatment because of the almost universal recurrence rate, but drainage followed by the addition of a sclerosing agent may be an alternative. Patients with one or a few cysts can be treated with laparoscopic fenestration or percutaneous drainage with sclerosis. The open surgical approach with cyst fenestration is more appropriate for deeper and larger numbers of cysts. Some surgeons have advocated open surgery with hepatic resection and cyst fenestration for patients with massive, highly symptomatic PCLD [228]. This procedure is most appropriate for patients with multiple cysts and areas of parenchymal sparing. OLT is reserved for patients with massive diffuse bilobar disease, who are homebound and unable to perform activities of daily living, or who have evidence of hepatic failure [235].

Table 35.6 lists selected series of both open and laparoscopic surgical results in the management of PCLD [228, 236–242]. In general, laparoscopic techniques have lower morbidity but higher rates of recurrence. Hepatic resection with cyst fenestration is the most effective technique in preventing recurrence, but it carries a high morbidity. Recurrence of symptoms is usually not caused by new cysts but by enlargement of the remaining cysts. Common postoperative complications include massive hemorrhage, biliary leaks, ascites, and infection. Careful patient selection is critical, especially with regard to the certainty that the symptoms are related to the liver cysts [243]. If there is doubt, consideration should be given to percutaneous cyst aspiration to assess clinical response.

Several small series with limited follow-up evaluation have shown successful sclerosis of hepatic cysts with alcohol and minocycline hydrochloride. This technique is generally more successful for the management of simple

hepatic cysts than as therapy for PCLD. Complications include abdominal pain, fever, and ethanol intoxication. Care must be taken to avoid sclerosis of cysts that communicate with the biliary tree.

There are about 100 case reports of patients who have been have undergone liver transplantation for highly symptomatic PCLD [244]. Deceased-donor liver transplant with or without kidney transplantation is typical, but there are a few cases of living-donor transplantation. Symptom relief was nearly universal among the surviving patients. The outcome of OLT is similar to that of OLT performed for other typical indications at 1 year and probably superior with longer follow-up. Previous attempts at surgery may increase the risk of perioperative complications. Earlier series typically performed liver and kidney transplantation, but more recent series suggest that combined transplantation is only necessary if significant renal dysfunction is present.

While there is currently no clear role for medical therapy for PCLD, there is recent evidence that somatostatin analogs and mTOR inhibitors can decrease cyst size and potentially reduce symptoms.

Simple hepatic cysts

Simple hepatic cysts are thought to result from congenital defects of intrahepatic bile ducts. They are lined with biliary-type epithelium but do not generally connect with the biliary tree. These cysts are estimated to have an incidence of 2.5% among the general population, with increased frequency with advancing age [200]. They are most often asymptomatic incidental findings on abdominal imaging. When symptomatic, simple hepatic cysts can produce the same range of symptoms and complications as PCLD, although less frequently. Simple hepatic cysts can be differentiated from PCLD by lack of an autosomal dominant inheritance pattern, lack of associated renal cysts, and smaller numbers of cysts, usually less than four [213]. Imaging with ultrasonography, CT, or MRI usually provides enough information for a diagnosis. On imaging the cysts appear as thin, smooth-walled, anechoic masses or water densities. Any septations or papillary projections should raise suspicion for cystadenoma or cystadenocarcinoma [245]. Management of symptomatic cysts is by percutaneous sclerosis, open surgical or laparoscopic fenestration, or resection. Percutaneous treatment with aspiration followed by alcohol or another sclerosing agent is successful in most cases, and the recurrence rate is low. Open and laparoscopic fenestration can be performed with similar success but higher morbidity.

Congenital hepatic fibrosis

Congenital hepatic fibrosis is a rare disorder that results in the fibrous destruction of interlobular bile ducts. The liver shows fibrous enlargement of the portal tracts; portal–portal bridging forms thick bands of scar that contain abnormal bile ducts. Normal-appearing cuboidal cells line the bile ducts in the scar (Fig. 35.13). CHF has been reported in association with other fibrocystic liver diseases, including adult PCLD, Caroli disease, choledochal cysts, and von Meyenburg complexes (see Fig. 35.9). CHF is most commonly associated with autosomal recessive polycystic kidney disease (ARPKD), which is caused by mutations in the *PKHD1* gene [246]. It is not known whether the genetic defect in ARPKD is responsible for CHF, but the gene products localize to the primary cilium, the same location as the proteins associated with ADPKD [246]. At least one half and probably more of patients with CHF have associated renal disease. CHF also has been associated with a variety of rare pediatric syndromes, including renal dysplasia, nephronophthisis, Joubert syndrome, COACH syndrome (*c*erebellar vermis hypoplasia, *o*ligophrenia, congenital

*a*taxia, *c*oloboma, and *h*epatic fibrocirrhosis), Meckel syndrome type 1, Jeune syndrome, vaginal atresia, tuberous sclerosis, phosphomannose isomerase 1 deficiency, Ivemark syndrome type 2, short-rib syndrome, and osteochondrodysplasia [247].

The incidence of CHF is unknown. Because of the many clinical associations and the variable clinical presentation, some investigators believe that CHF is not a single entity but a spectrum of diseases. The cause of CHF is unknown. Desmet hypothesized that at birth, patients who will eventually have CHF have ductal plate malformations of the interlobular bile ducts. These immature bile ducts undergo destructive cholangitis that results in the loss of bile duct profiles and the formation of fibrous scar. The destructive cholangitis progresses at variable rates and may arrest, explaining the variety of clinical presentations of the disease [247]. The cause of the associated portal hypertension has been hypothesized to be hypoplasia or compression of the small branches of the portal vein [247].

The four patterns of clinical presentation of CHF are portal hypertensive, cholangitic, portal hypertensive–cholangitic, and latent. Serum aminotransferase levels are usually normal, although the alkaline phosphatase level is sometimes elevated. These patients usually do not have cirrhosis and maintain normal hepatic lobular architecture with normal hepatic function. The diagnosis is based on findings at liver biopsy. Surgical biopsy may be needed to obtain sufficient liver for diagnosis.

The portal hypertensive presentation is most common, representing approximately 70% of cases [248]. Portal hypertensive CHF usually manifests in childhood or young adulthood as complications of portal hypertension, especially variceal bleeding, with intact hepatic function. Hepatosplenomegaly may be present. Wedged hepatic venous pressure is normal, a finding consistent with presinusoidal portal hypertension. Symptomatic portal hypertension has traditionally been managed with surgical placement of a portosystemic shunt. Development of hepatic encephalopathy after shunting is extremely rare, probably because hepatic function is intact. Endoscopic variceal band ligation may be used to control acute bleeding. Endoscopic obliteration of esophageal varices is at least theoretically useful, although it would entail long-term endoscopic surveillance. Long-term follow-up evaluation of surgical shunts has shown that 39% of patients have jaundice, 17% have recurrent bleeding, and 17% have hepatic encephalopathy [249].

The cholangitic form of CHF manifests as fever, right upper quadrant pain, and a cholestatic pattern in the levels of the liver-associated enzymes. At least initially, patients with cholangitic CHF do not have evidence of portal hypertension. Treatment is with intravenous antibiotics. Either ERCP or percutaneous transhepatic cholangiography (PTC) can be used to image the biliary tree and relieve obstruction. These patients often have associated Caroli disease, which results in the cholangitic signs and symptoms. Repeated bouts of cholangitis can lead to secondary biliary cirrhosis and the need for liver transplantation. Patients should be treated for Caroli disease as described later.

The portal hypertensive–cholangitic or mixed presentation is a combination of symptoms of portal hypertension and cholangitis. Treatment is based on the presence of the symptoms described earlier. The latent form is typically discovered either at autopsy or during evaluation for other problems. It is generally asymptomatic and therefore requires no treatment.

Rare reported associations with CHF include disease isolated to one lobe of the liver, cholangiocarcinoma, ascites, and cavernous transformation of the portal vein.

Von Meyenburg complexes

Von Meyenburg complexes, also called *biliary microhamartomata*, are usually incidental and asymptomatic findings at liver biopsy. They are found in approximately 5% of adults and 1% of children in series of consecutive autopsies. The complexes consist of variable numbers of dilated bile ducts embedded in a fibrous stroma and occur in small groups adjacent to portal tracts (Fig. 35.14). The complexes may contain inspissated bile concretions and polypoid projections into the lumen. They are hypothesized to result from fibrosis and occasionally from the involution of remnant ductal plate malformations of peripheral interlobular bile ducts [225]. Von Meyenburg complexes are thought to be the origin of the cysts in PCLD. They are also found in association with Caroli disease, CHF, and in normal liver. There are rare

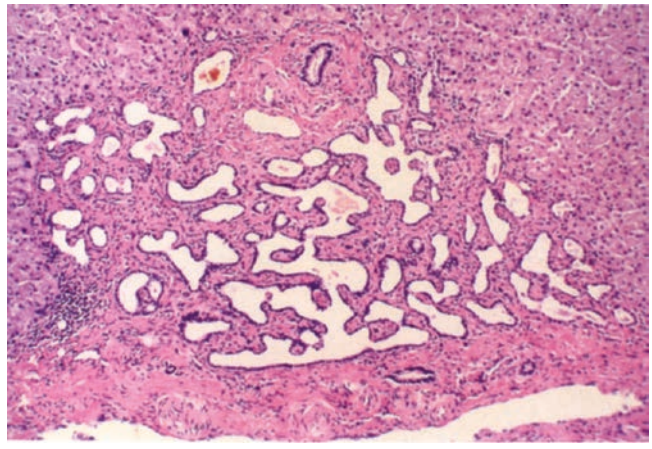

Figure 35.14 Photomicrograph of the liver showing a typical von Meyenburg complex with a group of dilated bile ducts in fibrous stroma. H&E. (Courtesy of Dr Elizabeth M. Brunt.)

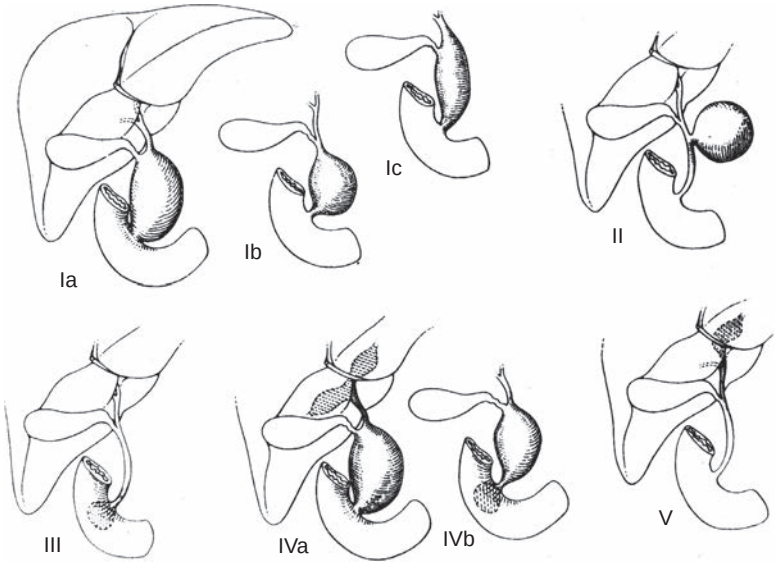

Figure 35.15 The Todani modification of the Alonso–Lej classification of choledochal cysts. (Adapted from Todani et al. [250] with permission from Elsevier.)

reports of cholangiocarcinoma developing within a von Meyenburg complex.

Choledochal cysts

Epidemiology, course of disease, and clinical features

Choledochal cysts are congenital dilatations of the intrahepatic and extrahepatic biliary tree. Vater and Elzer first described choledochal cysts in 1723. The Todani modification of the Alonso–Lej classification of choledochal cysts is the system most often used for planning the management of these cysts (Fig. 35.15) [250]. The estimated incidence varies from 1 in 13,000 in Japan to 1 in 2 million in England [251,252]. The frequency of diagnosis seems to be increasing, probably because of improvements in abdominal imaging [252]. Type I cysts represent approximately 85% of most series [253]. Type II cysts are rare, representing less than 2% of cases, and are sometimes called common bile duct diverticulum [254]. Type III cysts or choledochoceles also are rare, representing approximately 2% of cases, although they may be more common in tertiary referral endoscopy centers [255]. Type IV cysts represent the remaining approximately 10% of cases. Type V cysts are Caroli disease.

The cysts usually manifest themselves in childhood but may be diagnosed in the prenatal period through late adulthood. Only approximately 20% of cases manifest themselves in adults. There is a female predominance [256]. Neonates have jaundice and a palpable mass [257]. In the first decade of life, ascending cholangitis is a more likely manifestation. The diagnosis is made when ultrasonography, CT, hydroxy iminodiacetic acid (HIDA) imaging, endoscopic retrograde cholangiography, PTC, or magnetic resonance cholangiography shows characteristic dilatation of the biliary tree. Liver function tests may show elevated alkaline phosphatase, total bilirubin, and γ-glutamyl transpeptidase levels consistent with biliary obstruction [257]. Manifestation in adulthood is often preceded by several years of vague right upper quadrant abdominal pain [258]. At diagnosis the patient usually has a complication such as jaundice, cholangitis, or pancreatitis [258]. CHF is often associated with choledochal cysts, especially Caroli disease.

Etiology

There are several theories about their etiology, although the true cause of choledochal cysts remains unclear. One theory suggests that failure of canalization of the fetal biliary tree results in obstruction and, later, dilatation of the common bile duct. Another theory suggests that obstruction occurs from anatomic kinking or external pressure on the developing bile ducts that results in cyst dilatation. Probably the most accepted theory was first proposed by Babbit, which stated that the high insertion of the common bile duct into the pancreatic duct leads to reflux of pancreatic juice into the biliary tree. This leakage causes weakening of the bile duct wall, inflammation, and fibrosis. The distal bile duct becomes obstructed and therefore results in proximal dilatation with cyst formation [259]. There appears to be a high rate of anomalous pancreaticobiliary duct junction in the range of 90% in most series [260].

Management

Management of choledochal cysts is based on the type of cyst according to the Todani classification (see Fig. 35.15). Some authors argue that the Todani classification scheme is misleading and overcomplicated [261]. They

propose a simplified naming system matched to the treatment and risk of future malignant transformation, which is described at the end of this section. The first premise of treatment is to obtain adequate drainage and antibiotic coverage for any patient with signs and symptoms of cholangitis, as seen with PTC or ERCP.

The current standard of practice for type I and II choledochal cysts is complete cyst excision with anastomosis of the bifurcation of the hepatic ducts, common hepatic duct, or common bile duct with Roux-en-Y anastomosis to the jejunum or directly to the duodenum. The surgery can be performed either with an open or a laparoscopic approach. Biliary enteric anastomosis at the bifurcation of the hepatic ducts appears to offer the advantage of a lower rate of late strictures [262]. Cyst enterostomy is generally no longer performed because of the high rate of long-term complications, including anastomotic strictures that result in jaundice and cholangitis and the late development of cholangiocarcinoma [258,263]. Patients who have undergone previous cyst enterostomy and have late complications of surgery need complete cyst excision with Roux-en-Y hepaticojejunostomy. Patients with an asymptomatic cyst who are otherwise good surgical candidates should be considered for elective cyst excision and Roux-en-Y hepaticojejunostomy to prevent the development of cancer [258].

Type III choledochal cysts are also called *choledochoceles*. Patients have pancreatitis, obstructive jaundice, or biliary colic [264]. They may have a history of cholecystectomy for acalculous cholecystitis with continued symptoms after surgery [264]. The differential diagnosis includes papillary tumor, papillitis from an impacted stone, papillary fibrosis, pancreatitis, duodenal duplication, and submucosal contrast injection during ERCP [265]. This broad differential diagnosis warrants cholangiography and biopsy to rule out tumors [265]. Choledochoceles rarely develop into cancer, and therefore complete excision may not be mandatory [255,256]. Large cysts should be excised either partially or completely and the ducts reanastomosed to the duodenum [260]. Small choledochoceles can be managed with endoscopic sphincterotomy [256,261]. Endoscopic pancreatic sphincterotomy may be necessary if the pancreatic duct does not drain well [255].

Type IVa choledochal cysts with both intrahepatic and extrahepatic components make total cyst excision difficult. Total excision of the extrahepatic cysts can usually be accomplished, and anastomosis with the enteric tract should be performed at the hilum to prevent a high rate of anastomotic strictures. Formation of a Hutson loop, which provides easy percutaneous access to the reconstructed biliary tree, has been advocated, especially if intrahepatic cysts are not resected [266]. Partial hepatectomy, if technically feasible, has also been advocated for the removal of intrahepatic cysts because of malignant potential. The risk of biliary cancer in the retained intrahepatic cysts is not known but is probably low, with only a few reported cases.

The presence of type V cysts, also known as *Caroli disease*, results in multiple intrahepatic biliary cysts and makes treatment more difficult. Complete resection of biliary cysts is usually impossible because of the location of the cysts. For this reason, conservative treatment of cholangitis with antibiotics is usually the initial choice. Rotating antibiotics to suppress episodes of cholangitis is advisable but is of unproven value. If the cysts are superficial and limited in number, hepatic resection can sometimes be curative. An alternative is to relieve obstruction with partial cyst excision and Roux-en-Y cyst jejunostomy. Liver transplantation is generally reserved for patients with hepatic failure. Prognosis is much worse for this type of choledochal cyst than for the others. Tsuchida et al. [267] found a 63% mortality in a survey of patients whose cases were reported in the literature.

Without therapy for choledochal cysts, biliary cancer, usually cholangiocarcinoma, develops in approximately 15–19% of patients older than 20 years and generally carries a dismal prognosis [258,263]. The most common site of the cancer is the cyst wall, but as many as 40% of cases occur at other sites in the liver or pancreas, especially the gallbladder [254]. For this reason and to prevent future gallbladder-related symptoms, cholecystectomy is usually performed during cyst surgery. There are rare case reports of late cholangiocarcinoma after initial resection, particularly if any cysts can not be resected or if there is persistent dilatation of a segment of the biliary tree.

Complications include jaundice, pancreatitis, spontaneous cyst rupture, biliary cirrhosis, and signs of portal hypertension, including variceal bleeding and ascites [268]. The postoperative rate of recurrence of symptoms can be as high as 32%, but the symptoms most often respond to conservative therapy with antibiotics [269].

The simplified system calls type I and IVa cysts "choledochal cysts" because they are variations of a single disease with dilatation of the extrahepatic biliary tree and varying levels of involvement of the intrahepatic tree. They represent the most common type of choledochal cysts, have the highest risk of malignant transformation, are associated with pancreaticobiliary maljunction, and require complete excision of the extrahepatic biliary tree with a high biliary enteric anastomosis. Type II cysts are rare diverticuli of the common bile duct that can be treated with simple excision of the cyst. Type III should be called choledochoceles because they are lined with duodenal mucosa, do not require complete excision, and rarely develop malignant transformation. Type V cysts should be called Caroli disease and differ from the other types by affecting only the intrahepatic ducts, being

associated with ductal plate malformation, having low malignant potential, and being associated with CHF and portal hypertension.

Cystic neoplasms of the liver: cystadenoma

Cystadenoma, also called *biliary cystadenoma*, is a benign tumor of the liver in which an epithelial layer surrounds a large, fluid-filled cyst in the hepatic parenchyma or rarely in the extrahepatic biliary tree. It represents less than 5% of cystic lesions of the liver. Cystadenoma is hypothesized to arise from a congenital defect of the bile ducts or gallbladder. It may form out of rests of primitive foregut. It can be found in association with bile duct hamartoma.

Cystadenoma manifests itself any time from childhood onward, although 80–85% of cases occur among middle-aged women. The clinical manifestations are typically the result of compression of an expanding liver mass on adjacent structures. Approximately 70% of patients have epigastric or right upper quadrant pain, sometimes with radiation to the right shoulder. Approximately one half of patients have a palpable abdominal mass or increasing abdominal girth, and approximately one third of patients have compression of the biliary tree that leads to cholangitis or jaundice [270]. Some patients have symptoms of gastric compression, such as nausea, vomiting, bloating, and anorexia. In some patients, the cysts are incidental findings on imaging of the abdomen. Extrahepatic cystadenoma typically manifests as abdominal pain and jaundice [271].

Complications are rare and have been reported to include sepsis, hemorrhage, and rupture. Transformation into malignant cystadenocarcinoma can occur and result in local invasion and occasional distant metastasis. Nearly all the reported cases of malignant transformation occur in patients who have the stromal layer.

The diagnosis of cystadenoma is suggested by the ultrasonographic findings of a multilocular, anechoic, fluid-filled cyst with thickened walls and multiple septations or papillary projections [272]. The cyst is usually located in the hepatic parenchyma, although extrahepatic cysts have been reported. There is usually no connection with the biliary tree. Levels of liver-associated enzymes are usually normal unless there is biliary obstruction. The serum level of cancer antigen 19-9 (CA19-9) may be mildly elevated, but levels of carcinoembryonic antigen 125 (CA125) and α-fetoprotein are normal. Cyst fluid CA19-9 level is elevated, but aspiration carries a small risk of dissemination if carcinoma is present. The lesions should be differentiated from pyogenic abscess, amebic abscess, and echinococcal cysts on the basis of clinical manifestations and imaging findings.

Pathologic examination reveals cuboidal and columnar epithelial cells with vacuolizations lining the cysts. Usually adjacent to the epithelium is an area of spindle cell stroma (also called mesenchymal stroma) surrounded by a layer of collagenous connective tissue. Mesenchymal stroma are exclusively found in female patients and may represent a different form of the disease than those without stroma [273]. The cyst fluid is usually mucinous, but it may contain bile or blood.

Treatment is complete surgical resection by means of either enucleation (excision of a mass with a thin layer of normal tissue) or anatomic resection. In the past, incomplete excision or drainage procedures led to a high recurrence rate and did not remove the risk of malignant transformation. There is a 50% rate of recurrence of extrahepatic cysts without sleeve resection with biliary enteric anastomosis [274].

Ciliated foregut cyst

Foregut cysts derive from the primitive foregut and may occur in the mediastinum, pancreas, tongue, and upper aerodigestive tract as well as in the liver and subhepatic space. They are filled with mucinous, sometimes bloody, fluid and their main clinical significance is that they can sometimes be confused with solid tumors [275,276].

Echinococcal cysts

Hydatid disease caused by *Echinococcus granulosus* cystic echinococcosis is endemic in parts of western and southern Europe, the Middle East, northern Africa, South and Central America, Russia, and China. The annual incidence ranges from less than one case to as many as 42 cases/100,000 persons in some regions [277]. Humans are accidental hosts who ingest eggs from contaminated dogs that were usually infected from sheep. The liver is involved in one half to three fourths of cases. The cysts range from 1 to >20 cm in size. Rarely, hydatid disease called *alveolar echinococcosis* can occur due to *E. multilocularis.* It is endemic in parts of North America, central Europe, and northern and central Eurasia. Incidence is generally less than 1/100,000 [277]. Humans are accidental hosts who ingest eggs from foxes or forest rodents.

Diagnosis is based on a high index of clinical suspicion and findings on imaging with ultrasonography, CT, or MRI. The initial symptoms are usually caused by complications of the cysts or physical compression of adjacent organs by the cysts. Symptoms such as epigastric or right upper quadrant pain, fatigue, fever, nausea, and dyspepsia may be present. Cyst rupture can produce jaundice, cholangitis, acute pancreatitis, and immune reactions such as anaphylaxis or asthma. Ultrasonography, CT, and MRI are sensitive and specific for hydatid disease, with cross-sectional imaging being superior in identifying the location of the cysts, including extrahepatic cysts, and the type of cyst. Serologic tests, including an indirect hemagglutination test and enzyme-linked immunosorbent assay for antibodies to *Echinococcus* antigens are

approximately 90% sensitive but have variable specificity because of cross-reaction with other parasites and may not distinguish cystic from alveolar disease.

There is controversy about the most appropriate treatment for cystic echinococcosis. Some advocate treatment even in asymptomatic patients to prevent complications such as rupture, infection, or anaphylaxis. Others have shown that small, nonsuperficial, and asymptomatic cysts can remain stable for more than 10 years. The choice of treatment depends on the type of cyst (usually defined by ultrasonographic appearance), the location of the cyst, the general medical status of the patient, and local experience. Because of its potential for aggressive infiltration of the liver and other organs and high mortality, radical surgical resection and at least 2 years of chemotherapy is the first choice of treatment for alveolar echinococcosis.

Open surgery with cyst removal or drainage and obliteration of the cyst cavity was until recently the primary mode of treatment for cystic echinococcosis. Although in the literature results of series of open surgical treatment are variable, they generally show a mortality ranging from 0% to 5%, morbidity from 8% to 25%, and long-term recurrence rates of 2–25%. Several series of laparoscopic cyst surgery have shown morbidity and mortality similar to those of open surgery but they generally involve less difficult cyst types and locations. Any surgical or percutaneous therapy carries a risk of dissemination of daughter cysts into the abdomen, but modern techniques and experienced surgeons significantly limit the risk.

*P*uncture, *a*spiration, *i*ntroduction of protoscolicidal agent, and *r*easpiration (PAIR) is a percutaneous treatment developed by interventional radiologists in the mid-1980s. The connection of the cyst to the biliary tree is an absolute contraindication for this procedure, and only certain configurations of cysts are amenable to this treatment. Series of patients treated with PAIR and chemotherapy at experienced centers showed no mortality and less than 10% morbidity but the cysts were generally smaller, less complex, and amenable to a percutaneous approach. Long-term recurrence rates are not yet available but short-term results look promising.

Chemotherapy with benzimidazole compounds, mebendazole or albendazole, is generally reserved for patients not amenable to treatment by other means or as an adjunct to other treatment, especially PAIR [278]. Chemotherapy has approximately a 30% cure rate, but up to 70% of cysts will reduce in size. Relapse rates are about 25%.

Multiple choice questions

35.1 All of the following are risk factors for hepatocellular adenoma transforming into hepatocellular carcinoma except which one?

a Beta-catenin mutation.
b Male gender.
c Diameter greater than 5 cm.
d Hepatocyte nuclear factor 1α (HNF-1α) inactivation.
e Enlarging nodules.

35.2 Indications for operative or percutaneous interventions in polycystic liver disease include all of the following except which one?

a Right upper quadrant pain causing altered performance status.
b Cyst compression of the biliary tree leading to jaundice.
c Fever with evidence of infected cyst on imaging.
d Massively enlarged cysts throughout all segments of the liver.
e Hepatic venous outflow tract obstruction with ascites formation.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 36

Hepatocellular Carcinoma

Alejandro Forner, Carmen Ayuso, & Jordi Bruix

Barcelona-Clínic Liver Cancer Group, Hospital Clinic Barcelona, CIBERehd, Institut d'Investigacions Biomediques Agusto Pi i Sunyer (IDIBAPS), University of Barcelona, Barcelona, Spain

Key concepts

- Hepatocellular carcinoma (HCC) is a neoplasm that has well-defined risk factors, such as chronic viral infection and excessive alcohol intake. These induce chronic liver disease, that is, cirrhosis, and induce genetic damage, leading to cancer development.
- HCC is the leading cause of death in patients with cirrhosis.
- The sole option to reduce cancer-related death is to detect cancer at an early stage and apply effective therapy. Patients with cirrhosis who are candidates for therapy if HCC is diagnosed should be encouraged to enter screening protocols.
- Early detection of HCC should be based on hepatic ultrasonography every 6 months. Unfortunately, tumor marker determination lacks precision and efficacy.
- Diagnosis of HCC can be done without histologic confirmation in patients with cirrhosis by imaging techniques.
- Effective therapies for HCC with potential long-term cure include surgical resection, liver transplantation, and percutaneous ablation. Among palliative approaches, the only two therapies with a positive impact on survival are transarterial chemoembolization and sorafenib.
- Positive results with sorafenib are proof of the potential efficacy of molecular targeted therapies in the treatment of HCC.
- Prevention of HCC should come from the avoidance of risk factors through vaccination for the prevention of hepatitis B and the maintenance of proper health standards and adequate lifestyle (limitation of exposure to alcohol). Antiviral therapy may cure chronic hepatitis B and C and hence prevent progression to cirrhosis and cancer.

Until very recently, it was common to consider hepatocellular carcinoma (HCC) as a cancer with a low incidence in the western world. However, recent data show that its incidence has increased in several western countries [1]. In addition, cohort studies have revealed that HCC is currently the leading cause of death in cirrhotic patients. The feasibility of early detection along with the availability of several effective therapies has permitted encouraging long-term survival after diagnosis. As a result, the interest in all aspects of diagnosis and treatment has sharply increased [2]. In that sense, it has been recognized that hepatologists play a key role in the management of patients with HCC. Hepatologists decide if HCC surveillance should be pursued in patients at risk and are responsible for disease staging and treatment indication. The most critical decision is the selection of candidates for liver transplantation and, once selected, their management before and after surgery. In some countries, mostly in Asia, even surveillance and percutaneous treatment (alcohol injection and radiofrequency ablation) are performed by hepatologists after they have received specific training to acquire the needed expertise.

In the present chapter we summarize the most relevant issues about epidemiology, diagnosis, and treatment of this neoplasm.

Epidemiology

Primary liver cancer is now the sixth most common cancer in the world and the third cause of cancer-related mortality [3]. More than half a million cases are diagnosed every year and there are major geographic differences in incidence. The annual incidence rates in eastern Asia and sub-Saharan Africa exceed 15/100,000 inhabitants, while figures are intermediate (between 5 and 15/100,000) in the Mediterranean basin and southern Europe, and very low (below 5/100,000) in northern Europe and America [1]. Vaccination against hepatitis B virus (HBV) has induced a decrease in HCC incidence in countries where this virus was highly prevalent [4], while the contrary is true in areas where viral dissemination (mostly hepatitis C virus (HCV)) has occurred in the last decades. These data suggest that the geographic heterogeneity is related

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

to differences in the exposure rate to risk factors and time of acquisition, rather than to genetic predisposition. Studies in migrant populations have demonstrated that first-generation immigrants carry with them the high incidence of HCC that is present in their native countries, but in the subsequent generations the incidence decreases [5].

The age at which HCC appears varies according to gender, geographic area, and risk factor associated with cancer development. In high-risk countries with major HBV dissemination, the mean age at diagnosis is usually below 60 years, while it is not infrequent to observe HCC in childhood, underlying the impact of viral exposures early in life [1]. In intermediate or low incidence areas most cases appear beyond 60 years of age. In all areas, males have a higher prevalence than females, the gender ratio usually ranging between 2 : 1 and 4 : 1, and in most areas female age at diagnosis is higher than in males [1].

Risk factors for HCC

Cirrhosis underlies HCC in more than 80% of affected individuals [6,7]. Thus, any agent leading to chronic liver damage and ultimately cirrhosis should be considered as a risk factor for HCC. Obviously, the major causes of cirrhosis, and hence HCC, are HBV, HCV, and alcohol, but less prevalent conditions such as hemochromatosis, primary biliary cirrhosis, nonalcoholic steatohepatitis, and Wilson disease have also been associated with HCC development. The risk within cirrhosis increases in parallel to the impairment of liver function and is higher in males, in patients older than 50 years, and in subjects with increased α-fetoprotein (AFP) concentration [6]. Pathologic characteristics such as increased proliferation, the presence of dysplastic cells, or irregular regeneration have also been proposed as useful risk markers but are not fully validated.

Hepatitis B virus

The evidence linking HBV with HCC is unquestioned [8]. Active viral replication implies a higher risk and long-standing active infection resulting in cirrhosis is the major event resulting in increased risk [9]. The incidence of HCC in inactive HBV carriers without liver cirrhosis is less than 0.3% [6]. The role of specific genotypes or mutations is not well established. HBV can be integrated into the host cellular genome and induce genetic damage. DNA integration in nontumoral cells in patients with HCC suggests that genomic integration and damage precede the development of tumor. Thus, infection with HBV may be correlated with the emergence of HCC even in the absence of liver cirrhosis. In addition, some of the HBV proteins disrupt cellular functions and may favor neoplastic transformation, induce proliferation, and impede apoptosis [8].

Interestingly, occult HBV infection may become apparent if properly investigated by molecular techniques even in the absence of serologic markers of HBV itself [10]. Identification of the HBV genome has been reported in liver tumors of patients who are HCV-positive and hepatitis B surface antigen (HBsAg)-negative in the serum. The rate of occult infection in those patients can be as high as 63% [10]. Finally, the implementation of vaccination against HBV has resulted in a significant decrease of HCC incidence [4] and this is the final proof of the importance of this virus in the genesis of this cancer.

Hepatitis C virus

The prevalence of HCV in HCC cohorts varies according to the penetration of the agent in the population of each geographic area. There is a single prospective population-based study of the risk of HCC in patients with hepatitis C [11]. This study included 12,000 men and described a 20-fold increased risk of HCC in infected individuals, this figure being very close to the estimated risk obtained in a meta-analysis of 21 case–control studies [12]. The risk is clearly related to the degree of liver damage induced by the virus. There are some case reports of healthy HCV carriers with HCC, but several cohort studies have indicated that the incidence in patients with chronic hepatitis is low (below 1%) and that the risk sharply increases once cirrhosis develops [6,13]. At that time, the annual incidence ranged between 2% and 8% [6]. In addition, once the cirrhosis is established, the risk of HCC does not disappear after a sustained response to interferon for the treatment of chronic hepatitis C [14]. Finally, despite preliminary encouraging results, long-term treatment with interferon has not been shown to be efficacious for the prevention of HCC development in chronically infected HCV patients [15,16].

Patients infected with the human immunodeficiency virus (HIV) are now effectively treated with combined regimens and, if coinfected with HCV, manifest a faster evolution to cirrhosis and thus are at risk for HCC development. In fact, liver disease and/or HCC are the major cause of death in these patients [17].

Alcohol, tobacco, and coffee

A large proportion of alcoholic cirrhotics are infected by HCV, thus the risk based on studies done before the recognition of this virus are certain to have overestimated the role of alcohol. The risk for HCC increases linearly beyond an estimated intake of 40–60 g of alcohol per day and also with the period of alcohol consumption and with the presence of coinfection with HBV or HCV [18]. Upon the development of decompensated cirrhosis, the yearly incidence increases beyond 2%. Smoking

slightly increases the oncogenic risk [19], while coffee consumption reduces the risk [20].

Pathogenesis

Active inflammation with oxidative damage is thought to be the key event leading to liver cancer, but the detailed molecular mechanisms are not known. Cumulative genetic changes occur and allow the appearance of high-grade dysplastic hepatocytes without an overt malignant phenotype, that in one third of cases may evolve into overt HCC after a follow-up of 5 years [21,22]. Intense neoangiogenic activity accompanies this transition and results in a well-known enhanced blood supply derived from the hepatic artery that permits radiologic characterization. The most frequently affected chromosomes are 1, 4, 8, 16, and 17, but none of these is abnormal in more than 60% of cases [23]. Downregulation of p53 is observed in up to 40% of cases and a G to T mutation reflects genetic damage due to aflatoxin intake.

The expression of several genes has been related to initiation, growth, and dissemination, but none of them has been strongly enough validated to become part of the decision-making process in clinical practice. Over the last few years, several groups have proposed molecular classifications of HCC based on genomic expression [24]. A recent meta-analysis has revealed that common transcriptome-based subclasses exist across different studies, supporting the idea that there is a certain commonality in the global molecular status of HCC tumors irrespective of the clinical heterogeneity [25].

Pathology

The appearance of HCC changes from the early to advanced stages [21]. It is common to use the Edmonson and Steiner criteria to grade the differentiation degree according to nuclear irregularity, hyperchromatism, and nuclear : cytoplasmic ratio. The cytoplasm shows a fine granular eosinophilia and may accumulate bile and fat, Mallory bodies, and α_1-antitrypsin globules. Fat deposition is seen in 30–40% of tumors about 1.5 cm in size and translates into increased echogenicity at ultrasonography [21]. Immunostaining can recognize numerous proteins such as cytokeratins 7, 8, 18, and 19, carcinoembryonic antigen, α-fetoprotein (AFP), and several others, and preliminary studies have suggested that the detection of glypican 3, heat-shock protein 70, clathrin heavy chain, and glutamyne synthetase may be highly specific for HCC diagnosis [26]. Malignant hepatocytes accumulate as thin (microtrabecular) or thick (macrotrabecular) layers separated by sinusoids that may contain Kupffer and stellate cells. Gross appearance may be described as expansive, infiltrative, or diffuse. The first type shows distinct margins and a surrounding reticulin pseudocapsule. No distinct margins are seen in the infiltrative type and the diffuse type corresponds to a multinodular tumor that mimics a cirrhotic liver. Usually, HCC appears as a distinct nodule of varying size that increases in size together with the development of additional tumor sites, first in the vicinity and then in separate segments. Portal vein branches are invaded and at late stages all the liver may be occupied by malignant foci and the tumor spreads outside the liver (initially in lymph nodes, and then to adrenal glands, lung, and bone). The prevalence of portal vein invasion increases together with tumor size. Less than 20% of HCC under 2 cm in diameter have microscopic vascular invasion and well-differentiated HCC without such an invasive profile and the absence of minute satellite nodules has recently been named as very early HCC or carcinoma in situ [21]. This initial lesion does not have increased vascularization and, currently, is only confidently diagnosed after resection.

Clinical manifestations

Since most HCC cases appear in the setting of cirrhosis, a major part of the findings will be undistinguishable from the clinical picture observed in patients with advanced cirrhosis. Patients may present with jaundice, ascites, encephalopathy, or bleeding due to ruptured esophageal varices. Cancer-related symptoms such as abdominal pain or constitutional syndrome (weight loss, anorexia, malaise) reflect advanced tumor stage. Acute hemoperitoneum due to ruptured HCC or bone metastases is the first symptom in a minority of cases.

Advanced HCC is associated with increased bilirubin, alkaline phosphatase, and γ-glutamyl transpeptidase; alanine aminotransferase (ALT) and aspartate aminotransferase (AST) concentration have no diagnostic value. Paraneoplastic manifestations include diarrhea or severe hypoglycemia, which in some cases are the most relevant concerns. Other manifestations include hypercalcemia, sexual changes, polymyositis, thrombophlebitis, and skin rashes.

Diagnosis and staging

Diagnosis at an advanced stage when cancer-related symptoms are present and a large mass can be recognized even by physical examination is not difficult. The development of ultrasonography has permitted the detection of HCC at an asymptomatic stage, and its incorporation into the clinical workup of patients with known

or suspected liver disease has sharply changed the diagnostic algorithm. This has prompted the establishment of early detection plans for HCC in the population at risk, namely patients with cirrhosis. The efficacy of surveillance depends on the level of risk and on the availability of effective therapy. Hence surveillance should be initiated upon the development of cirrhosis and be restricted to patients who would be treated if diagnosed with HCC. Thus, screening should be limited to Child–Pugh class A and B patients, while Child–Pugh class C patients should be evaluated for liver transplantation as HCC in them could become a contraindication [7]. There is a single randomized controlled trial of surveillance versus no surveillance [27]. It included more than 18,000 Chinese patients and showed a survival benefit following a strategy based on surveillance with AFP and ultrasound every 6 months. Several cohort studies have also shown that surveillance advances the tumor stage at diagnosis and suggest an improvement in patient survival. AFP has very low sensitivity and slight increases may also be observed in cirrhotics in the absence of malignancy [28–31]. Thus, the clinical role of AFP is none for screening and a reduced one for diagnosis, this probably being limited to patients with very advanced tumor stage in whom no treatment will be applied [7]. In these terminal patients, no imaging technique is needed after ultrasonography to confirm and stage the disease. Other tumor markers such as lectin-bound AFP [30], des-γ-carboxy-prothrombin [30], or glypican [32] have been proposed to surpass the efficacy of AFP but their clinical efficacy is yet to be unequivocally proven. All these data indicate that surveillance programs should be based on regular ultrasonography examination (Fig. 36.1).

Based on the data about tumor volume doubling time, most experts recommend cirrhotic patients should be screened by ultrasonography every 6 months; a prospective study in France has shown that shorter intervals of evaluation do not improve the performance of surveillance programs [33]. It is important to note that increased risk does not mean faster tumor progression and thus cirrhotic patients at higher risk do not require screening at shorter time periods.

Once a nodule in detect by ultrasonography, an active diagnostic workup should be initiated. However, the unequivocal diagnosis of those nodules within a cirrhotic liver represents a major clinical challenge. Biopsy is not always possible because of the location of the tumor, ascites, and clotting disorders that may impede needle insertion, and it is flawed by false-negative results due to sampling error or to the difficulties of confidently distinguishing between dysplastic changes and well-differentiated HCC. This raises the need for well-defined noninvasive criteria that would allow an accurate diagnosis based on the imaging characterization. Several groups have demonstrated that the presence of arterial uptake followed by wash-out is highly specific for HCC [34–37]. Based on this specific feature, the American Association for the Study of Liver Diseases (AASLD) published a diagnostic algorithm following the detection of a nodule by screening ultrasonography, establishing diagnosis of HCC if a nodule within a cirrhotic liver exhibits intense arterial uptake followed by washout in the venous phase [7]. In the first proposal of the algorithm, in nodules between 1 and 2 cm in diameter, two coincidental imaging techniques showing a specific vascular pattern were requested. However, external validations have demonstrated that using a single contrast-enhanced modality has an outstanding positive predictive value [35,37]. Taking into account this information, the AASLD has updated the diagnostic algorithm and a confident HCC diagnosis can now be made in nodules larger than 1 cm when the specific vascular pattern is demonstrated by dynamic magnetic resonance imaging (MRI) (the preferred imaging technique) or computed tomography (CT) [38]. Contrast-enhanced ultrasound (CEUS) is unable to distinguish HCC from other primary neoplasia such as intrahepatic cholangiocarcinoma [39], so this imaging technique should not be used as the sole diagnostic tool for noninvasive diagnosis of HCC in cirrhosis. If the nodule displays an atypical vascular pattern on imaging techniques, a biopsy should be requested and a negative result should not discard the HCC diagnosis since sensitivity of percutaneous biopsy on these small nodules may be less than 70% [35]. Finally, in those nodules <1 cm, due to the low probability of malignancy and the difficulty of imaging and histologic

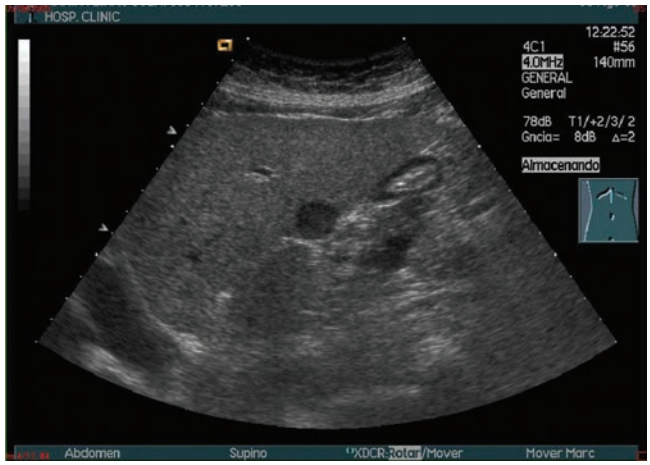

Figure 36.1 A small nodule measuring less than 20 mm detected during ultrasonography surveillance that corresponds to an early HCC site. Note its hypoechoic pattern as compared with the surrounding cirrhotic liver. This type of tumor is the target of early detection plans as it is at this stage that effective therapy (resection, transplantation, or percutaneous ablation) may provide long-term disease survival.

characterization, a close follow-up before initiating an active workup is recommended [7].

Staging of HCC should be based on expert CT or MRI [34]. Both techniques confidently detect tumors larger than 2 cm while smaller tumors pose major difficulties in being accurately characterized as benign or malignant. Angiography has currently no role in diagnosis and staging, while lipiodol CT is not reliable [7]. The detection of additional tumor sites and of vascular invasion indicates an advanced tumor stage. Extrahepatic spread is infrequent at early stages but should be ruled out by chest CT. Bone metastases are usually symptomatic and should be ruled out if needed using bone scintigraphy.

Prognostic prediction

Since cirrhosis underlies HCC in most of the patients, prognosis depends not only on tumor burden, but also on the degree of liver function impairment and the treatment received. At the same time, liver function and tumor extent determines the feasibility of treatment and all parameters should be considered in making clinical predictions [2].

Therefore, systems that only consider one dimension such as the TNM (tumor, node, metastasis) classification, the Child–Pugh score, or the model for end-stage liver disease (MELD) score, will be inaccurate. Similarly, scores that just consider general health status and physical capacity, such as the performance status or the Karnofsky index, will have reduced value. In fact, the sole usefulness of all unidimensional systems is to identify patients with very advanced disease stage and poor short-term outcome. There are several scores that combine liver function and/or tumor stage and/or physical status, but the majority just stratify patients according to expected outcome. Only the Barcelona Clinic Liver Cancer (BCLC) system considers all evolving stages and links staging with treatment indication, while recent studies have validated its usefulness [40,41]. This system was constructed years ago, taking into account the outcome data of several cohort investigations and randomized clinical trials. Patients are divided into the relevant evolutionary stages according to tumor stage, liver function, and presence of symptoms, and within each strata patients are classified using specific prognostic tools, finally linking stage to therapy [2].

Treatment

The only options that can achieve long-term cure are surgical resection, liver transplantation, and percutaneous ablation. These are effective for patients diagnosed at early stages, which represents less than 40% of patients. In those cases with more advanced disease who cannot benefit from curative therapies, there are two available treatment options that have been shown to have a positive impact on survival in well-selected candidates: transarterial chemoembolization [42] and sorafenib [43].

Treatment indication requires a careful evaluation of tumor stage, degree of liver failure, and general health. Figure 36.2 shows the BCLC staging and treatment algorithm.

Surgical treatment

There are no trials comparing resection against liver transplantation, thus the decision as to which should be the first option is highly controversial and should take into account the available resources and the survival expected by applying either approach.

Resection

Resection is usually restricted to patients with solitary tumors and is the optimal approach for patients with normal liver. Unfortunately this represents less than 5% of HCC patients in the western world, and the presence of cirrhosis heavily limits surgical resection. The selection of candidates with cirrhosis for treatment should aim at identifying those with a likely perioperative mortality of less than 1%, a transfusion rate of <10%, and a 5-year survival rate of >50%, which requires careful evaluation [44]. Allocation into Child–Pugh class A is not sufficent to identify the best candidates for resection. Studies in Barcelona have shown that measurements of portal pressure and bilirubin concentration are the best parameters for this purpose. Patients with normal bilirubin and without clinically relevant portal hypertension – defined as either a hepatic vein pressure gradient of ≥10 mmHg, esophageal varices, or splenomegaly with a platelet count of <100,000/mm^3 – will achieve 5-year survival rates of 70%, whereas this decreases to 50% in patients with portal hypertension, and to 25% in those with portal hypertension and a raised bilirubin [45]. HCC recurrence may affect more than 50% of patients at 3 years and its appearance indicates a decreased long-term survival. Early recurrence is thought to correspond to tumor spread prior to resection, while recurrence beyond 2–3 years may be due to the emergence of metachronic HCC that originated in a separate cellular clone [44]. The most powerful predictors of postoperative recurrence due to dissemination are the presence of microvascular invasion, poor differentiation, and satellite lesions. Contrarily, late recurrence is closely associated with damaged liver parenchyma ("field effect") and can be predicted by gene expression profiling [46]. Unfortunately, despite promising reports using interferon, selective radiation, adaptive immunotherapy, retinoids, and heparanase inhibitors, to

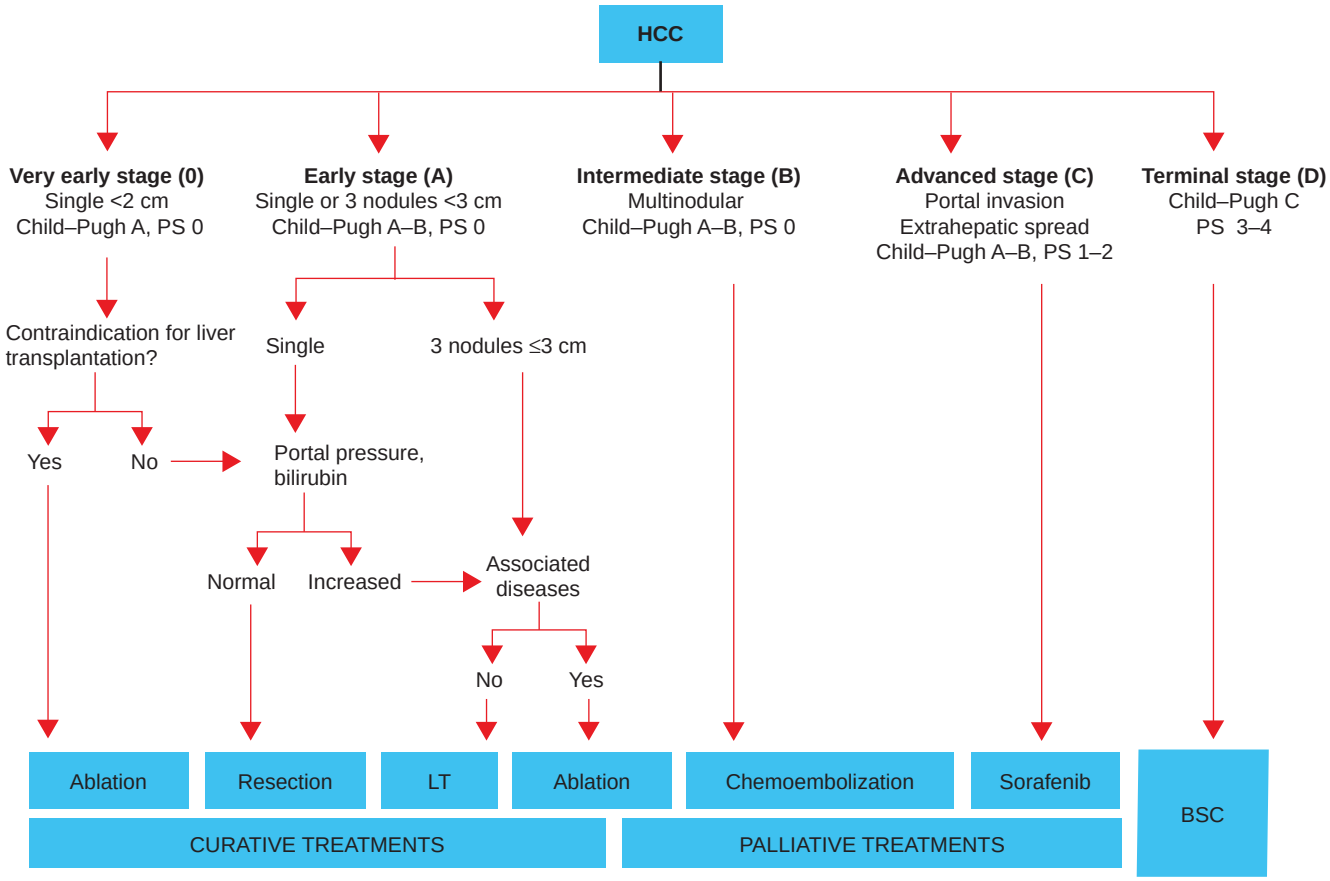

Figure 36.2 Barcelona Clinic Liver Cancer (BCLC) staging and treatment algorithm. BSC, best supportive care; HCC, hepatocellula carcinoma; LT, liver transplantation; PS, performance status. (Adapted from Forner et al. [2].)

date there is no effective method of diminishing recurrence rates after curative resection.

Transplantation

This option provides excellent outcomes if restricted to patients with early-stage disease, as defined by the Milano criteria: solitary HCC ≤5 cm or up to three nodules each measuring ≤3 cm (Fig. 36.3) [47]. The survival of patients selected according to this definition exceeds 70% at 5 years [47]. Disease recurrence is around 15% and affects mostly liver, lymph nodes, lung, and bones. Recurrence is more frequent if pathology discloses vascular invasion (macro- or microscopic) or additional tumor nests, characteristics that are highly prevalent in tumors exceeding 5 cm [48]. The main limitation for liver transplantation is the scarcity of livers. As a result, there is a waiting time between enlistment and transplantation. During this period of time the tumor may progress and impede successful therapy. Policies to prioritize patients with a high risk of exclusion because of tumor progression have been attempted but still have to be refined to insure equity between tumor and nontumor patients and to avoid the transplantation of patients with more aggressive disease and poor outcomes. Locoregional treatment such as percutaneous ablation or chemoembolization are

Figure 36.3 Explanted liver showing an HCC measuring 3 cm within a cirrhotic liver. The tumor has well-defined margins and exhibits a thin pseudocapsule. No satellite nodules are observed and the vessels appear free of invasion at macro- and microscopic examination. This pathology profile indicates a low recurrence risk during follow-up.

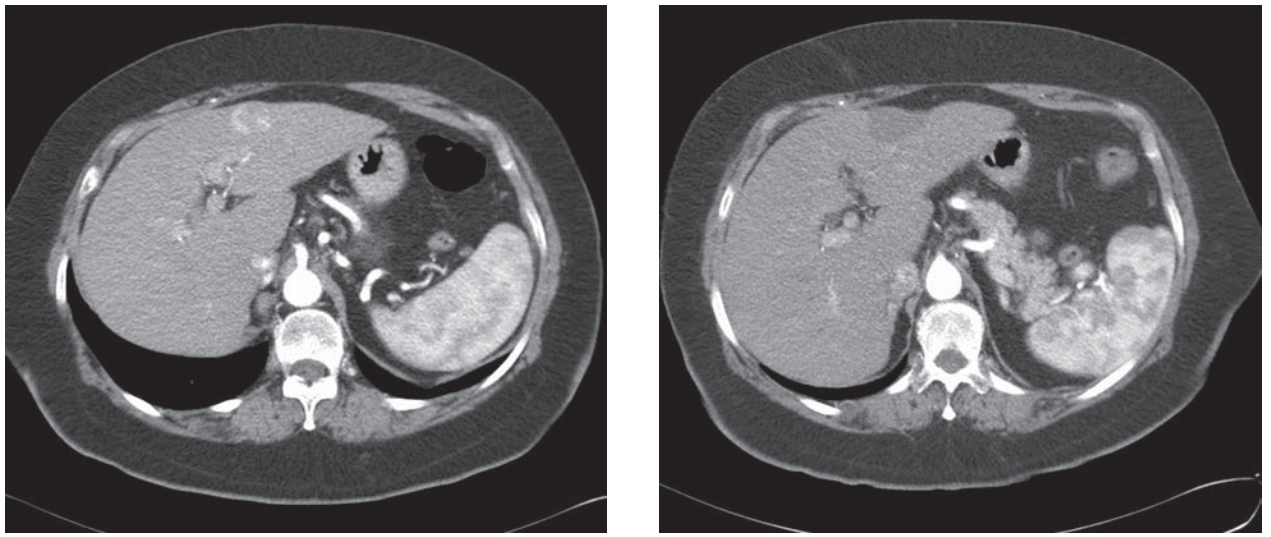

Figure 36.4 (A) Dynamic arterial CT scan showing a tumor with heterogeneous arterial vascularization located in the left lobe corresponding to a solitary HCC less than 20 mm in size. (B) Impaired liver function and associated conditions prevented resection or transplantation so the tumor was treated by percutaneous injection of ethanol. Dynamic CT evidence shows that no enhancement is present in the treated tumor, which now appears as a hypodense necrotic residual lesion.

considered when the waiting time exceeds 6 months as these techniques are able to delay tumor progression and, hence, decrease risk of exclusion [7]. The option that has raised most expectations is live donor liver transplantation. This requires a healthy donor to offer the right or left hepatic lobe to be implanted into the recipient. Donation implies a 0.5% mortality risk [49], and data from Korea suggest that outcome after live donation is very similar to that for cadaveric transplantation [50]. In recent years, several groups have reported excellent outcomes in transplantation in patients with HCC minimally exceeding the Milan criteria [48,51]. However, all these cohort studies are flawed by small sample size, short follow-up, and low applicability, and there is no reliable information regarding the impact of using the expanded criteria in the setting of scarce liver donations.

Percutaneous treatments

This is a therapeutic option that has rapidly grown during the last decade. Destruction or ablation of tumor cells can be achieved by the injection of chemical substances (ethanol, acetic acid, boiling saline) or by inserting a probe that modifies local tumor temperature (radiofrequency, microwave, laser, cryotherapy). The procedure can be done percutaneously with minimal invasiveness or during laparoscopy, and is currently considered the best option for patients with early HCC who are not candidates for surgery. Treatment is repeated on separate days and its efficacy is evaluated at 1 month by a dynamic imaging technique, where the absence of contrast uptake reflects tumor necrosis (Fig. 36.4). However, some of the tumors initially classified as having been completely necrosed present intratumoral recurrence later on, and this should be seen as treatment failure that has not been detected immediately after therapy. The recurrence rate after percutaneous ablation is similar to that seen after surgical resection and presents as separate nodules occurring nearby or in separate liver segments [52,53].

For several years, percutaneous ethanol injection (PEI) under ultrasound guidance was the optimal approach. Complete tumor necrosis is achieved in 90–100% of HCCs smaller than 2 cm in diameter [53], while success is lower in larger tumors [54]. This is due to the presence of septa that prevent the diffusion of ethanol, a limitation that does not exist for radiofrequency ablation (RFA). RFA can be performed through single or multiple cooled-tip electrodes, percutaneously, laparoscopically, or intraoperatively. Its efficacy is similar to ethanol injection in HCC <2 cm and is superior in larger lesions [55]. In addition, the number of treatment sessions is reduced, and, overall, radiofrequency has become the preferred approach. However, there are specific locations (near to the main biliary tree, abdominal organs, or heart) where the application of RFA is contraindicated because of the risk or severe complications and this still leaves ethanol as a useful option. Several randomized controlled trials (RCTs) have confirmed this superiority for the local control of tumors. Although the impact in survival is less well established, recently published meta-analyses have suggested that RFA is superior to PEI in terms of survival, particularly in nodules >2 cm [55,56]. The 3-year survival of patients treated percutaneously exceeds 50% at 5 years and it has been shown that initial response to treatment is an independent predictor of better survival [52].

Transarterial chemoembolization

Since the blood supply to HCC comes mostly through the hepatic artery, any intervention that blocks this vessel will result in tumor ischemia and necrosis to a variable extent. Obviously, the absence of portal blood flow (portal vein obstruction, portosystemic anastomosis, or hepatofugal flow) is a contraindication for the procedure, which is also not indicated in patients with extrahepatic spread. Liver function should be preserved and this limits its application to patients in Child–Pugh class A.

Hepatic artery obstruction requires an angiographic procedure with the advancement of a catheter into the hepatic artery in order to interrupt blood flow to the tumor as selectively as possible, thus limiting the injury of surrounding nontumor liver. Mere obstruction of the hepatic artery is known as transarterial or bland embolization, while if combined with prior injection of chemotherapy (doxorubicin, mitomycin, or cisplatin) the procedure is known as transarterial chemoembolization (TACE) (Fig. 36.5). There are several agents that can be used for arterial obstruction. The most common is gelfoam prepared as 1 mm cubes, but active research is underway to develop more effective obstructing agents [57]. In this regard, a relevant advance has been the development of drug-eluting beads. These are particles that are loaded with chemotherapy as well as the embolization device to deliver the drug to the tumor without initial systemic washout release. This results in higher concentrations of drug over a longer time period, reaching the tumor, with minimal systemic passage and, therefore, significantly less drug-related side effects [58,59]. The intervention is well tolerated but it is not free of side effects. The most frequent complication is the so-called "postembolization syndrome" that appears in nearly 50% of patients and consists of fever, abdominal pain, and a moderate degree of ileus. This is resolved in 48 hours and overlaps with the potential side effects of chemotherapy.

Objective responses as reflected by intratumoral necrosis and reduced tumor burden on dynamic CT scan or MRI are seen in nearly 75% of the patients [58,59]. Objective response is associated with delayed tumor progression and, as a whole, results in an improvement of survival as shown by two RCTs [60,61] and a cumulative meta-analysis [42].

In recent years, other potentially useful transarterial treatments have emerged. Radioembolization using yttrium-90 spheres stands out among them [62]. Preliminary phase II clinical trials on inoperable HCC subjects with portal vein thrombosis have shown a high tumor response rate and good clinical tolerance [63]. Despite the promising results, there are currently no conclusive data available regarding its benefits in terms of survival. It is an expensive and complex treatment, so at the moment its use is limited to experimental circumstances.

Systemic therapies: sorafenib

Conventional chemotherapy has no benefit (<10% objective responses) and is frequently associated with toxicity and hence is usually not recommended [7]. Estrogen blockade with tamoxifen has no benefit even if used at high doses, when it can also become toxic [42]. Antiandrogenic therapy is also inactive and induces hepatic

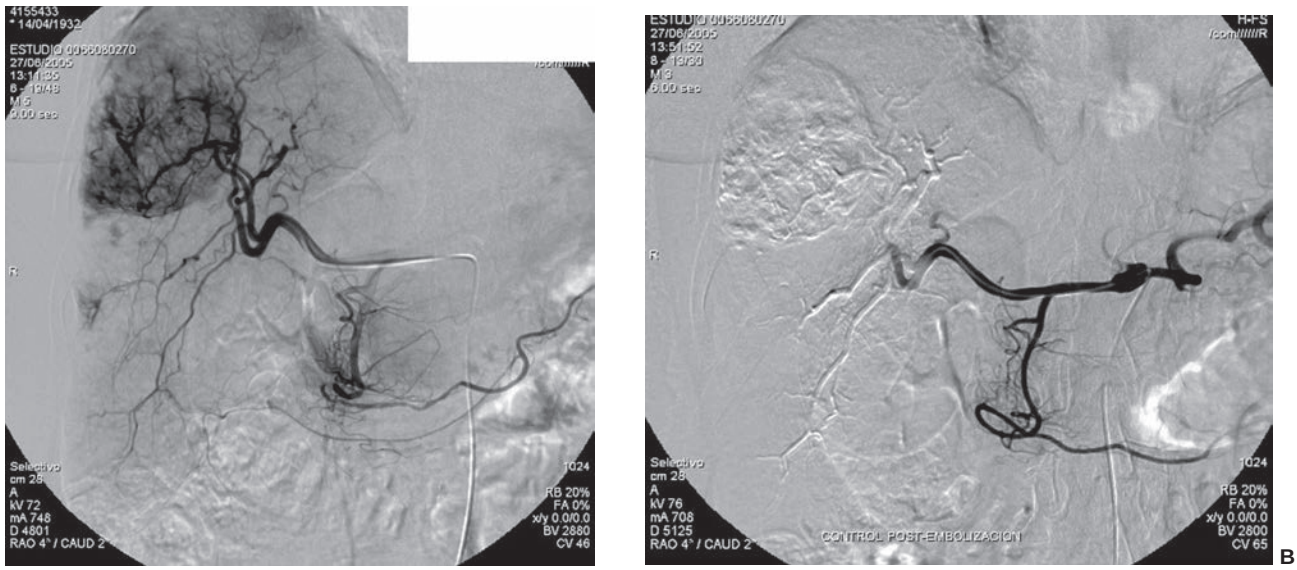

Figure 36.5 (A) Selective hepatic angiography showing a large HCC located in the right lobe. Additional sites are also recognized, and according to staging the appropriate treatment is chemoembolization. (B) After injection of chemotherapy suspended in lipiodol and arterial obstruction with gelfoam cubes, the tumor vascularization has been completely abolished. This combined therapy results in extensive tumor necrosis and improved patient survival.

toxicity that might even impair survival. Octreotide, vitamin D derivates, and interferon have also been tested with negative results [7].

Over the last few years, a great deal of progress has been made in understanding the molecular alterations that condition tumor initiation and progression [64]. This has allowed the development of several agents that act on the molecular pathways in specific ways. Several molecular treatments have been evaluated and in these studies the results are promising [65,66]. Until now, the only agent that has proven to be effective in terms of survival outcome in a phase III placebo-controlled study is sorafenib [43,67]. This is an oral, multikinase inhibitor that acts by blocking the different signaling pathways associated with hepatocarcinogenesis, especially the Raf/MEK/ERK pathway, by inhibiting Raf kinase and different tyrosine kinases (vascular endothelial growth factor receptor 2, platelet-derived growth factor receptor, and c-Kit receptors). Sorafenib basically acts by reducing angiogenesis and delaying cell proliferation. After obtaining positive results in preclinical studies [68] and in a phase II trial [69], two international, multicenter, randomized, controlled, double-blinded clinical studies were carried out. A dose of sorafenib 400 mg/12 h was compared with a placebo; both were administered to subjects with advanced HCC and compensated liver function. In both studies, sorafenib demonstrated a significant impact on survival (hazard ratio for survival compared with placebo of 0.69) and a delay of tumor progression measured by a significant increase of the time to progression (Table 36.1). The most common adverse events were diarrhea, weight loss, and hand/foot skin reaction. In most cases, the adverse events were mild and easy to manage so treatment was continued for 90% of subjects. Sorafenib has also been evaluated for treating subjects with compensated liver function (Child–Pugh grade A) but there are few data regarding its usefulness for treating Child–Pugh grade B subjects with regard to survival outcome. The pharmacokinetic profile is not significantly modified and there have been no reports of a significant increase in side effects. Therefore, the use of sorafenib in Child–Pugh grade B subjects should be evaluated on an individual basis. Contrarily, preliminary experience in Child–Pugh class C patients discourages the use of sorafenib in this population [70].

Table 36.1 Summary of the main results of the two randomized controlled trials assessing the benefit of sorafenib in advanced HCC.

	SHARP trial [50]	Asian-Pacific trial [67]
Number of patients	299 treated (303 placebo)	150 treated (76 placebo)
Median age	65 years	51 years
Liver function: Child–Pugh class A/B	95%/5%	97%/3%
BCLC stage B/C	18%/82%	4%/96%
Metastasis	51%	68%
Vascular invasion	36%	34%
PS 0–1/2	92%/8%	95%/5%
Failed previous treatment	67%	NA
Etiology of cirrhosis:		
HCV	29%	11%
HBV	19%	71%
Alcohol	26%	18%
Other	29%	NA
Response rate	DCR 43%	DCR 35%
CR/PR/SD/PD	0%/2%/71%/23%	0%/6%/54%/31%
TTP (control)	5.5 months (2.8 months)	2.8 months (1.4 months)
HR S/P (95% CI)	0.58 (0.45–0.74)	0.57 (0.42–0.79)
Median survival (control)	10.7 months (7.9 months)	6.5 months (4.2 months)
HR S/P (95% CI)	0.69 (0.55–0.87)	0.68 (0.50–0.93)

BCLC, Barcelona Clinic Liver Cancer; CI, confidence interval; CR, complete response; DCR, disease control rate; HBV, hepatitis B virus; HCV, hepatitis C virus; HR S/P, hazard ratio of sorafenib versus placebo; NA, not available; PD, progressive disease; PR, partial response; PS, performance status; SD, stable disease; TTP, time to progression.

Positive results with sorafenib provide a hope of molecular targeted therapy in HCC and open the possibility of multipathway blockade. Currently, there are several drugs, alone or in association, under evaluation as first- or second-line therapy in advanced disease or as adjuvants after surgical resection or locoregional therapies. Accordingly, in the near future we should witness a dramatic change in the therapeutic management of these patients [65].

Multiple choice questions

36.1 Which is the best treatment option for a 55-year-old patient with a history of chronic hepatitis C infection and a solitary, 4.5 cm hepatocellular carcinoma (HCC) located in segment 2 and diagnosed and staged by magnetic resonance imaging?

a Radiofrequency ablation.
b Liver transplantation.
c Surgical resection.
d Transarterial chemoembolization.
e Sorafenib.

36.2 Which statement is not correct?

a Conclusive HCC diagnosis can be done without histologic confirmation.
b AFP should not be used for the surveillance of HCC.
c The main cause of HCC worldwide is chronic HBV infection.
d Sorafenib increases survival in advanced HCC because it leads to tumor shrinkage demonstrated by dynamic imaging techniques.
e Vascular invasion and the presence of symptoms are relevant prognostic factors that usually indicate advanced disease.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 37

Surgical Options in Liver Cancers

B. Daniel Campos & Jean F. Botha

Division of Transplantation, Department of Surgery, University of Nebraska Medical Center, Omaha, NE, USA

Key concepts

- Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death worldwide. Surgical treatment (resection or transplantation) is the only form of curative treatment.
- The minority of patients with HCC are noncirrhotic; around 5% of patients are in western countries and around 40% in Asia. Nearly 75% of patients with HCC are not candidates for surgery because of advanced HCC stage or severity of underlying liver disease.
- In patients with underlying liver disease, imaging-based diagnosis of HCC can obviate the need of histologic diagnosis.
- Liver resection for HCC has good outcomes only when limited to noncirrhotic patients or patients with an early stage of cirrhosis (normal bilirubin, hepatic vein pressure gradient <10 mmHg, platelet count $>100{,}000/mm^3$).
- Liver transplantation provides the best chance of long-term survival, particularly when limited to patients who have a solitary HCC (less than 5 cm in diameter) or three or fewer tumors, none measuring more than 3 cm. The absence of vascular invasion is also associated with a better long-term prognosis.
- Preoperative ablative therapies (radiofrequency ablation, transarterial chemoembolization, percutaneous ethanol injection, etc.) are commonly performed in patients awaiting liver transplantation with the hope of improving long-term survival or preventing tumor growth while waiting. There is little evidence that these treatments are effective for either the prevention of dropout from the waiting list or improvement of long-term survival.
- Shortage of donor organs, which has traditionally limited the use of transplantation, has been partially addressed by the use of living donors. The definitive outcomes of living donor liver transplantation for HCC are still under scrutiny.
- Bile duct cancer is the second most common primary hepatic malignancy. Less than 20% of patients with hilar cholangiocarcinomas are candidates for a curative resection.
- Surgical resection is the standard of treatment. Intrahepatic tumors are treated by a partial hepatectomy, distal tumors are treated by a pancreatoduodenectomy, and hilar tumors are treated either by a hemihepatectomy or by a total hepatectomy with liver transplant if they are unresectable. Successful surgical treatment (resection or transplantation) remains the only hope for long-term survival. Surgical resection provides a 5-year survival ranging from 11% to 40% at best.
- Microscopic extension of bile duct cancer is always beyond the macroscopic margin. Superficial and submucosal infiltration often includes direct lymphatic and/or perineural invasion. A macroscopic surgical margin of at least 10 mm is recommended along with examination of frozen sections of the bile duct cut end.
- Portal vein embolization and biliary drainage are important and safe adjuncts to major hepatectomies in order to prevent liver failure.
- Liver transplantation in the setting of a rigorous protocol of neoadjuvant chemoradiation therapy has demonstrated a 5-year survival of 82% with a 5-year recurrence rate of 12%; which compares favorably with any other form of treatment for bile duct cancer.

The present chapter contains a detailed review of the variety of surgical options currently available to treat hepatocellular carcinoma (HCC) and cholangiocarcinoma (CC).

Hepatocellular carcinoma

Liver cancer, primarily HCC, is the third leading cause of death from cancer worldwide and the ninth leading cause of cancer deaths in the United States. Chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections account for an estimated 80% of global HCC cases [1]. In the continued absence of effective nonsurgical means for either prevention or treatment of HCC, surgery remains the mainstay of cure. Although resection has long been advocated as the first choice for those patients whose general condition, degree of liver dysfunction, and total tumor burden allow it, patients with underlying chronic liver disease face a lifetime risk of developing additional malignancies in the diseased liver left behind. In this

subset of patients, liver transplantation is currently viewed as the most effective form of treatment. Its application is tempered by an insufficient donor pool, the risks of lifetime immunosupression, and a high recurrence rate of hepatitis for those with chronic HCV.

Preoperative assessment

The outcome of patients with HCC undergoing surgical treatment is dependent on four major factors: (i) tumor grade and stage; (ii) severity of underlying liver disease; (iii) ability of the patient to withstand the treatment; and (iv) the proposed intervention. On the basis of an assessment of these factors, almost 80% of patients with HCC will be excluded from curative surgery (liver resection or transplantation) [2]. Patients deemed to have tumors not suitable for surgical treatment are offered one or more of the increasing number of available palliative therapies.

The need to establish a preoperative histologic diagnosis of HCC is controversial to some extent. It is generally agreed that in patients with evidence of cirrhosis, a definitive diagnosis of HCC can be made without tissue analysis in case of nodules >2 cm with a characteristic pattern on either computed tomography (CT) or magnetic resonance imaging (MRI) (hypervascularity in the arterial phase and washout in the early or delayed venous phase). Two concordant imaging techniques (triphasic CT and MRI) are needed to ascertain HCC in cases of nodules between 1 and 2 cm [3]. Biopsy is needed for making a diagnosis of HCC in patients with cirrhosis with nodules that do not fulfill the above criteria. Image-guided percutaneous needle biopsy is the most common approach to obtain tissue for histologic diagnosis despite evidence that aspiration cytology is both more accurate and more sensitive than standard histology [4]. The incidence of needle tract seeding is <2% in the largest series [5,6]. Multiple reports of late recurrences of HCC in subcutaneous tissue illustrate the risk associated with percutaneous needle biopsy [7,8].

Standard preoperative workup should include: complete blood count, comprehensive metabolic panel, coagulatory parameters, ultrasonography of the liver, and CT scan of the abdomen, pelvis, and thorax. Suspicious lesions found during metastatic evaluation should be biopsied using percutaneous techniques. Histologic documentation of extrahepatic disease obviates curative resection and is considered a contraindication to transplantation. Liver surgery inflicts significant physiologic stress on the patient. Patients should be carefully evaluated for possible cardiac disease with a screening electrocardiogram (ECG) and a careful evaluation of the patient's level of activity. Hepatic resection carries a high risk for cardiac events according to the classifications presented by Eagle and Boucher [9]. Further cardiac evaluations are usually required in patients with risk factors for coronary artery disease. Patients with unstable coronary syndromes, decompensated congestive heart failure, significant arrhythmias, or severe valvular disease often require extensive cardiac workup, medical management, and, potentially, cardiac surgery prior to hepatic resection. Patients with a known history of pulmonary disease should be evaluated with preoperative pulmonary function tests and an arterial blood gas.

Liver resection

Surgical resection for HCC is carried out with a curative intent. The minority of patients with HCC are noncirrhotic; around 5% of patients are in western countries and around 40% in Asia. In these patients, partial liver resection is without question the treatment of choice. The overwhelming majority of patients with HCC have different stages of cirrhosis, which makes the decision algorithm for resection far less straightforward. Despite the fact that any degree of portal hypertension along with hepatocellular dysfunction negatively impact on the outcome of resection, most experts would agree that patients with Child–Pugh class A cirrhosis, normal bilirubin, and minimal portal hypertension (e.g., platelet count $>100{,}000/mm^3$ and/or hepatic venous pressure gradient <10 mmHg) are excellent candidates for resection. This selected group of patients has almost no risk for postoperative liver failure and may achieve a 5-year survival of around 70%. The survival of those subjects with both adverse predictors (portal hypertension and elevated bilirubin) is less than 30% at 5 years, regardless of their Child–Pugh stage [10].

Improved patient selection in conjunction with advances in operative techniques and perioperative management have decreased the operative morbidity and mortality in patients undergoing liver resections. There is a large variation in survival, mortality, and recurrence rate following liver resections for HCC due to the lack of uniform definitions in the different series published. Table 37.1 presents the results of a number of published series of liver resection for HCC in the last two decades [11–24]. A recently published meta-analysis of the surgical outcomes of liver resections for the treatment of HCC reported a median perioperative (30 day in-hospital) mortality rate of 4.7%, median 1-, 3-, and 5-year overall survival rates of 80.1%, 55%, and 37.1%, respectively, and disease-free survivals of 64%, 38%, and 27% in the same time intervals [25]. Unfortunately, long-term survival is negatively affected by an overall tumor recurrence rate of well over 50%. Recurrence may occur in the liver or at extrahepatic sites. Recurrence occurs not only because of the biologic behavior of the tumor, but also because the remnant liver still has premalignant potential, with HCV-positive patients being at particular risk [26].

TACE, transarterial chemoembolization.

Tumor size appears not to be a mayor barrier to resection provided the tumor is circumscribed. Patients that have multiple tumors are not ideal candidates for resection due to the presence of intrahepatic metastasis. Macroscopic vascular invasion is a strong risk factor for recurrence; however, in selected cases with normal liver function, no portal hypertension, and with a unilateral intraportal tumor that does not completely occlude the bifurcation, resection and portal tumor extraction can be achieved with acceptable long-term survival [27].

The type of resection performed is dictated by the size and location of the tumor. Resections are usually segmental or lobar. Most commonly, a bilateral subcostal incision is used. Initial exploration of the abdomen should rule out extrahepatic disease. The arterial anatomy of the liver should be assessed to identify aberrant left or replaced right hepatic arteries. After the liver is mobilized, resectability of the tumor should be confirmed. The use of intraoperative ultrasound may give the surgeon information about the proximity of the tumor to hepatic veins and portal vessels. It also provides further assurance that no previously unidentified lesions are present in the liver. Traditionally, the hilar structures (hepatic artery, portal vein, and bile duct) leading to the lobe or segment(s) to be resected are identified and individually ligated prior to the parenchymal dissection. A Pringle maneuver may be used to occlude the inflow during the parenchymal division to minimize blood loss. Inflow can be occluded for up to 60 minutes continuously or intermittently. An alternative approach is total vascular exclusion where the vena cava is isolated above and below the liver and a soft vascular clamp is placed across the hilum of the liver prior to parenchymal division. This technique is useful for segmental and lobar resections. Patients who do not tolerate the lack of venous return may be supported with veno-veno bypass. All patients undergoing a hepatic resection should have blood products available for the operating room. We do not routinely use autologous shed blood recovery techniques when resecting malignancies in the liver. Patients with liver disease and prolonged prothrombin times should receive fresh frozen plasma (FFP) to correct the coagulopathy early in the surgery. Midorikawa et al. advocate the use of FFP routinely, both in the operating room and postoperatively, in all hepatic resections [28].

Prognostic assessment

Prognostic risk factors for intra- and extrahepatic recurrence after resection for HCC have been extensively studied and reported; the conventional pathologic features of HCC tumors are the most widely cited in the literature. Tumor size, gross or microscopic tumor involvement at the resection margin, tumor grade, macro- and microscopic vascular invasion, multiple tumors or satellite lesions, and α-fetoprotein (AFP) levels have all being

Table 37.2 Child–Pugh score.

Criterion	1 point	2 points	3 points

Serum albumin (g/dL)	>3.5	3–3.5	<3
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	Minimal	Advanced
INR	<1.7	1.7–2.3	>2.3

5–6 points, Child–Pugh class A; 7–9 points, class B; 10–15 points, class C; INR, international normalized ratio.

shown to predict recurrence and therefore negatively impact the outcome after surgical treatment [29]

The risk of liver failure after surgical resection has been less easy to predict. Numerous tests and formulas to calculate liver function have been proposed but there is no uniformly accepted method to assess functional hepatic reserve. The bromsulfophthalein retention test, the ^{14}C-aminopyrine breath test, the indocyanine green (ICG) clearance test, and the monoethylglycinexylidide (MEGX) test are a few examples of these. The ICG clearance test is the most widely used test (particularly in Japan). ICG is actively and solely removed from plasma by the liver. Clearance of ICG is considered to be impaired when 15% or more of the dye remains within the plasma 15 minutes after intravenous injection. Patients with HCC most often have cirrhosis, and it therefore comes as no surprise that liver failure after resection is a major cause of morbidity and mortality. Bruix et al. showed that the presence of portal hypertension, defined as a wedged hepatic vein to portal vein pressure gradient of greater than 10 mmHg, is associated with hepatic decompensation in up to 60% of patients with Child–Pugh class A cirrhosis after liver resection [30].

The Child–Pugh score is the first and most established predictive system. It is universally used to classify the degree of liver dysfunction (Table 37.2). This score was originally developed to predict the survival of patients with cirrhosis and variceal hemorrhage undergoing portocaval shunts. Numerous studies have failed to confirm its value in predicting morbidity and mortality after liver resection.

It is evident that current pathologic staging for HCC (pTNM) does not correlate with survival outcomes, mainly due to the fact that it does not take into account the severity of the underlying cirrhosis or the residual liver function. The TNM system was revised in 2002 and the new version has been demonstrated to be more accurate [31,32]. However, a recent Japanese cohort of over 900 patients failed to identify a correlation between their survival figures determined by Kaplan–Meyer analysis and those according to TNM staging and Child–Pugh classification [33]. Iwatsuki et al. reviewed a series of over 300 patients surgically treated for HCC [34]. They analyzed a number of clinical and pathologic variables to predict the risk of recurrence. Based on multivariate analysis they identified the following as risk factors of recurrence: bilobar distribution, tumor size either 2–5 cm or >5 cm, micro- and macrovascular invasion, and more than three tumors. A prognostic risk score (PRS) was calculated for each patient based the summation of each variable's relative risk of recurrence. This PRS system correlated extremely well with disease-free survival (Table 37.3) [34].

Table 37.3 Risk factors and prognostic risk score (PRS) for disease-free survival following liver transplantation for hepatocellular carcinoma. (a) Multivariate analysis of risk factors. (b) PRS and 5-year disease-free survival.

(a)			(b)					
Variable	**RR**	**95% CI**		**Grade 1**	**Grade 2**	**Grade 3**	**Grade 4**	**Grade 5**
Bilobar tumor	3.1	1.7, 5.4	PRS[a]	<7.5	7.5–11	11–15	15	LN, DM
Tumor size:			5-year disease-free survival (%)	100	61	40	5	0
2–5 cm	4.5	1.5, 13.0						
5 cm	6.7	2.2, 19.9						
Vascular invasion:								
Micro	4.4	2.1, 9.5						
Macro	15.0	6.7, 33.8						

CI, confidence interval; RR, relative risk.

[a]The PRS was calculated based on the addition of the relative risk of recurrence (based on multivariate analysis) identified for: bilobar distribution, tumor size 2–5 or >5 cm, and micro- and macrovascular invasion.

LN, lymph node; DM, distal metastasis.

From Iwatsuki et al. [34].

Many other prognostic staging systems have been developed in the last two decades: the Okuda staging system [35], Cancer of Liver Italian Program (CLIP) [36], Barcelona Clinic Liver Cancer (BCLC) [37], Groupe d'Etude du Treatment du Carcinome Hepatocellulaire (GRETCH) [38], Chinese University Prognostic System (CUPI), and Japan Integrated Staging Score (JIS) [39]. The Okuda staging system was developed in 1985. It is the first staging system to take into account variables related to liver function and tumor size on imaging or surgery. However, it failed to include important variables strongly associated with recurrence such as vascular invasion. It has been proven to be inaccurate for patients with early HCC. The BCLC system derived from the results of surgical treatment of early HCC and the natural history of untreated HCC. Several groups have validated it [41–43]. The CLIP uses four variables: the Child–Pugh score, tumor morphology, serum AFP level, and portal vein invasion. It appears likely that its broad inclusion criteria will reduce its value in cases of early HCC. The CUPI was based mainly on HBV-associated patients but only 10% of the patients received curative treatment. It appears to be complex and yet to be validated. The GRETCH system included mainly patients with alcoholic liver disease. Its validation in well debated [44]. The JIS system was proposed by Kudo et al. and combines the Child–Pugh score and the modified TNM classification according to the Liver Cancer Study Group of Japan (LCSGJ) [39]. This system is more suitable for patients with early HCC, and a recently modified JIS system proposed by Nanashima et al. was shown to be useful for predicting the prognosis of patients receiving resection [45].

The number of staging systems emphasizes the difficulty in adequately stratifying HCC based on different clinical, pathologic, and biochemical variables and produce a universally accepted system that reliably predicts survival outcomes of the current forms of treatment. It remains controversial as to which of these systems is best for staging HCC. It appears to this date that we do not have an adequate test to predict liver failure nor we have a staging system that reliably predicts outcomes after resection. No single test offers a better prediction of postoperative liver failure than the Child–Pugh score in conjunction with the judgment of an experienced liver surgeon.

In order to improve the outcomes of liver resection for HCC other adjuncts to resection have been theorized and studied. To date, preoperative chemoembolization of the tumor offers no benefit. The same is true for the general use of portal vein embolization of the hepatic lobe hosting the tumor to induce compensatory liver growth and to improve functional capacity in the nonaffected lobe prior to resection [46–48]. Additionally, there is no proven effective adjuvant postoperative therapy that can reduce recurrence rates.

Liver transplantation

The first patient to survive liver transplantation for more than a year was a child with HCC. Foreshadowing the failure of attempts to cure liver cancer reliably with total hepatectomy, the patient died with recurrent tumor 400 days following transplantation. The collected experience during the last two decades highlights a progression of improving outcomes. Today, total hepatectomy with transplantation is regarded as the best alternative for treating HCC in the cirrhotic patient. Liver transplantation removes the diseased liver, which is often associated with HCC, providing the widest surgical margins, which translates into the best survival outcomes and the lowest risk of recurrence.

In 1983, a National Institutes of Health consensus development conference endorsed the use of liver transplantation for the treatment of selected patients with HCC. As liver transplant centers proliferated throughout North America and Europe, wider experience underscored a serious concern. Although providing a chance for cure to patients with no other alternatives, when compared with the results for transplantation in the treatment of other liver diseases, the long-term survival probability for patients who underwent transplantation for HCC was disappointing in most and unacceptable in others. Five-year survival rates reported between 1985 and 1989 from three leading transplant centers were 25–40% [49–51]. In 1991, Penn, relying on data submitted by numerous transplant centers to the Transplant Tumor Registry, reported that the overall 5-year survival observed was 18%. These reports arrived at a time when the shortage of donor livers was beginning to drive waiting times for most patients beyond the 1-year mark, leading to an alarming increase in the risk of death for waiting candidates. With 5-year survival probabilities for other types of liver transplant recipients reportedly in excess of 80–85%, advocates for providing liver transplantation to patients with HCC were obliged to improve their results.

One approach involved better patient selection through examination of retrospective information about tumor staging and histologic grade. Others included a variety of pre- and post-transplant treatment regimens designed to lessen the risk of recurrence. Early reports suggested, and subsequent experience has confirmed, that the most favorable results are obtained in patients with so-called incidental HCC. In the experience reported by Iwatsuki et al. in 1991, no patients in this category experienced recurrence of tumor during the follow-up period [11]. The same report, as well as data from other authors, has confirmed that among patients with known HCC, those with small tumors fare better than those with larger

Box 37.1 Transplantation eligibility criteria for cirrhotic patients with hepatocellula carcinoma (HCC): the Milan criteria and University of California at San Francisco (UCSF) expanded criteria.

Milan criteria

- Largest HCC tumor: ≤5 cm *or*
- Multiple HCC tumors: ≤3 tumors none larger than 3 cm

USCS expanded criteria

- Largest HCC tumor: ≤6.5 cm *or*
- Multiple HCC tumors: ≤3 tumors none larger than 4.5 cm[a]

[a]Sum of the diameter of these tumors to less than 8 cm.

ones. Remarkably, in 1996, Mazzaferro et al. from Milan reported a randomized controlled study demonstrating that restricting liver transplantation to patients diagnosed with a single tumor less than 5 cm in diameter or two to three tumors less than 3 cm in diameter by radiologic standards prior to transplantation resulted in a 4-year overall survival of 75%, a recurrence-free survival of 92%, and a overall recurrence rate of 8% [52]. Other groups around the world have reproduced these results [53–55]. In the United States, the United Network for Organ Sharing (UNOS) has adopted the so-called Milan criteria (Box 37.1) for the allocation of organs.

In 2002, the model of end-stage liver disease (MELD) system was implemented in the United States. Livers from cadaveric donors are now allocated according to a patient's score that is based on their international normalized ratio (INR), creatinine level, and bilirubin level. Patients with HCC usually do not have decompensation of their cirrhotic state so the transplant community decided to implement a separate point system that would provide HCC patients access to organs before their disease progressed beyond the point where they were eligible for transplantation. The Milan criteria have been used to define which patients are eligible for liver transplantation. Documentation of the presence of tumor is through imaging and a positive biopsy, an AFP of more than 200 ng/mL, or previous ablative therapy of the lesion. Points are assigned on the basis of prediction of survival for patients with stage I and II disease. With the introduction of the MELD system for liver allocation in adult patients who underwent transplant, the incidence of transplantation for HCC has risen dramatically. In 2001, 2.8% of liver transplants in the United States were for a diagnosis of HCC with or without cirrhosis, and this rose to 7% in 2004. Since the origination of the MELD system, the point allocation for patients with HCC has been adjusted and currently only patients with stage II disease are eligible for point upgrades. Patient survival rates after liver transplantation for HCC are acceptable, with the 5-year survival being 61.1% in a review of patients transplanted between 1996 and 2001. This rate is lower than that for patients transplanted without HCC (5-year survival approximately 70%), but remains acceptable [54].

Expanding the transplantation criteria

The Barcelona group [56], The University of California at San Francisco (UCSF) group [57], and others have presented proposals for the expansion of the Milan criteria. None of these proposals are backed by rigorous prospective randomized data and their application has been a matter of debate [58,59]. The most common and studied proposal is the UCSF expanded criteria, which allows transplantation of patients with one tumor 6.5 cm or three or less tumors less than 4.5 cm, with the sum of the diameter of these tumors to be less than 8 cm, without compromising patient survival (Box 37.1) [59,60]. Multiple other studies have reproduced the UCSF results [60,61]. The largest retrospective review of HCC patients treated by liver transplantation published by the University of California at Los Angeles has validated the UCSF expanded criteria. In this report, patients meeting the Milan criteria had similar 5-year post-transplant survival compared to patients meeting the UCSF criteria by preoperative imaging and explant pathology [62].

The majority of patients within the UCSF criteria are also within the Milan criteria. The same group in Milan has recently published retrospective data regarding outcome in 1,112 patients exceeding the original Milan criteria. In this study, a 71.2% 5-year overall survival was achieved using expanded criteria (HCC with 7 as the sum of the size of the largest tumor (in centimeters) plus the number of tumors) [63]. This modest expansion of the Milan criteria does not appear to negatively impact post-transplant survival; however it only translates into a net increase of less than 10% to the potential recipient pool over conventional Milan transplant criteria. The true impact on the remainder of the waiting list is unknown and the broader application of expanded criteria is not yet accepted.

Salvage transplantation

Most agree that the best treatment strategy for small HCC, even in patients with preserved liver function (Child–Pugh class A), is liver transplantation. Some authors believe that small and resectable HCCs with preserved hepatic function should undergo liver resection as the first-line treatment, reserving transplantation in the event of HCC recurrence (salvage transplantation). This approach is a reasonable option in terms of saving valuable donated organs and sparing some patients from the burdens and risks associated with transplantation and immunosupression. However, this approach

seems to result in higher recurrence and decreased survival when compared with primary liver transplantation [64,65]. On average, only one out of five patients who undergoes liver resection for HCC will receive a "salvage" liver transplant, as reported by the transplantability rates of the groups in Spain, Italy, and France 16.2%, 21.2%, and 25%, respectively [66].

Living donor liver transplantation

Treatment of HCC with liver transplantation is limited by the availability of deceased donor liver grafts, particularly in Asia, where the rate of deceased donors is negligible (five donors per 1 million population compared to 10–35 per 1 million in western countries). Living donor liver transplantation (LDLT) has been increasingly used to treat hepatic tumors worldwide in recent years, and is currently the most effective alternative to deceased donor liver transplantation to overcome the problem of organ shortage. The indications for LDLT are not clearly outlined. Most groups agree that if a HCC patient meets conventional Milan criteria and cannot undergo liver resection because of poor liver function, and a cadaveric graft is not available within 6 months, LDLT may be selected. The benefits of LDLT for HCC are clear in terms of eliminating the waiting list time and therefore preventing tumor progression and dropout from the waiting list. The results from LDLT appear to show good long-term survival rates with retrospective studies showing comparable rates to orthotopic liver transplantation (OLT). Using a statistical decision analysis technique that considered a cohort of hypothetical patients with compensated Child–Pugh A cirrhosis and an unresectable 3.5 cm HCC, Cheng et al. satisfied themselves that live donor adult-to-adult liver transplantation offered a 4.5-year increase in tumor-free survival as compared with waiting for cadaveric donor liver transplantation or no transplant. The advantage persisted in their model even in the face of varying severity of cirrhosis, age, tumor doubling time, tumor growth pattern, blood type, regional transplant volume, initial tumor size, and rate of progression of cirrhosis [67]. A similar experience was reported by the Mount Sinai Hospital during the period from 1998 to 2001, where the average waiting time for a deceased donor was 414 days as compared with 83 days for a living donor. They also proposed that HCC is an ideal indication for LDLT [68]. There are, however, a number of published retrospective studies that show a higher rate of tumor recurrence in LDLT than with conventional OLT [69–71]. The reasons for this are not entirely elucidated. A multicenter adult-to-adult LDLT study reported a statistically significant higher HCC recurrence rate after LDLT versus deceased donor liver transplantation [72–74]. More studies are needed to better define the role of LRLT for HCC. Another concern for the application of LDLT are the morbidity (14–21%) and mortality (0.25–1%) associated with donor hepatectomy. Recently, and despite its smaller size, the use of left lobe grafts with surgical portal inflow modulation has demonstrated enhanced donor safety with comparable outcomes [75,76].

Adjunctive therapy

The most common pattern of recurrence for HCC following liver transplantation is a multifocal spread in the newly transplanted liver. Kar and Carr showed that patients with HCC can have as many as 1 billion tumor cells in the systemic circulation each day [77]. It was speculated then that efforts directed at circulating tumor cells might effectively reduce the risk of recurrence. Therefore, the use of pretransplant adjunctive therapies has received widespread attention during the last decades; particularly because most transplant programs are reluctant to simply observe cirrhotic patients with HCC while they await transplantation because of the latent risk of disease progression and dropout from the waiting list.

Pretransplant neoadjuvant therapy in the form of radiofrequency ablation (RFA), transarterial chemoembolization (TACE), and percutaneous ethanol injection (PEI) is often recommended to patients with HCC and cirrhosis awaiting liver transplantation. Neoadjuvant therapy has three potential benefits: (i) to down-size existing tumors that are bigger than the Milan criteria, thus expanding the transplantability of some patients; (ii) halting disease progression and thus preventing dropout while on the transplant list; and (iii) potentially providing a survival benefit after transplant. Single-center studies have documented advantages for pretransplantation TACE [78,79] and RFA [80] in minimizing waiting list dropout rates. In 2006, an evidence-based review of all the available literature to that date concluded that TACE as a bridge to liver transplantation did not improve long-term survival nor decreased dropout rates on the waiting list [81]. More recently, however, Freeman et al. have shown a survival benefit after transplantation for patients receiving pretransplant locoregional therapy [82].

Downstaging hepatocellular carcinoma

Early in the experience with TACE, prior to liver transplantation and in nonrandomized applications, several authors believed they had obtained improved survival. In 1997, Majno et al. from Paris, found a benefit for disease-free survival in those patients who responded to TACE (50% reduction in size) prior to liver transplantation compared with those who did not [78]. More recent studies, though, have not shown a significant survival advantage to patients undergoing TACE and liver transplantation [83,84]. Effectively downstaging tumors that are beyond the Milan criteria is emerging as a viable alternative to simply expanding the transplantation criteria. A

review of the UNOS database examined 1,377 histology reports from explanted livers and indicated that pretransplantation ablation treatment resulted in markedly more cases being downstaged than cases where no ablation was given, with TACE being more effective than RFA [85]. The UCSF group have recently reported excellent outcomes after liver transplantation in a strictly selected group of patients beyond the Milan criteria who were primarily downstaged by laparoscopic RFA and/or TACE. Tumor downstaging was successful in 70.5% of the patients. Survival rates at 1 and 4 years were 96.2% and 92.1%, respectively. No patient had HCC recurrence after a median follow-up of 25 months. Treatment failed in 29.5% mainly due to tumor progression. The authors inferred that successful downstaging dissects out those tumors with a more aggressive biologic behavior based on their progression despite treatment [86,87]. Pretransplantation neoadjuvant treatments remain an option for downstaging HCC tumors despite the absence of randomized data.

Most patients with HCC are not candidates for hepatic resection or transplantation. This is because of multifocal intrahepatic disease, extrahepatic disease, inadequate functional reserve, or involvement of the portal vein bifurcation. For these reasons, several techniques have been developed in order to provide therapeutic/palliative options for this subgroup of patients with HCC. Treatment modalities include systemic and regional chemotherapy, percutaneous ethanol or acetic acid injection, and cryotherapy and thermal ablative techniques such as laser, microwave, and RFA; most of these ablative therapies are applied percutaneously. It is not unusual to perform RFA or cryotherapy through laparotomy or laparoscopy. A detailed discussion of these techniques, indications, and outcomes escapes the scope of this chapter.

Cholangiocarcinoma

Bile duct cancer is the second most common primary hepatic malignancy. It is a slow growing and a highly aggressive malignancy difficult to diagnose in the early stage. Most patients with bile duct cancer have developed jaundice at presentation, and the tumor stage is already well advanced. Not surprisingly, less than 20% of patients with hilar cholangiocarcinomas are amenable to a potential curative resection. Successful surgical treatment remains the only hope for long-term survival. Those fortunate enough to undergo surgical resection have a 5-year survival ranging from 11% to 40%.

A detailed anatomic definition is necessary before discussing the role of surgical treatment in the management of bile duct cancer. Cholangiocarcinomas are divided into intrahepatic (5–10% of all cholangiocarcinomas) and

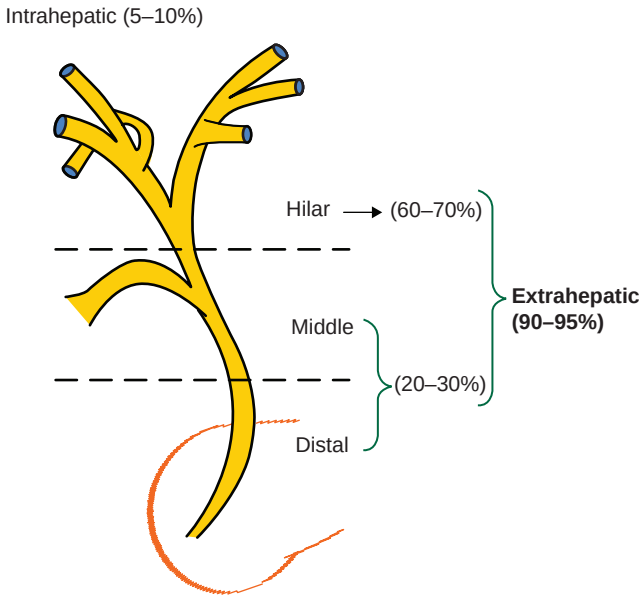

Figure 37.1 Distribution of bile duct cancer in the biliary tree.

extrahepatic (Fig. 37.1) Intrahepatic cholangiocarcinoma is treated as a hepatic tumor, because it requires liver resection alone. The surgical treatment of extrahepatic bile duct cancer is complex and depends on its location along the bile duct tree (hilar, middle, and distal bile duct cancer). Surgical resection by means of pancreatoduodenectomy is the choice of surgical treatment for middle and distal cholangiocarcinomas (20–30% of all bile duct cancers). Tumors arising high in the biliary tract above the cystic duct, in the territory of the confluence of the bile ducts (hilium), have been historically referred as hilar or perihilar cholangiocarcinomas or, if right at the confluence, Klatskin tumors. They represent approximately 60–70% of all cholangiocarcinomas. Determining resectability of these tumors is best guided by the Bismuth–Corlette classification (Fig. 37.2) [88,89]. Cholangiocarcinomas type I, II, and III are generally considered resectable by means of an extended hemihepatectomy. A type IV tumor, involving both sides of the bile duct confluence, is best resected by a total hepatectomy and could be considered an indication for liver transplantation.

Preoperative biliary drainage and portal vein embolization

Portal vein embolization has been used in the preoperative period in order to prevent liver failure after extended hemihepatectomy in patients with hilar cholangiocarcinoma [90]. Resecting a major portion of the liver results in a concomitant increase in the portal vein pressure. Excessive portal vein pressure can be detrimental to the function of a small remnant liver. Portal vein embolization can theoretically reduce the degree of portal

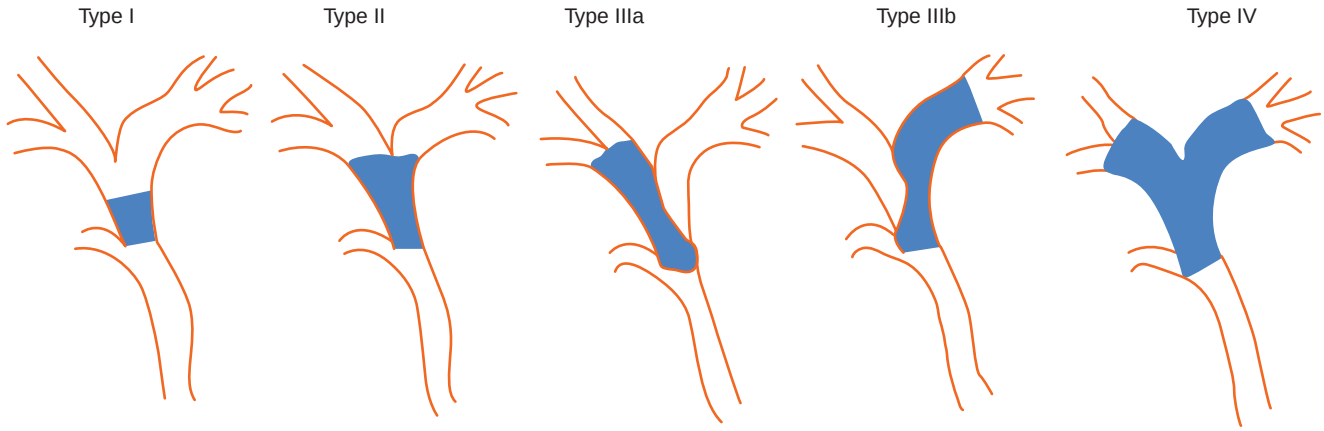

Figure 37.2 Modified Bismuth–Corlette classification of hilar cholangiocarcinomas. (Reproduced from Bismuth [82] with permission from Lippincott Williams and Wilkins.)

hypertensive damage and also improve the rate of liver volume loss due to the atrophy–hypertrophy theory. Kubota et al. delineated indication criteria for portal vein embolization according to the volume of liver to be resected [91]. Several recent reports have confirmed the safety of major hepatectomy following portal vein embolization [91–93]. The rate of liver volume to be preserved increased by 8–12% 2 weeks after portal vein embolization [94,95].

Preoperative biliary drainage aims to improve liver function and reduce morbidity and mortality after surgery. A major hepatectomy in a severely cholestatic liver (jaundiced patient) with a hilar cholangiocarcinoma is a set up for the development of postoperative liver failure. Multiple studies from Japan recommend that radical surgery be performed after complete recovery of liver function from cholestasis, which usually takes 4–6 weeks with a functioning biliary drain (bilirubin <2.0 mg/dL) [92–94]. Figure 37.3 shows a protocol for portal vein embolization and percutaneous biliary drainage in the management of hilar cholangiocarcinoma prior to surgical resection.

Many reports have emphasized the adverse effects of biliary drainage, i.e. infectious complications due to bile contamination and tract seeding [96–98]. A meta-analysis conducted by Sewnath et al. failed to show a definitive benefit of biliary drainage prior to surgery [99]. However, the rate of resection in the randomized controlled studies analyzed was only 15% on average, and pancreaticoduodenectomy composed nearly 90% of resected cases and hemihepatectomy only 2%. Strictly discussing biliary drainage in the treatment of hilar cholangiocarcinoma by a hemihepatectomy appears to our eyes to be a separate topic of discussion.

Particular attention has been given to bile contamination and suppurative cholangitis and its relation to postoperative infectious complications. We believe that

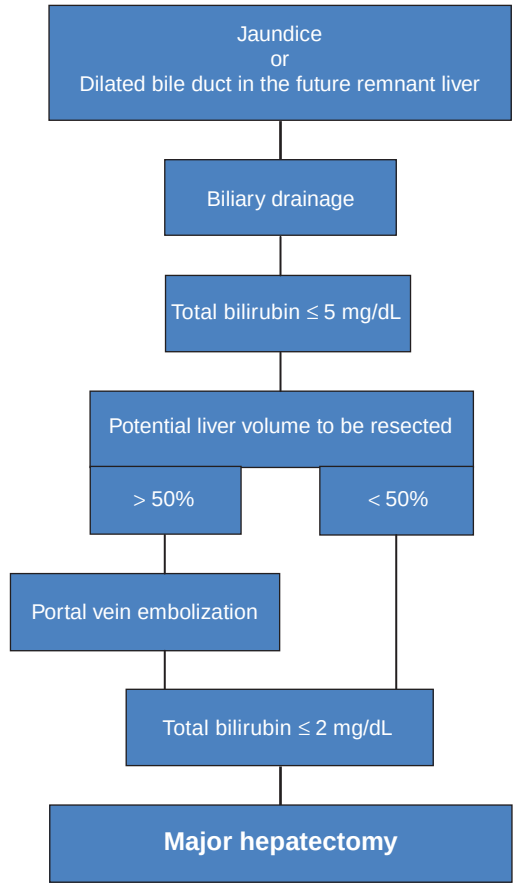

Figure 37.3 Protocol for percutaneous biliary drainage and portal vein embolization in the management of hilar cholangiocarcinoma prior to surgical resection.

infectious complications related to a biliary drain are, in the majority of cases, related to inadequate drain care, drainage tube failure, and particularly unnecessary cholangiography. Cholangitis is caused by pushing contaminated bile into the undrained area during

cholangiography or by occlusion of the drainage tube. The most important means of preventing cholangitis is to not perform cholangiography in patients whose right and left bile ducts are not communicated due to tumor obstruction. In this subset of patients the future remnant liver should be preferentially drained percutaneously [100–103]. Cholangiography should be limited to the time of placement of the biliary drain (percutaneous transhepatic or endoscopic retrograde) or to the afternoon of the day before surgery. Biliary stents placed endoscopically should be exchanged every 2 weeks to prevent tube occlusion [104]. Bile cultures should be performed routinely, and isolates should be tested for antibiotic sensitivity.

Catheter tract seeding is a complication related to percutaneous transhepatic biliary drain placement. Its incidence has been reported to be 5–10%. Multiple drains and cholangiograms may increase the risk of seeding. Sakata et al. reported that resection of an isolated metastasis along the catheter tract may prolong survival [105].

Surgical management of middle and distal cholangiocarcinoma

A conventional pancreatoduodenectomy or a pylorus-preserving pancreatodudodenectomy are the treatment of choice for middle and lower bile duct cancer. Short- and long-term results of both procedures are comparable [106, 107]. It is important to understand the modes of infiltration and spread of bile duct cancer in order to insure adequate surgical treatment. Microscopic extension of bile duct cancer is always beyond the margin observed macroscopically. Longitudinal extension consists of superficial and submucosal infiltration and includes often direct, lymphatic, and/or perineural invasion. A macroscopic surgical margin of at least 10 mm is recommended. Intraoperative pathologic examination of frozen sections is necessary to confirm the margin of the cut end of the bile duct. When a middle bile duct cancer arises midway along the extrahepatic duct, the decision has to be made as to whether a pancreatoduodenectomy or extended hemihepatectomy is more appropriate according to the tumor location and extension.

The reported 5-year survival rates after pancreatoduodenectomy for middle and distal bile duct cancers have ranged from 24% to 39% [108–110]. Favorable prognostic factors following surgical resection are: R0 resection, absence of lymphatic metastatic disease, well-differentiated histology, and tumor location (middle and distal).

Surgical management of hilar cholangiocarcinomas

Because of the complex anatomic relations between structures at the hepatic hilium, an experienced surgeon with three-dimensional knowledge of this area is required to determine the extent of tumor invasion and the extent of resection needed. There are two critical points to a radical resection of a hilar cholangiocarcinoma. The first is removal of the liver parenchyma adjacent to the hepatic hilum together with the hilar plate; an extended right or left hepatectomy is preferable for this purpose. The second is caudate lobectomy and resection of the inferior area of segment IV to extirpate cancer infiltration to the thinner bile ducts near the hilum. The importance of a caudate lobectomy in the surgical treatment of hilar cholangiocarcinoma was established in a retrospective study that demonstrated a clear difference in patient survival (46% with caudate lobectomy versus 12% without caudate lobectomy) [111].

An extended hemihepatectomy is recognized as the standard surgical procedure for hilar cholangiocarcinoma [92,93,112,113]. Extended right hemihepatectomy consists of resection of the right liver, the inferior part of segment IV, and the caudate lobe. Extended left hemihepatectomy consists of resection of the left liver, the hilar part of the anterior segment, and most of the caudate lobe. Even in patients with Bismuth type I or type II, an extended hemihepatectomy is needed to achieve curative resection according to the mode of tumor extension discussed previously. If the tumor is predominantly on the right side or centrally located, extended right hepatectomy is selected. Extended left hemihepatectomy is indicated for left-side dominant tumor. If the tumor has spread diffusely into the intrapancreatic bile duct, a pancreatoduodenectomy should be performed simultaneously [113].

In selected cases when a cholangiocarcinoma widely invades the hepatic hilum (Bismuth type IV), a right or left trisegmentectomy could be used to completely resect the tumor. The extent of this intervention offers an advantage in obtaining a cancer-free margin in the hepatic ducts. It is clear that the operative risk of a hepatic trisegmentectomy is greater than that of extended hemihepatectomy. Proper patient selection and adequate preoperative treatment are required when radical high-risk operations, such as trisegmentectomy, are preformed for hilar cholangiocarcinoma.

As highlighted in this section, major hepatectomy is the standard surgical procedure for removing hilar cholangiocarcinomas with a curative intent. It is currently also viewed as the standard procedure. Table 37.4 shows the results of several reports of major hepatectomies for cholangiocarcinoma over the last 10 years [114–125].

Liver transplantation for hilar cholangiocarcinoma

The results of liver transplantation for cholangiocarcinoma have been historically discouraging and much inferior to the results of transplantation for other liver

conditions. The early experience with liver transplantation for the treatment of cholangiocarcinoma reported a 5-year survival of 0–38%. In the present decade, the addition of neoadjuvant chemoradiation therapy in the treatment of cholangiocarcinoma has significantly improved the outcomes. In 2002, our group at the University of Nebraska reported a 5-year survival of 45% with the use of chemoradiation and liver transplantation [126]. In 2005, the group at the Mayo Clinic published an unprecedented report in the treatment of cholangiocarcinoma. A total of 38 patients underwent rigorous pretransplantation evaluation as well as neoadjuvant chemoradiation. This approach yielded a 5-year survival of 82%, which is not different to the results of liver transplantation for early HCC or other benign conditions. The 5-year recurrence rate reported was 12%. The intention to treat analysis of this group was 58% at 5-years which compares favorably to any other form of treatment for this disease [127].

These remarkable results are a reflection of meticulous pretransplantation evaluation and exclusion criteria. Nearly 50% of patients were excluded from transplantation during evaluation. Diagnosis was based on intraluminal brush cytology/biopsy or a carbohydrate antigen 19.9 (CA 19.9) >100 ng/mL in the setting of a radiographic malignant stricture or biliary aneuploidy demonstrated with digital image analysis (DIA) and fluorescent in situ hybridization (FISH). Staging studies included standard imaging plus endoscopic ultrasound with fine needle aspiration (FNA) of any suspicious lymph nodes. The neoadjuvant chemoradiation protocol was based on combination cycles of external beam radiation therapy (EBRT) and 5-fluorouracil (5-FU) followed by intraluminal iridium brachytherapy followed by infusional 5-FU. At the end of this protocol, an exploratory laparotomy with biopsies was performed on all patients. Of the total number of patients that completed neoadjuvant chemoradiation and reached operative staging, 23% were excluded because of intraoperative findings that precluded transplantation. A detailed algorithm of this protocol can be found in Fig. 37.4. The widespread application of their protocol awaits validation by other centers [127,128].

Resection and transplantation for hilar cholangiocarcinoma

Under the light of the most current results, a comparison between surgical resection and transplantation would be fundamentally inaccurate since the protocol of neoadjuvant therapy followed by transplantation is only applicable to patients with unresectable hilar cholangiocarcinoma. Historically, on average only 50% of patients that are explored with the intent of surgical resection are suitable for a potentially curative resection. The results of several published papers in the surgical treatment of cholangiocarcinoma by means of a major hepatectomy show a 5-year survival ranging from 20% to 45% (see Table 37.4) The Mayo Clinic group reported their results with liver resections as treatment for cholangiocarcinoma. Survival at 3 and 5 years was 53% and 18%, respectively, regardless of the presence of a node-negative R0 resection. The overall cumulative data of surgical resection as treatment of

cholangiocarcinoma denote persistent poor results. There are no reports of neoadjuvant therapy prior to resection as treatment for cholangiocarcinoma. Those patients with unresectable hilar cholangiocarcinoma enrolled in a protocol of neoadjuvant therapy followed by transplantation have, to this date, a better chance of survival. LDLT is an emerging viable option for the treatment of this disease. It overcomes the potential waiting list time as well as the limited supply of deceased donated organs. The introduction of neoadjuvant chemoradiation therapy has improved outcomes significantly. A rigorous pretransplant evaluation seems to be the key in order to reproduce comparable outcomes.

Infectious and Granulomatous Disease

CHAPTER 38

Amoebic and Pyogenic Liver Abscesses

Marco A. Olivera-Martínez[1] *& David Kershenobich*[2]

[1]Department of Internal Medicine, Section of Gastroenterology and Hepatology, University of Nebraska Medical Center, Omaha, NE, USA
[2]Experimental Research Unit, Universidad Nacional Autónoma de México, Hospital General de México, Mexico City, Mexico

Key concepts

- A liver abscess is a space-occupying suppurative lesion in the liver resulting from the invasion and proliferation of microorganisms, entering directly from an injury, through blood vessels, or by way of the bile ducts.
- The most common forms of liver abscesses are amoebic, pyogenic, or mixed in etiology.
- The invasive process of *Entamoeba histolytica* in the liver is driven by the motility of the parasite. The parasite relies on a dynamic actomyosin cytoskeleton and on surface adhesion molecules for dissemination in the tissue.
- Emerging new risk factors for amoebic liver abscess include the use of immunosuppressive drugs, sexual lifestyles, human immunodeficiency virus infection, traveling to endemic areas, and population migration.
- Risk factors for pyogenic liver abscess include aggressive treatment of liver and pancreas malignancies, intraluminal stent placement, sphincterotomy, tumor embolization, ethanol injection, or radiofrequency ablation.
- Distinguishing between amoebic or pyogenic liver abscess is crucial since the treatment and prognosis are different. Differential diagnosis relies on clinical history and laboratory and imaging findings.

A liver abscess is a space-occupying suppurative lesion in the liver resulting from the invasion of microorganisms entering directly from an injury, through the blood vessels, or through the bile ducts. The most common forms of liver abscesses are amoebic, pyogenic, or mixed in etiology. Approximately 60% are solitary and they are mainly located in the right lobe as a result of the streaming pattern of portal blood flow, secondary to the fact that the right lobe is supplied predominantly by the superior mesenteric vein and because most of the hepatic volume is in the right lobe. When multiple abscesses are present, pyogenic or mixed etiologies are the most likely. A detailed clinical history is useful in identifying risk factors that may suggest a possible etiology. Emerging new risk factors include the use of immunosuppressive drugs for neoplastic diseases or for organ transplantation, sexual lifestyles, human immunodeficiency virus (HIV) infection, history of traveling to endemic areas, and the population migration phenomena [1].

Amoebic liver abscess

Epidemiology

Entamoeba histolytica infection is the principal cause of liver abscess throughout the world, especially in tropical and subtropical regions. It is the most common form of extraintestinal invasive amoebiasis and its prevalence is higher in developing countries. It can be spread from person to person when polluted water is used to freshen vegetables and fruits sold by street vendors. The greatest risk is associated with cyst passers, especially if they are food handlers.

Landmark advances in the epidemiology of amoebiasis include the recognition that there are two distinct species: *E. histolytica*, which is the cause of dysentery, colitis, and liver abscess, and *E. dispar*, which is a nonpathogenic (commensal) form of amoeba [2]. Recent technologic advances exploring the genome of the different strains of *E. histolytica* may ultimately lead to the development of vaccines [3].

Specific probes derived from the analysis of repetitive DNA sequence in the *Entamoeba* genome have demonstrated possible candidates that distinguish between *E. histolytica* and *E. dispar.* For example, transposable elements that harbor non-long terminal repeat (non-LTR) retrotransposons (also called long interspersed repetitive elements or LINESs) [4] or short interspersed repetitive elements known as EhSINE1 [5].

More recently, a proteomic analysis of both species of amoebae showed that *E. dispar* has a lower activity of nicotinamide adenine dinucleotide phosphate

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

(NADP)-dependent alcohol dehydrogenase (ADH), while *E. histolytica* expresses higher concentrations of ADH2 and ADH3. Other differences among species are amino acid substitutions, splice variants, post-translational modifications, truncations, insertions, and different protein expression as in the case of grainin 2, a calcium-binding protein. The latter (overexpression) is particularly characteristic of *E. dispar*, suggesting that protein expression, specifically granins, might be related to the microorganism's virulence. On the other hand, *E. histolytica* expresses a higher level of proteins containing cysteine- and histidine-rich, zinc-coordinating domains that mediate protein–DNA or protein–protein interactions (Lin11-lsl-1-Mec-3 or LIM domain), which has a role in regulating eukaryotic nucleic acid transcription [6]. Genotyping has revealed an extensive genetic diversity among *E. histolytica* isolates, preventing an association of a single genotype with hepatic disease [7]. The HM-1:IMSS strain of *E. histolytica*, isolated in Mexico 30 years ago, and those isolated in India and Bangladesh, cause disease in experimental animals and humans and have been used for nearly all immunologic, biochemical, and molecular biologic studies of amoebae [8].

Pathogenesis

The invasive process is driven importantly by the parasite's motility. The parasite relies on a dynamic actomyosin cytoskeleton and on surface adhesion molecules for dissemination in the tissues. Myosin II is essential for *E. histolytica* intercellular motility through intestinal cell monolayers and for its motility in the liver, while surface galactose-binding lectins, mainly galactose acetylgalactosamine (Gal/GalNAc), modulate the distribution of trophozoites in the liver and their capacity to migrate in the hepatic tissue [9]. Gal/GalNAc acts as a major cell surface antigen activating target epithelial cells and triggering subsequent disease pathology and parasite survival. This lectin favors the synthesis of tumor necrosis factor α (TNF-α), contributing to inflammatory cell recruitment and cytokine synthesis and release.

Gal/GalNAc also inhibits the assembly of C5b-9 in the complement cascade, preventing in this way the formation of membrane attack complexes by the host. These complexes lead to lysis of the trophozoite [10]. Lectin-stimulated cells show an immediate rise in Ca^{+}, which in turn activates cyclic nucleotides and other protein kinases, leading to activation of the mitogen-activated protein kinases (MAPK) cascade. Activation of MAPK pathway is implicated in events such as apoptosis, proliferation, cytoskeleton rearrangements, and permeability changes [11].

One of the initial steps in tissue invasion is the release of proteases by trophozoites, which are capable of degrading extracellular matrix components. *E. histolytica* is a cytotoxic effector cell with an extraordinary capacity to lyse surrounding cells. The inflammatory response (mainly neutrophils and macrophages) initiated by amoebic invasion may further contribute to tissue damage by added lysis of parenchymal cells [12]. When amoebae are inoculated in the liver, significant areas of apoptosis develop within the amoebic liver abscess [13]. A major role in this regard is played by the protozoan phosphoglycans contained in the parasite's glycocalix since they can build a physical barrier that protects the cells from membrane attack complexes after tissue invasion [10].

Virulence

There is evidence that the virulence of this parasite depends on the overexpression of several genes in some strains of *E. histolytica*. Among these are the genes that induce a thiol-specific antioxidant known as peroxiredoxin, which has both peroxidase and antioxidant activities. Peroxiredoxin seems to increase virulence by conferring the amoeba protection against reactive oxygen species (ROS) [14]. The tissue invasion capability of *E. histolytica* resides mainly in the amoebapores – intravesicular proteins with pore-forming activity essential for the bacterial phagocytic activity of the amoeba [15].

The sequencing of the genome of *E. histolytica* has allowed a reconstruction of its metabolic pathways. It appears that some amino acids may play roles in both adenosine triphosphate (ATP) synthesis and nicotinamide adenine dinucleotide (NAD) regeneration [16]. *E. histolytica* uses a complex mix of signal transduction systems in order to sense and interact with different environments and encounters. The analysis of its genome has reveled almost 270 putative protein kinases [17].

Clinical manifestations

Amoebic liver abscess is found more frequently in men aged between 20 and 40 years, but can occur at any age. Gender differences in abscess formation in adults have been related to alcohol consumption. Other risk factors have also been identified, including a history of prior travel or residency in endemic areas.

Patients almost always present with a constant, dull, and intense right upper quadrant abdominal pain that exacerbates with movement and frequently radiates to the scapular region and right shoulder. Patients usually have a fever between 38 and 40°C, chills, and sweating. Very frequently they will give a history of malaise and nausea in the previous 2 weeks and moderate weight loss. Some patients have cough and chest pain. Most of them do not have coexistent dysentery, although a past history of diarrhea or dysentery is present in approximately 50% of cases. On physical examination the patient appears pale and wasted, with painful hepatomegaly, and

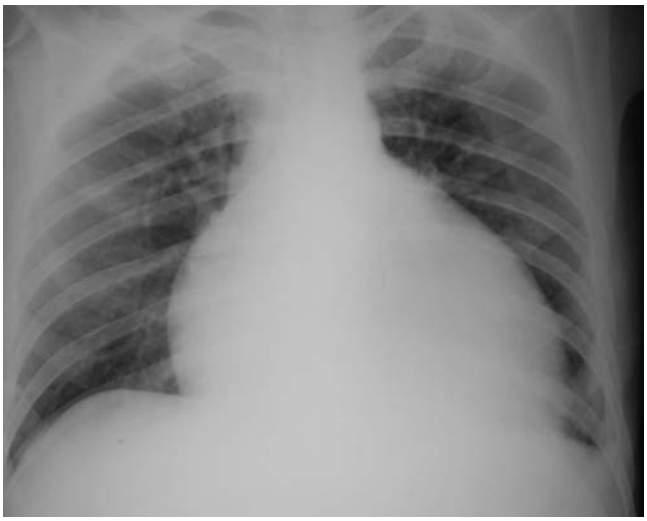

Figure 38.1 Amoebic liver abscess ruptured into the pericardium.

Figure 38.2 Liver metastases of colorectal cancer. No specific characteristics differentiate it from primary neoplasia, or pyogenic or amoebic liver abscess.

point tenderness over the liver, below the ribs, or in the intercostal spaces. When the abscess is located in the left lobe, the patient may have epigastric tenderness. Ventilation in the right lung is frequently restricted and respiratory sounds are reduced. Jaundice is infrequent. The pathophysiology of jaundice is not fully understood and multiple factors are involved; increased pressure within the biliary system posed by an expanding abscess [18] and, more recently, the presence of biliary vascular fistulas have been suggested as contributing factors [19].

Alarm signs include abdominal rebound tenderness, guarding, absence of bowel sounds, and pleural or pericardial rub. The abscess may extend to the peritoneum, abdominal organs, great vessels, pericardium (Fig. 38.1), pleura, bronchial tree, and lungs [20,21]. Common differential diagnoses include pyogenic liver abscess, primary hepatic carcinoma, liver metastases (Fig. 38.2), or hydatid cysts. The clinical presentation of amoebic liver abscess (ALA) among high-risk groups such as HIV patients or other immunosuppressed individuals is similar to that described for other patients [22].

Diagnosis

Leukocytosis ($>15\times 10^9$ cells/L) with neutrophilia, an increased erythrocyte sedimentation rate, slight anemia, and elevated alkaline phosphatase are common (Table 38.1). Serum antibodies to *E. histolytica* are detected in >90% of patients. An indirect hemagglutination (IHA) test with a cutoff value of 1 : 512 is considered diagnostic. The enzyme immunoassay (EIA) test, with a sensitivity of 99% and specificity greater than 90%, is also commonly used. In those patients in whom an aspirate is obtained, either for diagnostic or therapeutic purposes, the material should also be sent for Gram staining and culture [23].

Imaging studies are very important in the workup of patients with suspected ALA and have reduced the delay in diagnosis. Ultrasound is the initial screening choice. The abscess appears as a hypoechoic, round or oval lesion with well-defined margins. More advanced imaging techniques such as computed tomography (CT) or magnetic resonance imaging (MRI) are indicated for differential diagnosis. Chest X-ray may reveal elevation of the right diaphragm, atelectasis, and pleural effusion [24].

Therapy

The drug of choice is metronidazole at an oral dose of 1 g twice daily for 10–15 days in adults and 30–50 mg/kg

Table 38.1 Diagnostic differences between amoebic and pyogenic liver abscesses.

Amoebic liver abscess	Pyogenic liver abscess
Leukocytosis $>15\times 10^9$	Leukocytosis $>15\times 10^9$
Serum antibodies to *Entamoeba histolytica* >1 : 512	Serum antibodies to *E. histolytica* negative
Aspirated pus shows no microorganisms	Aspirated pus shows bacteria
Jaundice uncommon (<8% of patients)	Jaundice common in presentation
Abnormal chest finding in physical examination uncommon	Abnormal chest findings in physical examination common
Younger patients (usually 20–40 years)	Older patients (usually 60–70 years)
Previously healthy	Presence of debilitating disease (cancer)

daily for 10 days divided into three doses for children. When given intravenously the dosage is 500 mg every 6 hours for adults and 7.5 mg/kg every 6 hours for children for 10 days. Other nitroimidazoles include tinidazole or ornidazole at a dose of 2 g PO per day for 10 days. Secondary drugs include chloroquine 1 g PO daily for 2 days, followed by 500 mg/day for 2–3 weeks. In children the dose is 15 mg/kg PO daily for 2–5 days followed by 5 mg/kg daily for 2 weeks. Percutaneous drainage is still controversial; a recent Cochrane collaborative review concluded that there is no advantage of adding percutaneous drainage to metronidazole therapy in uncomplicated ALA [25]. However, this approach may be necessary in nonresponders to anti-amoeba therapy to rule out a pyogenic abscess or when less than 1 cm of rim liver tissue remains around a liquefied abscess.

Vaccination

Studies are ongoing in experimental animals using *E. histolytica* galactose and *N*-acetylgalactosamine-inhibitable surface lectin either for systemic application or oral administration. Research has focused on how to fuse surface lectin to the β-subunit of cholera toxin, attenuated *Salmonella*, or *Yersinia enterocolitica* for antigen delivery [26].

Pyogenic liver abscess

Epidemiology

The incidence of pyogenic liver abscess (PLA) is 0.007–2.2% of hospital admissions, 11 per 1 million in the general population, and between 0.29% and 1.47% in autopsy series. A recent population-based study revealed an incidence of 3.6% in the United States between 1994 and 2005, suggesting an increasing incidence of the disease [27]. PLA varies among different geographic regions, influenced by the local prevalence of bacterial, parasitic, and helmintic infections, the age of the population, and the presence of chronic debilitating diseases. Benign or malignant biliary tract disease, diverticulitis, and Crohn disease are the most common predisposing factors. The frequency of PLA has increased as a complication of the more aggressive treatment of liver or pancreatic malignancies: stent placement, sphincterotomy, embolization, ethanol injection, or radiofrequency ablation. In the past PLA was primarily a complication of a ruptured appendix [28]. Accordingly, the age of presentation has moved from the second and third decades of life to the sixth and seventh [28,29]. Advances in imaging techniques and new antibiotics have decreased the morbidity and mortality of PLA [29,30].

Pathogenesis

Abscess formation, a host defense strategy to contain the spread of infection, is promoted by a combination of factors that impair phagocytosis and the clearance of microorganisms. Neutrophils and platelets attached to the endothelial surface, and endotoxins produced by Gram-negative bacteria, contribute to tissue injury by releasing proinflammatory cytokines and ROS. When bacteria reach the liver, endotoxins stimulate the proliferation of Kupffer cells that engorge and produce toxic mediators that modulate the microvascular response. After adhesion, the bacteria diapedese through cell junctions. The inflammation thus produced causes obstruction of the sinusoidal lumen and secondary obstruction of the blood flow. These phenomena inhibit sodium and potassium ATP activity, impair the generation of energy for bile excretion, and promote biliary stasis. The sinusoidal diameter is reduced and hence the velocity of the blood flow decreases; as the number of obstructed sinusoids increases and hydrostatic pressure rises, hepatic ischemia develops [31].

The source of infection determines to a certain degree the localization and number of abscesses. If infection reaches the liver via the portal system, several abscesses may develop, mostly confined to the right lobe. The left lobe is usually involved in septic thrombosis of the portal vein. When bacteria reach the liver via arterial circulation, several small abscesses develop, equally distributed in both lobes. Forty percent of patients with PLA have multiple liver abscesses [32].

Clinical manifestations

An early clinical diagnosis requires a high index of suspicion; fever, malaise, right upper quadrant abdominal pain, nausea, and vomiting for more than 2 weeks are the most common presentations [28]. Abdominal pain in patients with PLA is similar to that found in patients with ALA [32]. Other symptoms such as anorexia, jaundice, and painful hepatomegaly are less prevalent in PLA as compared with ALA [33–35]. Jaundice predicts a complicated clinical course but has no impact on mortality. Approximately 60% have an underlying debilitating condition or have had a recent interventional procedure (e.g., biliary stent placement, ethanol injection). PLA should be suspected in elderly patients, those taking steroids, or in patients with right-sided pulmonary abnormalities of unknown origin [35,36].

Diagnosis

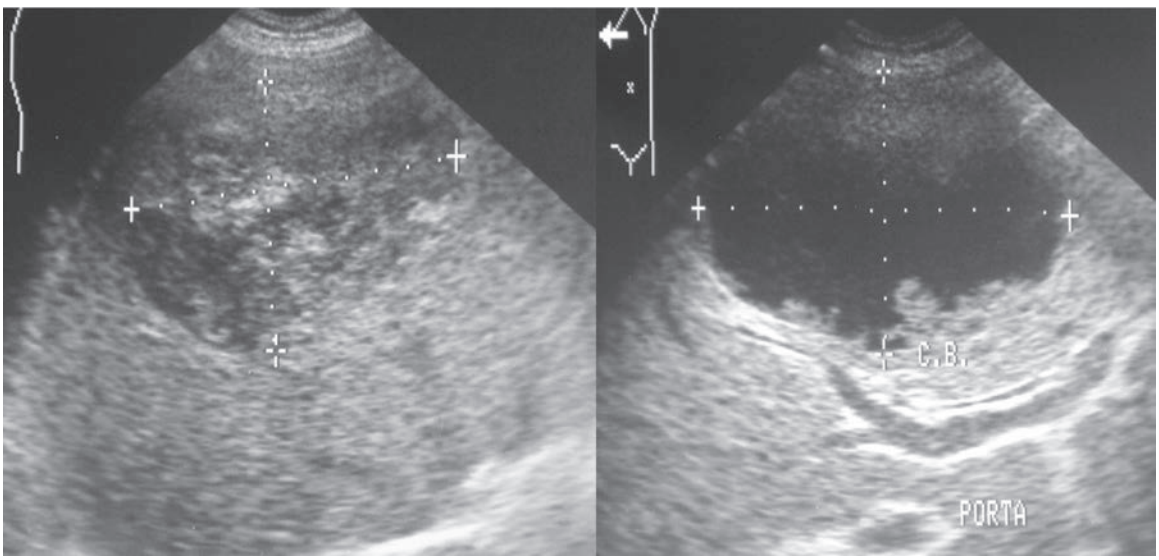
When PLA is diagnosed, prognostic factors associated with increased mortality include low albumin, anemia, high BUN (blood urea nitrogen) and creatinine, prolonged prothrombin time, polymicrobial infection,

pleural effusion, high APACHE II (acute physiology and chronic health evaluation II) score, disseminated intravascular coagulation, and septic shock. Multiple abscesses carry a high mortality independently of other risk factors [30]. Regarding PLA in cancer populations, morphology and topography are not different from that found in non-cancer patients [32,36].

Distinguishing characteristics

Distinguishing PLA from ALA is crucial since treatment and prognosis are different (see Table 38.1). The detection of PLA relies on laboratory and imaging findings. Abdominal ultrasound and CT scans have sensitivities >95% in detecting abscess formation [30], although PLA and ALA have similar imaging characteristics (Fig. 38.3) [33]. Patients with PLA are older than those with ALA, and are more likely to have debilitating diseases, which might explain the lower concentration of albumin found in patients with PLA. Abnormal chest findings are more prevalent in patients with PLA [33].

Laboratory and microbiology findings



These data include leukocytosis, anemia, elevated alkaline phosphatase, positive C-reactive protein, and negative *E. histolytica* antibodies. Other findings include increased total bilirubin, low albumin, and prolonged prothrombin time.

Microbiology studies are the gold standard in establishing the diagnosis of PLA. Specimens of pus and blood should be obtained for culture under strict anaerobic and microaerophilic techniques. Gram stain results should guide the selection of the antibiotic regimen pending the result of culture. One third of PLAs are caused by aerobic bacteria, one third by anaerobes, and one third by a mixture of both. Enteric Gram-negative rods are the most frequent isolates in either blood or pus aspirated from the abscess. In children *Staphylococcus aureus* is the most frequent organism. Only 50% of anaerobic PLAs are diagnosed by culture because of defective sampling or suboptimal laboratory techniques, but this should not delay the initiation of antibiotics. A combination of antibiotics against different microorganisms is the treatment of choice [28].

Bacteriology of PLA is evolving and in some areas of the world specific bacteria have been isolated. *Klebsiella pneumoniae* has been found in PLA in the Asian population in America suggesting either an epidemiologic transition or the continued prevalence of an endemic infection [29,32,33]. Resistant bacteria and fungi are opportunistic infections in patients with debilitating conditions [36]. The isolation of fungi is frequent in patients with manipulated biliary stents or with intermittent cholangitis treated with broad spectrum antibiotics. Immunocompromised individuals can develop PLA with other microorganisms such as *Salmonella* [35].

Imaging

Ultrasound is the screening test of choice. CT scans can detect collections as small as 0.5 cm in diameter and allow therapeutic interventions (e.g., needle aspiration/drainage). The presence of aggregates of multiple, small abscesses suggests coalescence into a larger abscess (cluster sign) and indicates PLA [28]. MRI using serial gadolinium-enhanced gradient-echo images can help differentiating PLA from other focal lesions [37]. Magnetic resonance cholangiograms can be useful in planning

A B

possible resectional therapy. All of these modalities are able to demonstrate loculation and consistency of the contained pus in order to make therapeutic decisions.

Therapy

Antibiotic therapy choices involve combining broad spectrum antibiotics: third-generation cephalosporin plus clindamycin or metronidazole; broad spectrum penicillin plus aminoglycosides; and second-generation cephalosporin plus aminoglycosides. Treatment should be started immediately after specimens have been obtained for culture without waiting for definitive results. Imipenem, aztreonam, piperacillin, tazobactam, ticarcillin, clavulanate, and quinolones are active against almost all aerobic Gram-negative bacilli [28]. Antibiotics should be given before, during, and after drainage and surgical procedures. Parenteral therapy for 2–3 weeks followed by oral antibiotics for 4–6 weeks is recommended. For a solitary abscess <5 cm in diameter, confirmed by aspirate and with available antimicrobial sensitivity, resolution can be achieved with antibiotics alone [38,39]. For an abscess >5 cm with thick and viscous pus, or for large multiloculated abscesses, surgical drainage or continuous percutaneous drainage may be necessary [40].

Aspiration and drainage

Under imaging guidance, PLAs can be aspirated and drained. Drainage is most effective when well-liquefied pus is completely evacuated. If the abscess is not well liquefied or has a thick wall, it is impossible to remove the pus completely. In such cases, most of the drainable pus is removed by needle aspiration, after which antibiotic therapy is necessary to treat the residual abscess. Needle aspiration should be performed with an 18-gauge fine-walled needle. In multiloculated abscesses, the needle tip should be inserted into the various loculi to evacuate pus as completely as possible. Percutaneous needle aspiration is considered unsuccessful when patients fail to improve clinically or radiologically after the second aspiration. Factors affecting drainage include accessibility, the number and size of the abscesses, communication of the abscess with the biliary tree, and, finally, the patient's general condition [41,42]. Those abscesses most accessible to percutaneous drainage are posterior deep-seated lesions of the right lobe (Fig. 38.4), those adhered to the abdominal wall, and peripheral abscesses of the right lobe [43].

Surgery

Surgical therapy is necessary for multiple macroscopic or multiloculated abscesses, or those in the left lobe, after percutaneous drainage failure. Surgical drainage may be required in the presence of ascites or renal failure, when there is evidence of clinical deterioration, persistent jaundice, or concomitant steroid therapy, or when abscesses

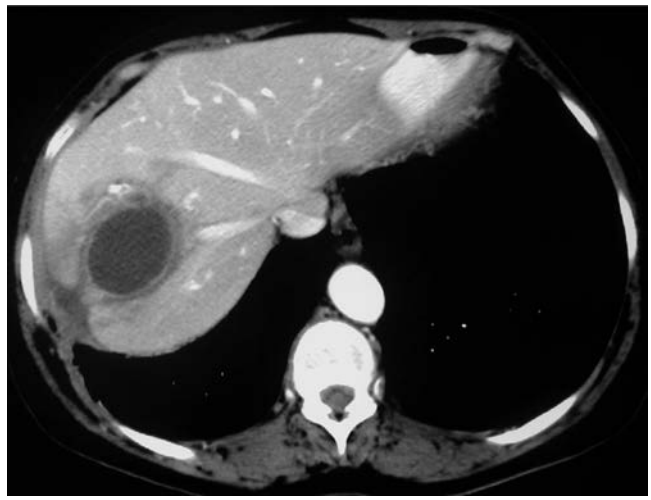

Figure 38.4 Pyogenic liver abscess in the right lobe showing a hypointense rim which is secondary to peripheral inflammation.

are not accessible to radiologic manipulation, and in the case of a ruptured abscess [39,40].

Endoscopic drainage

In patients with stones or strictures of the bile duct and abscess formation in continuity with the biliary system, endoscopic therapy provides biliary drainage, promoting abscess drainage [44].

Multiple choice questions

38.1 All of the following are features useful to identify *Entamoeba histolytica* from *E. dispar* except for which one?

a Differences in non-LTR retrotransposons.
b Differences in the activity of NADP-dependent alcohol dehydrogenase.
c Differences in protein expression, specifically grainin.
d Differences in the membrane's lipid arrangement on electron microscopy.
e All of the above.

38.2 In the pathogenesis of amoebic liver abscess which of the following is the most accurate statement?

a Myosin I and III are important in the parasites' motility in the intestine.
b Gal/GalNAc inhibits the synthesis of TNF-α, thus favoring parasite clearance.
c Gal/GalNAc inhibits the assembly of C5b-9 preventing the formation of the membrane attack complex.
d All of the above.
e None of the above.

38.3 The following are potential causes of pyogenic liver abscess except which one?

a Radiofrequency ablation of hepatocellular carcinoma.
b A perforated appendicitis.
c Bile duct manipulation and stenting of a cholangiocarcinoma.
d Active Crohn disease treated with biologic drugs.
e All of the above.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 39
Parasitic Diseases

Michael A. Dunn
Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh, Pittsburgh, PA, USA

Key concepts

- Liver parasites span a wide range of complexity, from intracellular protozoa to visible multicellular helminths with highly evolved life cycles. Different species mature and reproduce within hepatocytes, reticuloendothelial cells, the portal venous system, and the bile ducts.
- Well-adapted parasites cause minimal acute injury to the host organ as they generate enormous numbers of progeny that pass into the blood or bile with the potential to infect other hosts. Examples include the malaria parasites, the schistosome worms, and the bile duct flukes.
- When a parasite enters a species or an organ to which it is poorly adapted, acute or severe injury is likely: *Echinococcus* tapeworms, well adapted to canine–herbivore or canine–rodent life cycles, cause severe cystic liver disease in accidental human hosts. The protozoan *Entamoeba histolytica* and the roundworm *Ascaris*, both well suited to the human intestinal lumen, cause acute injury when they invade the liver parenchyma or bile ducts, respectively.
- Successful parasites have evolved to evade or to accommodate the effects of the defenses and immunologic responses of healthy hosts. Hosts with abnormal or compromised responses are at risk for severe disease manifestations, such as the reactivation of subclinical *Leishmania* infection with the development of advanced visceral leishmaniasis in human immunodeficiency virus-infected persons.

Protozoal diseases

Malaria, one of the world's most serious and widespread infectious diseases, is intimately involved with the liver during its preerythrocytic and exoerythrocytic stages of development. Visceral leishmaniasis is a cause of severe debility and hepatosplenomegaly in the tropics and a growing concern for immunosuppressed persons in temperate climates. In addition to these obligatory intracellular parasites, *Entamoeba histolytica*, an extracellular protozoan cause of liver abscess, is considered in Chapter 38.

Malaria

Malaria, the world's most prevalent fatal parasitic disease, is caused in humans by intracellular protozoa of four species: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. All are transmitted by mosquito bite, and involve the entry of mosquito-borne sporozoites into hepatocytes, where a preerythrocytic stage of the parasite multiplies and is subsequently released to invade erythrocytes. Malaria continues to kill 2 million persons a year and to frustrate eradication efforts because of the parasite's capacity to develop drug resistance. There is, therefore, great interest in defining the events within the liver that may account for complete protection of animals with vaccines directed against genetically attenuated sporozoites [1]. Protective immunity against preerythrocytic parasites binding to and entering hepatocytes involves a complex interaction of antibody-mediated and both innate and adaptive cellular responses [2].

The cyclic fevers, hemolysis, vascular stasis, shock, and multiple organ failure of severe malaria are the clinical end results of synchronized multiplication and release of the parasite's erythrocytic stage. Kupffer cells take up released hemoglobin degradation products known as malarial pigments, which appear as dark cytoplasmic granules in liver specimens from persons with a history of malaria. Humans with intact host defenses normally recover from acute episodes of malaria. The highest risk for severe illness and death is with *P. falciparum* infection. Falciparum malaria often produces clinical and laboratory evidence of multiple organ dysfunction. Patients often show modest elevations in serum bilirubin, aminotransferase, or alkaline phosphatase levels. Severe liver injury in malaria is infrequently seen in patients with heavy *P. falciparum* infections, and is commonly associated with acute renal failure and encephalopathy. In a report from India, seven such patients presented with the acute onset of jaundice, asterixis or impaired

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.
© 2012 John Wiley & Sons, Ltd. Published 2012 by John Wiley & Sons, Ltd.

sensorium, bleeding with prolonged prothrombin and partial thromboplastin times, and aminotransferase elevations at four-fold the normal [3]. *P. falciparum* infection was evident in their blood smears. The three survivors responded to intravenous quinine and supportive care that included lactulose and bowel cleansing. One of the four patients who died had submassive hepatic necrosis; focal steatonecrosis was present in postmortem liver specimens from the other three. As with earlier similar reports, it is unclear to what extent liver injury contributed to morbidity in these patients. The key message remains, however, that a clinical presentation suggesting acute hepatic failure in persons at risk for malaria infection should prompt consideration of this readily diagnosed and treatable illness.

Leishmaniasis

Visceral leishmaniasis, or kala-azar, is an infection of the reticuloendothelial cells of the liver, spleen, bone marrow, and other organs with an intracellular protozoan parasite, *Leishmania* [4]. Common throughout the tropics, visceral leishmaniasis has been increasingly recognized elsewhere as a potential problem for immunosuppressed persons with human immunodeficiency virus (HIV) disease or after organ transplantation. As an experimental disease model, leishmanial infection provides an opportunity to study liver inflammation and fibrosis with the same methods that have advanced our knowledge of these important processes in other diseases, such as hepatic schistosomiasis.

Infections with different species of *Leishmania* cause visceral, cutaneous, and mucocutaneous patterns of disease. Visceral leishmaniasis, involving the liver, normally results from infection of children and young adults with *L. donovani*. In the Indian subcontinent, the parasite is transmitted by sandflies that have bitten infected humans. Elsewhere – in South America, southern Europe, Africa, the Middle East, and China – *L. donovani* transmission to humans by sandflies is primarily enzootic, involving canine and rodent reservoir hosts. Visceral involvement with *L. tropica*, a species that normally causes cutaneous disease, occurred in veterans of the 1991 Persian Gulf War [5], and disease due to *L. donovani* has been seen in American soldiers exposed to infection in Iraq and Afghanistan [6]. Other than infection from the bite of sandflies in endemic areas, *Leishmania* can be transmitted by blood transfusion or needles shared for drug abuse, by sexual contact, and by transplantation of infected organs.

After bloodstream infection and uptake of the parasite by reticuloendothelial cells, its amastygote stage, shown in Fig. 39.1, multiplies within Kupffer cells and macrophages, infects new cells, and triggers cellular and humoral host responses. Immunocompetent persons

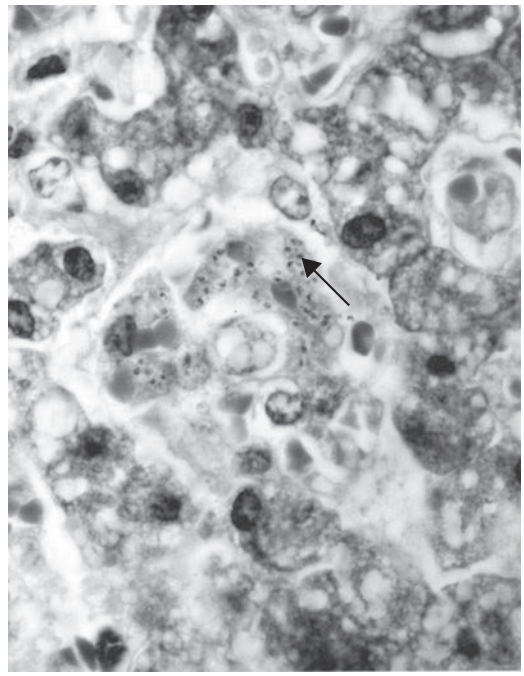

Figure 39.1 Visceral leishmaniasis showing dot-like organisms (arrow) present in several hypertrophied Kupffer cells. Hematoxylin and eosin (H&E), original ×1,000. (Armed Forces Institute of Pathology (AFIP) negative 87-5647.)

respond to infection with a successful combined T helper cell 1 (Th1) and Th17 cell-mediated host defense that prevents clinical disease and suppresses, but may not eliminate, the infection [7]. Such a cellular response, akin to that seen in tuberculoid leprosy or successfully contained initial *Mycobacterium tuberculosis* infection, involves the same T4 cells and cytokines – interferon-γ, interleukin 2 (IL2), IL12, IL17, IL22, and tumor necrosis factor (TNF) – as well as nitric oxide synthesis, that are critical for dealing with other intracellular organisms. Humoral antibody responses, also regularly present, do not appear to modify the course of leishmanial infection; nor do the Th2-type cellular responses seen in persons who develop clinically severe disease.

Pathologic examination of liver specimens shows findings that parallel the predominant host response [8]. In persons with minimal disease and few parasites visible in liver specimens, epithelioid granulomas (including fibrin-ring granulomas similar to those described in Q fever) may be present. Numerous parasites multiplying within activated Kupffer cells and macrophages, the appearance of myofibroblasts, deposition of intralobular collagen, and effacement of the space of Disse with connective tissue all accompany an ineffective response in persons with overt disease. A pattern of severe intralobular liver fibrosis as a predominant finding was described by Rogers [9] in 1908 as a "peculiar cirrhosis" in Indian patients

with visceral leishmaniasis. So-called Rogers cirrhosis, however, shows normal liver architecture and no regenerative nodules. Visceral leishmaniasis has attracted investigative interest because of its association with severe intralobular liver fibrosis, which appears to be fully reversible after treatment of the infection. When experimental animal systems for the study of liver fibrosis in visceral leishmaniasis are defined, we may gain information of comparable significance to that which has already been gained for the immunopathology of this disease.

The major clinical manifestations of visceral leishmaniasis include fever, weight loss, hepatomegaly, splenomegaly, lymphadenopathy, pancytopenia, and hypergammaglobulinemia. All organs with reticuloendothelial cells may be involved, including the entire gastrointestinal tract. Laboratory abnormalities may include modest elevations in serum aminotransferases and alkaline phosphatase levels and depressed albumin levels, as well as skin test anergy to common delayed hypersensitivity antigens. Although hepatic and splenic enlargement from cellular infiltration may be truly massive and intralobular liver fibrosis may be pronounced, overt ascites is uncommon, and the very rare occurrence of either hepatocellular failure or of clinically evident portal hypertension suggests another etiology. Persons with advanced disease are at risk of death from intercurrent infections or severe malnutrition. Conversely, malnutrition, immunosuppressive therapy, or an immunosuppressive disease such as HIV infection can precipitate the development of overt visceral leishmaniasis in previously healthy persons with latent infections acquired as long as 20 years earlier.

Severe HIV-associated visceral leishmaniasis has been described in reports from Spain, a *Leishmania* endemic area, as well as from nonendemic countries such as France and Germany [10]. Visceral leishmaniasis should be sought as a treatable cause of fever, hepatosplenomegaly, and rapid deterioration in HIV-infected persons with even a remotely positive travel history or risk factors for non-sandfly-transmitted blood-borne infection. Intracellular parasites may be seen in liver or intestinal biopsy specimens obtained during the evaluation of HIV-infected persons for persistent fever or diarrhea. Most such patients have CD4 cell counts less than $400/mm^3$, consistent with the importance of an intact Th1 cellular response for dealing with leishmanial infection. This relationship supports the suggestion that visceral leishmaniasis in HIV-infected persons should be considered as an acquired immune deficiency syndrome (AIDS)-defining illness [11]. Most HIV-positive patients with visceral leishmaniasis respond well to initial therapy; however, relapse after cessation of treatment is common, so that long-term suppressive therapy with fluconazole, ketoconazole, pentamidine, or intermittent liposomal amphotericin B is often used.

Visceral leishmaniasis may also become manifest in immunosuppressed solid organ transplant recipients; in one report, the donor liver was considered the likely source of parasite infection [12]. The reduction of immunosuppressive regimens to the minimum needed to support graft function, combined with long-term suppressive antiparasitic therapy, is the recommended management. New biologic therapies for chronic inflammatory diseases, such as the anti-TNF agent adalimumab, may also reactivate latent infection, as shown in a patient from Italy with rheumatoid arthritis [13].

The diagnostic procedure for visceral leishmaniasis with the highest accuracy, close to 100%, is the examination and culture of a needle splenic aspirate. In nonendemic areas where experience levels to safely perform splenic aspiration are lacking, examination and culture of bone marrow and liver biopsy specimens are more often performed. Either method provides a 50–80% yield. Polymerase chain reaction (PCR)-based detection of leishmanial DNA in peripheral blood has diagnostic accuracy comparable with that of bone marrow aspiration.

Until recently, therapy for visceral leishmaniasis usually involved intramuscular or intravenous administration of pentavalent antimonial compounds for 3 weeks or longer. Second-line anti-leishmanials have included pentamidine, amphotericin B, allopurinol, paromomycin, ketoconazole, and related azole compounds. A newer drug, miltefosine, is administered orally for 28 days. Intravenous liposomal amphotericin B represents a new drug delivery strategy that targets the intracellular location of the parasite. It has now become the preferred treatment for initial or relapsed disease because of its high efficacy, approaching 100%, its short duration of therapy, ranging from a single infusion to five daily infusions at a total dose of 10–20 mg/kg, and its minimal toxicity [14]. It is US Food and Drug Administration (FDA) approved for treatment of visceral leishmaniasis. Response to therapy is assessed by resolution of fever, regression of splenomegaly, and weight gain; serologic testing is not helpful.

Although the clinical manifestations of visceral leishmaniasis resolve with antiparasitic therapy, it remains unclear, especially in persons with underlying immunologic deficits, whether the infection is ever truly eliminated or only suppressed below detectable limits. The successful use of highly active antiretroviral therapy (HAART) in HIV-infected patients, for example, is thought to be responsible for recent major decreases in the incidence of clinically overt visceral leishmaniasis in France and Spain, although HIV-infected persons with inapparent leishmanial infection remain at lifelong risk for the occurrence of clinical illness [15].

Helminthic liver diseases

- *Schistosomiasis*. Schistosomes are blood flukes that are well adapted to long survival as male and female adults in the venous circulations of human hosts. Human disease involves host responses to the deposition of schistosome eggs in tissues.
- *Fascioliasis* is caused by flukes that primarily infect sheep and other herbivores. When humans are infected, a biphasic liver disease results from maturation of the parasite as it migrates through the liver parenchyma followed by an extended life span in the bile ducts.
- *Clonorchiasis* and *opisthorchiasis* are biliary infections by trematode flukes that are well adapted to humans. Asymptomatic or minimally symptomatic for many years in most infected persons, these infections are of major concern because of their potential for the development of cholangiocarcinoma.
- *Echinococcosis* is a potentially life-threatening cystic liver disease caused by the infection of humans as accidental intermediate hosts of three species of canine cestode tapeworms.
- *Biliary ascariasis*. Intestinal infection with the nematode roundworm *Ascaris lumbricoides* affects one quarter of the world's population. Biliary ascariasis, which is relatively uncommon, manifests as biliary colic, cholangitis, or pancreatitis induced by the migration of one or more of these large (up to 20 cm) adult worms into the ductal system [16]. Biliary ascariasis usually occurs in children or in adults with an abnormal, open ampullary orifice produced by preexisting biliary tract disease or after surgical or endoscopic sphincterotomy. *Ascaris* worms in the ductal system are readily visualized on ultrasonography or computed tomography (CT). If the worms do not spontaneously clear from the duct after antihelminthic treatment with mebendazole or an alternative agent, they may be removed endoscopically. Chronic biliary ascariasis has been implicated in the development of Oriental cholangiohepatitis, as discussed later for clonorchiasis and opisthorchiasis.

Abdominal imaging methods may show characteristic findings in helminthic liver diseases, as summarized in Table 39.1. The laboratory diagnosis of helminthic infections, as shown in Table 39.2, relies primarily on demonstrating eggs in the stool when the parasite's life cycle involves egg excretion by the human host. Serologic examinations, especially enzyme-linked immunosorbent assay (ELISA) methods, have become established for most infections as diagnostic adjuncts. Serologic diagnosis is especially helpful when positive in the acute stage of fascioliasis and in echinococcosis, situations in which fecal egg excretion does not take place. Eosinophilia is such a regular accompaniment of most helminthic infections that its occurrence should prompt their diagnostic consideration, and its persistence after presumed parasitologic cure may signal treatment failure.

Schistosomiasis

Schistosomes are trematode flukes that infect more than 200 million persons worldwide. Schistosomiasis has attracted more study and effort than all the other parasitic liver diseases combined. Few other diseases of any cause have posed the intensity and breadth of challenges in molecular biology, immunology, economic development, pharmacology, and surgical therapy that have been overcome and others that remain for this disease [17].

Disease mechanisms

Schistosomes begin their life cycles with the passage of eggs by adult females that live, paired with male worms, in the mesenteric or vesical venous beds. Viable eggs erode through the intestinal or bladder mucosa, are passed in feces or urine, hatch in water, and infect an intermediate snail host. Snails shed free-swimming

Table 39.1 Imaging characteristics in helminthic liver diseases.

Infection	Imaging methods	Findings	Reversibility
Schistosomiasis	Ultrasonography	Portal fibrosis	Years to permanent
Fascioliasis, acute	CT	Serpiginous linear subcapsular abscess tracts	Months
Fascioliasis, chronic	Ultrasonography, CT, cholangiography	Dilated ducts, visible adult worms	Months to years
Clonorchiasis and opisthorchiasis	Ultrasonography, CT, cholangiography	Dilated irregular ducts, stones, associated cholangiocarcinoma	Years to permanent
Cystic and alveolar echinococcosis	Ultrasonography, CT, magnetic resonance imaging	Cysts with variable wall calcification, complex internal structures, and daughter cysts	Years to permanent
Ascariasis	Ultrasonography, CT, cholangiography	Dilated ducts obstructed by worms	Months

CT, computed tomography.

Table 39.2 Diagnosis of helminthic liver diseases.

Infection	Stool examination for eggs	Serology
Schistosomiasis	Method of choice in active infection, may be supplemented with rectal mucosal biopsy	ELISA available
Fascioliasis, acute	Negative	ELISA highly sensitive and specific, serial testing useful to monitor response to therapy
Fascioliasis, chronic	Often positive but egg production may be intermittent	ELISA method useful in addition to stool examination
Clonorchiasis and opisthorchiasis	Method of choice in active infection, stool PCR may be useful in mass screening	ELISA available; limited utility
Echinococcosis	Negative	IHA or ELISA positive in 90% of cases, serial testing useful to monitor response to therapy
Ascariasis	Method of choice	Not applicable

ELISA, enzyme-linked immunosorbent assay; IHA, indirect hemagglutination assay; PCR, polymerase chain reaction.

ceracariae, the infectious stage for humans, which have the ability to penetrate human skin and transform into immature worms. The worms mature over a period of approximately 6 weeks as they traverse the venous, pulmonary, and systemic circulations and localize in their species-specific target vessels to form male–female copulating adult worm pairs and to initiate egg production that may continue for decades.

Five species of schistosomes, listed in Table 39.3, develop to maturity in humans. The great majority of schistosomal liver disease is caused by infections with *Schistosoma mansoni* in Africa and South America and *S. japonicum* in Asia. Although portal tract egg deposition, granuloma formation, and fibrosis have been reported in persons infected with *S. hematobium*, these findings are minor compared with urinary tract egg deposition and disease. *S. mekongi* and *S. intercalatum* have limited geographic distributions in Asia and Africa, respectively.

The preferential homing and predilection of maturing schistosomes of all species other than *S. hematobium* is to concentrate in the mesenteric venous system, and of the latter species to concentrate in the vesical plexus. This is central to the pattern of subsequent injury that their infections produce. Immature worms make several passes through the circulation before remaining at their preferred location. The mechanism that signals this remarkable preference for specific vascular beds is unknown. One potential localizing signal was suggested by the finding that human portal serum, but not peripheral blood, contains material of molecular weight greater than 1,000 that stimulates cell proliferation in immature *S. mansoni* worms [18].

Mature worm pairs in the mesenteric veins continuously produce large numbers of viable eggs that are carried to the intestine or the liver. Eggs deposited in the vessels of the intestinal mucosa may remain trapped within inflammatory granulomas, or erode into the lumen and be excreted. Liver disease in schistosomiasis results from the entrapment of eggs that lodge in portal venules. Eggs in the liver remain viable for approximately 3 weeks and secrete products that elicit a characteristic initial response, the schistosome egg granuloma, as shown in Fig. 39.2A. In some persons with heavy infections, the end result of hepatic schistosomiasis is severe portal fibrosis, as shown in Fig. 39.2B. Advanced schistosomal hepatic fibrosis gives a gross appearance of greatly enlarged fibrotic

Table 39.3 Human schistosomes.

Species	Geographic range	Preferred vascular bed	Main target organs
Schistosoma mansoni	Middle East, Africa, Central and South America	Mesenteric	Liver, colon
Schistosoma japonicum	Far East	Mesenteric	Liver, small intestine, colon
Schistosoma hematobium	Middle East, Africa	Vesical	Bladder, ureters
Schistosoma mekongi	Southeast Asia	Mesenteric	Liver, small intestine, colon
Schistosoma intercalatum	Central Africa	Mesenteric	Colon, less severe liver and small intestinal disease

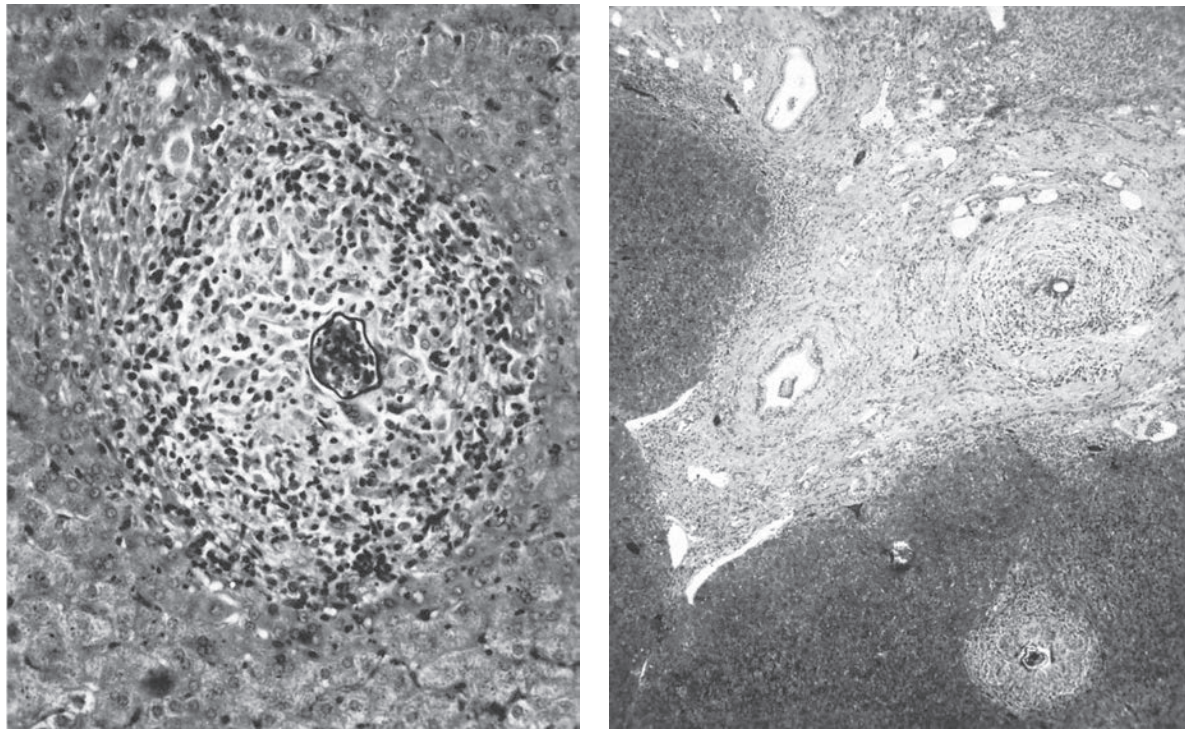

Figure 39.2 (A) A *Schistosoma mansoni* egg granuloma in the liver. The schistosome egg has lodged in a portal venule, with the formation of an epithelioid granuloma. H&E, original ×250. (AFIP negative 79-16805.) (B) Hepatic schistosomiasis. The large area of scarring corresponds grossly to pipestem portal fibrosis. portal tracts, described by Symmers [19] in 1904 as resembling clay pipestems thrust through the liver, and now termed Symmers pipestem fibrosis.

Schistosomiasis has become a valuable model disease, in both clinical and experimental animal studies, for advancing our understanding of the key processes of hepatic inflammation and fibrosis [20]. Important control points and mechanisms of immune regulation and collagen gene expression are more clearly defined in schistosomiasis than in other chronic liver diseases. The antigenic products secreted by living schistosome eggs first elicit a predominant Th1-type cellular response, marked by an influx of mononuclear cells and formation of highly cellular egg granulomas, with the initiation of increased collagen formation. Over time, from several weeks to months depending on the specific experimental model or human infection, a modulation of the initial cellular reaction takes place as egg deposition continues. There is a diminution of the intensity of inflammation and a shift to a predominantly Th2-type cellular response with prominent eosinophilic infiltration of granulomas and continuing deposition of fibrous tissue. Of the mediators associated with the Th2 response, IL13 appears to have strong potential as a pivotal mediator of fibrogenesis, based on studies in *S. mansoni*-infected gene knock-out mice that fail to express either IL13 or its receptor complex [21]. As the shift from a predominant Th1 to Th2 response takes place, the Th17 pathway associated with the production of IL17 and IL23 also appears important in helping to drive inflammation and fibrosis [22]. In humans, there appears to be a genetic component of susceptibility of infected persons to severe fibrotic disease, as suggested by a reported association of a codominant gene with an allele frequency of 0.16 in a heavily infected community in Sudan with severe schistosomal hepatic fibrosis. The gene, located on chromosome 6, was closely linked to the interferon-γ receptor gene [23]. In general, however, the most important single determinant of the severity of disease in hepatic schistosomiasis appears to be the intensity of egg deposition in the liver over time.

Hepatic fibrosis

The synthesis, deposition, remodeling, and turnover of collagen types I and III and basement membrane-associated collagen components, as well as that of fibronectin and accompanying matrix substances such as glycosaminoglycans, are greatly increased in hepatic schistosomiasis, as are the plasma levels of multiple markers of collagen deposition. Experimental schistosomiasis has been an especially useful model for the study of the specific inflammatory cytokines proposed to have an influence on fibrogenesis.

In schistosomiasis, cells in granulomas and in adjacent fibrotic portal tracts show the appearance of stellate cells known to produce collagen and other connective tissue components in other chronic liver diseases [24]. The potential interactions among granuloma macrophages, cytokines, and stellate cells, and angiogenesis within granulomas, appear to parallel those described in other experimental model systems and human diseases [25]. As disease progresses from initial egg deposition to advanced fibrosis, the portal tracts become less prominently involved with inflammatory cells, and prominent cellular infiltrates diminish and disappear. The portal tracts in persons with Symmers fibrosis are markedly expanded with broad, dense-appearing bands of relatively acellular, mature fibrous tissue (Fig. 39.2B).

Because normal liver architecture is preserved in hepatic schistosomiasis, the reversal of portal tract inflammation and fibrosis should allow resolution of the disease and restoration of normal function. Reversal of fibrosis has been well described after the cure of early *S. mansoni* and *S. japonicum* infections in mice. Murine schistosomiasis is one of the best studied examples of the increased activity of two competing processes, collagen biosynthesis versus collagenolysis, in inflammatory fibrotic liver disease. In this model system, cure of infection with cessation of new egg deposition in the liver appears to allow collagenolysis to predominate over continued collagen synthesis, with a resolution of fibrosis. It is unclear, however, to what extent the advanced dense portal collagen deposition associated with chronic human hepatic fibrosis might be subject to the same outcome. Two lines of evidence suggest that even dense pipestem fibrosis may be reversible, at least in part. First, rabbits infected with *S. japonicum* provide an animal model of dense portal collagen deposition that resembles human pipestem fibrosis morphologically and biochemically and shows slow reversibility of fibrosis over a 40-week period after cure of the infection [26]. Second, serial ultrasonographic examination of persons with schistosome infection has become a standard method of assessing pipestem hepatic fibrosis in population-based treatment studies. The ultrasonographic appearance of pipestem fibrosis is shown in Fig. 39.3. Ultrasonography in persons with acute nonfibrotic liver diseases may show a modest degree of portal tract expansion that cannot be distinguished from early schistosomal fibrosis, and the imaging method is not reliable for assessing fibrosis in persons with schistosomiasis and coexisting conditions such as chronic viral hepatitis. Taking these precautions into account, multiple reports now clearly document the partial or complete resolution over several years of the ultrasonographic findings of pipestem fibrosis after parasitologic cure of human infection [27]. In children and in adults treated after relatively short durations of infection, ultrasonographic resolution is more likely to be complete and accompanied by a reversal of hepatomegaly and splenomegaly as assessed on physical examination.

Clinical manifestations

The cercariae of all schistosomes, including those that die on skin penetration in humans, such as the avian schistosome species, may cause a hypersensitivity dermatitis called swimmer's itch. A potentially fatal acute illness, Katayama fever, is a serum sickness-like syndrome triggered by the onset of tissue egg deposition in heavy infections [17]. The cardinal characteristic manifestations of advanced hepatic schistosomiasis are related to portal fibrosis and the development of presinusoidal portal hypertension, with passive congestion of the portal system, hepatomegaly, potentially marked splenomegaly, and the enlargement of collateral vessels such as esophageal and gastric varices. Patients classically present with a history of one or multiple variceal bleeding episodes, accompanied by prominent splenomegaly, no ascites, and normal or nearly normal indices of synthetic liver function and other biochemical laboratory values. It has become increasingly evident from careful longitudinal study of the populations of endemic areas, however, that the greatest health and economic impact of chronic schistosomiasis may not be its dramatic end state with variceal bleeding, but retardation of growth and development, malnutrition, and generalized debility in heavily infected children and adults [28]. Growth retardation in children with schistosomiasis is specifically associated with the infection rather than other potential causes and is only partially overcome after parasitologic cure.

The prominent splenomegaly of persons with hepatic schistosomiasis is caused both by infiltration with inflammatory cells and by passive congestion. The spleen is firm, normally nontender on palpation, and may be the site of sufficient sequestration to produce clinically important reductions in red blood cells, leukocytes, and platelets, as well as significant discomfort attributed to the bulk of the enlarged organ. Symptomatic splenomegaly may persist after the cure of infection, so that simple splenectomy is one of the most common surgical procedures in endemic areas. Segmental splenectomy, with removal of the bulk of an enlarged organ and preservation of a functional remnant of approximately normal size, is safe and effective in experienced hands when hypersplenism in schistosomiasis requires surgical therapy [29]. When variceal bleeding is an additional concern, portal variceal disconnection may be added [30], although as discussed in the subsequent text, optimal therapy to prevent recurrent variceal bleeding in schistosomiasis is far from clear. Massive splenomegaly may suggest the presence of follicular lymphoma of the spleen, the only malignant tumor clearly associated with hepatic schistosomiasis. Follicular lymphoma was reported to occur in 1% of *S. mansoni*-infected Brazilian patients who required splenectomy [31].

Bacterial infections associated with schistosomiasis include pyogenic liver abscesses, predominantly caused by *Staphylococcus aureus* and chronic *Salmonella* bacteremia [32]. Liver abscesses tend to occur in persons with early schistosome infections, perhaps coincident with the effects of initial egg deposition and the initial formation of highly cellular and vascular egg granulomas. Chronic *Salmonella* bacteremia appears related to the sequestration of living bacteria in the integument of adult worms and may be permanently cured only after elimination of the parasitic infection. HIV and schistosome infections now coexist in a growing number of persons as the HIV epidemic spreads through areas endemic for schistosomiasis. HIV-infected persons treated for an active schistosome infection had a less rapid increase in HIV viral load and improved CD4 cell counts compared with those in whom antiparasitic therapy was delayed [33].

Schistosomiasis and viral hepatitis

The accepted clinical findings of hepatic schistosomiasis – normal liver architecture and cellular function in the presence of portal fibrosis and portal hypertension – are present only in a minority of schistosome-infected persons who require hospitalization for liver disease. Because testing for the markers of hepatitis B and C infections has become widespread, it is now evident that regions with a high prevalence of *S. mansoni* and *S. japonicum* infections also tend to have high endemicity for chronic viral hepatitis. In most populations studied, there is no higher occurrence of coinfection with schistosomiasis and hepatitis B or C than would be expected by their independent prevalence [34]. An increased risk for acquiring both infections has been reported, however, in persons with schistosomiasis who required transfusions, and a major increase in the risk for hepatitis C infection has now become evident as the unintended consequence of mass treatment programs for schistosomiasis prior to 1980 that used injections with inadequately sterilized, nondisposable syringes and needles. For example, in communities in Egypt with an overall prevalence of antihepatitis C virus (anti-HCV) of 15–20%, up to 50% of persons in age groups with a history of such mass parenteral therapy are now anti-HCV-positive. The intensive viral transmission attributed to these mass parenteral treatment programs, with the formation of a large reservoir of chronic HCV infection, is thought to be responsible for the high current prevalence and transmission rates of hepatitis C in these areas [35].

In persons who develop both hepatic schistosomiasis and chronic viral hepatitis, severe illness is common. Most of the subset of persons living in schistosomiasis endemic areas who are hospitalized for variceal bleeding, management of ascites, or decompensated hepatocellular failure do, in fact, have both schistosomiasis and chronic viral hepatitis, frequently with cirrhosis. Whether co-morbidity involves specific interactions of the pathologic mechanisms of both diseases or is simply a summation of their effects is unclear. When acute hepatitis C infection occurred in health care providers with preexisting chronic *S. mansoni* infection, they showed a uniform inability to clear viremia and an accelerated histologic progression of chronic hepatitis C compared with the course of hepatitis C infection in their colleagues without schistosome infection [36]. Persons with coexisting *S. mansoni* infection and chronic hepatitis C appear less likely than others to respond to interferon therapy and *S. mansoni*-infected persons respond less consistently to hepatitis B vaccination, although vaccination should be a high priority in schistosome endemic areas to prevent as much comorbidity as possible. Antiviral therapy for chronic hepatitis B or C should be considered for persons who have been cured of active schistosome infection and who would otherwise meet treatment criteria, bearing in mind that the predominant HCV genotype transmitted in Egypt is type 4 [35].

Diagnosis

The detection of schistosome eggs in the stool is the most useful diagnostic method for documenting active infection. Quantitative studies have shown generally strong relationships between the extent of fecal egg output, the host's worm burden, and the extent of pathology in both *S. mansoni* and *S. japonicum* infections [17]. Stool

examinations for eggs become negative after parasitologic cure of infection. Some persons with active untreated *S. japonicum* infections causing significant morbidity may also show few or no eggs on stool examination. Low-power examination of fresh rectal mucosal biopsies may show schistosome eggs that were not apparent in stool specimens. Serologic ELISA methods to detect the antibody to parasitic antigens show excellent sensitivity and are of value in population surveys, but may not be helpful in assessing the activity of infection in an individual patient. Of the standard abdominal imaging methods, ultrasonography, as discussed earlier, is by far the most practical for field application and appears to be of better diagnostic utility than CT or magnetic resonance imaging (MRI) for assessment of the extent of portal fibrosis.

Medical therapy

Praziquantel is an effective drug against all human schistosomes, producing parasitologic cures in approximately 90% of persons. It is orally administered, preferably in three doses of 20 mg/kg body weight given over 8 hours for a total of 60 mg/kg. Single-dose therapy of 40 and 50 mg/kg has been used in some community mass treatment programs for *S. mansoni* and *S. japonicum* infections, respectively. Praziquantel is approved by the US FDA for use in schistosomiasis. Gastrointestinal irritation is the major side effect of this generally well-tolerated drug. Another drug effective for *S. mansoni* infection is oxamniquine, used in mass treatment programs in Africa and South America.

Mass treatment programs have become a central element in the efforts of many countries to combat schistosomiasis. For *S. mansoni* infection, a community-based strategy of mass chemotherapy followed by periodic surveillance with stool examinations and prompt treatment of any reinfections has reduced morbidity and promoted resolution of ultrasonographic evidence of portal fibrosis [27]. Reducing new transmission by largely eliminating the contamination of water with shed parasite eggs underlies this approach. Although promising results have also been achieved in some *S. japonicum* endemic areas, adults in other treated communities show a persistence of hepatosplenomegaly and fibrosis even with decreased prevalence of infection [37]. The existence of numerous animal reservoirs of *S. japonicum* in other communities, coupled with the inability of stool examinations to detect all *S. japonicum* reinfections, suggests that in these locations, frequent mass retreatment would be more effective than surveillance by stool examination for reinfection. In addition, parasitologic cure followed by prompt reinfection might produce a rebound of the relatively severe inflammatory and fibrotic events that accompany acute infection rather than the persistence of a modulated, relatively less damaging long-term response. In such a situation, it may be especially important to maintain effective mass retreatment once a decision has been made to begin community-based therapy.

There are no clinical data to suggest that specific therapy directed at fibrosis promotes any greater degree of resolution of schistosomal liver fibrosis in humans beyond what would normally be expected after the cure of active infection, as discussed in the preceding text. However, administration of the immunomodulating Th1 cytokine interferon-γ to schistosome-infected mice, or promotion of its release by the inhibition of IL4, diminishes liver collagen deposition [38,39]. Schistosomes, along with all other multicellular parasites, continue to defy efforts to produce an effective antiparasitic vaccine. However, a combined antigen–cytokine vaccination concept may help limit parasite-induced host injury: sensitization of mice with *S. mansoni* eggs administered together with IL12 appears to prime the animals to respond with markedly diminished liver fibrosis when they are subsequently challenged with a schistosome infection [40].

Surgical therapy

Four major factors contribute to portal hypertension, increased collateral blood flow, and variceal enlargement in schistosomiasis [41]. They include: (i) portal fibrosis that produces presinusoidal obstruction of portal inflow; (ii) arterialization of abnormal vessels within the portal fibrous tissue that promotes increased hepatic arterial inflow; (iii) cellular infiltration of the spleen that adds to passive congestion to produce marked splenomegaly and increased splenic blood flow; and (iv) poorly understood functional disturbances that diminish splanchnic resistance and promote a hyperdynamic splanchnic circulation.

Nearly every form of medical and surgical therapy for bleeding varices has been advocated in schistosomiasis. Solid information to support evidence-based treatment decisions remains as elusive in schistosomiasis as it is for other causes of variceal bleeding. In the era before widespread variceal banding and transjugular intrahepatic portosystemic shunting (TIPS), the results of a randomized trial of schistosomal variceal bleeding treated with proximal splenorenal shunt, distal splenorenal shunt, and splenectomy with esophagogastric devascularization in schistosomiasis were reported [42] and critically reviewed [43]. Now that surgical shunts have been largely superseded by variceal banding [44] and TIPS, the remaining open surgical procedure that may be considered in experienced centers is splenectomy-devascularization for variceal bleeding refractory to endoscopic therapy. Devascularization may also be an appropriate option for persons at risk for variceal bleeding who require splenectomy for other indications. Propranolol decreases recurrent variceal bleeding in patients

with schistosomiasis. In a report from Sudan, sustained-release propranalol at a single daily dose of 160 mg showed a 40% reduction in mortality after 2 years [45].

The general movement toward medical, endoscopic, and nonshunting surgical therapy for variceal bleeding in schistosomiasis shares common ground with the same trends and uncertainties that apply to other liver diseases. Key considerations in schistosomiasis include the frequent occurrence of marked splenomegaly, which has attracted interest in evaluating the potential benefits of complete or partial splenectomy, as well as concern about encephalopathy after shunting. Shunted patients require lifelong vigilant prevention of reinfection to avoid iatrogenic pulmonary egg deposition and the development of schistosomal-induced pulmonary hypertension and cor pulmonale. Pulmonary hypertension is a known problem even in nonshunted persons with hepatic schistosomiasis, potentially related to incomplete hepatic clearance of vasoactive compounds and mediators [46].

Fascioliasis

Fasciola hepatica is a trematode bile duct fluke with a worldwide distribution in sheep and cattle [47]. The leaf-shaped male and female adult worms reach a size of approximately 2 cm and may remain viable in the bile ducts for more than a decade. They produce eggs that pass in feces, hatch in water, and infect a snail as an intermediate host. Snails release a cercarial stage of the parasite that contaminates aquatic plants ingested by sheep, cattle, or humans. When ingested, transformed metacercariae penetrate the intestine, traverse the peritoneal cavity and liver capsule, and burrow through the liver parenchyma for 1–3 months while maturing, finally entering the bile ducts to become mature adults and complete the cycle. Heavy infection of sheep and cattle, called *liver rot*, is an important economic cause of livestock loss in areas where animals regularly consume aquatic vegetation. Humans with fascioliasis generally give a history of eating watercress or drinking potentially contaminated water. Human fascioliasis is prevalent in developing countries with humid climates and largely agrarian populations and is less frequently seen in Europe and North America. In the Nile delta of Egypt, there is a positive association between *Fasciola* and *S. mansoni* infections [48].

Acute fascioliasis is a febrile illness, typically of up to 3 months duration, presenting with right upper quadrant discomfort and hepatomegaly. As immature flukes continue their course through the liver parenchyma, they leave behind a track of coagulation necrosis infiltrated by an intense eosinophilic inflammatory response. In sheep with experimental fascioliasis, the ability of the parasite to keep moving ahead of the host inflammatory response appears to allow it to literally outrun what would otherwise be an effective host defense [49]. The resulting tracks show a characteristic appearance of yellow-white serpiginous subcapsular cords at laparoscopy [50]. On CT, the tracks appear as tortuous linear arrays of small, 1–3 cm abscess-like lesions [51].

In acute fascioliasis, fever, leukocytosis, and right upper quadrant pain are each present in approximately two thirds of patients, and eosinophilia in the 15–65% range is a regular finding. Atypical manifestations of acute fascioliasis may result when penetration of the ductal system causes hemobilia or discrete abscess formation [52], or as reported in a Chilean patient, when a multisystem vasculitis occurred that resolved with cure of the infection [53]. Immature flukes that fail to migrate into the liver can produce ectopic masses or abscesses in many locations, most commonly appearing as subcutaneous nodules with an eosinophilic infiltrate surrounding the degenerating parasite tissues. In addition, a syndrome of eosinophilic pleuritis and pericarditis without direct parasitic involvement of these structures may accompany acute fascioliasis.

After bile duct penetration by mature flukes, egg production initiates chronic fascioliasis. Host responses to adult worms are limited to local inflammation, ductal epithelial proliferation, and fibrous thickening of the duct wall. *Fasciola* produces proline, a key precursor of collagen, as a major nitrogen excretion product. Animal experiments suggest that high local concentrations of proline in fascioliasis may promote ductal hyperplasia and fibrosis [54]. Large numbers of adult flukes in the ductal system may precipitate episodes of acute biliary obstruction and cholangitis. In addition to visualization of the adult flukes, dilated ducts may be seen by ultrasonography, CT, or cholangiography. CT is the preferred imaging study during the acute intrahepatic phase and ultrasonography is most effective for visualization of the mature flukes in the bile ducts [55].

Fever and right upper quadrant abdominal pain in acute fascioliasis, or biliary symptoms in chronic infection, coupled with a consistent dietary history, suggest the possibility of fascioliasis. Eosinophilia and consistent imaging findings strongly support the diagnosis. An ELISA test has high diagnostic accuracy and is especially useful during the initial stage of infection before adult flukes appear in the bile ducts and begin egg production [56]. Stool examination for eggs is useful only in chronic disease and may be negative when egg output is intermittent.

Bithionol has been the most widely used antihelminthic compound for fascioliasis. It is given in courses of 10–30 days for acute and chronic infections. Gastrointestinal irritation is common; rash, leukopenia, and hepatotoxicity are less frequent; and retreatment may be attempted for nonresponders to an initial course of therapy.

Triclabendazole, a benzamidazole compound widely used in veterinary practice, appears to be more effective and less toxic than bithionol in humans with fascioliasis [57]. Limited quantities of bithionol are available in the United States from the Centers for Disease Control and Prevention parasitic drug service as an investigational drug. Triclabendazole, the preferred agent, may now be imported for investigational human use in the United States with FDA approval of an expedited individual use request.

Clonorchiasis and opisthorchiasis

Clonorchis sinensis, *Opisthorchis viverrini*, and *O. felineus* are bile duct flukes acquired by humans who eat raw fish containing the parasite's infective metacercaria stage. Human hosts excrete eggs that hatch in water and pass through snail and fish stages to infect new humans and animals. With a size of approximately 1 cm and a ventral sucker that permits attachment to the intrahepatic bile duct epithelium, male and female adult flukes have life spans of 10 years or more. *C. sinensis* infects persons in China, Korea, and elsewhere in East Asia. *O. viverrini* has a more limited range in Thailand, Laos, and Cambodia but shows very high prevalence in northeast Thailand, where one third of the population is infected [58]. *O. felineus* infects cats and humans in limited areas of Russia and eastern Europe.

Most infected persons have relatively light parasite burdens of 100 or fewer worms. For *O. viverrini* infection, there is a strong quantitative relationship between the number of eggs excreted per gram of stool and a host's burden of adult worms. A new PCR-based fecal test as an alternative for microscopic stool examination may facilitate the screening of large populations. Study of the intensity of infection in population-based samples has provided strong evidence to support the linkage of bile duct fluke infection with chronic biliary tract abnormalities and with the ultimate development of cholangiocarcinoma, a leading cause of cancer deaths in endemic areas. In surveys using ultrasonography, the intensity of infection is strongly correlated with the occurrence of gallbladder enlargement and wall irregularity, biliary sludge, and enhanced portal tract echogenicity [59]. For cholangiocarcinoma in northeastern Thailand, a locality-adjusted odds ratio of 14.1 was found for male residents with the highest intensity of *O. viverrini* infection; 4% of the surveyed male population with more than 6,000 eggs/g feces had the malignancy [60].

The bile ducts that harbor adult *Clonorchis* or *Opisthorchis* worms can show dilatation, irregular thickening, and adenomatous epithelial hyperplasia (Fig. 39.4). Some of these changes may be reversible, especially after treatment of light or early infection. Ten months after eliminating *O. viverrini* infection with praziquantel treatment, repeated ultrasonographic study of 72 persons showed resolution of gallbladder enlargement, improved gallbladder contractility, and decreases in visible sludge and portal tract echogenicity [61]. However, repeat endoscopic cholangiography at an average interval of 32 months in persons treated for *C. sinensis* infection showed some improvement in the appearance of the intrahepatic ducts and loss of the filling defects caused by the presence of adult worms but no changes in measured duct enlargement or the presence of duct wall irregularities [62]. Adenomatous hyperplasia of the papilla in chronic clonorchiasis can produce radiographic duct abnormalities indistinguishable from those of cholangiocarcinoma.

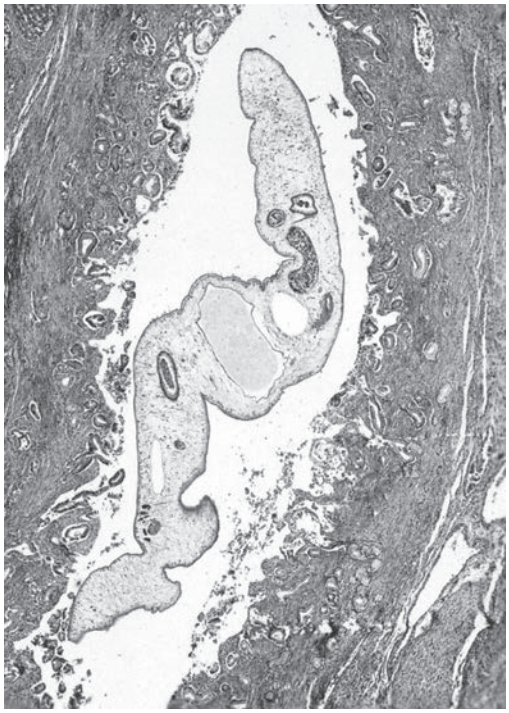

Figure 39.4 Clonorchiasis, showing a dilated intrahepatic bile duct containing an adult worm cut in cross-section. The ductal epithelium shows adenomatous hyperplasia. H&E, original ×40. (AFIP negative 72-11587.)

The development of cholangiocarcinoma appears to reflect the interaction of multiple processes. For example, *O. viverrini*-infected persons with ultrasonographic biliary abnormalities have increased activity of cytochrome P450 2A6, an enzyme that promotes activation of carcinogenic nitrosamines [63]. Administration of the carcinogen dimethylnitrosamine to *C. sinensis*-infected hamsters resulted in the development of cholangiocarcinomas that did not occur in uninfected animals or in infected animals not exposed to dimethylnitrosamine [64]. In a comparison of the histopathology of fluke-associated and sporadic cholangiocarcinomas, the fluke-associated tumors more frequently showed cells with an intestinal goblet cell

phenotype by immunostaining and overexpression of p53 antigenic protein compared with sporadic cancers occurring in persons outside endemic areas [65]. Although the morbidity associated with biliary fluke infection before the development of cholangiocarcinoma appears to be slight in most persons, the outlook is very poor in those who present with the tumor with expected survival measured in months, similar to that for sporadically occurring cholangiocarcinoma. With the currently available information, prevention would appear to depend both on persuading residents of areas with high prevalence of infection and cholangiocarcinoma to modify their dietary habits, and eliminating existing infection with praziquantel, an easily administered and effective curative drug [58]. Screening and parasitologic cure of immigrants to western countries, who are at high risk for infection, is also warranted.

Oriental cholangiohepatitis is a chronic illness marked by episodes of cholangitis with the formation of multiple pigment stones, irregular bile duct dilatation with a predilection for disproportionate severity in the left hepatic ductal system, and the formation of multiple strictures [66,67]. Its geographic range corresponds roughly to that of bile duct flukes and *Ascaris* infection. Figure 39.5 shows a cholangiogram from a patient with this condition and associated clonorchiasis. In many patients with severe distortion of the ductal system, recurrent episodes of cholangitis appear to be self-perpetuating in the absence of active parasitic infection. Helminth infection should be sought and eliminated in persons with the disease. In addition, recurrences due to obstructing stones were reported to be more easily managed in patients who had placement of a Roux-en-Y jejunal conduit for biliary access [68]. When hepatolithiasis and strictures mainly involve the left hepatic lobe, laparoscopic left hepatectomy combined with choledoscopic removal of right lobe stones is reported to be effective [69].

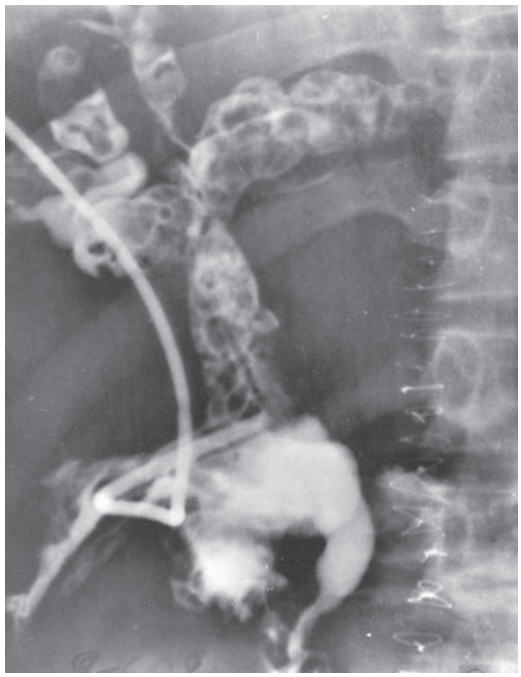

Figure 39.5 Oriental cholangiohepatitis associated with clonorchiasis. The cholangiogram shows a dilated, distorted intrahepatic ductal system with contrast material outlining numerous filling defects that represent adult *Clonorchis sinensis* flukes. (AFIP negative 96-22949.)

Echinococcosis

Echinococcosis, or hydatid disease, develops in humans when they become accidental hosts for a cystic intermediate stage of one of three canine tapeworms, *Echinococcus granulosus*, *E. multilocularis*, or *E. vogeli*. Humans become infected by eating food contaminated with eggs excreted by domestic or wild dogs or other canines such as foxes, coyotes, and wolves [70]. The parasite normally multiplies as a larval scolex stage within cysts in the solid organs of herbivores or rodents that have consumed excreted eggs. Consumption of the cyst-containing viscera of these animals by new canines completes the cycle.

Hydatid disease most often affects humans in contact with sheep-herding dogs infected with *E. granulosus.* The resulting cystic hydatid disease has a worldwide distribution. *E. multilocularis* infection, concentrated mainly in the Arctic and sub-Arctic regions of the northern hemisphere, causes human alveolar hydatid disease. *E. vogeli*, the cause of human polycystic hydatid disease, has a very limited range in Central and South America.

Hydatid liver cysts caused by *E. granulosus,* as shown in Fig. 39.6, are most often asymptomatic. They are fluid-filled structures delimited by a parasite-derived membrane (Fig. 39.7A) that contain germinal epithelium that buds viable scoleces (Fig. 39.7B). Imaging by ultrasonography, CT (see Fig. 39.6), or MRI may demonstrate the formation of daughter cysts, cyst wall calcification, and compression and fibrous reaction of the surrounding liver parenchyma. Imaging may also show in complicated disease communication of the cyst with the biliary system or external leakage of cyst material. The cysts formed in *E. multilocularis* infection are less well delimited. They tend to invade the liver parenchyma and seed adjacent organs and structures with scoleces and daughter cysts [71]. The polycystic hydatid disease of *E. vogeli* infection shows well-delimited multiple cysts.

Cystic hydatid disease now most often presents as a hepatic mass with a typical appearance on abdominal imaging, coupled with confirmatory serologic testing by indirect hemagglutination or ELISA, which is positive in approximately 90% of hydatid cysts. As discussed above, no fecal eggs are present in human hosts. Eosinophilia is usually present. Biliary or peritoneal extension or

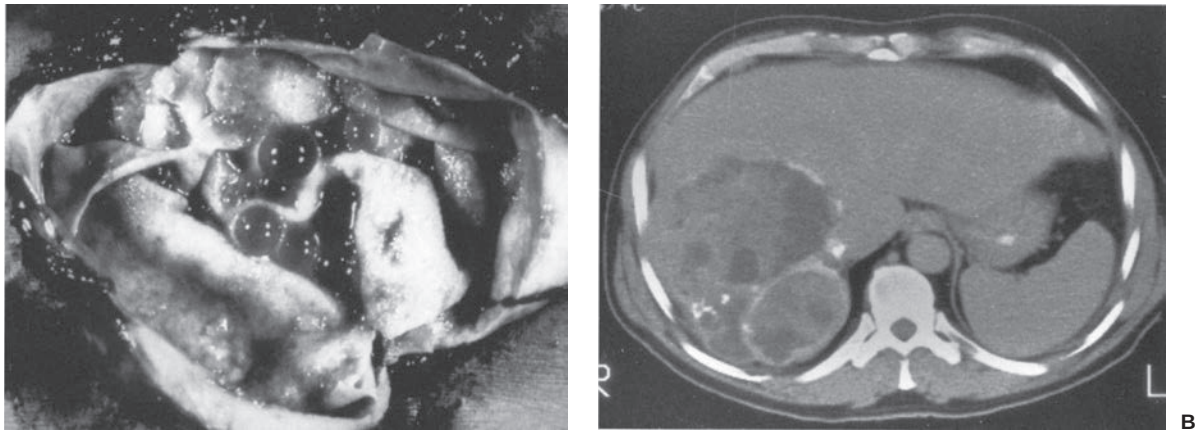

Figure 39.6 (A) Hepatic hydatid cyst of *Echinococcus granulosus*, opened to show folds of the pale, thickened germinal membrane associated with translucent budding daughter cysts. (AFIP negative 95-82642.) (B) Hepatic hydatid cyst of *Echinococcus granulosus.* A computed tomographic image showing a large cyst in the posterior right lobe of the liver with a complex internal structure similar to the cyst shown in (A) and areas of wall calcification. (AFIP negative 92-84646.)

pulmonary cystic disease is usually easily recognized; however, ectopic cysts in the kidney, spleen, brain, orbit, heart, and bone may produce unusual findings. Uncommon presentations of hydatid disease include segmental portal hypertension due to splenic vein compression by a cyst in the splenic hilum, with adjacent perihilar varix formation [72], and rupture of a hepatic cyst causing inferior vena cava thrombosis [73].

Until recently, most hydatid cysts came to clinical attention because of symptomatic enlargement, so that their management by surgical excision was a straightforward decision. Palliative resections for the spreading, poorly contained cysts of *E. multilocularis*-induced alveolar hydatid disease were often inadequate to deal with this frequently lethal disease. Now that many hydatid cysts are detected as incidental findings during abdominal imaging, and newer forms of medical and surgical therapy for hydatid disease are being reported, therapeutic options are at once more promising and more challenging.

After initial evaluation of the benzimidazole antihelminthic compound mebendazole, a related compound, albendazole, has become the current standard for medical therapy of hydatid disease [74]. Albendazole has strong scolicidal activity for *E. granulosus* and *E. multilocularis* and superior absorption, bioavailability, and distribution into hydatid cysts compared with mebendazole. Albendazole is an effective preoperative adjunct for disrupting the viability of *E. granulosus* and *E. multilocularis* cysts and in improving resectability in the latter disease. Albendazole as primary therapy, either alone or in combination with praziquantel, has been advocated for

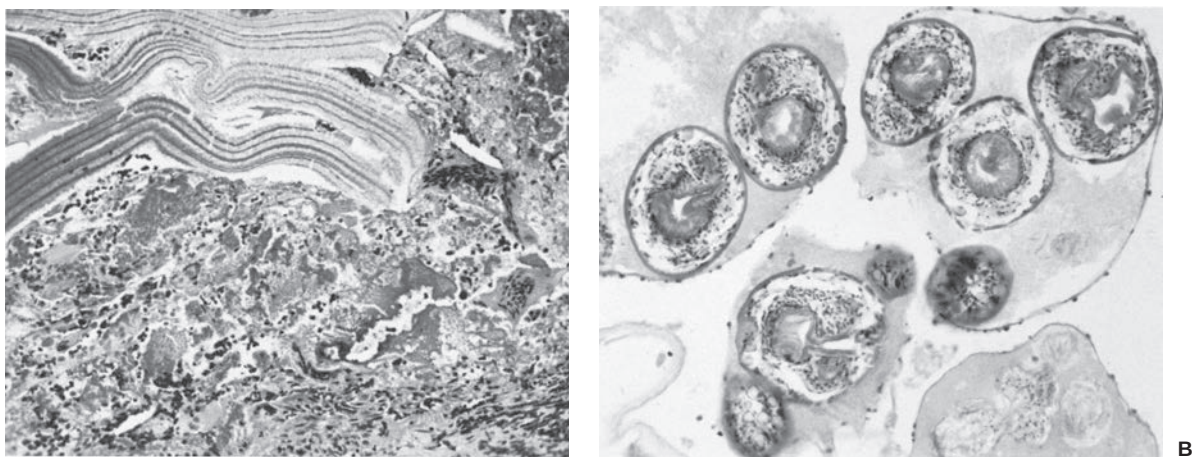

Figure 39.7 (A) Hepatic hydatid cyst of *Echinococcus granulosus* showing a laminated membrane at the top, and debris within the cyst. H&E, original ×160. (AFIP negative 82-12615.) noninvasive therapy of small uncomplicated *E. granulosus* cysts [75]. In an extensive series of 929 cysts in 448 persons treated with mebendazole or albendazole with up to 14 years follow-up, approximately one in four cysts recurred after initial resolution or regression [76]. Recurrence was greatest within 2 years of resolution. Albendazole, approved for use in the United States, is generally administered two to three times daily with food at doses ranging from 10 to 50 mg/kg per day, for 12–24 weeks or longer, with or without intervening rest periods. Toxicity includes variable alopecia and, in many patients, minor elevations in aminotransferase levels as well as transient pain perceived at the location of a cyst on the initiation of treatment. Elevation of aminotransferase levels more than four times normal or leukopenia requires discontinuing albendazole.

Traditional surgical therapy for hepatic *E. granulosus* cysts at laparotomy includes: isolation by packing; careful aspiration of cyst fluid to avoid spillage of viable scoleces or anaphylaxis; injection of the cyst with hypertonic saline, alcohol, or dilute silver nitrate to kill the scolices if the aspirated fluid is crystal clear; and resection of either the cyst alone or both the cyst and its pericystic rim of compressed liver tissue [77]. Aspiration of turbid cyst fluid suggests a biliary communication so that injection with potential sclerosants is avoided. The use of percutaneous drainage, described in the subsequent text, for an increasing proportion of patients with relatively simple cysts, has left the remaining patients who now come to open surgery as a population with relatively greater aggregate complexity and technical challenge than those of earlier surgical series.

Laparoscopic evacuation [78] and ultrasound-guided percutaneous drainage [79] are reported to be safe and effective for treating uncomplicated cystic hydatid disease. Percutaneous drainage has become the first-line management for cystic hydatid disease in many centers. The most extensive current experience is with an ultrasound-guided four-step PAIR process of: (i) *p*uncture; (ii) *a*spiration; (iii) *i*njection with hypertonic saline, silver nitrate, or other scolicidal solution; and (iv) *r*e-aspiration, with one or more days of subsequent percutaneous catheter drainage for large cysts. Patients normally receive a 10-day preprocedure course of oral albendazole, and are given antihistamine and steroid coverage for the procedure to minimize anaphylaxis in the event of cyst leakage at puncture, followed by continued albendazole for 2 months after the procedure. Advantages of the PAIR technique include minimal disability and early return to full activity, with a 1–2-day length of hospital stay compared to a typical 2-week stay after open cyst evacuation. In contrast to primary medical therapy without aspiration and drainage, the PAIR technique has the advantages of a much shorter duration of 2 months of adjunctive albendazole therapy postprocedure, compared with up to 6 months or more for albendazole as the primary treatment, as well as a minimal recurrence rate compared with a recurrence of 25% of cysts treated medically alone. PAIR and laparoscopic cyst evacuation in experienced centers have both shown low morbidity, with anaphylaxis being the most significant problem in the 1–2% range, which is generally easily managed in pretreated patients, and the potential for bleeding or duct injury common to all liver punctures. Communication of cysts with the biliary system due to rupture may be suspected when cholestasis or cholangitis are present. This problem, which tends to occur more often in larger cysts of 7.5 cm or greater diameter, may be identified by endoscopic cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP), and can often be managed with endoscopic drainage [80,81].

Patients with alveolar hydatid disease due to *E. multilocularis* have an infection whose biologic behavior resembles that of a malignant tumor as its complex cystic structures invade the liver parenchyma and spread by direct extension to adjacent sites. Albendazole therapy is administered in an effort to stabilize unresectable disease, or as an adjunct to liver resection, which may cure early localized disease. Alveolar hydatid disease may require multiple surgical procedures in an attempt to deal with severe complications such as hepatic vein compression and thrombosis, and secondary sclerosing cholangitis. Similar major problems occur much less frequently in cystic hydatid disease. Liver transplantation for patients with end-stage alveolar or cystic hydatid disease often presents a technical challenge related to extensive prior surgery, but transplantation may produce a good long-term outcome in patients whose disease has progressed beyond the point of cure or control by other methods [82,83].

Multiple choice questions

39.1 Factors that cause portal hypertension and predispose to variceal bleeding in hepatic schistosomiasis include which combination of the following?

1 Presinusoidal obstruction of portal inflow.
2 Cellular infiltration of the spleen with passive congestion and increased splenic blood flow.
3 Arterialization of abnormal vessels within portal fibrous tissue.
4 Functional decrease in splanchic resistance with a hyperdynamic splanchnic circulation.

a 1 and 3 only.
b 1, 2, and 3.
c 2 and 4 only.
d 1, 2, 3, and 4.

39.2 This parasitic liver disease can persist as a latent asymptomatic infection for many years in immunocompetent hosts. Within its geographic range it is recognized as an AIDS-defining illness in HIV-infected persons who develop immunosuppression. Choose the one correct answer.

a Fascioliasis.
b Alveolar echinococcosis.
c Visceral leishmaniasis.
d Clonorchiasis.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 40
Granulomas of the Liver

James H. Lewis
Department of Hepatology, Georgetown University Medical Center, Washington, DC, USA

Key concepts

- Hepatic granulomas are found in 2–10% of liver biopsy series, and represent a localized inflammatory response to a variety of infectious, immunologic, drug-induced, neoplastic, and nonmicrobial chemical and foreign body irritants. Both genders and all ages can be affected.
- While dozens of causes have been reported, worldwide the most common are tuberculosis and sarcoidosis, reflecting geographic differences in disease prevalence. Primary biliary cirrhosis represents the predominant cause of granulomas in several western population studies. More than 60 drugs have been associated with a granulomatous reaction, many of which are associated with a hypersensitivity reaction (e.g., allopurinol, sulfonamides, phenylbutazone, phenothiazines, carbamazepine).
- Two main types of granulomas are found: lipogranulomas that form around fat droplets associated with the ingestion of mineral oil, waxes, and other lipid materials, and epithelioid granulomas that are often formed in response to a hypersensitivity reaction. A special form of lipogranuloma is the fibrin-ring granuloma seen with Q fever, allopurinol, and a few other causes. Necrotizing epithelioid granulomas are usually caused by mycobacteria or other infectious agents.
- Granulomas may be found as a coincidental lesion or may serve to confirm a variety of infectious or other disorders associated with their development. They may be the only clue to the presence of certain infectious or neoplastic diseases, and occasionally are found as part of fever of unknown origin (FUO). Recent series still report that about 10% are considered "idiopathic" with no specific etiology able to be identified, even utilizing modern serologic and immunohistochemical methods.
- While biochemical tests are generally nonspecific, jaundice is unusual with most causes of granulomas, and should prompt a search for other etiologies. Certain histopathologic clues to the etiology of granulomas continue to be emphasized, such as sarcoidosis having multiple noncaseating granulomas of different ages; tuberculosis having caseating granulomas; many drugs and parasites being associated with surrounding eosinophils; and fibrin-ring granulomas suggesting Q fever or allopurinol exposure.
- Treatment of hepatic granulomas depends on their etiology and the degree of symptomatology. Chronic cholestatic liver disease leading to biliary cirrhosis may be seen in a small percentage of sarcoidosis patients. In general, however, granulomatous hepatic involvement due to most causes is nonprogressive. Drug-induced granulomas often resolve after the offending agent is withdrawn. Corticosteroid therapy has been helpful in certain cases of idiopathic granulomatous hepatitis causing FUO.

Granulomas are focal collections of epithelioid cells, including macrophages, mononuclear cells, and other inflammatory cells, that fuse together to form multinucleated giant cells in response to a variety of infectious, immunologic and neoplastic disorders, drugs, and nonmicrobial chemical irritants [1–3]. They are the end result of a complex interplay of inflammatory and immunologic factors [4], depending on the nature of the infectious or antigenic stimulus. The liver is a common location for granulomas due to its prominent blood supply that exposes most drugs, many infectious organisms, and other materials to its large numbers of reticuloendothelial (Kupffer) cells. When found, granulomas usually prompt a search for a specific etiology from a list that has grown to include dozens of causes, as will be discussed. Hepatic granulomas are present in only approximately 3% of large modern-day liver biopsy series, with a range of 1–15%, varying by geographic location and disease prevalence (Table 40.1) [5–22]. This also appears to apply to pediatric populations from around the globe [23,24]. Granulomas may be an anticipated or incidental finding, reflecting either a primary hepatic disorder (approximately 5%), or seen as part of a systemic disease process with hepatic involvement (70–75%), including fever of unknown origin (FUO) [1,25–28].

A variety of disorders are associated with a granulomatous histologic response that can involve one or more organ systems [3,4]. Infections are the most common

[a] % of liver bx is the frequency of finding granulomas in the series of liver biopsies being reported.
[b] Percent of total number of granulomas in the series listed under miscellaneous.
[c] Cause not established.
AIH, autoimmune hepatitis; CLD, chronic liver disease (not specified); DILD, drug-induced liver disease; HBV, hepatitis B virus; HCC, hepatocellular carcinoma; HCV, hepatitis C virus; PBC, primary biliary cirrhosis; TB, tuberculosis; –, not listed.

cause of disseminated granulomas, and previously unrecognized etiologic agents have been identified by improved diagnostic techniques [28]. Nevertheless, granulomas often still present a diagnostic challenge to the clinician. In the recent series by Drebber et al. from Germany, more than one third of the granulomas were considered idiopathic, despite the availability of polymerase chain reaction (PCR) testing for infections and the use of a diagnostic algorithm [22].

Men and women have been nearly equally represented in several large series of granulomas, although women not unexpectedly predominate when primary biliary cirrhosis (PBC) accounts for a significant percentage of cases [16,20,22]. The age of adult patients with hepatic granulomas generally has been in their forties to fifties, but children are affected as well [23,24].

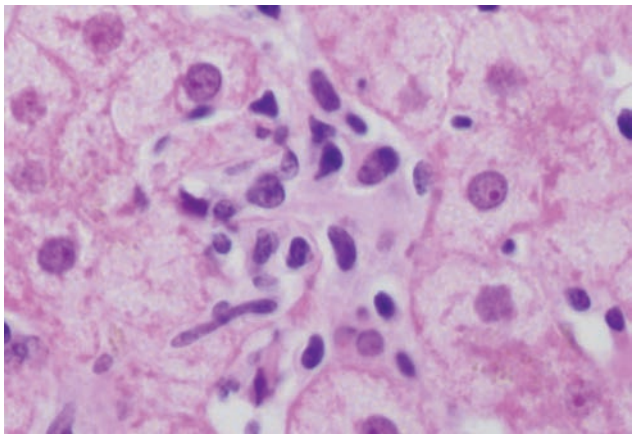

Figure 40.1 Microgranulomas are nonspecific small collections of macrophages, 3 to 7 cells across admixed with lymphocytes. (Reproduced from Kleiner [3] with permission from Elsevier.)

Histopathology

Histologically, two main types (and three subtypes) of granulomas are described based on their appearance as lipogranulomas or epithelioid granulomas (Box 40.1). *Microgranulomas*, as described by Kleiner [3], are small collections of macrophages 3–7 cells across, admixed with lymphocytes (Fig. 40.1). They stain purple with periodic acid–Schiff (PAS) after diastase, and are nonspecific, forming in response to a wide spectrum of chronic inflammatory conditions. As a result, they are regarded as clinically insignificant in most instances.

Lipogranulomas are composed mainly of loose aggregates of lymphocytes and macrophages surrounding lipid droplets, and are secondary to the ingestion of mineral oil or other lipid material (Fig. 40.2) [29,30]. They stain positively with oil red O. In a series of 44 cases in nonfatty livers reported by Dinscoy et al. [31], lipogranulomas were attached to or were closely associated with the walls of hepatic venules, and were most likely a reaction to absorbed mineral oils or other other saturated hydrocarbon foodstuffs. Lipogranulomas comprise a relatively smaller percentage of all granulomas, ranging up to 26% [16], but have been described as having nearly tripled in incidence between the early 1950s and the late 1970s in one series. This is attributed to the increasing use of mineral oils and saturated hydrocarbons used in processed foods [3,31]. Among autopsy specimens, lipogranulomas have been found in 48%, often in association with lipogranulomas in the spleen [29]. In the series by Dourakis et al. [20], lipogranulomas were found with nearly equal frequency to epithelioid granulomas (2.9% versus 3.7%). They may be discovered incidentally and are generally of little, if any, clinical significance [30,32]. However, reports of venous outflow obstruction have been published [33] and a case of prolonged fever associated with lipogranulomas from paraffin oil has appeared [34].

A distinctive subtype of lipogranulomas is that characterized by an eosinophilic *fibrin ring* enclosing a vacuolar clear space of necrosis [3,35]. These "doughnut"-shaped granulomas have traditionally been associated with Q fever (Fig. 40.3A) [36] and with allopurinol toxicity (Fig. 40.3B) [37]. However, this pathologic appearance is

Box 40.1 Types of hepatic granulomas.

- Lipogranulomas:
  - Fibrin-ring subtype
- Epithelioid granulomas:
  - Non-necrotizing
  - Necrotizing
- Microgranulomas (nonspecific)

Adapted from Kleiner [3].

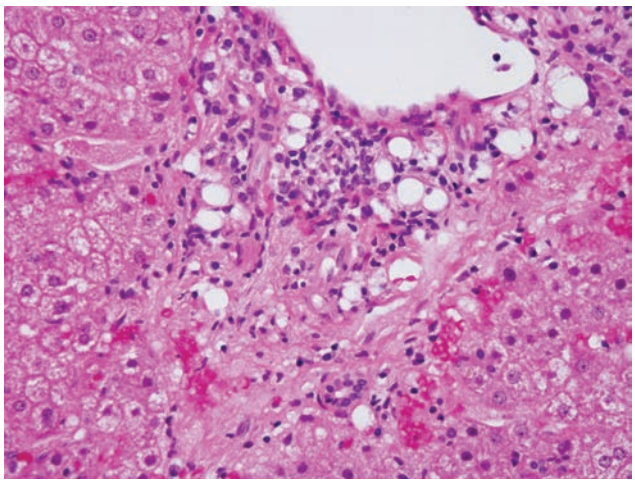

Figure 40.2 Lipogranuloma secondary to mineral oil. Hematoxylin and eosin (H&E), original ×250. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

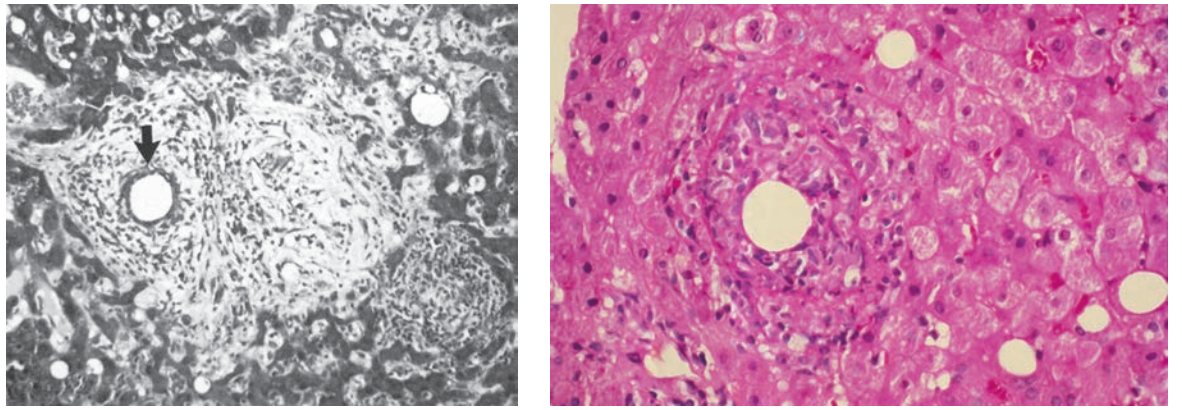

Figure 40.3 (A) Fibrin-ring granulomas secondary to Q fever. A fat globule is surrounded by a ring of fibrin (arrow). H&E, original ×160. (B) "Doughnut" type of fibrin-ring granuloma associated with allopurinol toxicity. H&E, original ×150. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

not limited to these causes, and several other infections and etiologies have been described (Box 40.2) [35,38–41]. The pathogenesis of fibrin-ring granulomas may be the result of endotheiliitis of sinusoidal cells [3].

Epithelioid granulomas are the predominant histologic form in most series. The name is derived from their polygonal shape and abundant cytoplasm (Fig. 40.4) [18]. They generally develop in response to delayed hypersensitivity reactions [4]. Cytokines mediating the T helper cell 1 (Th1) immune response attract CD4+ and CD8+ T lymphocytes and fibrocytes that form the periphery of many granulomas. Activation of the Th2 immune response occurs as a result of antigenic sensitization, leading to necrosis or caseation, depending on the nature of the antigenic stimulus [4,42].

The non-necrotizing (noncaseating) subtype is composed of either well-circumscribed, tight collections of cells, as in sarcoidosis, or by poorly formed gransulomas consisting of macrophages admixed with lymphocytes and other inflammatory cells, such as seen in PBC. As noted by Kleiner [3] and other others [1,43], at times the edges of these granulomas are indistinct, giving rise to the term "granulomatous inflammation." Both subtypes are generally small (100–300 μm in diameter), but may coalesce to form larger macroscopic lesions.

Box 40.2 Causes of fibrin-ring granulomas.

- Q fever
- Allopurinol
- Hodgkin disease
- Giant cell arteritis
- Hepatitis A
- Visceral leishmaniasis
- Epstein–Barr virus
- Toxoplasmosis
- Boutonneuse fever (*Rickettsia conorii*)
- Systemic lupus erythematosus
- Staphylococcal infection

Necrotizing epithelioid granulomas are generally larger (several hundred micrometers) and may form cavitary granulomatous abscesses rimmed by giant cells and often surrounded by connective tissue [3]. The necrotic material in the center is eosinophilic and granular (hence the term "caseating") and may contain calcifications.

Pathophysiology

Both foreign body-type granulomas (nonimmunologic) and hypersensitivity-mediated granulomas can be seen in the liver [44]. Granulomas are most likely to be seen when macrophages drawn to the site of acute inflammation are unable to clear antigens and inflammatory by-products. As a result, monocytes are attracted from the blood and bone marrow and help transform macropahges into epithelioid histiocytes that fuse together to become multinucleated (Langhans type) giant cells [2,44–46]. Such cells lose their phagocytic function and develop secretory

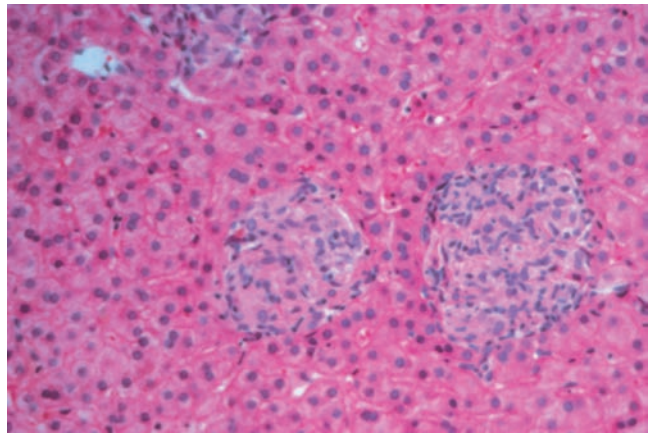

Figure 40.4 Noncaseating epithioid granuloma characterized by giant cell transformation. H&E, original ×300. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

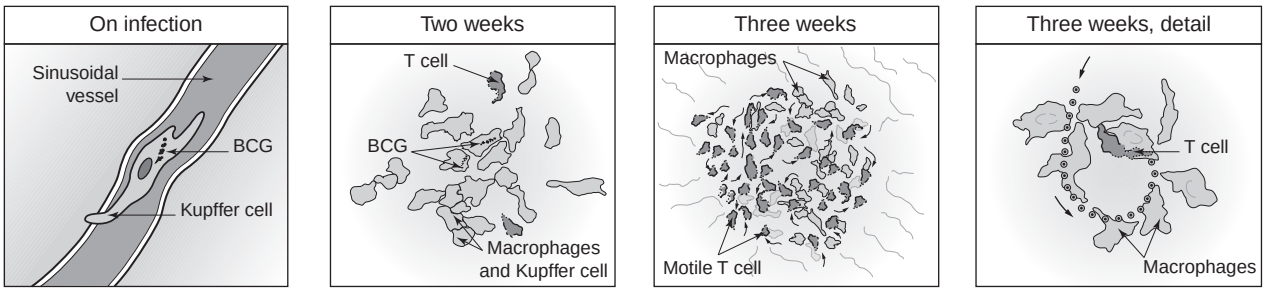

Figure 40.5 Stages of bacille Calmette–Guérin (BCG) granuloma formation: 2 weeks after BCG organisms are phagocytosed by resident Kupffer cells, infected Kupffer cells attract local macrophages and monocyte-derived macrophages and T lymphocytes arrive. By 3 weeks, T cells are plentiful and migrate in constant contact with macrophages, forming the "scaffold" of the granuloma. (Reproduced from Davis et al. [51] with permission from Elsevier.)

properties [47], such as sarcoid granulomas producing angiotensin-converting enzyme (ACE) [48]. The cytokine network and immunology associated with granuloma formation has been reviewed in detail by James [4].

Macrophages must be immunologically activated in order to encircle and destroy infectious organisms [2]. In the presence of T lymphocytes (CD4+ cells) with certain Th1 and Th2 cytokine profiles, they become bacteriocidal and aggregate to form granulomas [3]. Interferon γ plays an important role in the aggregation process [49]. Blocking tumor necrosis factor γ (TNF-γ) has been shown to cause regression of granulomas, but at the cost and risk of increasing a host's susceptibility to mycobacterial infections [3].

Elegant studies performed by Egen and colleagues [50] have demonstrated that granulomas are not merely participating in a passive defense reaction to "wall off" an infectious organism, foreign body, or other antigenic stimulus that cannot otherwise be destroyed. Utilizing blood-borne bacille Calmette–Guérin (BCG) as a model for tuberculosis (TB), these investigators have shown that granulomas form as part of a dynamic process, with T lymphocytes being in constant motion within and around each granuloma, in order to make direct contact with the macrophages that comprise all parts of the structure (Fig. 40.5) [51]. As a result, both innate and adaptive immune cells play an integral part in the development of granulomas, and the work of Egen et al. provides an important insight into the events involved in the containment and escape of mycobacteria [50].

Etiology

Depending on the geographic locale, the causes of granulomas vary according to the prevalence of diseases encountered (see Table 40.1). For example, in India and Saudi Arabia, most are due to TB [13,21]; in Europe, PBC tends to predominate [12,16,19,20,22]. In the midwest of the United States, histoplasmosis is seen more often than in other areas [5,52]; schistosomiasis is important in the Middle East and the tropics [17], Mediterrranean fever in Spain [7], and brucellosis and Q fever in sheep- and cattle-raising regions and in slaughterhouse workers [53,54]. In many series, infectious disorders are the leading causes of hepatic granulomas, consistent with the notion that granulomas form in response to intracellular pathogens that trigger active cell-mediated immunity, or to the persistence of nondegradable (foreign body) products [4]. Table 40.1 lists several representative series of hepatic granulomas from diverse geographic areas that attest to their spectrum of causes. The etiopathogenesis of hepatic granulomas often depends on the extent to which a specific diagnosis is sought, although no cause was identified in up to half of the cases in the older series. However, with the advanced diagnostic testing currently at our disposal, including serologic tests and the use of PCR analyses for a variety of infectious agents, the percentage of truly "idiopathic" (unexplained) granulomas has been reduced; in more recent series it is found to be about 10% [9,52]. A complete listing of the causes of hepatic granulomas is given in Box 40.3.

Clinical consequences

Granulomas come to attention based on the clinical setting in which they arise – either as part of an acute generalized hypersensitivity reaction or infection, during the evaluation of FUO, or as part of the workup for abnormal liver-associated enzymes (usually alkaline phosphatase, γ-glutamyltransferase (GGT), or hyperglobulinemia). In a Mayo Clinic series [11], 74% of patients had unexplained symptoms (including fever) present for a mean of 19 months, with the remainder of granulomas being discovered on liver biopsy for abnormal liver function tests (LFTs). While granulomas are often associated with a classic inflammatory response, significant hepatocellular dysfunction is unusual; hence the term "granulomatous hepatitis" [5] less commonly applies. The term favored by most authorities is "hepatic

Box 40.3 Causes of hepatic granulomas.[a]

Infections

- Bacteria:
  - Brucellosis
  - Catscratch disease (*Bartonella henselae*)
  - *Yersinia enterocolitica*
  - Melioidosis
  - Nocardiosis
  - Tularemia (*Pasturella tularensis*)
  - Salmonellosis
  - *Staphylococcus*
- Mycobacteria:
  - *Mycobacterium tuberculosis*
  - *Mycobacterium avium complex*
  - *Mycobacterium leprae* (leprosy, Hansen disease)
  - Atypical mycobacteria
  - BCG vaccination
- Fungi:
  - Histoplasmosis (*Histoplasma capsulatum*)
  - Coccidioidomycosis (*Coccidioides immitis*)
  - Candidiasis
  - Blastomycosis
  - Aspergillosis
  - Mucormycosis
- Parasites:
  - Schistosomiasis
  - Visceral larval migrans (*Toxacara canis*)
  - Toxocariasis (visceral larva migrans)
  - Visceral leishmaniasis (*L. donovani*, kala-azar)
  - Strongyloidosis
  - Fascioliasis
  - Giardiasis
- *Chlamydia*:
  - Psittacosis (*Chlamydia psittaci*)
- Rickettsiae:
  - Q fever (*Coxiella burnetti*)
  - Boutonneuse fever (*Rickettsia conorii*)
  - Scrub typhus (*Orientia tsutsugamushi*)
- Spirochetes:
  - Syphilis (*Treponema pallidum*)
- Viruses:
  - Hepatitis A
  - Hepatitis B
  - Hepatitis C
  - Cytomegalovirus
  - Epstein–Barr virus (mononucleosis)
  - Varicella

Neoplasms

- Hodgkin disease
- Lymphoma
- Hairy cell leukemia
- Renal cell carcinoma

Drugs

See Box 40.7

Metals

- Beryllium
- Copper sulfate
- Gold
- Aluminum
- Thorotrast (thorium dioxide)

Foreign materials

- Silica
- Talc (IV drug use, glove powder)
- Silicone (spallation of dialysis tubing, ball-valve prostheses)
- Mineral oil
- Barium sulfate
- Suture material
- Cement, mica dust
- Polyvinyl pyrrolidone

Miscellaneous causes

- Sarcoidosis
- Jejunoileal bypass
- Primary biliary cirrhosis
- Primary sclerosing cholangitis
- Chronic biliary obstruction
- Hypogammaglobulinemia
- Wegener granulomatosis
- Chronic granulomatous disease
- Giant cell arteritis
- Rheumatoid arthritis
- Crohn disease
- Postliver transplant rejection, recurrent disease

Idiopathic (no cause established)

Factitious

- Quinine

granulomas" as used by my predecessor of this chapter [55] and others [2,56]. Despite the relative absence of overt hepatic dysfunction with most granulomas, several clinicopathologically significant lesions are described in association with granulomatous involvement (Table 40.2).

Clinical evaluation

Clinical and historical clues

The extent to which a specific cause of granulomas in the liver is sought often corresponds to the frequency with which certain diagnoses are found in various geographic locales. A patient's travel history, drug history, occupation, presence of household pets, and proximity or exposure to domesticated farm or feral animals may provide useful clues as to the diagnosis (Table 40.3).

Table 40.2 Clinicopathologically significant hepatic lesions seen with granulomas.

Pathologic lesion	Causative granulomas	Reference
VOD	Lipogranulomas	Keen et al. 1985 [33]
Chronic cholestasis	Sarcoidosis	Rudzki et al. 1975 [58], Valla et al. 1987 [59]
VBDS	Sarcoidosis, PBC	Pereira-Lima & Schaffner1987 [60], Bass et al.1982 [61]
Portal hypertension	Sarcoidosis, PBC,schistosomiasis	Rudzki et al. 1975[58], Lipson et al. 2005[62], Lucey & Maguire1993 [63]
Granulomatous hepatitis[a]	Drugs, neoplastic/immunologic disorders,infections	Mir-Madjlessi et al. 1973 [5], Simon & Wolff 1973 [25], Telenti & Hermans1989 [26], Zoutman et al.1993 [27]

[a] Defined as fever, weight loss, abdominal pain, myalgias, and arthralgias.
PBC, primary biliary cirrhosis; VBDS, vanishing bile duct syndrome; VOD, venooclusive disease.

Table 40.3 Clinical and historical clues to the cause of hepatic granulomas.

Historic clue	Possible cause
Exposure to animals:	
Sheep, cattle, etc.	Q fever, brucellosis
Cat bites or scratches	*Bartonella*
Puppies	Visceral larva migrans
Wild rodents, dogs	Rickettsioses
Dog ticks	Boutonneuse fever (*Rickettsia conorii*)
Parrots and other birds	Psittacosis
Occupation related:	
Slaughterhouse workers, veterinarians	Q fever, brucellosis
Miners, atomic energy plant, or ceramics workers	Beryllium
Vineyard workers	Copper sulfate toxicity
Swimming, wading in streams	Schistosomiasis
HIV/AIDS, STDs	*Mycobactium avium*, *M. tuberculosis*, toxoplasmosis, syphilis
IV drug use	Talc
Medical procedure:	
Hemodialysis with silicon tubing or ball-valve prosthesis	Silicone spallation
Jejunoileal bypass for obesity	Lipogranulomas
Chrysotherapy for rheumatoid arthritis	Gold
BCG inoculation	BCG
Mineral oil ingestion	Lipogranulomas
Skin lesions	Leprosy, sarcoidosis, syphilis
Fever	TB, sarcoidosis, most infections, drugs causing hypersensitivity
Living in disease-endemic areas:	
Mexico, China, and South America	Leprosy
Worldwide	Tuberculosis, AIDS
Eastern and midwestern United States	Histoplasmosis
Southwestern United States	Coccidioidomycosis
Southeast Asia	Melioidosis
Tropics	Schistosomiasis

AIDS, acquired immune deficiency syndrome; BCG, bacille Calmette–Guérin; HIV, human immunodeficiency virus; STD, sexually transmitted disease; TB, tuberculosis.

Box 40.4 Classification proposed for diagnosing hepatic granulomas.

- Group 1: "*see the cause.*" Cause is readily identifiable on microscopy (e.g., AFB-positive mycobacteria, schistosomiasis ova or foreign body)
- Group 2: "*know the cause.*" Etiology identified serologically or by a consistent clinical picture (e.g., Q fever, PBC, etc.)
- Group 3: "*suspect the diagnosis.*" Cause surmised by clinical and drug history, clinical and biochemical findings (e.g., allopurinol associated with fibrin ring granulomas)
- Group 4: "*cause unknown.*" In the absence of any clinical or historical clues, negative serology, and immunochemical staining

Adapted from Denk et al. [2].

Guidelines proposed in 1994 by a preeminent group of hepatic histopathologists for diagnosing hepatic granulomas still appear to be quite useful (Box 40.4) [2]. While many causes can be identified using histopathology and serologic testing, granulomas of unknown or indeterminant etiology still account for about 10% overall.

Laboratory studies

Biochemical markers associated with hepatic granulomas are nonspecific [55]. An elevated alkaline phosphatase or GGT may give a clue as to the presence of granulomatous disease, but by themselves they are nondiagnostic, and may also signify cholestatic disorders. Clinical jaundice is unusual in TB and other infections, but may be seen in other causes, including the uncommon chronic cholestatic lesion of sarcoidosis [58]. Hyperglobulinemia may be present in TB and sarcoidosis. Other commonly employed laboratory tests that can be performed include ACE levels for suspected sarcoidosis, antimitochondrial antibody for suspected PBC, and rapid plasma regain (RPR) for syphilis.

Serologic tests

Serologic tests are available for a wide variety of infections including Q fever, mononucleosis, cytomegalovirus (CMV), *Brucella*, syphilis, hepatitis A, B, and C, psittacosis, among others. The reader is referred to other sources describing the most accurate diagnostic modalities for infectious causes of granulomas (Table 40.4) [28].

Additional diagnostic studies include ova and parasite examination of the stool to uncover schistosomiasis, *Toxocara*, or other parasites. Slit lamp examination of the eye revealing uveitis may be a clue to the presence of sarcoidosis. A chest X-ray may reveal changes suggesting TB, sarcoidosis, Hodgkin disease, etc. Diagnostic bone marrow or lymph node biopsy are available to help identify granulomas associated with TB, lymphoma, Hodgkin disease, etc.

Radiologic tests

Radiologic evaluation may yield clues as to the cause of granulomas, although most granulomas are often too small to be seen on standard imaging. However, the magnetic resonance imaging (MRI) appearance of

Table 40.4 Specific diagnostic tests and treatment of the most commonly encountered infectious causes of hepatic granulomas.

Cause	Diagnostic tests	Treatment[a]
Mycobacterium tuberculosis	Positive AFB smear and culture; PCR	INH, pyrazinamide, rifampin
Mycobacterium avium	Tissue culture; positive AFB smear	Macrolides, azalides, rifabutin
Mycobacterium leprae	Skin biopsy; positive Fite stain	Dapsone ± clofazimine, rifampin
Q fever	Serology; PCR; culture	Doxycycline; vaccine for prevention
Brucellosis	Serology; PCR; positive blood or tissue culture	Doxycyline + rifampin or streptomycin
Syphilis	Treponemal serology; PCR	Benzathine or procaine penicillin
Schistosomiasis	Positive serology	Praziquantel
Catscratch fever	Silver stain; tissue culture; PCR	Ciprofloxacin, doxycyline, erythromycin, TMP-SMX
Histoplasmosis	Skin testing; silver stain; serology	Azoles (e.g., fluconazole)
Coccidiodomycosis	Precipitin or other antibody tests; skin test; tissue culture	Azoles, amphotericin
Yersinia enterocolitica	Serology, culture	Aminoglycosides, tetracyclines, TMP-SMX, ciprofloxacin
Visceral larva migrans	Larvae in tissue; ELISA	Albendazole, etc.
Visceral leishmaniasis	Amastigotes in aspirates; promastigotes in culture; serology	Liposomal amphotericin B
Toxoplasmosis	PCR; serology; tissue isolates	Pyrimethamine + sulfadiazine, clindamycin + leucovorin
Psittacosis	Serology	Tetracycline, doxycycline

*Consult reference [28] for specific dosages and alternates regimens used for hepatic involvement.
AFB, acid-fast bacilli; ELISA, enzyme-linked immunosorbent assay; INH, isoniazid; PCR, polymerase chain reaction; TMP-SMA, trimethaprim sulfamethoxazole.

granulomatous hepatitis includes nodules 0.5–4.5 cm in diameter; with caseating granulomas being intermediate to high signal on T2-weighted images and low signal on T1. Noncaseating granulomas were found to have an increased enhancement on arterial phase images that persisted into late phases [64]. On ultrasound, multiple echogenic lesions 3–5 mm in size surrounded by a hypoechoic halo have been described [65]. Diagnostic laparoscopy is described as revealing a range of liver capsule findings, including exudative, pinpoint, granular, macular, and cord-like features. TB was most often granular, while brucellosis was exudative [66].

Histopathologic appearance

Granulomatous reactions may take one of several forms as described by Goodman [43] and Kleiner [3]: (i) simple (bland) granulomas without other associated injury; (ii) granulomatous hepatitis with hepatocellular injury, including apoptosis and parenchymal inflammation; and (iii) granulomatous cholangitis or vasculitis. The pathologic appearance and location of the granulomas may offer important clues to their cause, as listed in Box 40.5. Special stains for acid-fast bacilli (AFB) and fungi, the use of polarizing microscopy looking for talc, and immunohistochemical stains for hematogenous malignancies, etc., may be helpful. The culture of liver biopsy material has a relatively low yield in terms of *Mycobacterium tuberculosis* and other infections, but is often performed, especially in patients with FUO. Kleiner [3] has emphasized the need to avoid mistaking isolated, incidental granulomas for a generalized disease process, such as sarcoidosis or hepatitis C.

Box 40.5 Histopathologic clues to the etiology of hepatic granulomas.

- Large number of granulomas: sarcoidosis, miliary TB
- Lipogranulomas: mineral oil, food stuffs containing waxes or other saturated hydrocarbons
- Associated bile duct injury: PBC, sarcoidosis
- Well-formed granulomas: sarcoidosis, TB, schistosomiasis, histoplasmosis, coccidioidomycosis, chronic brucellosis, phenylbutazone
- Poorly formed granulomas (granulomatous inflammation/necrosis): *Mycobacterium avium*, acute brucellosis, Q fever, many drugs, PBC
- Caseation (central necrosis): TB
- Non-necrotizing but AFB positive: BCG
- Uniform age of granulomas: drug injury
- Noncaseating granulomas of different ages: sarcoidosis
- Multinucleated giant cells: sarcoidosis, TB
- Inclusions (stellate-shaped (asteroid bodies) and sarcoidosis lamellar (Schaumann bodies)): sarcoidosis
- Fibrin-ring granulomas (central vacuole surrounded by a ring of fibrin) often staining positive for PTAH: Q fever, allopurinol, Hodgkin disease, other causes listed in Box 40.2
- Eosinophils: drug injury, schistosomiasis, toxocariasis, visceral larva migrans, catscratch disease, Hodgkin disease, non-Hodgkin lymphoma (excludes TB and sarcoidosis)
- Positive AFB stain: TB, *Mycobacterium avium*
- Positive silver stain: fungi
- Foamy macrophages/histiocytes: *Mycobacterium avium*
- Foreign body reaction: talc, silica, schistosome eggs, etc.
- Pigment/crystals:
  - Black granules: gold, titanium
  - Grey-tan birefringent material in RES: barium
  - Coarse, pink-brown granules: thorium dioxide
  - Colorless amorphous birefringent crystals: silicone
- Location/distribution of granulomas:
  - Lobular: drugs, sarcoidosis, brucellosis
  - Portal/periportal: sarcoid, TB, Q fever, drugs
  - Periductal: PBC
  - Perivenous: mineral oil
  - Periarterial: phenytoin

AFB, acid-fast bacilli; BCG, bacille Calmette–Guérin; PBC, primary biliary cirrhosis; PTAH, phosphotungistic acid hematoxylin; RES, reticuloendothelial system; TB, tuberculosis.

Specific causes

A number of the most common causes of hepatic granulomas listed in Box 40.3 are described in the following section.

Sarcoidosis

Sarcoidosis is a chronic multisystem granulomatous disease that is seen in all races and ages, and is the leading cause of hepatic granulomas in the United States. It preferentially affects young African-Americans, who have a ten-fold higher prevalence compared with Caucasians, and tends to have a more severe clinical course [67]. The liver is the third most common site of involvement after the lungs and lymphatics. The diagnosis requires the presence of noncaseating granulomas in at least two organs, with negative staining for AFB and being able to exclude other causes [68]. The presence of systemic symptoms (fever, weight loss, malaise) may occur without pulmonary disease. Hepatic involvement generally does not cause significant morbidity, but a small subset may develop progressive cholestatic disease that can lead to cirrhosis and portal hypertension [58,59]. Serum alkaline phosphatase levels can reach very high levels (>1,000 IU/L), but aminotransferases and bilirubin levels are generally normal.

Sarcoid granulomas are compact aggregates of large epithelial cells, often with multinucleated giant cells and a rim of lymphocytes and macrophages (Fig. 40.6). They occur diffusely throughout the liver, but are most prominent in the portal and periportal zones. Klatskin [1]

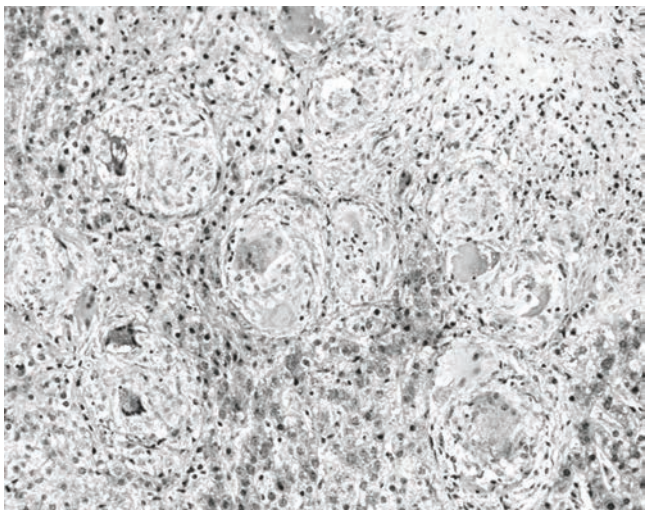

Figure 40.6 Sarcoidosis with multiple noncaseating epithelioid granulomas with multinucleated giant cells. H&E, original ×150. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

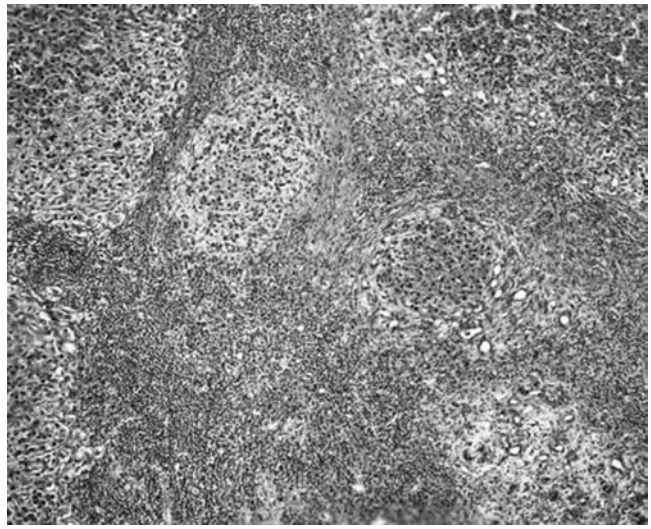

Figure 40.7 Chronic cholestasis of sarcoidosis with micronodular biliary cirrhosis. H&E, original ×60. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

estimated that there were as many as 75 million granulomas in the liver at various stages of maturation. Inclusions in giant cells (Schaumann and asteroid bodies) are characteristic, but not pathognomonic [69,70]. The pathogenesis of sarcoid granulomas involves their transformation from tissue macrophages that are derived from circulating blood monocytes. According to Okabe [71], they are under the control of colony-stimulating factors and possibly vitamin D3, which promote their proliferation. Their transformation to secretory cells, producing ACE, was described by Gronhagen-Riska and others [48].

Three stages of development were described by Klatskin [1]: early on the granulomas are small, later on they become well defined and ovoid in shape with associated Kupffer cell hyperplasia, and finally they form fibrinoid nodules. Sarcoid granulomas tend to segment as they enlarge, forming multilobulated granulomas [18] that may persist for long periods of time. Confluent granulomas may result in extensive, irregular scarring [72]. They are never caseating (in contrast to TB) and should not be confused with the fibrinoid necrosis that can occasionally be seen [70,72]. Tissue eosinophilia is also absent (in contrast to drug-induced granulomas). Bile duct damage may be seen, although less commonly and with less severity than in PBC. Large sarcoid nodules situated in the hilum may produce biliary obstruction. Chronic cholestasis resembling PBC is a well-described but less common clinical outcome (Fig. 40.7) [58,60,61]. Progression to frank biliary cirrhosis with portal hypertension (from occlusion of intrahepatic portal vein branches) requiring transplant is relatively uncommon, but the disease may recur in allografts [62]. Moreno-Merlo et al. [73] suggested that cirrhosis and focal fibrosis may be caused by ischemia secondary to primary granulomatous phlebitis of portal and hepatic veins, with portal hypertension occurring secondary to portal vein thrombosis, as cirrhosis was absent at the onset of variceal bleeding in two patients they described.

Sarcoidosis may be present in association with untreated hepatitis C [74] and can reactivate during interferon therapy [75,76], possibly through the stimulation of the Th1 immune response [77].

In a series of 100 patients with hepatic sarcoidosis studied by the Armed Forces Institute of Pathology (AFIP) [70], the volume of granulomas was estimated from <1% to 90%; 99% of which were noncaseating. Three biochemical patterns were found: cholestatic in 58% (nearly half of whom had bile duct lesions similar to PBC or primary sclerosing cholangitis (PSC)); necroinflammatory in 41% (with spotty necrosis and/or chronic portal inflammation); and vascular in 20% (with sinusoidal dilatation and nodular regenerative hyperplasia). Ductopenia was found in 37 of 58 individuals with chronic cholestasis. Another 12 had acute cholangitis changes without clinical evidence of ductal obstruction. Fibrosis was seen in 21 patients (periportal in 13, bridging in two, and cirrhosis in six).

The therapeutic options for sarcoidosis have been reviewed by others [67]. Treatment of hepatic granulomas is usually administered only when the patient has systemic symptoms from granulomatous hepatitis or cholestatic liver disease, or other symptomatic organ involvement [68]. There is no evidence that corticosteroids prevent progression of hepatic disease in asymptomatic individuals [78], although alkaline phosphatase levels may decline. Granulomas may heal without a trace

[70]. In a series by Gottlieb et al. [79], patients with hepatic involvement had a three-fold higher risk of relapse after a course of steroids compared with those without liver disease. Ursodiol may be beneficial in patients with the cholestatic form of the disease [80,81].

Mycobacterium tuberculosis

Granulomas are the most common histologic feature of TB involving the liver, but a wide spectrum of nonspecific histopathologic lesions may be present [81–85]. Granulomas are seen in approximately 20% of patients with pulmonary TB (depending on how many sections are examined) and are seen nearly universally in those with miliary TB [85]. Isolated hepatic involvement is also well described [86]. As many as two thirds of patients with acquired immune deficiency syndrome (AIDS) coinfection have extrapulmonary involvement, that frequently involves the liver (as described below) [87].

The granulomas associated with *Mycobacterium tuberculosis* are composed of mononuclear (epithelioid) cells surrounded by lymphocytes, with or without Langhans-type multinucleated giant cells (Fig. 40.8). They are generally 1–2 mm in size, but large tuberculomas up to 12 cm are reported [87]. Caseation (central necrosis surrounded by peripheral macrophages) is considered a hallmark finding of TB granulomas, and is present in 33–100% of liver biopsy specimens from various series [85]. Caseation is thought to occur as a result of overwhelming acute dissemination of mycobacterial organisms, and therefore occurs more commonly in miliary TB. It is characteristically granular and "cheesy" in appearance, hence the term "caseous" (Fig. 40.9A). Giant cells are often present and AFB stains are positive in about 60% (Fig. 40.9B), in contrast to cultures often being negative [85]. PCR assays are diagnostic in most patients with TB granulomas in the liver [88,89].

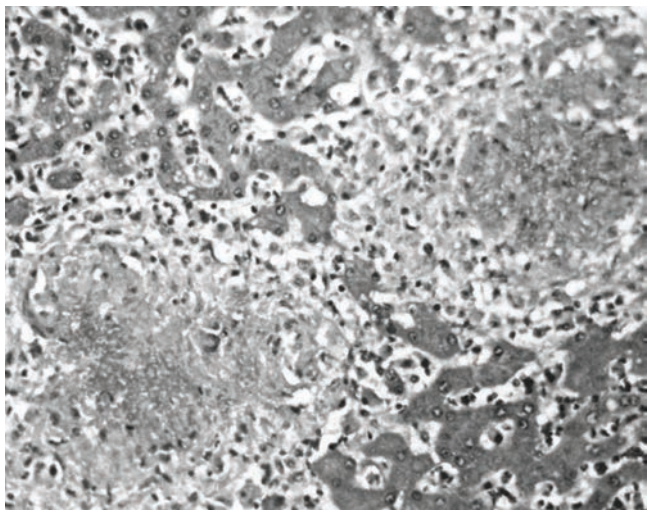

Figure 40.8 Granulomas with caseation necrosis in miliary tuberculosis. H&E, original ×100. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

Clinical and biochemical clues to the presence of hepatic TB are nonspecific [85]. Hyperglobulinemia is often seen and serum alkaline phosphatase levels are often raised, while aminotransferase values remain normal in pulmonary disease and mildly elevated in miliary TB [90,91]. Jaundice is unusual and should prompt a search for biliary obstruction or associated hepatotoxicity from anti-TB drug therapy. An uncommon form of acute miliary TB described by Essop et al. [92], called "tuberculous hepatitis," was accompanied by fever, tender hepatomegaly, and splenomegaly, and had a very high incidence (96%) of hepatic granulomas, with caseation seen in 83%. However, tubercle bacilli were found in only 9% of cases. The demonstration of AFB has generally been low in pulmonary TB, and higher in military disease, but

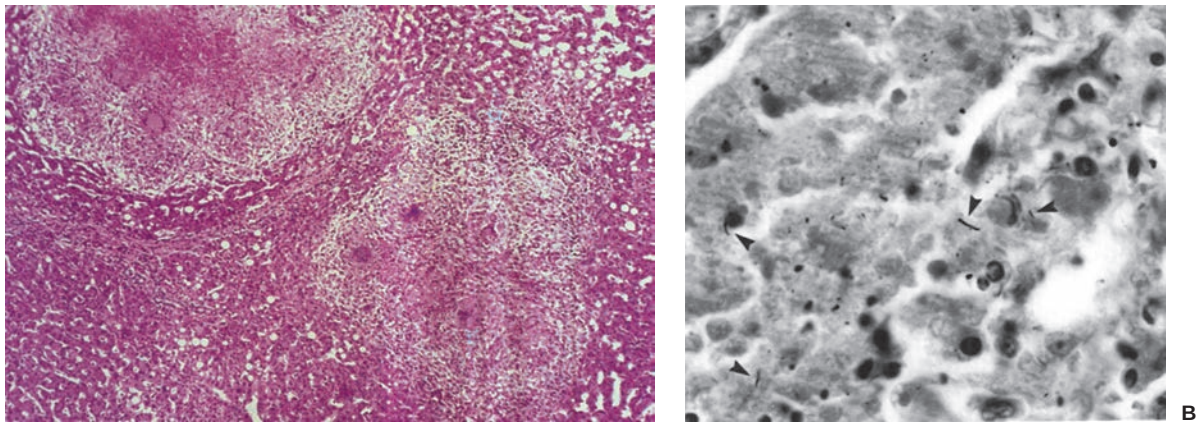

Figure 40.9 (A) Caseous necrosis with multinucleated Langhans giant cells in granulomas associated with *Mycobacterium tuberculosis*. H&E, original ×100. (B) Higher magnification demonstrated acid-fast organisms (arrows) in a caseating granuloma. Ziehl–Neelson stain, original ×1,000. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

positive cultures have been rare in the literature [85]. Following successful anti-TB treatment, complete resolution of hepatic granulomas is described as occurring within a few months [92,93].

TB rarely affects liver allografts in contrast to renal and other solid organ transplants [94]. In a series of 42 post orthotopic liver transplantation (OLT) patients with granulomas on liver biopsy, Ferrel et al. [95] found only one patient with documented TB (a prevalence of 2.4%). Granulomatous hepatitis has been attributed to isoniazid and pyrazinamide, although one wonders whether the underlying TB may have been responsible for the finding of granulomas in this setting. In general, hepatotoxicity from isoniazid and pyrazinamide takes the form of acute hepatocellular injury, including fulminant hepatic failure [85,96].

Rarely is a mycobacterium other than *M. tuberculosis* isolated from the liver. *M. kansasii*, *M. mucogenicum*, and other atypical mycobacterial organisms have been found [85].

Granulomatous hepatitis caused by BCG is reported in 12–28% of patients receiving BCG as immunotherapy for neoplastic disease [97,98], often several months after the last inoculation. A role for both BCG bacilli and a hypersensitivity reaction has been proposed as the mechanism. O'Brien and Hyslop [99] note that BCG organisms may remain viable for weeks to months. BCG preparations are antigenic, with granulomas forming as a result of a hypersensitivity response [98].

Leprosy (*Mycobacterium leprae*)

Granulomas are common in lepromatous leprosy, but symptoms and signs of hepatic involvement are generally absent, apart from hyperglobulinemia [100]. Histologically, a spectrum of epithelioid, tubercular, and foam cell granulomas is seen [101]; the first two suggesting the tuberculoid form of the disease and the latter lepromatous leprosy. Foam cells consist of Kupffer cells that are filled with *M. leprae* organisms. The *M. leprae* bacteria are much less common in epithelioid granulomas. Hepatic granulomas in leprosy correlated with cutaneous involvement in the series by Chen et al. [102].

Granulomas in HIV and AIDS

Hepatic granulomas were seen in 37% of 501 liver biopsies in one large series [103] and in 16–48% of smaller series [87,104,105]. A microbiologic diagnosis was apparent only after liver biopsy in over 50% of a series of patients presenting with fever and elevated alkaline phosphatase and GGT levels [106]. The most common cause of granulomas appears to be due to *M. avium* complex (MAC), which was present in 20–50% of all autopsy series in fatal AIDS cases and in 10–70% of those undergoing liver biopsy for suspected AIDS hepatopathy [87,107].

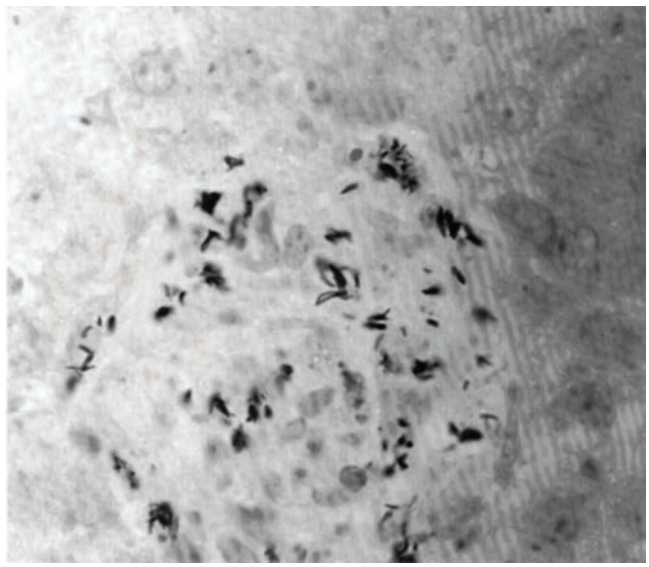

Figure 40.10 *Mycobacterium avium* in a poorly formed granuloma in a patient with AIDS. Numerous acid-fast bacteria are seen in distended histiocytes. H&E, original ×630. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

MAC has been reported to develop in up to 20% of patients after an AIDS-defining illness has occurred. The granulomas are generally poorly formed and composed of foamy histiocytes with a paucity of other cells, but they contain numerous AFB (Fig. 40.10). Granulomas may be absent in a severely immunosuppressed host. In a series of liver biopsies and autopsies from 71 AIDs patients from 1982 to 1986 in Paris, Astagneau et al. [108] found granulomatous hepatitis in 22 patients, half of which were associated with opportunistic infections and the remainder remained unexplained. Well-formed necrotizing and non-necrotizing granulomas are described in immunocompetent patients infected with MAC [109].

M. tuberculosis has been described in 60% of AIDS patients with pulmonary disease and in 7.5% with extrapulmonary disease, often as a result of reactivated disease from a previous focus [87,110]. These granulomas tend to be better formed and occur earlier in the course of HIV infection compared with those in MAC. However, fewer AFB are present on immunohistochemical stains. In contrast to *M. tuberculosis*, MAC is usually the result of a primary infection, typically in the late stages of AIDS with CD4+ counts $<200/mm^3$ [87]. An improved response to multidrug regimens has correlated with improved survival. Alkaline phosphatase values, reflecting hepatic involvement, may normalize after successful therapy.

A number of parasites can cause granulomatous disease in the HIV population. *Pneumocystis carinii* pneumonia (PCP) with extrapulmonary spread is seen in over

30% of cases at autopsy. Toxoplasmosis, leishmaniasis, and schistosomiasis are described in this population. Fungal causes of granulomas may also be seen [55].

Schistosomiasis

Schistosomiasis (*Schistosoma mansoni*, *S. japonicum*, *S. mekongi*) is acquired by contact with fresh water infested by the parasitic larvae (cercariae) carried by their host snails. Several hundred million persons are affected worldwide, mostly in tropical regions of the Middle East, the Caribbean (Puerto Rico), Central America, Africa, and Southeast Asia. The life cycle of schistosomes is well described [63]. The adult worms can survive in the host for up to 35 years, depositing hundreds to thousands of eggs daily. Most eggs find their way to the portal circulation and become trapped in several organs, notably the liver. Constant deposition of eggs results in a CD4+ T-helper-cell-mediated granulomatous response to egg antigens (e.g., Sm-p40 and the presence of interleukin 23 (IL23)) [111–113]. This can cause a chronic hepatic reaction with large granulomas in portal areas (hepatosplenic involvement) that become surrounded by fibrosis leading to noncirrhotic portal hypertension (Fig. 40.11) [114]. Following the death of the ova, a dense portal fibrosis may be the only histologic remnant of the infection [18].

Clinically, a serum sickness-like illness from circulating immune complexes produces fever, myalgias, arthralgias, cough, diarrhea (sometimes bloody), and eosinophilia [115]. Eggs may be found in the stool, but an enzyme-linked immunosorbent assay (ELISA) test to detect schistosome antibodies is more reliable. Features of periportal fibrosis and portal hypertension on abdominal imaging tests may also be helpful in making the diagnosis [28]. Several groups of researchers have found that zinc administration leads to a reduction in the number and size of hepatic granulomas in animal studies [116,117].

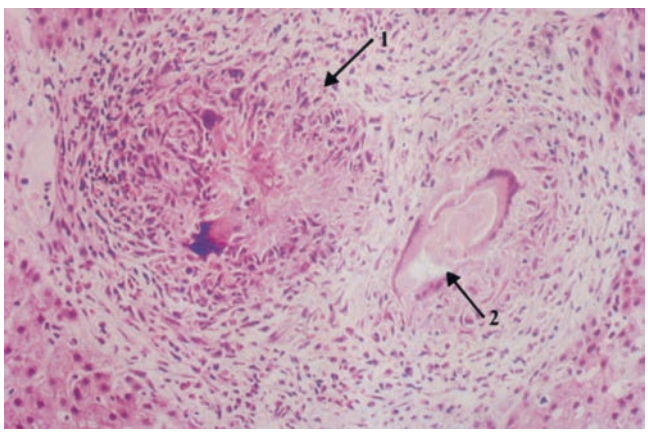

Figure 40.11 Schistosomiasis (*Schistosoma mansoni*) granuloma (arrow 1) next to an ovum blocking an intrahepatic portal vein branch (arrow 2) in a patient with portal hypertension. H&E, original ×400. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

Q fever

This worldwide zoonosis among ruminants and birds is caused by tick-borne *Coxiella burnetti*, an obligate intracellular Gram-negative bacterium forming spore-like forms that inhabits monocytes and macrophages [118]. Acute infection in humans occurs primarily by inhalation of contaminated aerosols and dusts from domestic animals, particularly after contact with partuent females and their birth products as the placenta harbors millions of the bacteria [119]. Q fever may present as a community-acquired pneumonia with high fever, cough, headache, and myalgias [119,120], or as a self-limited febrile illness without pulmonary symptoms [119]. Up to 50% of patients present with acute hepatitis-like symptoms, several of which have hyperbilirubinemia, including jaundice [121]. Hepatic involvement also presents as fever of unknown origin and as an incidental finding in patients with pneumonia. Industrial outbreaks (from aerosolized spores) have been described [122], but the infection occurs most frequently among workers on sheep [54] and cattle farms or in slaughterhouses [123] outside the United States. A chronic form of the disease can result in endocarditis, myocarditis, pericarditis, and chronic fatigue syndrome [124]. Hepatitis generally affects younger patients, while pneumonia is seen in older individuals [53].

The characteristic histologic appearance is a fibrin-ring granuloma [36], previously referred to as a "doughnut" granuloma (125) (see Fig. 40.3) [125]. They are usually in portal areas and accompanied by prominent lymphoid hyperplasia. Toll-like receptor 4 appears to play a role in the uptake of virulent organisms and the development of granulomas [118]. In mice, the intraperitoneal route of infection led to hepatic involvement, while the intranasal route was more often associated with pneumonitis [126]. Serology and PCR testing are available to confirm the diagnosis. Treatment has been successful with the use of doxycycline and steroids [53,127]. A preventative vaccine is also available [53].

Other infectious causes

- *Syphilis*. Secondary lues (*Treponema pallidum*) involves the liver in up to 50% of cases, often with tender hepatomegaly and sometimes overt jaundice. Elevated alkaline phosphatase with lesser elevations in aminotransferases is the most common biochemical finding. Spirochetes have been demonstrated by appropriate staining in up to half of affected liver specimens [128]. Following successful antibiotic treatment, resolution of granulomas and other hepatic abnormalities can be expected. In tertiary syphilis, single or multiple hepatic gummas are seen that may give rise to a

lobulated appearance (hepar lobatum). Although much larger than granulomas, gummas may also resolve following treatment [28].

- *Yersinia enterocolitica*. Diffuse granulomas of the liver and spleen are seen in the septicemic form. Twelve percent of infections may involve the liver, in some cases causing chronic hepatitis [129].
- *Bartonella henselae* (catscratch fever) develops after a scratch or bite by a cat or kitten and usually results in regional lymphadenitis, although peripheral adenopathy is not always present [130,131]. Scattered granulomas with central necrosis may coalesce to form abscesses. It has been diagnosed in a liver transplant patient with FUO [132]. Warthin–Starry silver staining may identify the Gram-negative bacillus early in the course of infection. An antigen skin test is positive in 90%, but PCR tests are now available [133].
- *Visceral leishmaniasis* (*Leishmania donovani*, kala-azar) is transmitted by the bite of the sandfly, causing a papular or ulcerative skin lesion with systemic symptoms occurring after a latent period of 2–6 months or longer. Intermittent fever, weight loss, tender hepatosplenomegaly, and occasional jaundice are seen. Phagocytosis of the parasite by macrophages in the reticuloendothelial system allows the organism to multiply in the affected liver, spleen, bone marrow, and lymph nodes. The diagnosis is based on the finding of amastigotes in aspirates or promastigotes in culture from these tissues as well as serologic testing [39,134].
- *Visceral larva migrans*, caused by *Toxacara canis*, typically produces hepatic granulomas containing numerous eosinophils. In a series of 43 cases reviewed by Kaplan et al. from the AFIP [135], 30% were under the age of 20 years and 60% were asymptomatic with the disease discovered incidentally. Fever and/or abdominal pain were the most common symptoms reported in the remainder. Granulomas were multiple in 61% of cases and central necrosis was characteristically surrounded by eosinophils and neutrophils, often with Charcot–Leyden crystals. Remnants of the parasite were detected in 23%, and immunohistochemical staining and serology confirmed the diagnosis in many others.
- *Brucellosis*. Acquired from infected cattle (*Brucella abortus*), pigs (*B. suis*), sheep (*B. ovis*), and goats (*B. melitensis*), often from raw, unpasteurized milk and dairy products, brucellosis typically presents as an acute febrile illness with hepatic involvement [136–139]. Jaundice is fairly common [136,137], as is relapsing (undulant) fever. Epithelioid granulomas are most often seen in the chronic form of the disease, with a lobular location more common that the portal tracts. Central necrosis, a polymorphic infiltrate, relatively few giant cells, and peripheral fibrosis is typically seen. The diagnosis is confirmed by serology, positive *Brucella* PCR [138,140], or culture of liver tissue [140]. Untreated, the clinical course is usually one of spontaneous resolution within 3–12 months, although antibiotics may shorten the illness [28,136].
- *Histoplasmosis* (*Histoplasma capsulatum*) is found most commonly in the midwest and central parts of the United States, especially in river valleys, and usually affects young children more than adults [52]. Four to 8.5% of patients have rare well-formed granulomas [52,141]. Rarely they are caseating, resembling tuberculosis. Clinically, adrenal insufficiency may be a diagnostic clue [141].
- *Coccidioidomycosis* (*Coccidioides immitis*) is most likely to be found in the deserts of the southwest United States. Granulomas are more likely to be found in the liver compared with histoplasmosis, and eosinophilia is often present [142].

Granulomas associated with chronic viral hepatitis and its therapy

Several reports have described granulomas in patients with hepatitis C infection [143–147], although some of these may be related to suspected or unsuspected sarcoidosis [77,148] or PBC [149]. As noted by Kleiner [3], granulomas are not usually considered part of the normal histopathologic spectrum of acute or chronic hepatitis C. Emile et al. [144] described multiple epithelioid granulomas in 10% of cirrhotic livers due to hepatitic C virus (HCV) without any other cause identified. These granulomas were located within cirrhotic nodules and not in portal areas suggesting that they were most likely unrelated to the viral infection. Nevertheless, a small percentage of granulomas in this setting do not have another readily identifiable etiology [150].

In contrast, interferon (IFN) has been associated with granuloma formation in HCV patients [143,144,151] although the exact pathogenesis is not always certain. IFN-induced cutaneous sarcoid has been described in hepatitis C patients [79], and induction [80] and reactivation [78] of systemic sarcoidosis has also occurred, possibly through the production of inflammatory cytokines mediated by IFN [152] or entanercept [153].

Granulomas have been seen in a small percentage of chronic hepatitis B patients; 1.5% among 663 patients in one series [154], although the cause is uncertain.

Granulomas after liver transplantation are reported to occur in 3–9% of allografts [95], and may reflect recurrence of the original disorder, such as PBC, sarcoidosis, etc., or possibly de novo formation from IFN therapy for HCV in the post-transplant setting (Box 40.6) [155]. Granulomatous cholangitis may be seen in acute cellular rejection or a delayed vanishing bile duct syndrome (VBDS) [156]. Infections with opportunistic agents, including TB

Box 40.6 Causes of granulomas in the postliver transplant setting.

- Recurrence of primary disease: primary biliary cirrhosis, sarcoidosis, HCV, HBV
- Interferon therapy-induced
- Acute cellular rejection: granulomatous cholangitis
- Chronic ductopenic rejection: VBDS
- Post-transplant opportunistic infections: cytomegalovirus, tuberculosis, fungi, toxoplasmosis

HBV, hepatitis B virus; HCV, hepatitis C virus; VBDS, vanishing bile duct syndrome.

[85] and *Toxoplasma gondii*, is described. Toxoplasmosis appears as within the first 3 months with fever, pneumonia, and possibly meningitis or encephalitis, usually from activation of a latent infection [157].

Granulomas in other chronic cholestatic liver diseases

Primary biliary cirrhosis

Epithelioid granulomas are found in at least 25% of PBC patients, usually in the early stages of the disease [158]. PBC typically affects middle-aged women who may present with subclinical alkaline phosphatase elevations or with symptoms reflecting chronic cholestasis, including pruritus. The disease is associated with positive antimitochondrial antibodies in >95% of cases and this may serve to differentiate PBC from sarcoidosis. In addition, PBC often occurs in association with other autoimmune disorders, such as the sicca syndrome, Sjogren syndrome, and CREST (calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) syndrome among others [158]. Granulomas in the portal areas are in close proximity to injured bile ducts, and may give the appearance of being germinal centers (Figs 40.12 and 40.13). It is thought that they form as part of the immune-mediated ductal injury, but the release of bile acids and phospholipids from injured ducts may also contribute to their development [159,160].

Granulomas located in the hepatic lobules are noncaseating and show less central matrix deposition than is usually seen in sarcoidosis [72]. The highest prevalence of granulomas is seen in the early stages of the disease [70,72] and generally confer a favorable prognosis [3,158]. As PBC progresses, granulomas become less frequent [161]. Treatment with ursodiol therapy may also be associated with a reduction in granulomas through its beneficial effects on the histologic features of cholestasis [162,163]. The presence of granulomatous bile duct lesions can help differentiate and confirm the diagnosis of recurrent PBC from chronic rejection after liver transplant [161].

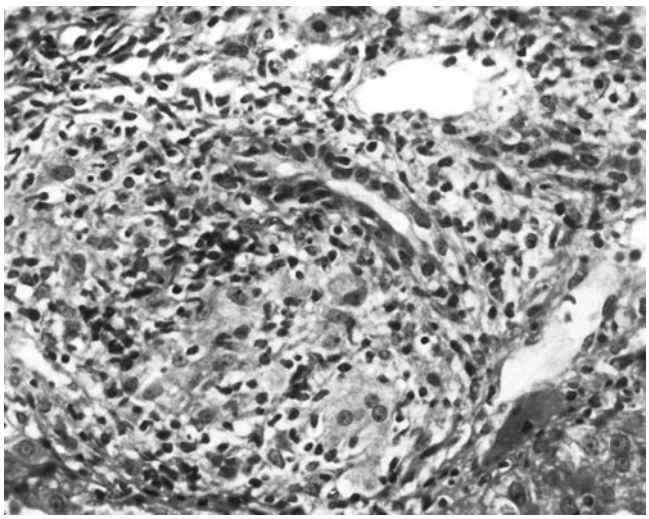

Figure 40.12 Granulomatous cholangitis in primary biliary cirrhosis. H&E, original ×400. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

Primary sclerosing cholangitis

Granulomas have also been reported in PSC [159,164]. Thirteen percent of 100 patients undergoing liver transplant for PSC had noncaseating, non-necrotizing epithelioid granulomas, some with giant cells [164]. They were found in the portal areas, in scars, and in the hepatic parenchyma, and were present in all stages of the disease, but do not represent granulomatous cholangitis (in contrast to PBC where the granulomas are a feature of duct destruction). Ludwig et al. [164] surmise that the granulomas in PSC form in response to bile acid leakage as perigranulomatous lymphocytic infiltrates were common.

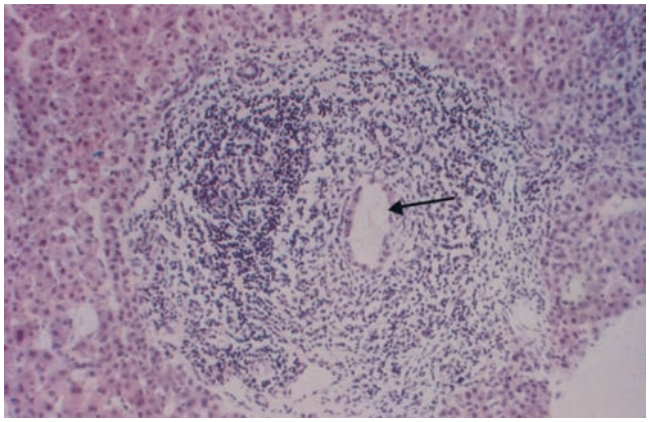

Figure 40.13 Primary biliary cirrhosis with a granuloma in an expanded portal area near a damaged bile duct (arrow). H&E, original ×160. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

Drug-induced granulomas

More than 60 drugs have been implicated (Box 40.7) although most are isolated case reports [165,166]. A few agents appear to be well documented as causing granulomatous hepatitis, usually as part of a hypersensitivity syndrome, e.g., phenylbutazone (Fig. 40.14) [167], sulfonamides, allopurinol (see Fig. 40.3B) [37], phenothiazines, and penicillins. Drug-induced granulomas have been reported with a frequency of up to 29% of all causes of hepatic granulomas [8], although the prevalence has usually been far lower. In the McMaster case series [8] the drugs that were listed as probably or possibly related were predominantly from antihypertensive, antirheumatic, anticonvulsant, and antimicrobial drug classes, and included methyldopa, hydralazine, phenytoin, isoniazid, cephalexin, penicillin, sulfonamides, procainamide, etc. Up to 9.5% of granulomas in other series were due to many of the same drug classes [10,11,16,20,22] and included chlorpropamide, allopurinol, phenylbutazone, synthetic penicillins, quinidine, carbamazepine, and phenothiazines, among others.

The most frequent clinical presentation is an acute febrile illness, with or without a rash and peripheral eosinophilia, followed by jaundice and biochemical evidence of hepatic dysfunction [8]. A latency period of 1–16 weeks is described by McMaster et al. [8], which is consistent with the time frame for other hypersensitivity reactions from drugs [96,166]. Histologic features suggesting a drug-induced cause include the relatively uniform age of the granulomas, and the present of eosinophils, apoptotic bodies, acute cholangitis, and/or vasculitis [3,43]. In contrast, tissue eosinophilia is not seen in sarcoidosis or TB. The prognosis is generally good with recovery after the offending agent is withdrawn. Healing without sequellae is the rule [8,43]. Histopathologic clues to drug-induced granulomas are given in Table 40.5.

Granulomas associated with metals and minerals

- *Beryllium poisoning* uncommonly involves the liver, as the chronic form of the disease is primarily a pulmonary granulomatosis with dyspnea and cough [168]. It should be suspected in occupational exposure where beryllium is employed, such as in the manufacture of ceramics and alloys, and in atomic energy workers. The granulomas seen in beryllium disease may contain Schaumann and asteroid inclusion bodies, which are the end-products of actively secreting epithelioid cells [4] and may be confused with those seen in sarcoidosis [169]. Tissue analysis for beryllium may be confirmatory.
- *Talc* microcrystals are commonly seen in intravenous drug users, many of whom "cut" their heroin with

talcum powder. They are found in hypertrophied portal macrophages, but generally do not develop into well-formed granulomas [170], in contrast to silica, which forms foreign body-type giant cells that contain the birefringent crystals [171]. The presence of talc in the liver, however, may be an important clue as to the etiology of chronic hepatitis C in IV drug users [172].

- Refractile *silicone* particles (confirmed by X-ray energy dispersive spectroscopy) were described in association with sarcoid-like granulomas, some with giant cells, in hemodialysis patients where embolization (spallation) of silicone was traced back to tubing traumatized in the roller pump [173]. Abnormalities in liver-associated enzymes persisted more than 4 years later in two patients [174].
- Multiple granulomas were described in long-term hemodialysis patients [175] with *aluminum* found in the cytoplasm of macrophages in the liver, spleen, and lymph nodes.

Table 40.5 Histopathologic clues to the cause of drug-induced granulomas.

Feature	Drug causing granuloma
Associated cholestatic hepatitis	PBZ, quinidine, allopurinol
Associated cholangitis	CPZ, methyldopa, allopurinol
Associated vasculitis	PCN, sulfonamides, DPH, allopurinol, glibenclamide
Fibrin-ring granulomas	Allopurinol

CPZ, chlorpromazine; DPH, diphenylhydantoin; PBZ, phenylbutazone; PCN, penicillin.

Granulomas associated with malignancy and immunodefieciency states

Hodgkin disease, *lymphomas* and certain hematogenous malignancies (e.g., *hairy cell leukemia*) are associated with granulomas. Granulomas are seen in approximately 10% of those with Hodgkin disease (Fig. 40.15) [176,177], and were present in 31% of those with hairy cell leukemia [178]. Granulomas in the liver may precede the diagnosis of Hodgkin disease or lymphoma [179], and may be a source of diagnostic confusion with sarcoidosis [4]. Rarely, the granulomas associated with Hodgkin disease are caseating [180]. The presence of granulomas does not appear to convey any clinical advantage as suggested by early reports [181]. Mimics of lymphomas that may be associated with hepatic granulomas include *Kikuchi lymphadenitis*, among others [182].

Common variable immunodeficiency is associated with noncaseating granulomas in the liver and spleen [183]. *Chronic granulomatous disease* [184] may appear in adults as well as children [185]. Hepatic involvement was found in nearly one third of 429 patients in a European series [186].

Miscellaneous causes

- *Jejunoileal bypass*. Granulomas were among several hepatic lesions, including steatohepatitis, that were seen following jejunoileal bypass surgery for morbid obesity; 24% of patients undergoing jejunoileal bypass in a series of 25 patients reported by Banner et al. developed granulomas [187]. They developed within 3 months to 4 years after the surgery and were much more common than the incidence (4%) of granulomas seen in obese patients prior to surgery. Their exact etiopathogenesis is unclear.
- *Rheumatoid arthritis* is a rare cause of granulomas [188], as are other rheumatic disorders.

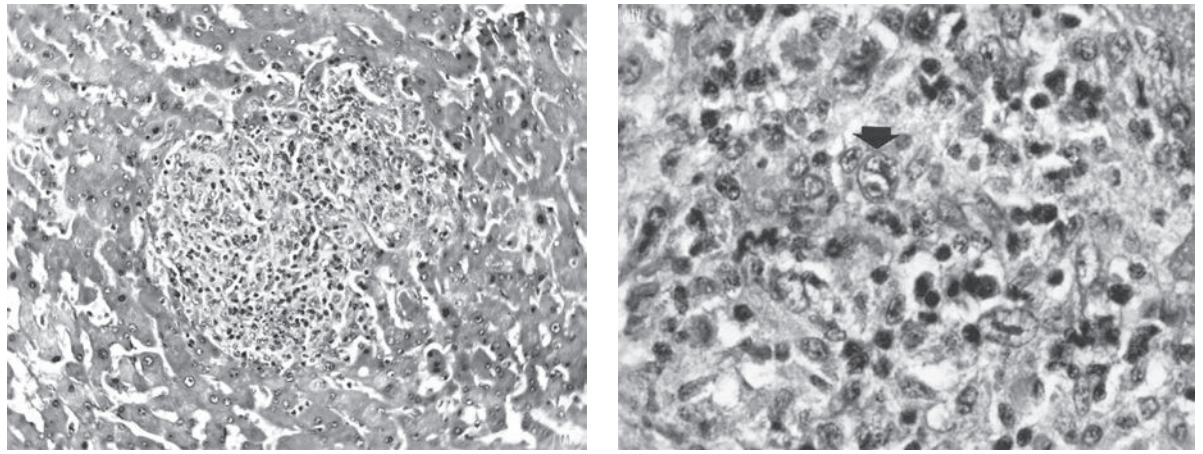

Figure 40.15 Hodgkin disease granulomas. (A) Focal granulomatous infiltrate. H&E. original ×180. (B) Higher magnification showing a pleomorphic infiltrate with a Reed–Sternberg cell (arrow). H&E, original ×750. (Courtesy of Dr K. G. Ishak, Armed Forces Institute of Pathology.)

Idiopathic granulomatous hepatitis and fever of unknown origin

Up to 74% of hepatic granulomas in early series were not identified with a specific diagnosis [27]. Many of these patients had FUO (Table 40.6) or other systemic symptoms or hypersensitivity features, and were designated as "granulomatous hepatitis" [25]. Sarcoidosis has been found in a number of such patients [189], and infectious agents in some of the others [190,193] although no cause was apparent in many [22,26]. Aderka et al. [191] found that certain clinical parameters could differentiate idiopathic granulomas from those that are secondary to lymphoma and other malignancies – namely smaller spleen size, small liver size (<4 cm below the respective costal margin), lower number of eosinophils (<4%), and fever lasting <4 weeks. The spectrum of hepatic candidiasis includes granulomas, especially among patients with hematologic mailgignancies presenting with fever, and elevated alkaline phosphatase levels [192]. In a series by Cunningham and colleagues [9], 31% of granulomas that were considered initially to be "idiopathic" were subsequently diagnosed as having a specific cause based on more in-depth study. In contrast, the etiology of more than one third of the granulomas reported in the series by Drebber et al. from Germany remained obscure [22]. Schlegel [57] described what he termed "factitious" granulomatous hepatitis in a health care worker who had hepatic granulomas and leukopenia attributed to quinine ingestion that was likely being taken surreptiously.

Table 40.6 Hepatic granulomas as a cause of fever of unknown origin.

Number of cases	Diagnoses	Reference
60	Sarcoidosis 47%; tuberculosis 25%; idiopathic 17%	Terplan 1971 [193]
25	36% "positive" diagnosis	Bruguera et al. 1981 [190]
15	Sarcoidosis 100%	Israel et al. 1984 [189]
20	Idiopathic 100%	Telenti & Hermans 1989 [26]
23	Idiopathic 74% (41% spontaneous regression), 26% specific diagnosis (Q fever, tuberculosis, histoplasmosis)	Zoutman et al. 1991 [27]

Treatment of hepatic granulomas and granulomatous hepatitis

General principles

Granulomas that are found incidentally are often asymptomatic but should prompt a workup for the most common causes of granulomas (see Box 40.2, Tables 40.2 and 40.5). They may may not require treatment if involvement is isolated to the liver. Individuals presenting with granulomatous hepatitis, including those with FUO and other systemic symptoms, can be treated for a specific cause, if found. Those that are considered *idiopathic* may respond to an empirical course of corticosteroids [5,25–27]. In a series of 23 cases reported by Zoutman et al. [27] presenting with FUO, 74% were considered idiopathic. Forty-one percent of this group resolved spontaneously, while the remaining 59% received corticosteroids or indomethacin, 18% short term and 41% long term (mean 33 months). All were described as having remained afebrile and healthy after a 5-year follow-up. A similarly good prognosis after long-term corticosteroid therapy of up to 10 years was described by Telenti and Hermans [26] with no

progression or dissemination of an unrecognized infectious process.

In sarcoidosis, corticosteroids are usually given when there is evidence of extrahepatic sarcoidosis as most experts do not believe that isolated hepatic involvement requires therapy unless there is evidence of severe cholestasis [67]. Methotrexate has also been utilized in this disorder [194], as has ursodiol [67], especially for the cholestatic form. Liver transplantation has been required to treat some patients with end-stage chronic cholestatic sarcoidosis [62].

Specific antibiotic therapy for various infectious causes and other treatment options directed at specific causes of hepatic granulomas are reviewed elsewhere (see Table 40.4) [28]. Empirical treatment for TB has been offered in some instances [194]. Drug-induced causes generally resolve spontaneously once the medication has been discontinued.

In cases of symptomatic idiopathic granulomatous hepatitis (such as FUO), corticosteroids have been the mainstay of treatment [26]. Longstreth and Bender [195] described the use of cyclophosphamide as a steroid-sparing maintenance agent in preventing the recurrence of idiopathic hepatic granulomatosis. Methotrexate was described as being effective in seven patients presenting with fever and anorexia in a series by Knox et al. [194]. Nonsteroidal anti-inflammatory drugs were used successfully in a child with necrotizing granulomatous inflammation [196].

Conclusions

Hepatic granulomas are not infrequently encountered in the evaluation of a variety of infectious, chronic cholestatic, inflammatory, hypersensitivity-mediated, and neoplastic disorders. Granulomas can be expected to be present in 3–10% of routine liver biopsies, and in a substantially higher percentage of patients with suspected localized or systemic granulomatous diseases. Both genders and all ages can be affected. The list of possible etiologies, including dozens of drug-related causes, has been expanding, although certain causes still predominate, namely sarcoidosis, tuberculosis, PBC, and certain drugs (especially those acting through hypersensitivity mechanisms), often relating to the geographic location of the patient. Less common causes remain a diagnostic challenge, but are being found more frequently, commensurate with the wider availability of serologic and other PCR-based test systems. Hepatic granulomas may be the only histologic clue as to the presence of several infections, such as tuberculosis and Q fever, among others. Once found, a decision regarding the extent of a further diagnostic evaluation must be made and, ultimately, what treatment, if any, is required. The cause of up to 36% of granulomas remains undefined (idiopathic), some of which are associated with unexplained fever and other symptoms (including arthralgias and rash) that define "granulomatous hepatitis." These cases are arguably the most challenging, often having to rely on empirical treatment regimens. It is anticipated that further advances in clinical and histopathologic diagnostic methodologies will help identify even the most refractory causes of hepatic granulomas in the future.

Elegant studies in BCG-induced granulomas demonstrate the dynamic movement of T cells in and around macrophages.

Ishak KG, Zimmerman HJ. Drug-induced and toxic granulomatous hepatitis. *Baillieres Clin Gastroenterol* 1988;2:463–80.

The most comprehensive review of drugs and chemical toxins associated with hepatic granulomas from two of the leading experts in the fields of drug-induced hepatotoxicity and hepatopathology, emphasizing the role of liver biopsy in this setting. Histologic lesions that suggested a drug etiology included associated tissue eosinophilia, acute cholangitis, and the uniform age of the granulomas. Special stains and other histopathologic analyses may also play an important role in helping to confirm the diagnosis and assigning causality to a drug.

James DG. A clinicopathological classification of granulomatous disorders. *Postgrad Med J* 2000;76:457–65.

An excellent review of the pathophysiology and immunology of granuloma formation. The author describes the interplay of the invading organism, drug, chemical, or other irritants and the cytokines and other biologic mediators

involved in the transformation of macrophages to epithelioid cells that comprise a majority of granulomas. An overview of many infectious, chemical, and other causes of granulomas is provided.

Kleiner DE. Granulomas in the liver. *Semin Diagn Pathol* 2006;23:161–9.
A comprehensive review of the histopathology of granulomas, including pathologic clues to their various etiologies.

Taylor TH, Lewis JH. Tuberculosis of the liver, biliary tract and pancreas. In: Schlossberg D, ed. *Tuberculosis and Nontuberculous Mycobacterial Infections*, 6th edn. Washington, DC: ASM Press, 2011:372–408.
A comprehensive review of tuberculous infections of the liver and the spectrum of granulomatous disease they produce. Hepatic granulomas are found most often in miliary TB and less often in pulmonary and extrapulmonary disease. Caseating necrosis is seen most commonly in association with the acute disseminating infections of miliary TB. The yield of special stains and culture remains low, but PCR-based tests of TB have improved disgnostic yields.

Raoult D, Tissot-Dupont H, Foncault C, et al. Q fever 1985–1998. Clinical and epidemiologic features of 1,383 infections. *Medicine (Baltimore)* 2000;79:109–23.
A comprehensive review of Q fever from France. This organism (Coxiella burnetti) is responsible for a characteristic fibrin-ring type of granuloma. Acute hepatitis was the most common clinical presentation, seen in 40% of cases, often associated with Q fever pneumonitis. The authors describe a number of patient host factors that appear to dictate the clinical expressions of the disease.

Wanless IR, Geddie WR. Mineral oil lipogranulomata in liver and spleen. A study of 465 autopsies. *Arch Pathol Lab Med* 1985;109: 283–6.
Lipogranulomas are less common than epithelioid granulomas, but were found in 48% of livers examined in this large series. The authors describe the clinicohistologic features of lipogranulomas, which are generally clinically silent. They appear most often in older adults, particularly men, and are associated with the ingestion of mineral oil in most instances.

Zoutman DE, Ralph ED, Frei JV. Granulomatous hepatitis and fever of unknown origin. An 11-year experience of 23 cases with three years' follow-up. *J Clin Gastroenterol* 1993;17:89.
One of the largest series that helps to define the natural history of idiopathic granulomatous hepatitis associated with FUO. The authors were able to identify a specific diagnosis in only 26% of their patients. Among the cases without a precise etiology, 41% eventually resolved spontaneously, 18% resolved after short-term treatment with corticosteroids and anti-inflammatory drugs, while the remaining 41% required long-term corticosteroid therapy to maintain clinical remission and prevention of fever over nearly 6 years of follow-up.

Multiple choice questions

40.1 Match the most likely etiology of hepatic granulomas with the appropriate histologic feature from the following lists.

Feature:

a Lipogranuloma.
b Fibrin ring granuloma.
c Non-necrotising granulomas.
d Acid-fast bacilli positive.
e Periductal granulomas.

Etiology:

1 Q fever.
2 Sarcoidosis.
3 Primary biliary cirrhosis
4 BCG.
5 Mineral oil.

40.2 Which one of the following statements regarding the granulomas of sarcoidosis is false?

a Sarcoidosis is associated with the greatest number of hepatic granulomas.
b Granulomas tend to be in different stages of development.
c Granulomas are most prominent in portal and periportal areas.
d Granulomas are non-necrotizing.
e Giant cell inclusions (asteroid bodies) are pathognomonic of sarcoidosis.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 41

Hepatobiliary Manifestations of Human Immunodeficiency Virus

Marie-Louise Vachon, Ponni Perumalswami, & Douglas T. Dieterich

Division of Liver Diseases, Department of Medicine, Mount Sinai School of Medicine, New York, NY, USA

Key concepts

- Liver disease is the second most common cause of death among patients with human immunodeficiency virus (HIV) after acquired immune deficiency syndrome-related mortality because of the increased life expectancy as a result of antiretroviral therapy (ART).
- Coinfection with hepatitis B virus (HBV) and hepatitis C virus (HCV) is common. HIV accelerates the natural history of HBV and HCV infections. Chronic HBV and HCV infections are responsible for the increasing morbidity and mortality due to liver disease in this population.
- Treatment of chronic HCV with pegylated interferon and ribavirin results in a cure in about 40% of patients. The use of HCV direct-acting antivirals to increase cure rates is under study.
- The HIV population is aging. New complications of HIV and ART are recognized and include noncirrhotic portal hypertension. This adds to the burden of liver disease in this population.
- Hepatic steatosis is common in patients with HIV, and long-term ART use is associated with metabolic changes including lipodystrophy.
- ART has substantially decreased the incidence of opportunistic infections, although in immunosuppressed HIV patients the liver and biliary tract are frequent sites of infection.
- Hepatocellular carcinoma is a growing problem and presents at a younger age and most often with coinfection with HCV and/or HBV.
- Early referral, a lower model for end-stage liver disease score at the time of transplantation, and well-controlled HIV disease are predictors of successful outcomes after liver transplant in HIV-infected patients.

Since its recognition nearly three decades ago, the natural history of infection with human immunodeficiency virus (HIV) has undergone a vast change, from a disease associated with high mortality due to opportunistic infections, to a chronic illness that may last for decades associated with age- rather than HIV-related morbidities. The introduction of antiretroviral therapy (ART) in the mid-1990s was responsible for the dramatic prolongation of survival of patients diagnosed with HIV. Along with acquired immune deficiency syndrome (AIDS)-related complications, liver diseaseve has now become one of the most important factors affecting survival, quality of life, and health care costs among HIV-infected patients. HIV-infected patients experience an array of hepatobiliary manifestations. Most liver diseases in these patients are due to hepatitis C virus (HCV) or hepatitis B virus (HBV) coinfection, but other entities such as steatosis, steatohepatitis, and drug hepatotoxicity add to the burden of liver disease in this population. Aging of the HIV population facilitates the development of liver disease and allows for the recognition of long-term complications of HIV and ART such as noncirrhotic portal hypertension (NCPH). Liver transplantation is a promising option for HIV-infected patients with end-stage liver disease (ESLD). HIV has become a disease of older adults and represents a completely different challenge.

Human immunodeficiency virus and viral coinfections

Hepatitis B virus coinfection

Prevalence and importance

Human immunodefiency virus and HBV share common risk factors for transmission. As a result, evidence of prior exposure to HBV can be found in as many as 90% of HIV-infected patients, and the prevalence of chronic HBV infection in HIV-infected patients is around 7–10%. Testing for the presence of HBV infection should thus be part of the initial evaluation of all HIV-infected patients, as should screening for the presence of chronic HCV infection and immunity to hepatitis A virus (HAV). The

likelihood of spontaneous clearance after acute HBV infection is lower in HIV-infected patients compared with HIV-uninfected patients. HIV/HBV coinfection is associated with higher HBV DNA levels, lower aminotransferase levels, decreased spontaneous loss of hepatitis B e antigen (HBeAg), and decreased seroconversion rates of antibodies to hepatitis B e antigen (anti-HBe). HIV accelerates progression to cirrhosis, ESLD, development of hepatocellular carcinoma (HCC), and liver-related mortality [1]. The high coinfection prevalence coupled with the aggressive course of liver disease and the increased life expectancy with effective ART among HIV-infected patients have led to an increase in the burden of hepatitis B (and C) coinfections in all age groups.

Chronic liver disease, driven by the high prevalence of viral hepatitis coinfections, has emerged as one of the leading causes of morbidity and mortality in HIV-infected patients in the post-ART era [2,3]. In a European prospective cohort study of HIV-infected patients, liver disease was the second most common cause of death among patients with HIV/HBV coinfection (22% versus 38% AIDS-related deaths) [2]. In other studies, liver-related mortality has been found to be 3–14 times higher in HIV/HBV-coinfected patients compared with HBV-monoinfected patients [1,4,5]. An increase in the CD4+ T-cell count reduces the risk of liver-related mortality. HCC development is a frequent cause of liver-related death in these patients and can present in the absence of cirrhosis. In HIV/HBV-coinfected patients, HCC development has been shown to be significantly associated with a lower absolute CD4+ T-cell count and percentage [6], and a longer survival is observed in patients with undetected HIV RNA [7].

The effects of HBV on the natural history of HIV are less clear. Although previous studies indicated that HBV had no effect on the course of HIV and its response to ART [1], recent data suggest that coinfection may be associated with lower CD4+ T-cell counts at the time of ART initiation and that response to ART may be slower in patients with HBeAg-positive HBV compared to HBeAg-negative HBV infection [8].

Diagnosis and prevention in susceptible individuals

All HIV-infected patients should be tested for HBV markers at the time of initial evaluation with a minimum of hepatitis B surface antigen (HBsAg), antibodies to hepatitis B surface antigen (anti-HBs), and antibodies to hepatitis B core antigen (anti-HBc). In patients with a positive HBsAg, the HBV DNA level, HBeAg, and anti-HBe markers will characterize the status of infection [9–11]. As for HBV monoinfection, HIV/HBV-coinfected patients should have a close follow-up of HBV DNA and alanine aminotransferase (ALT), in addition to periodic HCC screening. When to perform a liver biopsy is an area of controversy. Most experts agree it should be done only when treatment indications are not clear, to rule out necroinflammation and/or significant fibrosis that would argue toward the need for treatment. In no way is it a requirement for treatment. Alternative methods of fibrosis assessment such as transient elastography are not US Food and Drug Administration (FDA) approved although transient elastography is standard of care in Europe and Canada.

In the setting of HIV infection, HBV serologic testing often shows an isolated anti-HBc in the absence of other markers of HBV exposure. Isolated anti-HBc is more common among HIV-infected patients compared with HIV-uninfected patients. The prevalence is estimated to lie between 17% and 81% depending on the cohorts studied, compared with 2–5% in HIV-uninfected patients [12]. Isolated anti-HBc represents either the result of a false-positive test, past HBV infection with loss of or undetectable levels of anti-HBs, or occult HBV infection. The clinical significance of isolated anti-HBc is unclear and the need for HBV vaccination is controversial in these cases. Occult HBV infection is defined as the presence of HBV DNA in the absence of HBsAg; usually an isolated anti-HBc is found at serology testing [10]. Occult HBV infection occurs predominantly in HIV-infected patients. In one study, patients with HIV RNA levels >1,000 copies/mL and without HCV coinfection were more likely to have occult HBV infection [13]. The exact significance of occult HBV and its long-term consequences are not well characterized, although it has the potential to reactivate secondary to immunosuppression or the interruption of ART containing active anti-HBV agents [14].

When serologic testing does not show any evidence of prior HBV exposure, the complete HBV vaccination series should be given and repeated a second time if no immune response is elicited 1 month after the third dose. The response rate to HBV single-dose vaccine is between 18% and 56% compared with 90% of immunocompetent individuals. Efforts should be made to increase the CD4+ T-cell count to >200 cells/mm^3 to optimize the immunologic response to the vaccine. Some studies have found a higher response rate to the double-dose vaccine (40 μg) when the CD4+ T-cell count was above 350 cells/mm^3 [15]. However, HBV vaccination should not be deferred while waiting for the CD4+ T-cell count to reach that threshold. The use of granulocyte–macrophage colony-stimulating factor (GM-CSF) as a vaccine adjuvant did not increase response rates [16].

Treatment

The goals of HBV therapy in patients with HIV/HBV coinfection are the suppression of HBV DNA, the

normalization of ALT, seroconversion from HBeAg to anti-HBe, and ideally the loss of HBsAg and seroconversion to anti-HBs to prevent liver disease progression and reduce the risk of potential complications such as the development of HCC. Because of the close interactions between HIV and HBV, any treatment decision for hepatitis B should take into account the possible impact on HIV and vice versa. Recent evidence of a benefit for earlier initiation of ART in HIV-infected patients has led to a change in the HIV treatment recommendations issued by the US Department of Health and Human Services (DHHS) [17]. The recommendations are now to initiate ART with anti-HBV active agents whether treatment is needed for HBV (independent of the CD4+ T-cell count), HIV, or both. At the time of ART initiation and change of ART, it is important to use agents active against HBV to reduce the risk of immune reconstitution inflammatory syndrome and hepatic flare, which can be life threatening. Drugs approved for the treatment of chronic HBV infection are interferon (IFN), pegylated interferon α-2a (pegIFN-α-2a), lamivudine, adefovir dipivoxil, entecavir, and tenofovir disoproxil fumarate (TDF). Emtricitabine, approved for HIV therapy, is active against HBV but not FDA approved for the treatment of chronic HBV infection yet. Most studies in HBV treatment have been done using lamivudine and results have shown histologic and clinical improvement, and a significant reduction of liver-related death per year of treatment. Emergence of resistance is frequent and the highest with lamivudine use. After 4 years of lamivudine use, 90% of HIV/HBV-coinfected patients develop resistance mutations. The combination of two drugs active against HBV is recommended to prevent the emergence of resistance in HIV/HBV-coinfected patients. The antivirals that have activity against both HIV and HBV viruses are TDF, emtricitabine, lamivudine, and entecavir. Entecavir is not used to treat HIV but has some activity against it and has the ability to select for the M184V resistance mutation in HIV [18]. The preferred regimens are the combination of TDF and emtricitabine or TDF and lamivudine. TDF is a potent agent active against lamivudine-resistant HBV strains [19]. The mutation rtA194T has been reported to be associated with TDF resistance in one report, but not confirmed in other studies [20]. In the rare cases where HIV treatment is not desirable and HBV treatment is indicated, pegIFN and adefovir 10 mg are recommended to avoid HIV resistance development. In these cases, the criteria used to evaluate the need to treat HBV do not differ from those used in HBV-monoinfected patients, although some experts recommend treating HBeAg-positive and HBeAg-negative HBV at any HBV DNA level in all HIV-infected patients due to their accelerated liver disease progression. ALT levels, HBeAg status, and HBV DNA levels with or without fibrosis assessment determine the indication of HBV treatment. Guidelines for HIV-uninfected individuals with HBeAg-positive HBV infection recommend that treatment be considered for patients with serum HBV DNA above 20,000 IU/mL. For HBeAg-negative patients, a threshold of 2,000 IU/mL is used [10,21].

HCV coinfection

Prevalence, transmission, and importance

Human immunodeficiency virus and chronic HCV infection are two major public health problems. An estimated 170 million people are infected with HCV worldwide and 4–5 million are coinfected with HIV. In addition to both being major health issues, HIV and HCV have many similarities. Both viruses possess a single-stranded RNA genome and result in subclinical chronic infection. Each virus is able to evade the host's immune system because of high genetic variability, and the replication rate of both viruses is extremely high. Approximately 25–30% of HIV-infected patients are coinfected with HCV. Coinfection rates vary depending on the country and the region under study, the population, and the risk factors for HIV acquisition. The most efficient mode of HCV transmission is by direct exposure to blood or blood products. The main risk factor for acquisition in the United States is intravenous drug use. In this high-risk group, the rate of coinfection can reach 95%. HCV is not transmitted efficiently during heterosexual relationships, however HIV-infected men who have sex with men are emerging as a group at risk for sexual transmission of HCV. Several recent outbreaks of acute hepatitis C in Europe, Australia, and the United States have been reported [22]. In one of these reports, the majority of patients with acute HCV had stage 2/4 liver fibrosis at liver biopsy [23]. The vast majority of these patients share the same risk factors –high-risk sexual behavior, concomitant ulcerative sexually transmitted infections, and the use of recreational, IV or non-IV drugs such as methamphetamine. Vertical transmission of HCV is infrequent and increases in the setting of coinfection.

The improvement in HIV control with ART is evidenced by the emergence of chronic illnesses such as liver disease in this population and its associated complications. Liver-related death is now the most frequent cause of non-AIDS-related death among patients with HIV [3]. In a European prospective cohort study of HIV-infected patients, liver disease was the first cause of death among HIV/HCV-coinfected patients (31% of deaths versus 29% AIDS-related) [2]. In a prospective cohort study of 3,730 HIV-infected patients followed between 1995 and 2003, hospitalization rates decreased significantly in HIV-monoinfected patients but increased significantly in HIV/HCV-coinfected patients [24]. In the coinfected group, hospitalization rates increased for liver-related

complications and HCV coinfection was an independent predictor of hospitalization.

Impact of human immunodeficiency virus and antiretroviral therapy on hepatitis C virus

Human immunodeficiency virus significantly affects the natural history of HCV-related liver disease. HIV-infected patients have a lower likelihood of spontaneous clearance of HCV compared with HIV-uninfected ones. Recent data in HCV-monoinfected patients have shown that the C/C genotype at a single nucleotide polymorphism (SNP) near the *IL28B* gene is associated with spontaneous clearance of HCV [25]. The same study among HIV/HCV-coinfected patients has not yet been published [26]. Serum and liver HCV viral loads are higher in HIV/HCV-coinfected patients compared with HCV-monoinfected patients because of greater HCV replication reflecting the immunosuppressed state. Liver fibrosis progression is accelerated compared to HCV monoinfection. Coinfected patients have an increased rate of progression to cirrhosis, ESLD, HCC, and death compared with monoinfected individuals [27–29]. As in HCV-monoinfected patients, liver fibrosis at baseline predicts the development of significant liver disease and death in HIV/HCV-coinfected patients [30]. In a study of 637 HIV/HCV-coinfected patients followed over a median duration of 5 years, the incidence rates of ESLD, HCC, or death increased in a stepwise manner according to the baseline fibrosis stage (METAVIR scoring system). Figure 41.1 shows Kaplan–Meier curves of ESLD/HCC/liver death-free survival according to the baseline METAVIR score in this study. Fibrosis stages 2 and above were significant predictors of ESLD, HCC, or death from any cause.

The incidence of HCC in the United States is rising overall and among the HIV-infected population. HCC is more aggressive in HIV with a higher frequency of infiltrating tumors, extranodal metastases at presentation, and portal invasion. HIV/HCV-coinfected individuals seem to be younger at the time of HCC diagnosis and have a faster progression from initial HCV infection to HCC development (26 versus 34 years) [7]. Data are contradictory as to whether HIV infection is independently associated with shorter survival in these patients [7,31].

The impact of ART on the evolution of HCV-related liver disease is contradictory. ART has been shown to slow the rate of fibrosis progression. One study showed that coinfected patients on ART with undetectable HIV RNA (<400 copies/mL) had a slower rate of fibrosis progression compared to those with HIV viremia and similar to HCV-monoinfected individuals [32]. A meta-analysis looking at the natural history of chronic hepatitis C in the HIV-infected population found that HIV/HCV-coinfected patients had a 2.1-fold higher risk of cirrhosis compared with HCV-monoinfected patients [33]. The increase was 2.5-fold in those not receiving ART and 1.7-fold in those receiving ART. This study suggests a partially protective role of ART against development of cirrhosis in this population. ART was found to reduce liver-related mortality in a retrospective study [34], although the same beneficial effect was not found in prospective studies [3,35]. In other reports, ART was associated with fibrosis progression and was dependent on the regimen used [36,37]. Hepatotoxicity of ART has been shown to be more likely to occur in patients with underlying HCV [38]. Effective treatment of HCV in coinfected individuals reduces ART-related hepatotoxicity [39]. These contradictions in study results are likely due to the opposing effects of immune restoration and hepatotoxicity of ART regimens.

The presence of steatosis has been observed in up to 40% of patients with HIV/HCV coinfection. Patients with steatosis are more likely to have a higher stage of liver fibrosis and more severe HCV-related liver disease.

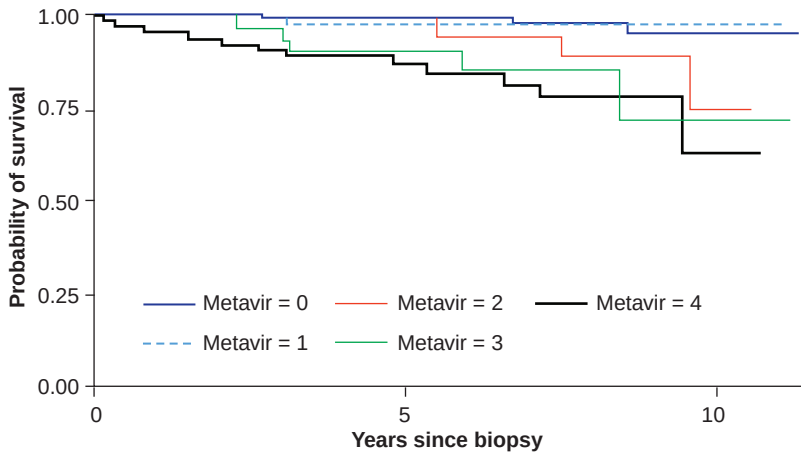

Figure 41.1 Probability of ESLD/HCC/liver death-free survival according to baseline METAVIR score. (Reproduced from Sulkowski et al. [30] with permission.)

Obesity, insulin resistance (IR), and the use of stavudine have been identified as modifiable risk factors for steatosis in this population.

Impact of hepatitis C virus on human immunodeficiency virus

Data regarding the influence of HCV on the natural history of HIV disease are conflicting. Overall, HCV does not seem to affect HIV disease progression, HIV RNA suppression following ART initiation, CD4+ T-cell count recovery, or the risk of AIDS. However, some studies have found a more rapid HIV disease progression and increased mortality in HIV/HCV-coinfected patients compared with HIV-monoinfected ones. HCV may negatively impact HIV disease by influencing ART tolerability and ART discontinuation.

Diagnosis

All patients with HIV should be screened for HCV. There is an estimated 3–4% false-negative rate with enzyme-linked immunosorbent assay (ELISA) testing in coinfected patients because of impaired HCV antibody production with immunosuppression, a rapid decline in HCV antibody titer, and a possible interaction between the two viruses. Therefore, screening with HCV RNA is useful in some high-risk coinfected patients such as those with low CD4+ T-cell counts, those on chronic hemodialysis, those who have hemophilia, or those who are former intravenous drug users. HCV screening is warranted at least at the time of initial evaluation and thereafter depending on risk factors for acquisition. The evaluation of elevations of ALT levels in HIV-infected patients should always include HCV testing, but HIV-infected patients are less likely to present with elevated ALT than HIV-uninfected patients [40]. Liver biopsy is the gold standard in staging liver fibrosis in the United States. Serologic biomarkers such as APRI and FIB-4 can be useful in discriminating advanced fibrosis from no fibrosis, but are less accurate than liver biopsy, especially in the intermediate stages of fibrosis. Transient elastography (FibroScan®), a noninvasive technique, seems more accurate but has not been approved by the FDA although it is standard of care in Europe and Canada.

In HIV-infected patients, staging of liver fibrosis with liver biopsy is not mandatory to guide treatment decisions in any HCV genotype and should not be a barrier to HCV treatment. There is every reason to treat HCV in HIV-infected patients. This includes patients with compensated (Child class A) cirrhosis. Patients who are willing to start therapy and who do not have contraindications to pegIFN and ribavirin (RBV) should be encouraged to undergo treatment based on the rapid progression of HCV-related liver disease, acceptable sustained virologic response (SVR) rates, and availability of early viral monitoring (weeks 4 and 12) to identify rapid responders and nonresponders.

The indication for HCV treatment is clear in those with stage 2 and above on the METAVIR fibrosis scale. When the liver biopsy indicates fibrosis stage 0 or 1 and the decision is made to postpone treatment, repeat fibrosis assessment is recommended at 3-year intervals [41].

Treatment

Given the impact of HIV on the natural history of HCV disease, HCV should be managed aggressively. HCV treatment is aimed at achieving viral eradication to slow the progression of liver disease and to prevent liver-related complications such as HCC. Successful treatment of HCV results in a reduced incidence of complications as demonstrated by several studies [43]. The simultaneous treatment of HCV and HIV is associated with the occurrence of drug interactions, overlapping toxicities, and increased incidence and severity of side effects. HIV/HCV-coinfected patients are in need of treatment, however state-of-the-art management requires different strategies in order to achieve cure with minimal adverse events. Viral eradication of HCV is termed SVR. SVR is defined as undetectable HCV RNA 24 weeks after completion of HCV treatment. When SVR is achieved, both in HCV-monoinfected patients and HIV/HCV-coinfected patients, this translates to a cure, and subsequent positive HCV RNA may reflect reinfection rather than HCV relapse [42]. Achievement of SVR reduces liver-related complications and mortality in HIV/HCV-coinfected patients [43].

SVR rates are lower in HIV/HCV-coinfected individuals compared with HIV-uninfected ones. Until recently, the best predictors of SVR were HCV genotype 2 and 3 and a low baseline HCV RNA. HCV RNA levels less than or equal to 400,000 IU/mL are predictive of treatment success [44]. Other factors have been found to be associated with SVR (Box 41.1) Recently, a strong association between a SNP near the *IL28B* gene and SVR in HCV-monoinfected and HIV/HCV-coinfected patients

Box 41.1 Favorable predictors of sustained virologic response (SVR).

- IL28B CC genotype
- Hepatitis C virus (HCV) genotype 2 or 3
- Low baseline HCV RNA (<400,000–800,000 IU/mL)
- Naïve to HCV treatment
- White race
- Younger age
- Low-stage fibrosis
- Absence of steatosis on liver biopsy
- Absence of insulin resistance
- Low body mass index

was found [45,46]. Individuals who carry the homozygous C/C genotype at this SNP have a significantly higher chance of achieving SVR with the standard of care. The study performed in HIV/HCV-coinfected patients has found that 65% of patients infected with HCV genotype 1 carrying the C/C genotype achieved SVR compared with 30% of those with the C/T or the T/T genotype [46]. The C/C allele is unevenly distributed among races and explains in part the lower response rate to HCV treatment among blacks. The C/C allele is most commonly found in Asia and Europe and is uncommon in Africa. A test for genotyping this SNP is now available in the United States to help predict treatment response. It is unclear to what extent the baseline CD4+ T-cell count influences SVR rates. In a recent study, patients infected with HCV genotype 1 had better SVR rates with higher baseline CD4+ T-cell counts [47]. No such association was found in HCV genotype 2 and 3 infected patients. When HCV treatment is considered, the best approach is to attempt to increase the CD4+ T-cell count before starting HCV treatment, but to avoid deferring treatment when the expected rise does not occur. There is no CD4+ T-cell threshold under which HCV treatment should not be attempted as long as HIV is optimally controlled.

The standard of care for HCV treatment in HIV/HCV-coinfected patients is pegIFN plus weight-based RBV for HCV genotypes 1 and 4 [41]. A 800 mg/day fixed-dose of RBV is recommended in HCV genotypes 2 and 3.

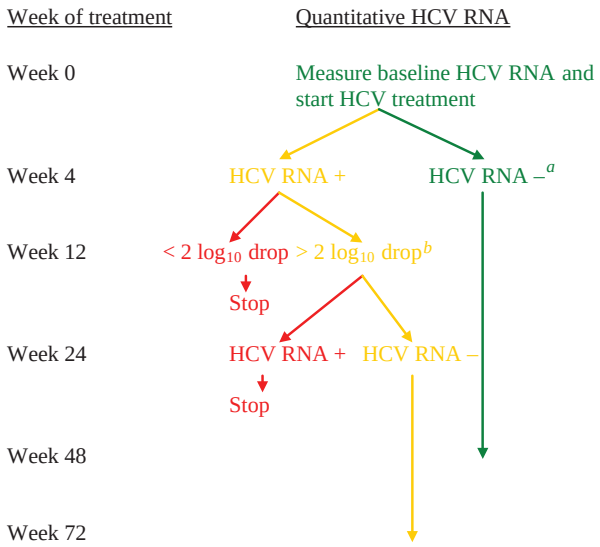
The present treatment recommendations are based on four main randomized controlled trials [48–51]. APRICOT enrolled 868 patients, of all genotypes and naïve to HCV treatment [48]. They were randomized to one of the three treatment arms to receive either: (i) pegIFN-α-2a 180 μg + RBV 800 mg; (ii) pegIFN-α-2a 180 μg + placebo; or (iii) standard IFN (3 million IU three times a week) + RBV 800 mg – all for 48 weeks. The pegIFN and RBV combination showed superiority with an overall SVR of 40% compared to 20% with pegIFN monotherapy and 12% with standard IFN. Higher baseline HCV RNA levels (>800,000 IU/mL) led to lower rates of SVR. The absence of early virologic response (EVR) (at least a 2 $\log_{10}$ decrease in HCV RNA at week 12) had a high negative predictive value to predict virologic failure as in HCV monoinfection. During HCV treatment, the absolute CD4+ T-cell count decreased but the mean CD4+ T-cell percentage increased. Safety issues were mostly hematologic and comparable to HCV-monoinfected patients.

The RIBAVIC trial compared standard IFN (3 million IU three times a week) + RBV to pegIFN-α-2b + RBV (1.5 μg/kg/week) [50]; 412 patients were enrolled. The overall SVR rate was 27% in the pegIFN group. Bridging fibrosis or cirrhosis were present in 40% of the patients. Many patients experienced adverse events not related to treatment and discontinued therapy. Serious adverse events, although similar in both groups, were higher than reported in the monoinfected population. Eleven cases of pancreatitis/hyperlactatemia were diagnosed in patients taking didanosine as part of their ART regimen.

The AIDS Clinical Trials Group (ACTG) A5071 study randomized 133 subjects to receive either pegIFN-α-2a (180 μg/week) + RBV or standard IFN-α-2a + RBV in a dose escalation schedule: 600 mg for 4 weeks, then 800 mg for 4 weeks, and then 1,000 mg for a total of 48 weeks [49]. PegIFN showed superiority over standard IFN with a reported SVR rate of 27% compared with 12%. A liver biopsy was performed at week 24 of treatment in patients with no virologic response; 35% of them had histologic improvement suggesting that benefits from the therapy extend beyond virologic control. In this study, the inadequate schedule of RBV may have explained the low SVR (high relapse) rates observed.

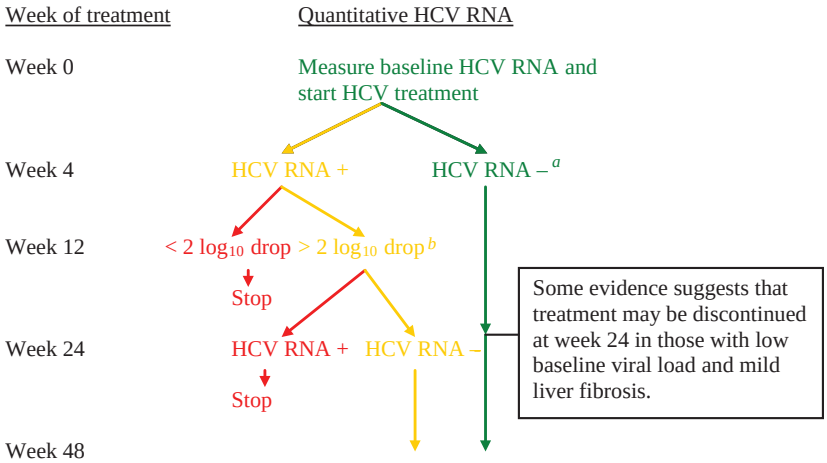
Laguno et al. [51] randomized patients to receive either standard IFN (3 million IU three times a week) or pegIFN-α-2b (100–150 μg/week) with weight-based RBV 800–1200 mg for 48 weeks. Patients with HCV genotype 2 and 3 infections who had HCV RNA <800,000 IU/ml were treated for 24 weeks only. Ninety-five patients, of whom 30% had bridging fibrosis or cirrhosis, were randomized. Overall, 44% achieved a SVR. This was the first randomized trial to use weight-based RBV and it yielded an increase in SVR. Patients with HCV genotype 2 and 3 infections experienced a high relapse rate after 24 weeks of treatment. Side effects were frequently reported, including depressive symptoms in 43% patients. There were nine cases of mitochondrial toxicity in patients receiving didanosine and/or stavudine.

The nonrandomized PRESCO trial sought to determine the role of weight-based RBV and extension of the duration of therapy in 389 coinfected patients [52]. These patients received pegIFN-α-2a (180 μg/week) + RBV (1,000 or 1,200 mg according to weight). Participants were treated for 48 versus 72 weeks. They achieved an overall SVR rate of 49.6%. SVR rates were significantly greater in the 72-week arm but with a withdrawal rate of 36/45 (80%) in patients with HCV genotype 1 infection. Higher dosage of RBV was well tolerated.



Overall, the expected SVR rates are 14–38% with HCV genotype 1 and 4 and 44–73% with HCV genotypes 2 and 3. State-of-the-art treatment of HCV involves individualizing treatment based on HCV viral kinetics. In the coinfected individuals, the kinetics of response is slower compared with HCV monoinfection. Response is first assessed at week 4 and undetectable viremia is termed rapid virologic response (RVR). In a substudy from RIBAVIC, authors reported no chance of SVR when HCV RNA could not be suppressed below 460,000 IU/mL at week 4 (negative predictive value of 100%) [53]. A similar analysis from APRICOT showed that RVR was the best

predictor of SVR [54]. In a retrospective review of HCV genotype 2 and 3 coinfected patients from two prospective studies, Shea et al. reported a 100% (39 patients) SVR rate after a 24-week treatment with optimal doses of pegIFN and RBV when RVR was achieved [55]. Response is later assessed at week 12 and is termed EVR. EVR can either be partial (decrease of at least 2 logs from baseline viral load with detectable viremia) or complete (undetectable viremia). Coinfected patients who fail to achieve EVR have a 2% likelihood of SVR and thus treatment is discontinued when EVR is not achieved [48]. When partial EVR occurs and HCV RNA is still detectable at week 24, treatment should also be discontinued. Both RVR and EVR correlate with SVR in mono- and coinfected patients [52,53,56].



The two formulations of pegIFN (α-2a and α-2b) have been shown to have comparable safety in the treatment of HCV in HIV-infected patients in the recently published GESIDA study [57]. Weight-based RBV was not found to be superior in the treatment of HCV genotype 1 in the randomized clinical trial PARADIGM; however, the study was powered to study safety of weight-based RBV and not efficacy [58].

In the nonrandomized PRESCO trial, 72% of patients with HCV genotypes 2 or 3 coinfected with HIV achieved SVR [52]. The use of a higher dose of RBV was not associated with an increased incidence of adverse events. Although not demonstrated to be superior in randomized controlled trials, most experts recommend weight-based RBV dosing for all HCV genotypes in HIV-infected patients. The treatment duration should be individualized to the treatment response (Fig. 41.2).

The use of pegIFN and RBV in coinfected patients is associated with many toxicities and drug interactions

A

Figure 41.2 (A) Treatment algorithm for HIV/HCV genotype 1 and 4 infected patients. (B) Treatment algorithm for HIV/HCV genotype 2 and 3 infected patients. [a]HCV RNA under the limit of detection at week 4 is termed rapid virologic response (RVR) and its positive predictive value for achieving SVR is around 90%. [b]HCV RNA under the limit of detection at week 12 is termed complete early virologic response (cEVR). >2 $\log_{10}$ drop of HCV RNA at week 12 with HCV RNA that remains above the limit of detection is termed partial early virologic response (pEVR). HCV, hepatitis C virus.

with ART. Mitochondrial toxicity and its clinical manifestations have been reported and are mainly due to the simultaneous use of RBV and the HIV nucleoside reverse transcriptase inhibitors (NRTIs), mostly didanosine and stavudine. This has led to the current recommendation to avoid the use of didanosine and stavudine with RBV. Zidovudine should also be avoided due to the occurrence of severe anemia when used with RBV. There is a possibility that some ART may impact SVR rates. A few studies have reported a better response to pegIFN and RBV in those with TDF-based regimens compared to abacavir [59,60]. Other studies did not support these findings.

HCV drug development is the subject of active research in HCV-monoinfected subjects. Over 30 compounds are under development. The first two direct-acting antivirals (DAAs), the HCV protease inhibitors boceprevir and telaprevir, have been recently approved by the FDA in May 2011. Both are presently being studied in HIV/HCV-coinfected patients. Other clinical trials of DAAs in HIV/HCV-coinfected are expected to start soon. Drug–drug interactions with ART will be a challenge in this population.

Acute hepatitis C virus in HIV-infected men who have sex with men

Acute HCV in HIV-infected individuals differs in many ways from acute HCV monoinfection in non-HIV-infected patients. This has been the focus of a recent review article [22]. Diligence in diagnosis is essential to identify these patients. When ALT levels increase in HIV-infected men who have sex with men, HCV RNA load and HCV antibody testing should be included in the initial blood tests. Toxicity secondary to ART is a diagnosis of exclusion. Data on treatment effectiveness in acute HCV in the setting of coinfection are limited. Treatment of acute HCV leads to higher SVR rates compared with the chronic stage; SVR rates are around 60–90%. The treatment recommendation is pegIFN (±RBV) for 24 weeks, for all genotypes when RVR is achieved according to recent European guidelines. If HCV RNA is still detectable at week 4 of treatment, a total of 48 weeks should be considered [136]. There should be 12 weeks of observation before starting HCV therapy allow for spontaneous clearance to occur. When HCV RNA levels are monitored every other week, treatment can be instituted at the time viremia establishes a plateau or starts to increase.

Adverse effects of hepatitis C virus treatment

Common side effects of IFN and RBV therapy include fatigue, influenza-like symptoms, hematologic abnormalities, gastrointestinal disturbances, and neuropsychiatric symptoms. Both standard IFN and pegIFN have similar side effect profiles and discontinuation rates. In the major trials in HIV/HCV-coinfected patients, discontinuation rates with pegIFN and RBV were 12–17% [48–50]. In APRICOT, pegIFN dosage was reduced in 34% of patients secondary to neutropenia and thrombocytopenia [48]. The dose of RBV was reduced in 16% secondary to anemia. In the RIBAVIC trial, serious side effects were seen in 32% cases [50]. The toxicities observed in this population are due to their co-morbidities and drug interactions. A clinically significant interaction is seen between IFN and zidovudine, leading to anemia from bone marrow suppression. The more profound anemia seen during HCV therapy in coinfected patients is a combined effect of hemolytic anemia caused by RBV and the failure of the suppressed marrow to compensate for the loss of red blood cells. Anemia in this setting can be managed by reducing the dose of RBV and avoiding zidovudine. Erythropoietin is effective in treating anemia in coinfected patients undergoing anti-HCV therapy and has an efficacy similar to that in monoinfected patients. PegIFN-induced neutropenia does not lead to a higher rate of infection in the group of HIV/HCV-coinfected patients without cirrhosis or with well-compensated cirrhosis. RBV enhances the phosphorylation of didanosine, resulting in an increased risk of mitochondrial toxicity, pancreatitis, lactic acidosis, and fulminant hepatic failure. Therefore RBV is not used with didanosine and the FDA has issued a black box warning regarding their interaction. Toxicity may also be seen with other NRTIs, particularly those with a high affinity for the mitochondrial enzyme DNA polymerase-γ, such as stavudine and zalcitabine. Liver decompensation during HCV treatment is a possible complication. In HIV/HCV-coinfected patients with cirrhosis, hepatic decompensation occurs in 8–10% [48,50] and is associated with increased total bilirubin, anemia, and the use of didanosine. Therefore, it is recommended to monitor these patients closely and avoid the use of didanosine. Active psychiatric illness and active alcohol and drug use are possible barriers to anti-HCV treatment in coinfected patients. In general, current treatment with pegIFN and RBV is well tolerated with adverse events similar to those observed in HCV-monoinfected patients. Benefits of HCV treatment must be weighed against the risks of therapy, and individualization of treatment is the key to success. Judicious use of erythropoietin, granulocyte colony-stimulating factor (GCSF), and antidepressants can improve tolerance to treatment and outcome of therapy.

Retreatment of prior relapsers and nonresponders

Patients who are nonresponders to HCV therapy have a significantly higher frequency of overall death, liver-related death, and liver decompensation compared with those who achieve SVR [43]. Retreatment decisions should be individualized. Those who received a suboptimal treatment in the past (standard IFN, IFN, or pegINF

monotherapy, suboptimal RBV dosage due to poor adherence or limiting toxicities) should be retreated adequately. Prior relapsers may have a higher chance of SVR than nonresponders, especially with extended treatment durations. Studies of retreatment in HIV/HCV-coinfected patients have reported overall SVR rates of 16–30% [61–65]. Predictors of SVR in retreatment have not been well studied. We found that in a population of HIV/HCV-coinfected patients carrying multiple negative predictive factors of response to HCV treatment, the strongest predictor of failure to achieve SVR at retreatment was insulin resistance, and the highest SVR rate of 35% was seen in patients with a homeostatic model of assessment of IR (HOMA-IR) of less than 2 [65]. When negative predictive factors of SVR can be modified, such as weight loss in IR and decreased steatosis/steatohepatitis at liver biopsy, retreatment may lead to SVR although it has not been demonstrated in HIV/HCV-coinfected patients. Maintenance therapy with pegIFN monotherapy has not been proven effective in prior nonresponders. New direct-acting antiviral agents are being developed and tested in HIV/HCV-coinfected patients and should significantly improve SVR rates compared with standard of care. For nonresponders, the current approach is to wait until these new antivirals are available.

Hepatitis B virus and hepatitis D virus coinfection

Hepatitis delta virus (HDV, delta agent) is a defective RNA virus that requires HBsAg in order to replicate. The prevalence of antibodies to HDV, ranging from 15% to 50% of HIV-infected patients, depends on the risk factors for acquisition and geography [66]. HDV and HBV can infect the liver simultaneously (coinfection) or HDV can occur in a HBV carrier (superinfection); the latter is more likely in HIV-infected patients [66]. HDV superinfection causes a more severe liver disease than HBV infection alone, with progression to cirrhosis in 70–80% of immunocompetent patients. Evolution towards cirrhosis tends to be faster, and the outcome worse in patients with coinfections compared with monoinfection. Results of studies in patients with HIV/HBV/HDV triple infection are limited by the small samples of patients studied. One group compared liver fibrosis in patients with HIV/HBV/HDV triple infection with those with HIV/HBV alone [67]. They found a significant association between advanced fibrosis (METAVIR stage 3–4) in those with HIV/HBV/HDV triple infection. In a case–control study of 26 HIV/HBV/HDV triple-infected patients and 78 HDV-uninfected patients with a median follow-up of 55 months, those with triple infection had higher rates of hepatitis flares, hyperbilirubinemia, liver cirrhosis, hepatic decompensation, and death [68]. No studies have been published on treatment of HDV in HIV/HBV triple infection except for two case reports of the use of pegIFN, one in a case of quadruple infection (HIV/HBV/HDV and HCV) [69,70]. One group evaluated the impact of treatment of HBV infection with potent nucleos(t)ide analogs on HDV replication in HIV/HBV/HDV triple infection and reported a decrease in HDV RNA in 13 out of 16 patients and HDV RNA undetectability in three of them [71].

Hepatitis A virus, hepatitis E virus, and GB virus C

The prevalence, morbidity, and mortality of HAV infection are not altered by HIV infection. Despite this, vaccination of HIV-infected patients is recommended, particularly for men who have sex with men who are at a higher risk of transmission through person-to-person sexual contact. A few studies have compared the presentation of HAV infection in HIV-infected men with uninfected controls. In one study, 15 HIV-infected men with acute HAV were compared with 15 HIV-uninfected men with acute HAV and found no difference in the severity of symptoms [72]. The main differences were that HIV-infected men had a higher HAV viral load, longer period of viremia, and less elevation of ALT, suggesting these patients might be more infectious and for a longer period of time then HIV-uninfected patients. The impact of HIV on the clinical presentation of HAV infection is unclear but does not seem to be significant. However, it is important to bear in mind that HIV-infected patients are at a high risk of contracting HAV because of shared risk factors for acquisition. HIV is not a risk factor for fulminant HAV infection, but coinfection with chronic HCV is [73,74]. Patients with HIV have poorer immune responses to the HAV vaccine. The response rates range from 48% to 95% with an overall response rate of 64% [75,76]. A three-dose schedule at 0–4 and 24 weeks of inactivated vaccine might be superior to the standard two-dose schedule at 0 and 24 weeks (83% versus 69% response at 1 month after the last dose) [77].

Hepatitis E virus (HEV) is a water-borne or fecal–orally transmitted virus. Its prevalence has been reported to be higher in HIV-infected patients compared with uninfected individuals – between 5% and 11% compared to <2% of the general population [78]. Until recently, HEV was known to cause acute infection only. Chronic infection has been shown to occur in recipients of solid organ transplants, in an immunosuppressed patient with lymphoma, and in patients with HIV infection, along with progressive liver disease [79,80].

GB virus C (GBC) is a flavivirus that, although closely related to HCV, has not been reported to cause hepatitis or other disease in humans. Transmission is parenteral, sexual, and vertical. Infection with GBC is

common and higher among intravenous drug users compared with those with sexual risk exposure [81]. GBC, like HIV, is lymphotropic and replicates in CD4+ T cells. Inhibition of HIV replication has been shown to occur when lymphocytes were previously infected with GBC. Clinically, GBC has been shown to slow HIV disease progression. GBC viremia has been associated with increased survival among HIV-infected men and loss of GBV viremia has been associated with an increased hazard ratio of death 5–6 years after HIV seroconversion [82]. GBC testing is not routinely done in clinic.

Steatosis and lipodystrophy in HIV-infected patients

Nonalcoholic fatty liver disease (NAFLD) is characterized by the accumulation of lipid in the liver. The spectrum of fatty liver disease ranges from mild steatosis to nonalcoholic steatohepatitis (NASH), which may in turn lead to progressive fibrosis, cirrhosis, and even HCC. The prevalence of NAFLD in the HIV population is not known exactly due to lack of histologic data, but the estimated prevalence of NAFLD in patients with HIV has been shown to be 31% by ultrasound [83]. The classic risk factors for hepatic steatosis such as obesity, diabetes, and alcohol are also valid in HIV-infected patients. A recent cohort analysis suggested that more than a quarter of Danish patients infected with HIV met criteria for the metabolic syndrome [84]. ART can cause a variety of liver injuries, including hepatic steatosis, which may be associated with lipodystrophy or result from direct hepatotoxicity. HIV-related lipodystrophy (HIVLD) is a disorder of adipose tissue characterized by selective peripheral fat wasting or lipoatrophy (in the face, limbs, and buttocks) and central fat accumulation or lipohypertrophy (enlarged dorsocervical fat pad, circumferential expansion of neck, breast enlargement, and abdominal visceral fat accumulation). HIVLD is strongly associated with IR, glucose intolerance, and dyslipidemia and is characterized by hypertriglyceridemia, elevated total low-density lipoprotein (LDL) cholesterol, reduced high-density lipoprotein (HDL) cholesterol, and increased levels of nonesterified fatty acids. The latter are identical to the risk factors for development of the metabolic syndrome that is associated with NAFLD. In essence, lipodystrophy is an accelerated aging process characterized by metabolic syndrome effects on the body, including the liver. HIVLD represents a moderate- to long-term complication of ART, reported in at least 40–50% of patients with HIV taking ART. The combination of NRTIs and a protease inhibitor (PI) acting synergistically are primarily responsible for HIVLD [85]. Large cohort studies found a correlation between the duration of therapy with PIs or NRTIs and the development of HIVLD. In vitro studies have demonstrated that PIs induce the inhibition of adipocyte maturation as well as apoptosis and increase lipolysis. PIs have also been associated with hyperlipidemia, IR, and consequent hepatic steatosis. The proposed mechanism of action for PIs inducing lipoatrophy is via inhibition of SREBP1 (sterol regulatory enhancer-binding protein 1)-mediated activation of the nuclear hormone receptor, PPARγ (peroxisome proliferator-activated receptor γ). While there is no definite therapy for HIVLD, exercise and resistance training reduce visceral adiposity and improve lipid parameters. However, the effects on liver histology are still unknown. In several studies, the use of metformin decreased IR and visceral adipose tissue [86]. Among the currently available therapies, pioglitazone seems to be the best option as it increases insulin sensitivity and subcutaneous adipose tissue while decreasing visceral adipose tissue [87]. Switching from a PI regimen to another regimen offers very little clinical benefit [88].

Direct hepatotoxicity from ART can manifest in a variety of patterns including fat accumulation. NRTIs have been the cornerstone for ART but carry the risk of inducing severe microsteatosis along with lactic acidosis through the impairment of mitochondrial β-oxidation. Stavudine, didanosine, zalcitabine (now removed from the market), and zidovudine are/were the most common culprits. Whether NRTI-induced chronic mitochondrial toxicity and lactic acidosis play a role in the development of NASH in patients with HIV infection is unknown, but it represents a plausible hypothesis [89]. The mechanism of NRTI-related mitochondrial toxicity appears to involve inhibition or alteration of the human RNA-dependent DNA polymerase γ, which is a key regulatory enzyme of mitochondrial DNA replication. Inhibition of this polymerase leads to complex alterations in mitochondrial function including in adipose tissue [85]. Rarely, this type of mitochondrial hepatotoxicity can lead to an acute, severe lactic acidosis, hepatic steatosis, and multiorgan failure with high mortality [90]. A common milder form, often chronic, is characterized by mild hyperlactatemia with nonspecific symptoms, mild hepatomegaly, and mild aminotransaminase elevations.

Several recent studies point to steatohepatitis as a major cause of chronic liver enzyme elevations in HIV-infected patients. A French study prospectively enrolled 30 HIV-monoinfected patients with unexplained elevations in serum transaminases for more than 6 months and correlated them with liver biopsies [91]. It is noteworthy that these patients were older HIV-infected individuals with a mean age of 46 years, mean duration of HIV infection of 13 years, and all with extensive exposure to ART. Histologic abnormalities were present in 22/30 patients. Eighteen patients had steatosis (severe in 9/18) and 16 of them also showed features of steatohepatitis. Six of 30 had liver fibrosis stage ≥2 (METAVIR scale) and 3/30

had cirrhosis. A similar study performed in the United States prospectively enrolled 24 HIV-infected adults with chronic transaminase elevations while on ART [92]. In this study, patients had a mean age of 50 years, mean duration of HIV infection of 17 years, and mean duration on ART of 12 years. On liver biopsy, 9/24 (37.5%) had steatohepatitis with 6/9 presenting bridging fibrosis. Steatohepatitis correlated with a higher body mass index (BMI) and IR. These two studies clearly demonstrate the high prevalence of steatosis and steatohepatitis in this subgroup of older, treatment-experienced HIV-infected patients. Other cofactors, more common in the HIV population, are associated with the development of steatosis and steatohepatitis, including alcohol and drug exposure and chronic viral hepatitis.

There is increasing evidence that hepatic steatosis and associated steatohepatitis contribute to the advanced hepatic fibrosis in HIV/HCV-coinfected patients. Recent biopsy data on HIV/HCV-coinfected patients on ART show rates of steatosis of 40–61% [93–95]. Investigators from the APRICOT study have demonstrated an association between hepatic steatosis and genotype 3 HCV, higher triglyceride levels, increased hip circumference, and advanced fibrosis in patients who are coinfected with HIV and HCV [96]. Furthermore, steatohepatitis with the associated histologic features of cytologic ballooning and pericellular fibrosis was found in 30% of HIV/HCV-coinfected patients in a North American cohort [97]. IR and the incidence of lipoatrophy are significantly increased in HIV/HCV-coinfected patients compared with those with HIV alone. In addition, IR is also significantly associated with steatosis and fibrosis in this group of patients and has an important role in histologic progression of the disease [98,99]. A recent Spanish multicentre cross-sectional study examined the relationship between IR as measured by the HOMA-IR method and hepatic fibrosis as determined by transient elastography in a cohort of patients coinfected with HIV/HCV and demonstrated that 60% of those with evidence of IR had elastography scores in the significant fibrosis range [98]. These data also suggest that hepatic steatosis is associated with more severe HCV-related liver disease in HIV/HCV-coinfected patients than has been shown previously for HCV-monoinfected patients.

All HIV-infected patients with NAFLD should be encouraged to pursue dietary and lifestyle modification that encourage maintenance of normal body weight. The treatment of associated conditions such as diabetes mellitus, hypertension, and hyperlipidemia is advised although the effects on liver histology have not been studied. For patients with ART-induced lipodystrophy and IR, the benefits of changing ART regimens might be minimal and must be balanced against the risk of HIV disease progression. The effects of using insulin sensitizers, either metformin or pioglitazone, in this setting have yielded inconclusive results without any data on liver histology improvement, although both drugs have been used in fatty liver disease in HIV-uninfected patients.

Interactions between HIV, age, and the liver

Older individuals represent a higher proportion of patients infected with HIV. In 2005, 15% of new HIV infections were in persons aged 50 years and older compared with 6% in 2000 and 4% in 1995 in the United States. Persons aged 50 and older represented 24% of those living with HIV/AIDS compared with 17% in 2001. Liver diseases are now a leading cause of death in the HIV-infected population and are significantly associated with older age, among other factors [3]. Aging is associated with decreased cellular immunity or immunosenescence. Older age at infection with HIV is a predictor of accelerated HIV disease progression [100,101]. Besides the natural aging process on the CD4+ T-cell compartment, there is evidence that HIV itself accelerates aging of both naïve and memory CD4+ T cells and CD8+ T cells [102]. Aging and HIV seem to share common mechanisms by which they alter cellular immunity. Aging of the immune system and HIV disease both lead to reductions in naïve CD4+ and CD8+ T cells. Aging is also associated with a decrease in expression of CD28 on CD8+ T cells. In HIV, decreased CD28 expression on CD4+ and CD8+ T cells has been linked to accelerated progression to AIDS [103]. The effect of age on CD4+ T cells has not been clearly determined, while CD4+ T-cell depletion is the hallmark of HIV infection.

An important and recently recognized consequence of HIV targeting the immune system is the alteration of mucosal immunity [104]. Acute HIV infection leads to a drastic destruction of CD4+ T cells, mainly in gut-associated lymphoid tissue (GALT), which is an extralymphoid CD4+ T-cell reservoir [105,106]. The depletion of gut CD4+ T cells persists during the chronic phase of HIV, despite ART [107]. This breach in the integrity of the gut mucosa allows bacteria and bacterial products to cross over and reach the portal and systemic circulations. This process, called microbial translocation, contributes to the proinflammatory state characterizing chronic HIV infection [108]. Microbial translocation may also accelerate liver disease progression in HIV/HCV coinfection, as suggested by one retrospective study [109]. The impact of aging on gut immunity is not known.

Decreased immunity and age both have an impact on liver disease progression. Advanced immunosuppression (CD4+ T-cell count $\leq$200 cells/mm^3) is a risk factor for accelerated progression of liver fibrosis in HIV/HCV coinfection. Aging has also been associated with faster fibrosis progression. The degree of immunodeficiency

is an independent predictor of liver-related death. In the Data Collection on Adverse Events of Anti-HIV Drugs (D:A:D) study, the risk of liver-related death was inversely proportional to the CD4+ T-cell count. Those with a count lower than 50 cells/mm^3 had a 16-fold increased risk of death compared to those with a CD4+ T-cell count over 500 cells/mm^3. Other predictors of liver-related deaths in this population were coinfection with HCV and/or HBV, intravenous drug use as a risk factor for HIV acquisition, and older age [3]. The latter was found to have a relative risk of 1.3 (95% CI 1.2–1.4) per 5 years, meaning that an individual 10 years older has a 60% increased risk of death compared with the younger patients.

There is some evidence to suggest that HIV directly infects hepatocytes. For example, the detection of HIV antigen and RNA in hepatic cell lines in vivo, the detection of HIV proviral DNA in vivo, HIV infection of different cell lines with the production of infectious HIV particles in vitro, and the detection of hepatotropic variants of HIV in liver tissues [110]. HIV has also been found to infect and replicate within hepatic stellate cells leading to cell activation and fibrogenesis, suggesting a role in liver fibrosis progression in HIV/HCV-coinfected patients [111]. The role of HIV infection of the liver as well as how it relates to liver disease progression in this population needs further study.

Long-term complications of HIV and antiretroviral therapy

The HIV-infected elderly have increased co-morbidities compared with younger patients and are more likely to be taking multiple drugs besides ART, resulting in an increase in the likelihood of drug interaction and toxicity. Many potential factors contribute to the risk of hepatotoxicity in the HIV-infected individuals undergoing ART. The type of ART, coinfection with HBV and HCV, CD4+ T-cell count, alcohol intake, baseline elevated levels of transaminases, female sex, older age, and other factors have all been shown to influence the occurrence of hepatotoxicity. Among the mechanisms of liver injury in HIV-infected patients undergoing ART, mitochondrial toxicity has attracted much attention leading to potentially severe complications such as hepatic steatosis, lactic acidosis, and hepatic failure. The liver demonstrates mitochondrial toxicity by the accumulation of microvesicular steatosis and depletion of mitochondria; it is the signature toxicity of NRTIs. The toxicity is delayed and occurs after cumulative exposure during treatment with one or more NRTIs. In decreasing order of frequency, the NRTIs that cause lactic acidosis are: zalcitabine, didanosine, stavudine, zidovudine, lamivudine, abacavir, and TDF (with the latter three having the same effect) [112, 113]. Persistent, unexplained liver enzyme elevations in HIV-monoinfected individuals on ART are being reported at an increasing frequency. In some studies, it mostly affects individuals with longer duration of HIV infection and longer exposure to ART. In the Swiss HIV Cohort Study, chronic ALT elevation had an incidence of 3.7/100 person-years in HIV-monoinfected patients [114]. Multivariate analysis found prolonged ART exposure (NRTI and protease inhibitor), increased BMI, and high alcohol intake to be predictive of ALT elevation. In another study, using transient hepatic elastometry in 258 consecutive HIV-monoinfected patients (ALT variable not mentioned), Spanish investigators reported abnormal liver stiffness (defined as measurement $\geq$7.2 kPa) in 11.2% of patients [115]. Independent factors associated with liver stiffness were time on didanosine and abacavir, alcohol consumption, and a CD4+ T-cell count <200 cells/mm^3.

Some studies have failed to show a link between cryptogenic liver disease (CLD) and exposure to ART. A recent retrospective study of 13 HIV-monoinfected persons who met the definition of CLD (persistent elevated hepatic transaminase levels for more than 6 months in the absence of common causes of chronic liver disease) and had a liver biopsy performed, showed no association between the development of CLD and prolonged use of ART [116]. The mean age of patients was 45 years (39–65 years), the median CD4+ T-cell count was 187 cells/mm^3, HIV was undetectable except in one patient, and all were ART experienced. However two of the 13 patients showed features of nodular regenerative hyperplasia (NRH; see below) and both had been on didanosine for 59 and 102 months, respectively.

A few studies have relied on liver biopsies to elucidate the cause of CLD in HIV-monoinfected individuals. Among the liver lesions identified in these patients, hepatic steatosis and steatohepatitis [91,92], fibrosis [91,116,117], cirrhosis [91,116], cholangiopathy [116], sclerosing cholangitis [116], NRH [116–119], and hepatoportal sclerosis [120] have all been reported.

Noncirrhotic portal hypertension in HIV-infected patients

Nodular regenerative hyperplasia and hepatoportal sclerosis have been recently described in the HIV-monoinfected population and may now represent the most striking manifestations of the long-term consequences of HIV and its treatment on the liver. They are likely to be different liver histologic lesions on the same spectrum of disease. Our knowledge about these conditions, their exact risk factors, and pathogenesis are, however, limited. Both manifest clinically as NCPH, and esophageal variceal bleeding is the most frequent complication. A case series of 12 patients with HIV on

ART with abnormal liver function tests and/or symptomatic portal hypertension of unknown cause has been recently published [121]. NRH was defined as the finding of diffuse, small, regenerative liver nodules in the absence of significant fibrosis and HPS was characterized by varying degrees of portal fibrosis, sclerosis of portal vein branches, and dilatation of sinusoidal spaces. Out of 11 biopsies, NRH was found in three of them and HPS was found in the remaining eight. The median age of these patients was 47 years (28–67 years) and the median duration of HIV infection was 11 years. Out of the 12 patients, six experienced variceal bleeding. Liver biopsy did not show cirrhosis despite the presence of portal hypertension and its complications. Didanosine was reported as the sole drug received by all subjects and was thought to be the cause of the NCPH. Prior to this report, a case series of four HIV-infected patients presenting with NCPH was reported. The histologic diagnosis was also consistent with HPS. Another case series of six HIV-infected patients with unexplained portal hypertension showed similar histologic findings in five of the six patients with exposure to didanosine [119]. A nested case–control study inside the Swiss HIV Cohort Study identified 15 HIV-monoinfected patients with NCPH who were matched with 75 HIV-monoinfected controls for duration of HIV infection and time of follow-up [122]. All 15 had esophageal varices, splenomegaly, and no cirrhosis on liver biopsy, seven had a history of variceal bleeding, eight had ascites, five had portal thrombosis, two had hepatic encephalopathy, and four died of hepatic complications. The only independent risk factor associated with NCPH in bivariate models was prolonged exposure to didanosine.

A proposed mechanism for NCPH is that an initial endothelial cell injury, likely caused by didanosine, might lead to occlusion of the terminal branches of the portal venules and result in portal hypertension. A direct effect of HIV has been suggested but is less likely since most of the patients have undetectable HIV RNA levels and a CD4+ T-cell count above 200 cells/mm^3 at the time of diagnosis.

Liver infections in HIV-infected patients with severe immunosuppression

In the era of ART, HIV infection for those with access to medication and who are adherent to treatment has turned into a well-controlled chronic disease with relatively preserved CD4+ T-cell counts. As a consequence of this, the incidence of opportunistic infections has declined substantially in patients with HIV. However, in immunosuppressed HIV-infected patients, the liver and biliary tract are frequent sites of infection. Opportunistic infections have been seen in 33–78% of cases in autopsy series in patients with AIDS, and in liver biopsy of almost 90% of HIV-infected patients with abnormal liver function tests. A thorough clinical and diagnostic workup is warranted, which may include liver biopsy with appropriate cultures and staining, provided that less invasive tests are not conclusive.

Viral infections

Hepatitis B virus and HCV infections in HIV are discussed elsewhere in this chapter and therefore will not be discussed in this section. Opportunistic viral infections of the liver are often members of the Herpesviridae family. Although clinically significant hepatitis secondary to cytomegalovirus (CMV) or herpes simplex virus (HSV) is rare, CMV is detected frequently in autopsies of severely immunosuppressed patients with CD4+ T-cell counts <100 cells/mm^3 and is often a component of systemic involvement. Serum transaminases may be markedly elevated. Liver histology typically shows large intranuclear and cytoplasmic owl's eye inclusions with significant inflammation of portal and periportal regions and sparse necrosis. CMV infects every type of cell within the liver. CMV infection is being detected earlier now owing to pp65 antigen flow cytometry and CMV polymerase chain reaction. In addition, the development of ganciclovir (both IV and oral) has reduced the morbidity and mortality of CMV infection [123]. The major toxicity of ganciclovir and valganciclovir is bone marrow suppression. Resistance can also be a problem with ganciclovir, which may require switching to foscarnet. The major side effect limiting the use of foscarnet is its nephrotoxicity. Patients with HSV hepatitis may develop submassive hepatic necrosis with severe transaminitis and liver failure. Pathologically, HSV hepatitis is characterized by multinucleated hepatocytes and Cowdry A intranuclear inclusion bodies, which may be differentiated from those of CMV by specific immunohistochemistry. HSV hepatitis may be treated with IV aciclovir, ganciclovir, or foscarnet. However, hepatitis secondary to either CMV or HSV responds poorly to current treatments. Varicella-zoster virus (VZV), Epstein–Barr virus (EBV), and adenovirus are other agents responsible for viral hepatitis in patients with HIV.

Mycobacterial infections

Mycobacterium avium complex (MAC) is the most common opportunistic pathogen affecting the liver. However, with the introduction of ART the incidence of disseminated MAC infection has declined, and the prognosis has significantly improved. Infection with MAC manifests with systemic symptoms and signs, such as fever,

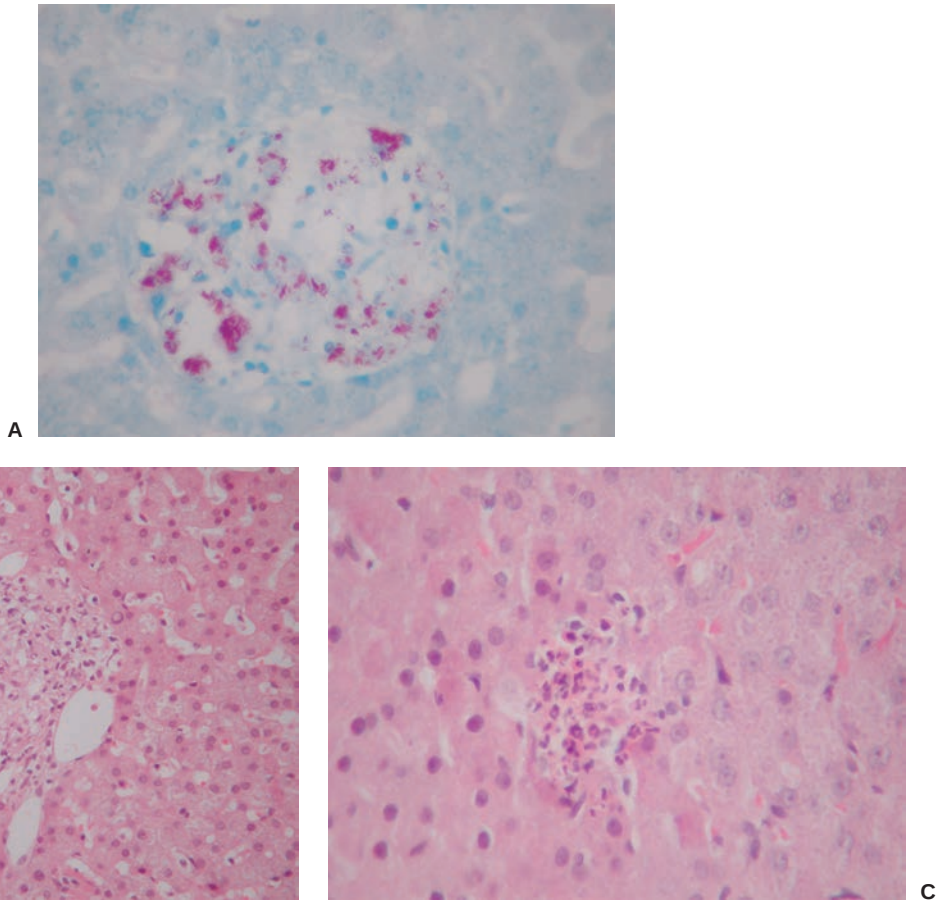

Figure 41.3 (A) An epithelioid granuloma containing *Mycobacterium avium*. Acid-fast bacilli stain, original ×200. (B) A microgranuloma in a patient with mycobacterial infection. Hematoxylin and eosin (H&E), original ×200. (C) A microabscess in the liver of a patient with acquired immunodeficiency syndrome (AIDS) and cytomegalovirus (CMV) infection. H&E, original ×200.

abdominal pain, wasting, and biliary obstruction secondary to enlarged lymph nodes at the porta hepatis. It is seen in late-stage AIDS patients when the CD4+ T-cell count is less than 50 cells/mm^3. MAC is detected in 20–55% of autopsies and in 10–30% of liver biopsies in patients with AIDS. Typical laboratory features include severe cholestasis with marked elevations in alkaline phosphatase (ALP) levels, although high transaminases may be the only abnormality. Icterus is rare. Blood cultures are the most sensitive test for diagnosis of MAC. However, liver biopsy showing diffuse, poorly formed, noncaseating granulomas is necessary for definitive diagnosis of liver involvement. Abundant acid-fast bacilli (AFB) may be seen on staining (Fig. 41.3), but liver tissue culture is needed to distinguish between different *Mycobacterium* species. Liver biopsy has been reported to be more sensitive than bone marrow biopsy in diagnosing disseminated mycobacterial infection in AIDS.

The long-term prognosis of disseminated mycobacterial infection is poor with a median survival of only 6 months. Combination therapy with a macrolide such as clarithromycin or azithromycin, rifampin, and ethambutol is the most common treatment. Ciprofloxacin or amikacin may be added in more severe cases. Previous data suggest that 12 months of therapy may suffice for patients who are on ART with a sustained CD4+ T-cell count >100 cells/mm^3 [124]. Primary prophylaxis with azithromycin or clarithromycin is indicated in patients with a CD4+ T-cell count of less than 50 cells/mm^3.

Extrapulmonary *Mycobacterium tuberculosis* infection involving the liver occurs in 5–10% of HIV-related tuberculosis cases and may present with tuberculous liver abscess in severely immunocompromised patients. However, ART and rifampicin-containing antitubercular therapy have decreased the incidence, recurrence, and mortality rate of tuberculosis [125]. Hepatic involvement of tuberculosis is usually because of the reactivation of a latent infection. Liver tuberculosis is associated with fever, abdominal pain, hepatosplenomegaly, and wasting similar to that found in MAC infection. However, as the virulence of *M. tuberculosis* is greater than in the other species of *Mycobacterium*, it may infect patients who have

higher CD4+ T-cell counts, of more than 200 cells/mm^3. Cholestasis is seen with significantly elevated ALP and mild increases in bilirubin and transaminases. The specific diagnosis is made by culture and polymerase chain reaction of blood, urine, or tissue specimens including liver. AFB may be seen in the liver histology, which is typically characterized by the presence of caseating granulomas. As this infection often occurs in the setting of lesser immunosuppression, hepatic granulomas are better formed than those of MAC. The combination of isoniazid, rifampin, ethambutol, and pyrazinamide for 9–12 months is the treatment of choice for tuberculosis of the liver. Liver chemistry tests should be closely monitored during treatment, especially in elderly patients. Rarely, liver infections with other mycobacterial species such as *M. kansasii*, *M. xenopi*, and *M. genavense* have also been reported.

Fungal infections

Major fungal pathogens infecting the liver are *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Candida* species. They are uncommon, and are ordinarily seen in the setting of disseminated disease and in patients with less than 100 CD4+ T cells/mm^3. Fungal pathogens typically cause cholestasis, and imaging studies often demonstrate focal or diffuse liver lesions. Liver histology often reveals poorly formed granulomas with minimal inflammatory reaction. Meningitis is the most common manifestation of cryptococcal disease in HIV-infected patients. Liver involvement occurs as a result of hematogenous spread. The common presenting features are fever and hepatosplenomegaly. Histoplasmosis is particularly common in the midwestern United States, Central and South America, and the Caribbean, including Puerto Rico. Disseminated histoplasmosis is often the first sign of immunodeficiency in patients with AIDS in endemic areas. Constitutional symptoms along with hepatosplenomegaly and lymphadenopathy are the common features. *Coccidioides immitis* infection usually occurs in patients infected with HIV who are living in endemic areas such as the southwestern United States. The disease typically presents as a subacute illness with pulmonary involvement; hepatic infection is again secondary to disseminated disease. Despite the frequent esophageal involvement of candidiasis in AIDS, systemic infection and liver involvement are quite rare in the absence of neutropenia. The symptoms are nonspecific and include nausea, vomiting, abdominal pain, and hepatomegaly. The most common laboratory findings of hepatic candidiasis include neutropenia and elevated ALP. Imaging may demonstrate a single lesion, classically described as having a bull's eye appearance. *Cryptococcus neoformans* and *H. capsulatum* may be rapidly detected by polysaccharide capsular antigenemia; other causes of fungal hepatitis need special staining and culture of liver tissue for definitive diagnosis. There are also rare reports of *Aspergillus fumigatus* causing liver abscess and disseminated *Sporothrix schenckii* involving the liver. Treatment consists mainly of amphotericin B for fungal hepatitis; however, as the relapse rate is high for most of the fungal infections in immunocompromised patients, fluconazole or itraconazole have been suggested as suppression therapy indefinitely in most cases.

Protozoal infections

Protozoa are rare pathogens causing infections in patients with AIDS. Routine prophylaxis with trimethoprim/sulfamethoxazole (TMP-SMX) has reduced the incidence of *Pneumocystis jirovecii*, *Toxoplasma gondii*, and *Listeria monocytogenes*. In the past, *P. jirovecii* (formerly *Pneumocystis carinii*) hepatitis was associated with the prophylactic use of aerosolized pentamidine for *Pneumocystis* pneumonia. Inhalation failed to provide adequate drug levels to extrapulmonary sites and up to 39% of such patients developed extrapulmonary spread. A mixed pattern of elevated liver enzymes is usually seen. Abdominal computed tomography (CT) scans may demonstrate diffuse and punctuate calcifications in the liver. Liver biopsy shows foamy nodules that are periportal or diffuse containing numerous *Pneumocystis* cysts that stain with Gomori methenamine silver. Treatment is with IV TMP-SMX or pentamidine. *T. gondii* also involves the liver rarely through hematogenous dissemination and may present with granulomatous disease or hepatitis. Diagnosis is made by culture or microscopic examination of Giemsa-stained specimens. TMP-SMX is the drug of choice for toxoplasmosis. Microsporidial infection of the liver is rare and is associated with a rise in bilirubin, transaminases, and high ALP levels. Light microscopy reveals focal granulomatous and suppurative necrosis, mainly in the portal area, accompanied by characteristic spores. Although there is no established therapy for microsporidial hepatitis, treatment with albendazole may be efficacious for *Encephalitozoon intestinalis*. *Strongyloides stercoralis*, a helminth of the nematode family, may result in a hyperinfection syndrome in the immunocompromised patient. The liver is involved through the hematogenous spread of the larvae from the gastrointestinal tract. *Entamoeba histolytica* may invade the bowel wall and spread to the liver, forming an abscess. Reactivated leishmaniasis is another rare infection of the liver.

Infections of the biliary tract

The biliary tree, including the gallbladder, is a common site of infection in HIV-infected patients with immunosuppression. It may be involved in the form of cholangiopathy or acalculous cholecystitis.

Cholangiopathy

Cholangiopathy in AIDS is a form of secondary sclerosing cholangitis that occurs because of opportunistic infections in advanced stages of HIV infection, particularly in patients with a CD4+ T-cell count of less than 135 cells/mm^3. Affected patients develop right upper quadrant pain, fever, and cholestasis. ALP is often elevated up to 10–20 times above normal. Icterus is seldom seen as biliary obstruction is usually partial. There are multiple opportunistic organisms that have been identified in the biliary tree of patients with AIDS cholangiopathy including CMV, *Cryptosporidium* sp., and *Microsporidium* sp., and less often MAC, *Isospora belli*, and *Enterocytozoon bieneusi*. However, no pathogen is isolated in up to 50% of cases. Although liver ultrasonography may show biliary dilatation, and magnetic resonance cholangiopancreatography (MRCP) may demonstrate characteristic findings of cholangiopathy, endoscopic retrograde cholangiopancreatography (ERCP) is more sensitive and has the advantage of allowing both tissue biopsy and sphincterotomy to be performed when necessary. Four patterns of abnormalities shown by ERCP have been described: (i) stenosis of the papilla of Vater with dilated extrahepatic bile ducts; (ii) sclerosing cholangitis; (iii) combined sclerosing cholangitis and papillary stenosis; and (iv) long extrahepatic strictures with or without sclerosing cholangitis. Duodenal and papillary biopsies and biopsies from inside the biliary ducts may be sent for both culture and pathologic examinations. Endoscopic sphincterotomy may provide benefit for symptomatic patients with papillary stenosis. Prognosis depends on the degree of underlying HIV-related immunosuppression rather than the hepatobiliary disease [126]. A review of 94 HIV-infected patients over a period of almost two decades in the era of ART demonstrated a median survival of patients with AIDS cholangiopathy to be 9 months. Poor prognostic factors were opportunistic infections (especially cryptosporidiosis) and markedly elevated serum ALP. ART has significantly improved the survival of patients with AIDS cholangiopathy [126].

Acalculous cholecystitis

Acalculous cholecystitis usually occurs in later stages of HIV infection with a CD4+ T-cell count of less than 50 cells/mm^3. Concurrent cholangitis is commonly seen. Patients usually present with abdominal pain, fever, nausea, and vomiting. Icterus is rare, but ALP and γ-glutamyltransferase (GGT) are markedly elevated in most cases. In acalculous cholecystitis, the gallbladder wall appears thickened and edematous on imaging without any gallstones. Pericholecystic fluid may be present. Gallbladder histology often reveals an opportunistic organism as a cause. The spectrum of responsible pathogens is similar to that identified in AIDS cholangiopathy. Complications of acalculous cholecystitis include perforation and peritonitis. Cholecystectomy can be performed in most patients; in the remaining cases, CT or ultrasonography-guided percutaneous cholecystostomy may be an option to decompress the gallbladder.

Hepatic mass lesions in HIV-infected patients

The most common hepatic neoplastic mass lesion is Kaposi sarcoma (KS) caused by human herpesvirus type 8 (HHV-8). The incidence of KS in HIV-infected patients may be 10–20%, more than 100,000 times that in the general population. Fortunately, its incidence in AIDS continues to decrease and the lesions often respond to ART. Among HIV-infected individuals, KS occurs predominantly in men who have sex with men. Despite the presence of hepatic KS in approximately one third of patients with cutaneous involvement, it is seldom diagnosed on antemortem biopsy. Patients may present with abdominal pain and hepatosplenomegaly with an elevated ALP level, but most commonly it is asymptomatic. There is no specific finding on CT scan; however, the lesions are hypoattenuated and enhance after a bolus of IV contrast. The tumor appears to be a vascular proliferation characterized by the presence of spindle cells, vascular channels, and a mixed cellular infiltrate on histology.

B-cell lymphoma is the second most common neoplasm in patients with HIV infection after KS. It is controversial whether the incidence of non-Hodgkin lymphoma has changed since the introduction of ART. Non-Hodgkin lymphomas in patients with AIDS are often of B-cell phenotype with high grade and advanced stage, and predominantly extranodal, involving most frequently the central nervous system and the gastrointestinal system. They appear to be a late manifestation of HIV disease with rates rising directly with the duration of infection. The liver is involved in approximately 10% of cases. The CD4+ T-cell count is usually less than 200 cells/mm^3. Primary hepatic lymphoma usually presents with multiple masses and involvement of other abdominal organs or lymph nodes. Persistent fever, tender hepatomegaly, and mildly abnormal liver chemistry tests combined with an elevated lactate dehydrogenase (LDH) level may give a clue to the diagnosis. The lesions appear hypodense on both noncontrast and contrast-enhanced CT imaging. Diagnosis can be established by laparoscopic or CT-guided biopsy. However, as bone marrow involvement is frequent, a bone marrow aspirate or biopsy should be considered before a more invasive liver or retroperitoneal lymph node biopsy. AIDS-associated lymphomas have generally an aggressive course and respond poorly to treatment.

Bacillary peliosis hepatis is a vascular lesion caused by *Bartonella henselae*, a fastidious Gram-negative bacillus. It usually occurs in patients with CD4+ T-cell counts of less than 200 cells/mm^3. Peliosis hepatis may be found incidentally on liver biopsy or occasionally can present with abdominal pain, hepatosplenomegaly, liver failure, and portal hypertension in extensive cases. Systemic symptoms such as fever, anemia, and cutaneous lesions of bacillary angiomatosis may be observed. Laboratory analysis may reveal an elevated ALP level and prothrombin time. Abdominal CT scans display multiple, small, low-attenuation lesions scattered in the liver parenchyma. Biopsy shows cystic blood-filled spaces within the liver that are usually a few millimeters in size. They are associated with fibromyxoid stroma containing clumps of bacilli that can be detected by Warthin–Starry stain. Erythromycin is the drug of first choice for the treatment of peliosis. Other options include clarithromycin, tetracycline, or doxycycline. Liver abscess secondary to mycobacterial infections and HCC that may be seen in the setting of HCV or HBV coinfection are other mass lesions observed in HIV-infected patients. The incidence of mycobacterial liver abscess is decreasing since the introduction of ART and effective antimycobacterial therapy. On the other hand, the incidence of HCC in HIV-infected patients is increasing because of improved survival with ART and the rising incidence of end-stage liver disease because of HCV and/or HBV coinfection and alcohol abuse [127].

Hepatocellular carcinoma in HIV-infected patients

Increased survival of HIV-infected patients in the era of ART has lead to an increase in liver-related mortality in this group of patients. A French survey on the causes of death in HIV-infected patients confirmed the increasing role of HCC as a non-AIDS-related cause of death: the prevalence rate increased from 4.7% in 1995 to 11% in 1997 and 25% in 2001 [128]. Additionally, an estimated 25–30% of patients with HIV are coinfected with HCV and the accelerated progression of HCV-related liver disease places this group of patients at extremely high risk of liver disease and its complications including HCC [129]. A retrospective European study of 41 patients with HCC in HIV-infected persons found most patients to be coinfected with HCV, to have a younger age at onset, a shorter estimated duration of disease, and a more aggressive clinical course when compared with HIV-uninfected patients with HCC [31]. A multicenter, US/Canadian study of 63 HIV-infected patients with HCC found similar results of younger age and more frequent infection with HCV or HBV than in HIV-uninfected patients. They also found tumor staging and survival to be similar between the HIV-infected and HIV-uninfected cohorts [7]. Additionally, other causes of liver disease including hepatic steatosis and steatohepatitis that are increasing in frequency may pose additional risks for HCC development and will need to be studied in the future. Despite the increasing number of patients with HCC and the prolonged survival of HIV-infected patients, there are no updated guidelines on screening for HCC in this population [130]. Current screening guidelines for patients with cirrhosis should apply to HIV-infected patients with cirrhosis, and should at a minimum include imaging of the liver every 6 months.

Liver transplantation in HIV-infected patients

The introduction of ART has dramatically reduced disease progression and death among patients with HIV infection. As the life expectancy for HIV-infected individuals has increased, liver disease has become a leading cause of non-AIDS-related death in those infected with HIV [3,5,130]. A French study found 28% of non-AIDS-related deaths were attributed to ESLD [130]. Prior to ART, HIV with or without AIDS was considered a contraindication to liver transplantation (LT) by most centers due to poor outcomes with a high incidence of opportunistic infections post-transplant resulting in higher mortality and 3-year survival rates of 45%. Even in the era of ART, until recently, the presence of AIDS was an absolute contraindication to LT, and asymptomatic HIV infection remained a relative contraindication. However, in recent years, with widespread use of ART and increased numbers of HIV-infected patients living with chronic liver disease, LT has been reconsidered as a possible therapeutic option for these patients.

In 2003, Ragni and colleagues prospectively studied the survival rates of 24 HIV-infected LT recipients. With 1-, 2- and 3-year survival rates of 87.1%, 72.8%, and 72.8%, respectively, in these HIV-infected patients, the results were not statistically different to the rates of 86.6%, 81.6%, and 77.9% found among 5,225 age- and race-matched HIV-uninfected patients from the United Network of Organ Sharing (UNOS) database [131]. In HIV-infected patients the etiology of liver disease was chronic HCV infection in 63%, chronic HBV infection in 29%, and acute liver failure in 13% of subjects. However, in the HIV/HCV-coinfected group, survival was worse compared with the HCV-monoinfected group. In this study, worse outcome was associated with post-transplant ART intolerance, a CD4+ T-cell count of less than 200 cells/mm^3, an HIV viral load of greater than 400 copies/mL, and HCV coinfection. In another early

series from King's College Hospital in London, 14 HIV-infected liver allograft recipients were evaluated [132]. HCV was the etiology of liver disease in seven patients, HBV in four patients, alcohol in two patients, and acute liver failure in one patient. In the non-HCV group ($n = 7$), all patients were still alive with a survival range of 668 to 2,661 days after transplantation, none experienced HBV recurrence, and graft function was normal in all patients. However, five of the seven HCV-infected patients died after transplantation at 95–784 days (median 161 days). Most deaths were because of complications of recurrent HCV and sepsis. This study demonstrated a poor outcome in the HIV/HCV-coinfected patients, but more recent studies have shown better results.

A recent Spanish study by Murillas revealed that the model for end-stage liver disease (MELD) score and the inability to reach an undetectable plasma HIV-1 RNA viral load at any time during follow-up were the only variables independently associated with the risk of death ($P < 0.001$) [133]. While 104 patients were included in the study, only 14% met inclusion criteria for listing for LT and five patients were transplanted. The waiting list mortality rate in patients with a MELD score <20 and in patients with a MELD score >20 was 58% and 100%, respectively (median follow-up of 5 months). A recent US cohort of HIV in Solid Organ Transplantation Multi-Site Study (HIVTR) enrolled patients with HIV infection and ESLD who were candidates for LT at 20 transplant centers in the United States between February 2003 and September 2007. Patients were required to meet standard site criteria for placement on the LT waiting list as well as HIV-specific study inclusion criteria. The latter included a CD4+ T-cell count of >100 cells/mm^3, or >200 cells/mm^3 if there was a history of prior opportunistic infection or HIV-1 RNA <50 copies/mL or >50 copies/mL in those with hepatotoxicity or ART intolerance in whom HIV suppression was predicted post-transplantation. HIV-infected subjects ($n = 167$) were matched with HIV-uninfected LT candidate controls ($n = 792$) without HCC from the UNOS database. It should be noted that 75% of cases and controls were HCV-infected patients. Pretransplantation mortality characteristics were similar between HIV-infected and HIV-uninfected candidates. The authors concluded that although lower CD4+ T-cell counts and detectable levels of HIV RNA might be associated with a higher rate of pretransplantation mortality, the baseline MELD score (cutoff value of 25) was the only significant independent predictor of pretransplantation mortality in HIV-infected LT candidates. These recent findings suggest that survival of HIV-infected LT recipients does not differ from that of HIV-uninfected recipients and that HIV should not be a contraindication to LT, provided patients meet the current inclusion and exclusion criteria for listing.

While there has been a significant decline in LT in patients with chronic HBV due to improvement in antiviral therapy, HBV coinfection remains an important cause of liver failure in HIV-infected patients [5]. In patients transplanted for HIV/HBV coinfection, post-transplant survival was not limited by HBV reinfection of the allograft because of effective prophylaxis using hepatitis B immune globulin and antivirals such as lamivudine, adefovir, or TDF [5,132,134].

All HIV-infected patients with ESLD should be considered as candidates for LT provided they do not have advanced HIV disease. Those with severe immunosuppression (<100 CD4+ T cells/mm^3) should be treated with ART to control viral replication before they are evaluated for transplantation. Patients with a good response to ART, but with prior AIDS-related opportunistic infections and neoplasm, have a higher risk of relapse while on immunosuppressive medication after transplantation. These findings highlight the importance of early referral and multidisciplinary care to expand the number of HIV-infected patients with ESLD who could be candidates for successful LT and to minimize the number of deaths occurring whilst on the waiting lists. The essential condition for LT in patients with HIV is that the patient must be able to undergo effective and long-lasting ART during the post-transplant period. The ideal situation is one in which the patient tolerates ART before transplant and is ready for the transplant with undetectable plasma HIV viral load by ultrasensitive techniques (<50 copies/mL).

There are some important pharmacokinetic drug interactions between protease inhibitors and non-NRTIs and immunosuppressive agents like tacrolimus and ciclosporin. Protease inhibitors can increase the levels of tacrolimus and ciclosporine through the inhibition of cytochrome P450, whereas non-NRTIs can reduce their levels. Therefore, some ways to improve survival after LT in HIV-infected patients is to optimize the dose of immunosuppressive medication to prevent toxicity secondary to drug interactions with ART agents, the use of ART to suppress HIV RNA, and to maintain CD4+ T-cell counts >200 cells/mm^3 to decrease the risk of opportunistic infections [135]. Therefore, while LT in HIV-infected patients is complex and requires a multidisciplinary approach, it is a promising treatment option.

Conclusions

The HIV/AIDS epidemic is changing. The HIV population is aging and with older age comes the increased risk of chronic disease development. In the field of liver diseases, we are faced with the increasing incidence of metabolic complications leading to hepatic steatosis and steatohepatitis. As the HIV population ages, we

see complications of long-term ART of which NCPH is the newest. Opportunistic infections are becoming rarer. The aging population coinfected with HBV and/or HCV has a considerable impact on the burden of liver-related morbidity and mortality. LT is an option to consider in HIV/HCV-coinfected patients. The importance of primary prevention of transmission of chronic viral illnesses cannot be overemphasized. Effective treatment of HBV with TDF-containing regimens has altered the landscape of liver diseases in patients infected with HBV and HIV. HCV treatment has clearly demonstrated survival benefits when SVR is achieved and should be considered for all HIV/HCV-coinfected patients. The year 2011 is the dawn of a new era in HCV treatment in both mono and coinfected patients. In May 2011, the first direct-acting antiviral agents, the two protease inhibitors boceprevir and telaprevir were approved by the FDA for use in HCV-monoinfected patients. The results are awaited in HIV/HCV-coinfected patients. Combination treatment with direct antiviral agents of different classes with nonoverlapping resistance mutations is clearly the way of the future. Whether pegIFN and RBV will be part of the new direct antiviral agent regimens has yet to be determined. We all eagerly anticipate the new decade where we will see great leaps forward in antiviral treatment of HCV.

Multiple choice questions

41.1 Noncirrhotic portal hypertension (NCPH) has been most consistently associated with the use of which antiretroviral?

- **a** Lamivudine.
- **b** Zidovudine.
- **c** Zalcitabine.
- **d** Nevirapine.
- **e** Didanosine.

41.2 Predictors of successful outcomes after liver transplant in HIV-infected patients include all the following except which one?

- **a** Well-controlled HIV disease.
- **b** Lower model for end-stage liver disease (MELD) score.
- **c** Early referral to transplant team.
- **d** HCV coinfection.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

PART XI

Elements of Liver Transplantation

Overview

Michael F. Sorrell

The success of liver transplantation has transformed the discipline of hepatology. The potential role of liver replacement has changed how physicians approach the care of end-stage liver disease. Because of the centrality of transplantation, the practice of liver disease is now intertwined in a multidisciplinary manner with multiple other specialties. Much of the success of liver transplantation in the past 30 plus years can be attributed to advances in these sister disciplines. This is particularly true with regard to radiologic imaging and intervention. Now that liver transplantation is firmly established as a proven treatment option, attention has shifted to the long-term consequences of transplantation and the central role of post-hospital care with an emphasis on the resultant quality of life. Not withstanding the success of liver transplantation, new challenges and controversies surface as would be expected in such a dynamic and changing field.

Perhaps the most prominent of the challenges and controversies remains that of donor liver distribution and to some degree allocation. The challenge of allocation was met by the development of the model for end-stage liver disease (MELD) score, with subsequent modifications termed MELD exception scores. The move to MELD with its objective criteria substantially eliminated many of the disparities surrounding organ allocation and reduced deaths on the waiting list. However, marked disparities in organ distribution remain because of variation in the number of available organs between individual organ procurement organizations. The US Institute of Medicine recommendation that access to organs be more equitably distributed by the development of regional sharing has been stoutly resisted by transplant physicians who would be adversely affected by the adoption of these recommendations. Further changes in organ allocation will require a political solution.

In response to the shortage of donor organs, transplant surgeons have responded by expanding the donor organ pool in several ways. The use of living donor grafts was at one time thought to be a partial answer both to donor organ shortage and optimal timing of liver grafting. The absence of a living donor death registry does not allow for an accurate assessment of the risk of live donor donation. Within the United States, the wide dissemination within the popular press of live donor deaths has contributed to a halving of live donor grafting. It is estimated that at least 23 donor deaths directly attributed to the surgical procedure have occurred in the United States and Europe. The use of deceased cardiac donors has been another approach to increasing the organ donor pool. Although short-term graft survival in some centers is similar using deceased donors, the surgical complications, particularly diffuse biliary strictures, have lessened the appeal of using such donors.

The value of liver transplantation as a life-saving modality is firmly established. The technical aspects of the transplant procedure itself have been largely worked out and only minor emendations appear in the literature; however, long-term management challenges remain. The major indication for liver transplantation is chronic hepatitis C followed closely by nonalcoholic steatohepatitis (NASH). Recurrence following transplantation is the rule. The lack of a predictably effective treatment for recurrent hepatitis C has resulted in a decreased 5-year survival rate when compared to primary biliary cirrhosis, primary sclerosing cholangitis, and alcoholic liver disease. NASH recurrence is common, and in a similar vein, effective drug therapy for recurrent disease is lacking.

The increased incidence of vascular disease, cancer, metabolic complications, and renal failure influence not only morbidity and mortality but also quality of life. Many of the long-term complications are caused by immunization protocols required to maintain graft survival. The development of new immunosuppressive drugs and solving the puzzle of tolerance remain the best hope for the future of improved survival and enhanced quality of life.

CHAPTER 42
Selection and Timing of Liver Transplantation

Richard B. Freeman Jr.
Department of Surgery, Dartmouth-Hitchcock Medical Center, Lebanon, NH, USA

Key concepts

- The selection of candidates for liver transplantation is not necessarily linked to the timing of liver transplantation due to the severely constrained organ donor resource. This means that individual candidates cannot always receive a transplant at the optimal time for his or her benefit.
- For most patients with chronic liver disease, selection for transplantation depends on their risk of dying from the liver disease weighed against their risk of dying from the transplant procedure and attendant medications. Mortality risk scores have been helpful in determining when the risk of death without a transplant is greater than the risk of the procedure. Survival benefit, or the life gained with a transplant compared with lifetime gained staying on the list without a transplant, is an increasingly accepted concept for selecting liver transplant recipients.
- For some liver conditions, the benefit of liver transplantation cannot be weighed against the mortality risk from intrinsic liver disease. Thus other methods, such as estimates of disease progression, must be used for proper selection of waiting candidates. Disease progression estimates are limited by lack of good natural history data.
- Pediatric patients with liver disease face unique problems and mortality risk models utilizing variables specific for children have been developed to address these differences.
- Efficient selection of liver transplant candidates with acute liver failure is especially challenging because of the need to rapidly assess the probable natural course of the disease so that patients not likely to recover will receive transplant priority but those more likely to recover do not receive needless organs.
- Living donor liver transplantation improves the ability of the clinician to "time" the transplant at the most advantageous point in the disease process for the waiting candidate. However, donor risks and informed consent must not be subjugated in an effort to maximize the timing benefit.

Inhabitants in the developed world are fortunate that, in large measure, effective treatments for most medical conditions are generally available, with access to these treatments limited mostly by socioeconomic, or distributive, problems rather than scarcity of the therapeutic substrate itself. This is not the case for transplantation. Unlike any other field in medicine, the clinician's ability to apply transplantation therapy is not completely defined by the risk–benefit ratio of that therapy for the patient in question. For patients who could potentially benefit from liver transplantation, the constrained donor liver resource problem is acutely severe since alternative liver support technologies are not perfected. Thus, the application of liver transplant therapy depends not only on the diagnosis of a problem for which liver transplantation is likely to provide more benefit than harm, but also on the availability of the therapeutic substrate – the liver itself. Consequently, and in contrast to most other medical conditions, determining if a patient diagnosed with progressive liver disease will receive benefit from liver transplantation is not sufficient for initiation of delivery of the treatment. This makes the optimal timing for liver transplantation a two-sided proposition: (i) determining when a patient's disease has advanced far enough that he or she will receive more benefit than harm from the transplant procedure and subsequent maintenance treatments; and (ii) determining who, among all those who are deemed to likely receive benefit, should come first when donor constraints allow only one patient at a time to be treated. The former patient-based issue can be categorized as the selection of appropriate candidates for transplantation. The second topic, timing of liver transplantation, is not entirely under the control of the treating physician or patient but is much more influenced by allocation and distribution rules. Only in the case of living liver donor transplantation can treating clinicians completely control the timing of liver transplantation for candidates they have deemed appropriate. This chapter addresses the selection of patients for liver transplantation, the optimal timing of liver transplantation absent

organ donor constraints, the timing of liver transplantation in the context of living donor liver transplantation, and finally organ allocation priorities and their influence on the timing of liver transplantation.

Selection of candidates for liver transplantation

Mortality risk

Liver transplantation, like all therapies, should be offered when the risks are outweighed by the benefits. Quantifying risk and benefit, however, is no easy proposition and is fraught with subjective interpretations of need for transplantation. For any candidate, co-morbid conditions such as cardiopulmonary disease [1], renal function, chronic or active acute infections, neurologic and psychiatric impairments, as well as the social support system available to the patient must be assessed and considered in the overall determination of surgical risk. Caregivers and patients must weigh mortality risks, disease progression, and the impact of deterioration in quality of life for those with liver disease who may be candidates for liver transplantation. In the past, most patients were deemed reasonable candidates for transplantation based on the development of signs or symptoms of decompensation usually related to portal hypertension. These original assessments of liver transplant candidacy were subsequently incorporated into minimal listing criteria based on an anticipated 1-year survival of 90% or less if no transplant was performed [2]. This 1-year waiting list survival criterion was equated to a Child–Turcotte–Pugh (CTP) [3] score of greater than or equal to 7. However, the use of subjective variables, and differences in cholestatic versus noncholestatic liver diseases, as well as a "ceiling effect" inherent in the CTP score for more advanced chronic liver disease, led investigators to look to other models to predict mortality. To this end, Malinchoc et al. defined a mathematical model to predict mortality risk in any patient with portal hypertensive complications undergoing a transjugular intrahepatic portosystemic shunt (TIPS) procedure regardless of the underlying chronic liver disease [4] and without using the subjective variables employed by the CTP score (Box 42.1). The model for end-stage liver disease (MELD) score has subsequently been shown to be highly predictive of 3-month mortality for a variety of cohorts of patients with chronic liver disease [5,6] and for a cohort of US patients waiting for liver transplantation [7]. The MELD model has been widely accepted as a measure of chronic liver disease severity where severity of disease is defined as 3-month mortality risk and has been incorporated in liver allocation systems in the United States and many other areas around the world. Thus, if one defines need for liver transplant in terms of risk of dying of liver disease, the MELD score provides an objective, readily available, easily applied measure for the selection of liver transplant candidates with chronic liver disease.

Box 42.1 Model for end-stage liver disease (MELD) and pediatric end-stage liver disease (PELD) scores.[a]

MELD score

- $R = 0.957 \times \log_e(\text{creatinine mg/dL}) + 0.378 \times \log_e(\text{bilirubin mg/dL}) + 1.120 \times \log_e(\text{INR}) + 0.643 \times (\text{disease etiology}^b)$

MELD score, UNOS/OPTN policy

- $R = [0.957 \times \log_e(\text{creatinine mg/dL}) + 0.378 \times \log_e(\text{total bilirubin mg/dL}) + 1.120 \times \log_e(\text{INR}) + 0.643] \times 10$

PELD score

- $R = [0.463 \times (\text{age}^c) - 0.687 \times \log_e(\text{albumin g/dL}) + 0.480 \times \log_e(\text{total bilirubin mg/dL}) + 1.857 \times \log_e(\text{INR}) + 0.667 (\text{growth failure}^d)] \times 10$

Health-related quality of life

Mortality risk, however, may not be the only measure of need for liver transplantation. Numerous studies have documented that health-related quality of life (HRQOL) is poor for patients with progressive chronic liver disease [8–10] and that measures of mortality risk may not necessarily correlate with measures of HRQOL for these patients [11]. Nonetheless, when weighing quality of life considerations, physicians must account for mortality risk because, for patients who die, there can be no *quality* of life. Thus, mortality risk usually takes precedence in determining appropriate timing of liver transplantation for individual patients when the risks of death from transplantation surgery and immunosuppression are relatively low in relation to the mortality risk without transplantation even though the patient's quality of life may be poor. For example, offering liver transplantation to patients with limitations in their HRQOL who face a higher risk of dying due to the surgery and post-transplant treatments than they face if they wait until their disease becomes more severe, may not be in the best interest of that patient. Interestingly, however, in one

Table 42.1 Health-related quality of life indices in 20-year liver transplant survivors.

Category	20-year survivors ($n = 68$)	US population ($n = 2,474$)	*P*	Chronic liver disease ($n = 210$)	*P*

study of end-stage liver disease patients, subjects were frequently willing to accept a reduction in life expectancy in return for improved health and onehalf of the subjects would accept a 50% mortality risk in exchange for perfect health [12]. Almost all studies have shown significant improvements in HRQOL after transplant [13], and the HRQOL outcome is not associated with the severity of illness before transplant [14]. Moreover, even 20 years after transplant, recipients have acceptable quality of life and achieve many of the important life events that the general population enjoys (Table 42.1) [15]. Thus, regardless of how ill patients are before the transplant, if they survive, most can expect a reasonable HRQOL or functional status afterwards. Therefore, there does not seem to be justification for selecting one group of patients for liver transplantation because they are likely to achieve a better HRQOL afterwards, than another. The available literature suggests that all recipients report relatively similar and significantly improved HRQOL afterwards.

Transplant benefit

The concept of selecting patients based on estimates of transplant benefit, as measured in number of life years gained, has garnered increasing attention. Merion et al. compared the mortality risk for liver transplant candidates remaining on the list with mortality risk for recipients of deceased donor liver transplants and stratified their results by MELD score at listing (Fig. 42.1). These investigators found that recipients with MELD scores <15 experienced a higher hazard for death than the

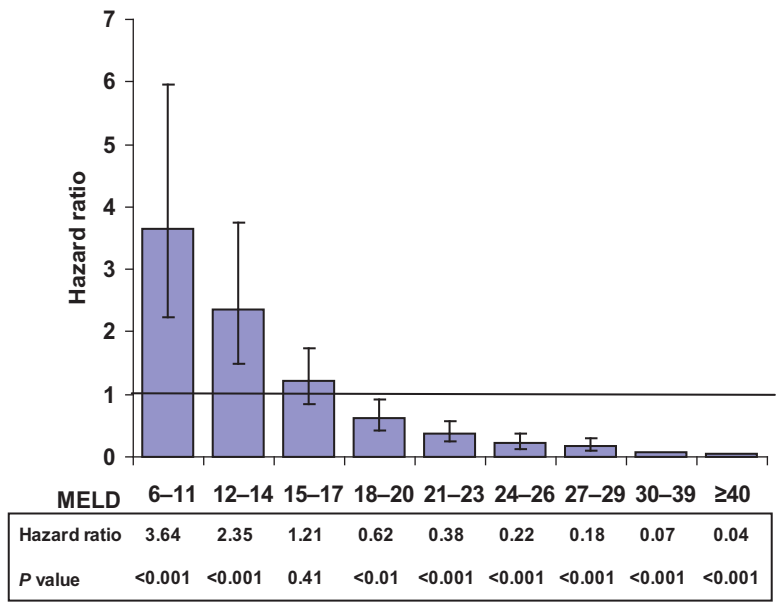

Figure 42.1 Comparison of mortality risk expressed as hazard ratio by MELD score for recipients of liver transplants compared to candidates on the liver transplant waiting list. (Reproduced from Merion et al. [16] with permission from Wiley-Blackwell.)

candidates who remained on the list without transplantation at 1 year of follow-up. The authors concluded that, "liver transplants are being performed for some candidates who have a higher risk of dying from the transplant procedure than they have from dying from their underlying liver disease" [16]. It is interesting to note that, in this study, there was no MELD score beyond which a benefit in survival was obtainable. Therefore, even for candidates with very high pretransplant mortality risks as defined by their MELD score, a significant benefit was achieved by liver transplantation because the success rate was still acceptable and their survival probability without transplant was essentially zero. However, the posttransplant survival results were based only on candidates for whom liver transplantation was performed and many more patients with high MELD scores were removed from the waiting list for reasons of death or being too sick than patients with lower MELD scores [17]. These results indicate that there is a selection process by which centers are choosing candidates with high MELD scores for whom they expect a good chance of success. The transplant benefit concept has been further analyzed by stratifying recipient benefit across donor quality indices. Transplanting livers with higher risks of failure confers even more risk on recipients who have low risks of dying without the transplant. These high-risk livers, or so-called extended criteria donor livers, still confer a survival benefit to patients with the highest risks of dying without the transplant because the increased risk of the organ and surgery is still considerably less compared with the near 100% mortality risk for patients with the highest MELD scores [18]. From these data the optimal timing of liver transplantation for patients with chronic liver disease can be estimated based on their mortality risk as defined by their MELD score. Most patients with chronic cirrhosis who have MELD scores >15 will receive a benefit from liver transplantation even when using grafts from higher risk donors, whereas those with lower MELD scores have a better chance of surviving without a transplant. Giving these low-risk candidates higher risk grafts reduces the survival benefit for these candidates because the risks of surgery and graft failure are higher than remaining on the list and continuing to wait for a lower risk graft.

Clearly, however, there are diagnostic groups of patients with chronic liver disease for whom the MELD score may not accurately reflect mortality risk. Patients with human immunodeficiency virus (HIV) and hepatitis C virus (HCV) coinfection [19], patients with intestinal failure [20], and perhaps patients with severe ascites [21] may have higher mortality risks than their MELD score defines. Attempts to better calibrate the MELD score for patients with ascites and hyponatremia have produced mathematical models that incorporate serum sodium along with other laboratory values, and these may be more accurate in predicting death for such patients [22]. Overall, for individual patients with severe symptoms or poor HRQOL but low mortality risks, transplantation must be carefully weighed to determine if there is sufficient justification to accept greater hazards of death for potential improvement in HRQOL.

Other disease progression end-points

For some patients with liver diseases treatable by transplantation, mortality or HRQOL risk may not be the correct metrics to judge need. Examples of such conditions are hepatocellular carcinoma (HCC), metabolic liver diseases, and hepatopulmonary and portopulmonary hypertension syndromes. Patients with these disorders usually do not have significant mortality risks due to their underlying liver disease but face risks of disease progression beyond a point at which liver transplantation can be offered with a reasonable chance of success. Unfortunately, risk models for disease progression for these conditions have not been derived, making evidence-based selection problematic.

Hepatocellular cancer

Since HCC is increasingly recognized as a worldwide health problem, much more attention has been focused on its natural history and treatment. Excellent short and longer term results have been achieved with liver transplantation for patients with small HCC lesions arising in cirrhotic livers. Specifically, cirrhotic patients with a single HCC lesion less than 5 cm in diameter or three or fewer lesions, the largest of which is less than 3 cm in diameter – the so-called Milan criteria [23] – have 4-year survival rates in excess of 80%. These rates are comparable to liver transplant recipients with nonmalignant primary liver diseases [24] and are better than surgical resection [25]. These excellent results depend on timing the transplantation for patients before the tumor extends to a larger size and/or disseminates. Thus, more accurate selection of appropriate candidates with HCC for liver transplantation requires the development of prognostic models of tumor progression. Increasingly, clinicians have recognized that HCC can progress at variable rates and that some tumors beyond the Milan criteria have favorable recurrence patterns after transplantation. Investigators at the University of California at San Francisco (UCSF) demonstrated that selecting HCC candidates for liver transplantation with single tumors <6.5 cm in size, or three or fewer tumors with the largest being <4.5 cm and the total tumor diameter of <8 cm, can achieve 5-year survival results comparable to patients selected using the Milan criteria [26]. Extending this concept, European investigators assessed post liver transplantation outcome for HCC patients with various tumor numbers and sizes and developed the Metro ticket

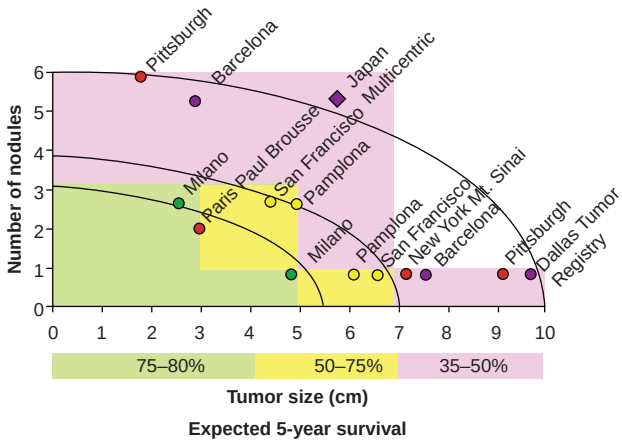

Figure 42.2 Metro ticket concept for hepatocellular cancer.

concept (Fig. 42.2) [27]. More recent single center studies have suggested that the probability of progression for HCC tumors that are less than 3 cm in size is approximately 10% within 1 year after listing, while larger tumors have an approximately 60% chance of progressing beyond Milan criteria within a year of listing [28]. The concept of downstaging tumors presenting beyond Milan criteria has gained acceptance as a criterion of selection for liver transplantation. Patients responding to local treatment whose tumors do not progress for 3–6 months after treatment appear to be associated with favorable long-term results after transplantation [29].

Diagnostic accuracy for HCC, however, confounds optimal timing of liver transplantation for these candidates. Screening high-risk populations for HCC and subsequent confirmatory computed tomography (CT) or magnetic resonance imaging (MRI) scans can achieve sensitivity and specificity of 70–80% [30–32]. The accuracy of imaging tests is further reduced for lesions less than 2 cm in size (Table 42.2). Liver biopsy has been advocated to overcome some of these problems [33], but risks of bleeding, needle tract seeding by tumor, and sampling errors have limited its widespread use [34]. Liver transplantation for patients with false-positive diagnoses of HCC who otherwise do not have severe underlying liver disease, exposes these patients to increased surgical and immunosuppressive risks relative to medical management and diverts scarce organs away from those who could benefit more (see discussion below regarding timing of liver transplantation in the context of liver allocation).

The available evidence suggests that patients with documented HCC within the Milan criteria who otherwise are acceptable liver transplant candidates should be selected for transplantation. Diagnostic inaccuracy compels caregivers to confirm the diagnosis with complementary modalities [35]. In the future, improved genomic or proteomic testing may be widely available and may provide much more accurate diagnostic [36] as well as prognostic information to optimize the selection of patients for surgical resection or transplantation [37].

Pulmonary syndromes

Some patients with chronic liver disease develop pulmonary symptoms that impair their HRQOL and increase their risk for surgical intervention [38]. These patients may or may not have severe intrinsic liver disease [39] and may not have advanced CTP or MELD scores [40]. Hepatopulmonary syndrome (HPS) defines a constellation of symptoms including dyspnea, hypoxia, reduced diffusion capacity, and increased pulmonary arteriovenous shunting in the presence of chronic liver disease. Recent reports have better characterized patients at risk for death on the waiting list who would also have significant benefit if they receive liver transplantation in a timely fashion [41]. These data along with others have led to changes in the Organ Procurement and Transplantation Network (OPTN) policy that assigns increased priority to patients with HPS and have helped to define mortality risk and more precisely define the disease. Results for HPS patients selected for transplantation have been acceptable, with a majority of patients experiencing improvement or resolution of their pulmonary condition [42]. For these reasons, patients with signs and symptoms of HPS who do not have severe pulmonary hypertension should be considered for transplantation before their

Table 42.2 Comparison of radiologic sensitivity for diagnosing HCC in candidates for liver transplantation.

pulmonary function deteriorates to a point where anesthetic and surgical risks become prohibitive.

Individuals with cirrhosis also can present with pulmonary hypertension or so-called portopulmonary hypertension (PPH). In some cases these patients are asymptomatic, and their increased pulmonary resistance is discovered only at the time of invasive monitoring for the transplant procedure. Patients with PPH have an increased mortality risk above that expected from their underlying liver disease, and increased perioperative cardiovascular mortality has been reported for patients with elevated pulmonary artery pressures who undergo liver transplantation [43]. Nonetheless, many of these cases can be managed effectively with medical therapy [44] and outcomes for selected candidates, though sparsely reported, have been reasonable [45]. These patients have to be carefully selected with multidisciplinary evaluation by transplant hepatology, pulmonology, anesthesiology, and surgical specialists. Patients with elevated pulmonary artery pressures who respond to pulmonary vasodilator treatment have better results after liver transplantation than those who do not, making a trial of medical management a reasonable diagnostic and therapeutic choice prior to selection for transplantation [46,47]. At this time, the available literature suggests that patients with moderate PPH or those who respond to vasodilator treatment should be selected for liver transplantation since their outcomes are acceptable and transplantation may improve their PPH afterward [48].

Metabolic liver diseases

Individuals with metabolic liver disease may also have legitimate indications for liver transplantation but may not have significant synthetic liver failure. Diseases such as Wilson disease, porphyria-associated liver disease, hemachromatosis, cystic fibrosis, and α_1-antitrypsin disease generally cause cirrhosis, portal hypertension, and hepatic synthetic failure. Consequently, mortality risk and existing measures of HRQOL should function well for these patients because they can be selected for transplantation using a mortality risk-based need for transplantation defined by their intrinsic liver disease. However, patients with conditions such as familial amyloid polyneuropathy (FAP), hereditary oxalosis, and inborn errors of hepatic metabolism – such as urea cycle defects, Crigler–Najjar syndrome, tyrosinemia, and other rare enzymatic diseases – may not develop hepatic fibrosis, portal hypertensive symptoms, or deterioration in hepatic synthetic function as is normally captured in measurements of bilirubin, coagulation factors, albumin synthesis, or assessment of portal hypertensive signs and symptoms. Nonetheless, particularly for metabolic defects that are intrinsic to the liver, liver transplantation has offered excellent short- and long-term results for properly selected individuals. The prime factor in selecting these patients for transplantation is whether the effects of the disease will be reversed by liver transplantation regardless of the anatomic location of the metabolic defect.

In adults, the best example of such a condition is FAP, where the enzymatic defect occurs in an otherwise normal liver but causes severe systemic problems due to deposition of a mutant transthyretin (TTR) protein. Deposition of these fibrils in neurologic, cardiac, gastrointestinal, and urinary tissues results in progressive loss of function, and an untreated median survival of 9–13 years [49]. Liver transplantation restores normal TTR synthesis with the disappearance of the mutant protein from the blood of affected recipients and a slowing or partial resolution of symptoms in successful cases [50,51]. Thus, the extent of secondary manifestations of FAP at the time of presentation, especially myocardial dysfunction and progressive neuropathy, limits successful recovery after liver transplantation. Optimal selection of liver transplantation candidates with FAP requires early identification and assessment of the severity of end-organ involvement so that the candidate has sufficient cardiopulmonary reserve to survive the surgery and before these complications become irreversible. In some cases, the end-organ disease does not improve after restoring normal TTR synthesis with transplantation.

Children with primary hyperoxaluria type 1 (PH-1) develop severe renal calculi and resultant renal failure but the metabolic defect resides in the alanine glycoxalate aminotransferase gene that is exclusively expressed in hepatic peroxisomes. Thus liver transplantation cures the enzyme defect because the deficient genes are replaced with the newly transplanted liver's enzymes, although established renal damage does not resolve after liver transplantation. Thus, most PH-1 patients are selected for liver transplantation after conservative measures have failed and renal disease has progressed. Consequently, many PH-1 patients are treated with combined liver–kidney transplants [52]. Preemptive liver transplant, performed before renal complications have progressed, has been advocated for some PH-1 cases [53] but the morbidity and mortality risks incurred by liver transplantation and immunosuppression must be considered carefully for these minimally symptomatic patients with relatively preserved renal function who may enjoy a good HRQOL and survival with nonoperative management for many years [54].

Other examples of diseases intrinsic to the liver are the urea cycle disorders [55], other hyperammoniemic syndromes [56,57], maple syrup urine disease [58], and hereditary tyrosinemia type 1 [59] where defects cause extremely elevated ammonia levels, neurologic disease and coma, all of which can be reversed with liver transplantation if recognized early. In some cases, the

neurologic consequences of these diseases progress to a point where they cannot be reversed by liver transplantation, making early recognition the most critical aspect in selection of patients with these conditions for liver transplantation.

Pediatric considerations

As alluded to above, selecting children for liver transplantation is complicated by the fact that growth retardation, delayed development, and neurologic impairment are all deleterious sequelae of many of the liver diseases and metabolic disorders presenting in childhood. There is evidence that liver transplantation can help reverse some of the growth retardation [60,61] and developmental delay [62] but may not completely do so [63–65]. Most children do not return to the same level of functioning as the general, unaffected, population [66]. For these reasons, pediatricians have emphasized the need to select children at a stage early enough in their disease so that liver transplantation will provide a reasonable chance for some catch-up growth and development [66]. However, it clear that striving to achieve these desirable outcomes must be weighed against the mortality risks of the surgery and immunosuppression, as children who do not survive the transplant procedure cannot possibly achieve catch-up growth, accelerate their mental and physical development, or improve their HRQOL.

Mortality risk factors for children with liver disease differ from mortality risk variables in adults. The pediatric end-stage liver disease (PELD) score (see Box 42.1) utilizes bilirubin, international normalized ratio (INR), albumin, age, and growth failure factors to predict 3-month mortality in patients less than 19 years of age, with reasonable accuracy [67]. Other prognostic scores such as the Wilson disease index employ white blood cell count and serum aspartate aminotransferase (AST) levels in addition to albumin, bilirubin, and INR levels [68]. Since children often present with metabolic diseases for which liver transplantation can be beneficial but without intrinsic liver synthetic failure, selection of these candidates requires early diagnosis and identification of extrahepatic manifestations before they become irreversible.

Acute liver failure

Acute liver failure, also known as fulminant hepatic failure, remains a vexing and lethal clinical problem for pediatric and adult liver specialists, although there is evidence that the incidence is decreasing. The diverse etiologies and difficulty in predicting which patients will recover spontaneously from those who will die without timely liver transplantation contribute to the complexity of selecting these patients for transplantation. Liver transplantation remains the best option for long-term recovery, but predicting who will recover without liver transplantation and who will not remains the critical issue for clinicians caring for these patients. Several prognostic scores have been developed to assist decision-making in this regard. The King's College group [69] and a French group [70] each published models for the prediction of death from acute liver failure (Box 42.2). Both of these models have excellent positive predictive value for determining which patients will die from acute liver failure but, in subsequent studies, both models have been shown to have relatively low negative predictive values [71–73]. While it may be desirable to err on the side of transplantation when the consequences of failure to transplant a patient destined to die of liver failure are so extreme, use of these models can result in inappropriate utilization of donor organs for patients who would otherwise recover without engraftment. More recently, in a study where patients with acetaminophen toxicity were excluded, the MELD score was shown to have superior positive and negative predictive value and a higher concordance for predicting which patients would die and which would recover with acute liver failure [74]. These results have been further supported by a recent study of the US liver transplant database in which the MELD score for patients with nonacetaminophen-induced acute liver failure was highly predictive of mortality risk [75]. Prognostic indicators for early mortality in patients with acetaminophen toxicity such as acetaminophen plasma half-life levels [76], coagulation factor levels [77], Gc protein levels [78], APACHE II score [79], phosphate levels [80], or addition of serum lactate [81] to the King's College models have been reported. However, a recent meta-analysis found that these prognostic models have limited sensitivity and specificity, making them of questionable usefulness for the selection of patients with acetaminophen-induced liver failure for transplantation [82]. Other prognostic scores for specific causes of acute

Box 42.2 King's College and Clichy criteria for probability of death from acute liver failure.

King's College criteria

- INR >6.5

Or any three of the following:

- Age <10 or >40 years
- Etiology of drug toxicity or viral hepatitis
- Duration of jaundice before onset of encephalopathy >7 days
- INR >3.5
- Bilirubin >17.5 mg/dL

Clichy criteria

- Portosystemic encephalopathy
- Factor V <20% for age <30 years or <30% for age >30 years

liver failure have been developed that may have better predictive value for those disease etiologies [83] and several new biomarkers have been identified as potentially useful in preliminary studies [84].

Accurate prognostic information is essential for the selection of patients with acute liver failure for transplantation. The King's College criteria, Clichy criteria, MELD score, and disease-specific scores may be helpful tools for patients with nonacetaminophen-induced fulminant failure but their low negative predictive value should be kept in mind. The selection of patients with acetaminophen-induced liver failure remains more problematic, and careful clinical observation for encephalopathy and trends in hepatic synthetic function remain indispensable in the selection of these and all patients with acute liver failure.

Timing of liver transplantation

Living donor liver transplantation

The advent of living donor liver transplantation (LDLT) in the late 1980s for children [85] and early 1990s for adults [86] introduced the possibility of electively timing liver transplantation. With this innovation, it became possible for those patients with liver disease treatable with liver transplantation who are fortunate enough to have a suitable and willing donor, to receive their transplant at a point where the risks of the surgery are outweighed by the risks of not doing the transplant. This was the main justification for the application of LDLT to children [87] since pediatric deceased donor organs are even more scarce than adult organs and, as discussed previously, the timing of transplantation for children may not always be best estimated by mortality risk derived from the intrinsic liver disease. Patients selected for LDLT have included children with most indications for liver transplantation including acute liver failure, and adults with HCC [88,89] and other conditions that do not consistently receive enough priority on the waiting list. In general, LDLT has been reserved for patients with less severe liver disease and estimates of mortality risk can be helpful in selecting candidates who will derive benefit from the transplant [90]. A report from Japan used the MELD score to identify candidates who could receive the smaller left lobe graft and still achieve an acceptable outcome [91]. A concern for more rapid recurrence of HCV in regenerating liver segments transplanted from living donors limited the early use of living donors for patients with HCV. More recent data suggest that HCV recurrence is no more frequent or aggressive in recipients of living donor grafts when compared with recipients of deceased donor livers [92,93].

Although there are limited reports of LDLT being performed for acute liver failure in adults [94], most clinicians reserve the living donor procedure for patients with moderately severe chronic liver disease. There is then sufficient time for a complete donor evaluation and informed consent without the added coercion of an acute, potentially immediately fatal liver disease in the recipient candidate. Conversely, LDLT for pediatric candidates, where an adult donor donates a smaller portion of his or her liver and thus faces a lower operative risk, seems applicable for nearly all indications for liver transplantation in children.

Paramount to the selection of recipient candidates for LDLT is a thorough assessment of the donor's risks for donation, estimation of the potential of success for the recipient, and fully informed consent for both donor and recipient. There are several recent reviews compiling these risks, which should be used to inform potential living liver donors [95].

Timing of liver transplantation in the context of organ allocation

In an ideal world all patients would receive the most effective treatment at the time when they are most likely to gain the most benefit and suffer the least harm from that intervention. However, since liver transplantation is severely limited by the availability of the therapeutic substrate, there must be some method for selection from all those who could potentially benefit, the few individuals who will receive the treatment. Thus, the timing of liver transplantation for individual patients will be determined in large part by this allocation selection process regardless of the presence of the beneficial potential a transplant may pose for any of the waiting patients. Living donor transplantation introduces some flexibility for the timing of these cases, but since only about 3% of liver transplant procedures were from living donors in 2009 [96], the timing of the vast majority of liver transplants procedures depends on the allocation system. Timing for these patients, then, is not so much determined by what is most appropriate for that individual to maximize success and minimize complications and/or failures, but is much more determined by what is the most equitable for all users of the organ donor pool. Equitability is difficult to define, but prioritization of measures of equitable outcomes is possible. Since deceased individuals cannot have a quality of life or growth or development or other improvement in their burden of disease, it is difficult to accept any form of liver allocation where nonmortality end-points supersede the risk of death. Consequently, prioritizing an individual with a very poor quality of life or delayed growth and development before someone with a higher mortality risk is difficult to justify. However, risk of disease progression as is conceptualized in liver allocation for HCC patients in the United States can also serve as an equitable prioritization tool.

Thus, timing of deceased donor liver transplantation will depend mostly on which individual from among all the waiting candidates has the highest mortality risk (or risk of disease progression) if he or she continues to wait even though there may be many other individuals on the list for whom transplantation at that point time would also be beneficial.

CHAPTER 43

Immunosuppression: The Global Picture

Russell H. Wiesner

Transplant Center, Mayo Clinic, Rochester, MN, USA

Key concepts

- Advances in immunosuppression in recent years have led to impressive patient and graft survival rates and reduced rejection rates in liver transplantation.
- The administration of immunosuppression remains an art in that there are few markers of overall immunosuppression, tolerance, or measurements of alloreactivity.
- There is a poor correlation between rejection and degree of abnormalities of liver function tests and immunosuppressive levels.
- Graft loss related to rejection occurs in less than 7% of patients undergoing liver transplantation.
- The major challenge with immunosuppression has been long-term complications, particularly renal dysfunction, hypertension, hyperlipidemia, diabetes mellitus, and de novo cancers.
- Data suggest that liver transplant patients are overimmunosuppressed and that reducing the side effects of immunosuppression today is a major goal.
- The goals of immunosuppression are to control alloreactivity rather than eliminating it and thus minimize toxicity using larger number of agents with smaller doses.
- Individualization of immunosuppressive therapy, when possible, should be utilized for patients undergoing transplant for alcoholic liver disease, hepatitis C, autoimmune liver disease, and hepatocellular cancer.
- The ultimate goal is the development of therapeutic strategies to promote tolerance or a state in which the allograft is specifically accepted without the need for chronic immunosuppression.

New developments in immunosuppression, along with advances in surgical and anesthetic techniques, have led to continued improvements in patient and graft survival following liver transplantation. Recent data indicate that patient survival at 1 and 5 years following liver transplantation approaches 90% and 75%, respectively [1]. Today, over 40,000 patients in the United States are living with a hepatic allograft, and survival of greater than 30 years following the procedure has been reported [2]. Thus liver transplant has become overwhelmingly the best therapeutic option for patients suffering from end-stage liver disease.

Historical perspective

After multiple unsuccessful attempts, the first successful liver transplantation was performed by Dr Thomas Starzl in 1967 on an 18-month-old child with hepatoblastoma [2]. Immunosuppression was achieved using corticosteroids, azathioprine, and antilymphocyte globulin, which enabled the child to survive over 1 year without the development of major hepatic allograft dysfunction related to rejection. However, it was not until 1979 with the discovery of cyclosporine and its potent immunosuppressive properties that markedly diminished the incidence and severity of hepatic allograft rejection. Liver transplantation now truly became a realistic therapeutic option. Using cyclosporine-based immunosuppression Dr Starzl was able to obtain a 1-year patient survival of over 60%, which was a major achievement at the time [3]. Indeed, cyclosporine-based immunosuppression rapidly became the standard of care for all solid organ transplants, and paved the way for the recommendation by the National Institutes of Health (NIH) in 1983 to make liver transplantation an acceptable and financially reimbursable therapeutic option for patients with end-stage liver disease [4].

The next advancement in immunosuppressive therapy came nearly a decade later in the discovery and development of a drug named FK506. This drug also had potent immunosuppressive properties and was demonstrated in a controlled clinical trial to be associated with a lower incidence of acute rejection and a decreased incidence of

steroid resistant rejection [5,6]. Over the ensuing years, FK506 (also known as tacrolimus) became the calcineurin inhibitor of choice and is presently being used in over 85% of patients undergoing liver transplantation in the United States [7].

Immunosuppression was further refined by the development and introduction of other immunosuppressive agents that could be used in combination with corticosteroids and calcineurin inhibitors. Some of these agents included mycophenolate acid mofetil, rapamycin, and a number of cytokine antibodies antagonistic to specific targets in the antigen recognition pathway such as OKT3 and antithymocyte globulin [8]. As immunosuppressive therapy further evolved, it became clear that combination therapy with lower doses of each agent, which were able to control rejection, and reduce and prevent the development of immunosuppression related side effects, became the standard of care. Even today, the minimization of immunosuppressive therapy to control alloreactivity and to lower the severity of related side effects remains a persistent challenge.

Immunologic mechanisms of rejection response (three-signal pathway of lymphocyte activation)

Hepatic allograft rejection relates to the recipient immunologic response precipitated by donor recipient mismatches of a major histocompatibility complex (MHC), which leads to what is referred to as an alloimmune response. In the hepatic allograft and its surrounding tissue, dendritic cells or antigen-presenting cells of donor and recipient origin become activated by their interaction with foreign antigens and subsequently migrate to the T-cell areas of secondary lymphoid organs [9].

There, the antigen-bearing cells engage alloantigen, reactive naïve T cells and memory cells and trigger lymphocyte activation transduced through the T-cell receptor (CD3 complex) which is often referred to as *signal 1* [10,11]. Dendritic cells provide co-stimulation or *signal 2* when CD80 and CD86 markers on the surface of dendritic cells engage CD28 receptors on T lymphocytes [12, 13]. Signals 1 and 2 activate signal transduction pathways including: (i) the calcium–calceurine pathway; and (ii) the Ras–mitogen-activated protein kinase (MAPK) pathway and the nuclear factor κB (NF-κB) pathway. These pathways activate transcription factors that trigger the expression of many new molecules including interleukin 2 (IL2) and other cytokines that are able to activate the target of rapamycin pathway providing *signal 3* or the trigger for cell proliferation [12]. Lymphocyte proliferation also requires nucleotide synthesis. This proliferation of T cells leads to the differentiation and production of large numbers of effecter T and B cells. Effecter cells that emerge from lymphoid organs infiltrate the hepatic allograft and orchestrate an inflammatory response [13]. In T-lymphocyte-mediated rejection, the graft is infiltrated by effector T cells, activated macrophages, secretory B cells, and plasma cells, which leads ultimately to organ damage (Fig. 43.1). T-cell-mediated damage results from the secretion of numerous factors such as tumor necrosis factor α (TNF-α) and TNF-β, fas ligand expression, as well as the secretion of cytotoxins such as perforin and granzyme F. The diagnostic pathology of lymphocyte-mediated rejection is mononuclear cells invading the liver that target small arteries, veins, and bile duct epithelium [13–15].

In addition, antibodies against donor antigens are also produced through these mechanisms. However, antibody-mediated rejection in liver transplantation appears to be a rare phenomenon and rarely thought to be of clinical significance.

Classification of immunosuppressive drugs

Immunosuppressive drugs can be broadly classified into two categories: (i) pharmacologic or small molecule drugs (Table 43.1); and (ii) biologic agents consisting of polyclonal and monoclonal antilymphocyte antibodies (Table 43.2). The latter can be further classified as lymphocyte depleting and nonlymphocyte depleting.

Most small molecule immunosuppressive agents are derived from microbial products and target proteins that are important in the alloimmune response (Fig. 43.2) These agents include corticosteroids, cyclosporine, tacrolimus, mycophenolate acid, azathioprine, and rapamycin (Table 43.1).

Biologic immunosuppressive drugs include lymphocyte-depleting immunosuppressive agents, which are antibodies that destroy T cells, B cells, or both (Fig. 43.2). T-cell depletion is often accompanied by the release of cytokines, which produce severe systemic symptoms, especially after the first dose (Table 43.2). The use of depleting antibodies reduces the risk of early rejection but increases the risk of infection with cytomegalovirus (CMV), fungi, and the development of post-transplantation lymphoproliferative disease. Recovery from immune-depleting lymphocyte antibodies takes months to years and may never be complete in older individuals. The depletion of antibody-producing cells is better tolerated than T-cell depletion, because it is not usually accompanied by cytokine release, and immunoglobulin levels are usually maintained. However, depletion of antibody-producing cells is incomplete

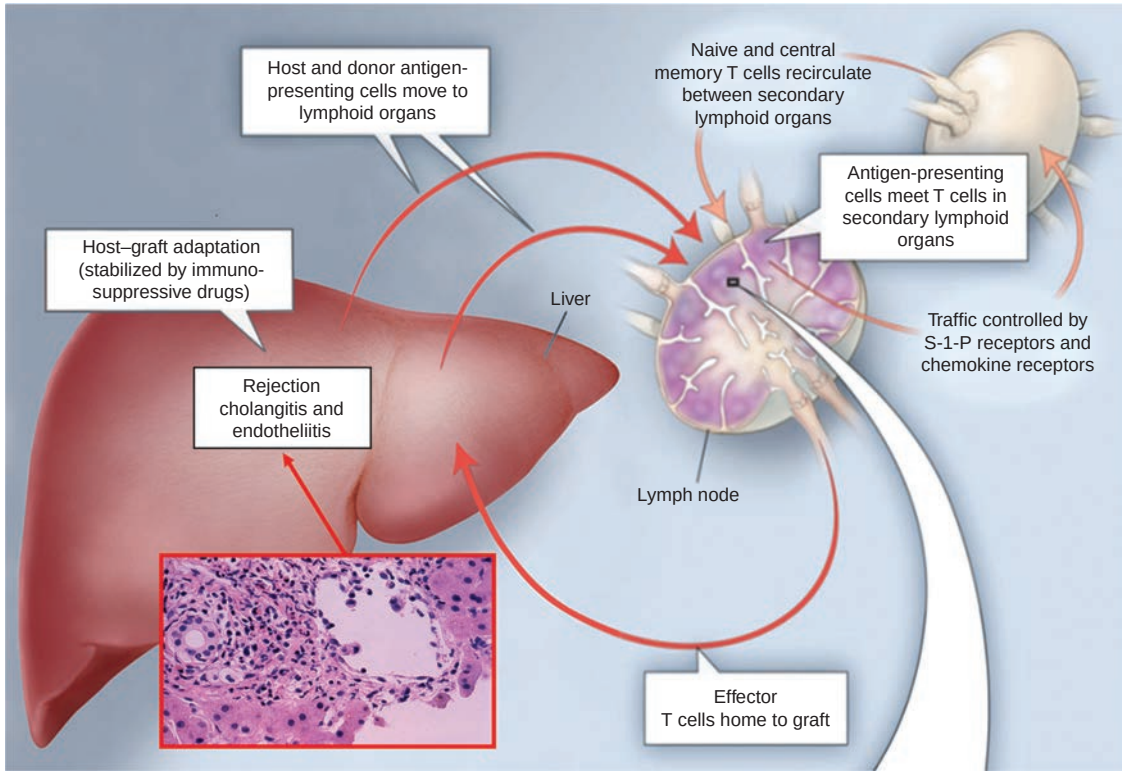

Figure 43.1 Antigen-presenting cells and the activation of T cells leading to hepatic allograft rejection.

because many plasma cells are resistant to available antibodies that target B cells such as anti-CD20 antibody (rituximab).

Nonlymphocyte-depleting immunosuppressive agents are monoclonal antibodies or fusion proteins that reduce responsiveness without compromising lymphocyte populations (Table 43.2). These drugs have low nonimmune toxicity because they target proteins that are expressed only on immune cells and trigger little release of cytokines. They typically target mechanisms such as IL2 receptors, which explains their limited efficacy and the absence of immune deficiency complications. They are generally used in combination with corticosteroids, calcineurin inhibitors, and antimetabolites.

Table 43.1 Classification of pharmacologic (small molecule) immunosuppressive agents.

Agent	Effects
Corticosteroids	Inhibits cytokine transcription by antigen-presenting cell
Calcineurin inhibitors:	Inhibits signal 2 transduction
Cyclosporine	
Tacrolimus	
Azathioprine	Inhibits purine and DNA synthesis Prevents T-cell proliferation
Mycophenolic acid:	Inhibits purine and DNA synthesis
Cellcept	Prevents T-cell proliferation
Myfortic	
Rapamycin (mTOR inhibitors):	Inhibits signal 3 transduction
Sirolimus	Prevents T-cell proliferation
Everolimus	

mTOR, mammalian target of rapamycin.

Table 43.2 Classification of biologic immunosuppressive agents.

Agent	Effects
T-cell depleting agents	
Anti-CD3 (monoclonal): OKT3	Interferes with signal 1
Antithymocyte globulin: Horse and rabbit ATG, ALG	Interferes with signals 1, 2, and 3
Anti-CD52 monoclonal: Campath 1-H (alemtuzumab)	Depletion of thymocytes, T cells, B cells, and monocytes
Non-T-cell depleting	
Anti-IL2 receptor: Basiliximab Daclilumumab	Inhibits T-cell proliferation Inhibits signal 3
Belatacept	Inhibits signal 2
Daclizumab	Competes with CD28 for CD80/86 binding

Small molecule immunosuppressive agents

Corticosteroids

Corticosteroids were one of the earliest agents used for immunosuppression, first developed in the late 1940s and introduced into immunosuppressive regimens in the late 1950s [16]. They have been applied in a variety of ways in liver transplantation. These include: (i) as induction immunosuppression by way of bolus corticosteroid therapy at the time of organ implantation; (ii) as maintenance therapy to prevent rejection; and (iii) in the treatment of established acute cellular rejection. Although their chronic, long-term use is somewhat disputed in recent years, they continue to be widely used both in induction and during short-term maintenance therapy in liver transplant recipients.

The most common agents used in liver transplantation include prednisone, prednisolone, and methylprednisolone. These corticosteroid agents possess a

predominantly anti-inflammatory immunosuppressive potency with relatively low mineralocorticoid activity. Prednisone is rapidly absorbed from the gastrointestinal tract; however, it needs to be metabolized by the liver to prednisolone for biologic activity. Following absorption, corticosteroids are primarily metabolized into inactive compounds by the liver and excreted in the urine.

Corticosteroids exert their effects through their actions on a wide variety of white cells including lymphocytes, granulocytes, macrophages, and monocytes. Glucocorticoids circulate either in a free form or in association with cortisol-binding globulin in the blood. The free form of the steroid readily diffuses through the plasma membrane of lymphocytes and binds with high affinity to intracellular glucocorticoid receptors. This ligand–receptor complex, following activation, modulates transcription both positively and negatively, in the nucleus of specific genes and coding factors critical in the generation and maintenance of the immune and inflammatory responses. In addition to modulating transcription, glucocorticoids can also influence later cellular events including RNA translation and protein synthesis and secretion [17]. Leukocytes, through their mechanism of localization and activation, generate numerous products that play a key role in cellular rejection, and glucocorticoids therefore modulate this function. On lymphocytes, the major mechanism of action of corticosteroids seems to be a negative regulation of cytokine gene expression. Regulation of cytokine gene production occurs through the inhibitory action of glucocorticoid on gene transcription through the inhibition of activator protein 1 (AP-1) and NF-κB. Glucocorticoids also affect other cells such as macrophages, neutrophils, eosinophils, basophils, mast cells, and endothelial cells. Glucocorticoids antagonize macrophage differentiation and inhibit many of their functions that promote inflammation. Glucocorticoids inhibit neutrophil adhesions to endothelial cells, thereby decreasing their extravasation to the site of inflammation. This process may partly explain the neutrophilia that is seen with glucocorticoid therapy. Additionally, glucocorticoids downregulate endothelial cell function including expression of class II MHC antigen, expression of adhesion molecule 1 (ELAM-1), and the intracellular cell adhesion molecule 1 (ICAM-1) formation of IL1 and arachidonic acid metabolites, thereby inhibiting the expression of cyclooxygenase type 2.

Corticosteroids are administered at various stages of liver transplantation. In general, high-dose methylprednisolone is usually administered intravenously around the time the liver is implanted and is continued for several days postoperatively. Induction doses range from 300 to 1,000 mg intravenously per day. Initially thought to be essential, trials have now demonstrated that corticosteroid-free regimens do not necessarily lead to increased rejection. These trials have used other induction agents such as antithymocyte globulin or IL2 receptor antibodies [18–20].

For maintenance therapy, steroids are rapidly tapered from the time of surgery to a daily maintenance dose of 5–10 mg per day. Many centers now taper and stop prednisone after 3–6 months. Indeed 50% of liver recipients are off corticosteroids 1 year after transplantation [7]. Prednisone cessation does not seem to adversely affect the hepatic graft in most instances and may be beneficial in ameliorating some of the side effects of long-term prednisone use such as osteoporosis, diabetes, weight gain, hypertension, cataracts, hyperuricemia, and cosmetic problems.

In patients who have undergone transplantation for autoimmune liver diseases such as primary biliary cirrhosis, primary sclerosing cholangitis, or autoimmune hepatitis, the continuation of low-dose prednisone indefinitely may be prudent [21]. In addition, patients who have ulcerative colitis have been reported to have a major flare following discontinuation of prednisone.

Corticosteroids have been used in the context of treating acute cellular rejection [22]. In this context, intravenous methylprednisolone is given in a dose of 1,000 mg on alternate days for a total of three doses. Some centers use what is called a recycle, which involves giving high oral doses of prednisone (i.e., 60 mg) and tapering down to 10 mg over a 7-day period. Excellent responses to these regimens in patients with acute rejection have been reported in that 75–80% of patients have histologic resolution following high-dose IV bolus corticosteroid therapy [23].

Corticosteroid therapy is not without side effects. Short-term corticosteroid use such as IV boluses to treat acute cellular rejection may cause transient hyperglycemia, and infections can be unmasked or exacerbated. In patients with hepatitis C, the use of bolus high-dose IV corticosteroids to treat acute rejection has been associated with high hepatitis C RNA levels and early and more severe recurrence of hepatitis C [24,25]. Long-term corticosteroid therapy is associated with a number of side effects, some of which may be reversed by steroid withdrawal (Box 43.1). Cosmetic side effects such as acne and hirsutism may adversely affect compliance, especially in the younger population undergoing transplantation.

Azathioprine

Azathioprine, which is derived from 6-mercaptopurine (6-MP), was the first immunosuppressive agent to achieve widespread use in organ transplantation. The developers of azathioprine, Gertrude Elion and George Hitchings, were acknowledged by a share of the 1988 Nobel Prize. Azathioprine is thought to act by releasing 6-MP, which interferes with DNA synthesis. Azathioprine is

absorbed readily from the gastrointestinal tract, and peak plasma concentrations are achieved 1–3 hours after oral administration. Azathioprine is rapidly cleared from the circulation, but approximately 30% is bound to serum proteins. The half-life of azathioprine is approximately 3 hours with normal kidney function and up to 50 hours in patients with anuria. The active metabolite acts as a purine analog, which is incorporated into cellular DNA and inhibits purine nucleotide synthesis and metabolism. The resultant alteration in RNA synthesis and function prevents mitosis and proliferation. 6-MP undergoes two major inactivation routes. The main metabolite route is thiomethylation, which is catalyzed by the enzyme thiopurine *S*-methyltransferase (TPMT) to form the inactive metabolite methyl-6-MP. TPMT activity is controlled by a genetic polymorphism. For Caucasians and African-Americans, approximately 10% of the populations inherit one nonfunctional TPMT allele (heterozygous) conferring intermediate TPMT activity. In addition, 0.3% of the population inherit two TPMT nonfunctional alleles (homozygous) for low or absent TPMT activity. Patients with intermediate TPMT activity may be at increased risk of myelotoxicity if receiving conventional doses of azathioprine. Patients with low or absent TPMT activity are at increased risk of developing severe, life-threatening myelotoxicity if receiving conventional doses of azathioprine. TPMT genotyping or phenotyping can help identify patients who are at increased risk for developing azathioprine toxicity and is recommended particularly in the transplant population. One note of caution: accurate phenotyping may give unreliable results in patients who have received recent blood transfusions.

Azathioprine was first used in combination with corticosteroids for renal transplantation and was found to be highly efficacious. It is currently used in combination with a calcineurin inhibitor and corticosteroids. Daily doses vary between 1 and 2 mg/kg and are generally used in combination therapy. More recently, azathioprine has been replaced by mycophenolic acid in a large number of liver transplant recipients, as reported by the United Network for Organ Sharing (UNOS) registry from their analysis of the UNOS database [7]. Use of azathioprine at the time of discharge from the hospital is noted in only 1% of patients compared with mycophenolic acid, which is used in 65% of patients undergoing liver transplant [7].

Azathioprine is associated with well-established side effects, which include myelosuppression, reversible hepatotoxicity, alopecia, and gastrointestinal side effects such as nausea, dyspepsia, and acute pancreatitis. Other short-term side effects include the development of fever, skin rash, arthralgias, myalgias, and acute hypersensitivity reactions. During long-term therapy, an increased incidence of malignancy of the skin such as squamous cell carcinoma and non-Hodgkin's lymphoma has been reported. Xanthine oxidase, a major enzyme in the metabolism of azathioprine metabolites, is blocked by allopurinol and, hence, when used concurrently with allopurinol, the dose of azathioprine must be decreased by 25–30%. Other drugs that interact with azathioprine and worsen its bone marrow suppression include methotrexate and angiotensin-converting enzyme inhibitors.

Cyclosporine

Cyclosporine is a highly aliphatic, cyclic, undecapeptide molecule. It was originally isolated from the soil fungus of *Cylindrocarpon lucidum*. Since its discovery, cyclosporine has remained the cornerstone of immunosuppression, not only for liver transplantation but also for kidney, heart, and other solid organ transplantations. Cyclosporine came into widespread clinical use in the early 1980s, and in liver transplantation Starzl et al. reported the first use of cyclosporine and prednisone in 1981, achieving an 83% patient survival after 8–14.5 months of follow-up [3].

Cyclosporine enters cells and lymphocytes through diffusion and at high concentrations by active transport through the low-density lipoprotein cholesterol receptor. In the cell, cyclosporine binds to a number of carrier proteins, including cyclophilin, which are important for protein folding. The cyclosporine–cyclophilin complex binds to calcium-activated calcineurin, a serine/threonine phosphatase important in the lymphocyte activation cascade, preventing the dephosphorylation of the transcription factor NFAT (nuclear factor of activated T cells) [26,27]. This prevents NFAT from engaging to specific DNA-binding sites in the promoter region of several T-cell growth factors and the synthesis cytokines such as IL2, interferon-γ, TNF-α, and co-stimulation molecules such as CD40. This lack of engagement downregulates the expression of these various cytokines essential for the alloimmune response. Therefore, cyclosporine enables the activated T cells to potentially return to

their quiescent state inhibiting early antigen recognition, reducing clonal expansion, and inhibiting the synthesis of multiple cytokines necessary for the alloimmune response. Cyclosporine is not cytotoxic and does not inhibit myeloid or erythroid cell lines.

An earlier formulation of cyclosporine (Sandimmune®) was notable for very low absorption and bioavailability. However, with the recent introduction of a microemulsion nonaqueous form (Neoral®), absorption and bioavailability had become more predictable [28]. Cyclosporine in generic forms has become widely available, and in switching to generic forms of the drug, blood levels should be checked.

Cyclosporine is absorbed primarily in the proximal jejunum and achieves peak blood levels in 2–4 hours. It is widely distributed with the highest concentrations found in adipose, kidney, adrenal, pancreatic, and liver tissues. Cyclosporine is metabolized primarily through the liver, occurring through the cytochrome P450 system, and is excreted predominantly through the bile. Therefore, with liver failure, or in the case of split liver transplantation, the propensity to develop toxic cyclosporine concentrations should be recognized. Cyclosporine has an average half-life of approximately 27 hours (range, 10–40 hours) [28]. Various drugs that stimulate or inhibit the hepatic cytochrome P450 enzyme system may increase or decrease blood levels and can result in under-immunosuppression or toxicity (Box 43.2). These agents include calcium channel blockers, antifungal agents, macrolide antibiotics, prokinetic agents such as cisapride and metoclopramide, and a variety of miscellaneous agents such as amiodarone, cimetidine, omeprazole, and protease inhibitors. Of note, the new protease antihepatitis C drugs including telaprevir and boceprevir are potent cytochrome P450 inhibitors, and close monitoring of calcineurin inhibitors will be needed when these drugs become available and utilized in liver transplant patients.

Dosing of cyclosporine is generally regulated by examining a 12-hour trough level, as this is convenient for patients. However, it has been shown that trough concentrations do not actually reflect the area under the curve for cyclosporine exposures in all individuals. More recently, peak cyclosporine levels at 2 hours after oral administration is thought to be a better measure of the area under the curve and may be more useful in controlling toxicity and enhancing efficacy. However, this causes a tremendous inconvenience to the patient.

Target trough and peak levels vary with respect to time after liver transplantation. Within the immediate posttransplant period, 12-hour trough levels between 250 and 300 ng/mL are desirable. With time, however, 12-hour trough levels between 100 and 125 ng/mL are sufficient to prevent rejection and minimize toxicities.

Cyclosporine is commonly used in conjunction with prednisone and mycophenolic acid. With time, prednisone and other agents may be withdrawn leaving cyclosporine as the sole immunosuppressive agent.

The main side effects of cyclosporine include nephrotoxicity and hypertension (Box 43.3). With long-term follow-up of liver transplant recipients, it is becoming apparent that up to 20% of patients on calcineurin inhibitors will end up with chronic renal insufficiency requiring dialysis and/or a renal transplantation after 10 years of follow-up [29,30]. The nephrotoxicity of cyclosporine was thought to result from vasoconstrictor effects on renal blood vessels. Although early toxicity resulting in renal dysfunction may be reversible, late stages of cyclosporine nephrotoxicity resulting in

advanced tubular interstitial fibrosis and scarring may be irreversible.

Other significant side effects from cyclosporine include neurologic sequelae that occur in 10–20% of patients, usually in the earlier post-transplant course. These include paresthesias, tremors, hallucinations, confusions, migraine headaches, and rarely seizures. Cyclosporine may also cause hirsutism and gingival hyperplasia, which can lead to significant cosmetic problems in younger patients undergoing liver transplantation. Cyclosporine can also induce hyperlipidemia, post-transplantation diabetes mellitus, and rarely the hemolytic uremic syndrome.

Tacrolimus

Tacrolimus (FK506) is a metabolite of a fungus, *Streptomyces tsukubaensis*, and was isolated in 1986. Tacrolimus engages another immunophilin, FK506-binding protein 12, to create a complex that inhibits calcineurin with greater molar potency than does cyclosporine. Tacrolimus has been shown to be 10–100 times more powerful than cyclosporine. The first successful use was reported by Dr Starzl in 1989 as a rescue therapy for liver grafts failing conventional therapy with cyclosporine [31]. Subsequently, tacrolimus was evaluated for routine use in liver transplantation. Multicenter trials that compared the efficacy and safety of tacrolimus with cyclosporine showed that tacrolimus was associated with significantly less rejection, in particular corticosteroid-resistant rejection [32–36]. Similar results were also demonstrated in a European multicenter trial with an additional finding that there was a lower incidence of chronic rejection and infection. However, like cyclosporine, tacrolimus was associated with significant nephrotoxicity and neurotoxicity. Furthermore, tacrolimus compared with cyclosporine was associated with less hyperlipidemia, hypertension, and cosmetic problems such as hirsutism and gingival hyperplasia. On the other hand, it has a slightly higher incidence of post-transplant-induced diabetes mellitus [37].

Tacrolimus is absorbed in the duodenum and jejunum, and, unlike cyclosporine, does not require the presence of bile for absorption. The recommended initial dose is 0.1 mg/kg per 24 hours administrated in divided dose every 12 hours. Initial blood levels after liver transplantation are maintained between 10 and 15 ng/mL whole blood trough levels. With time, 12-hour trough levels may be lowered to between 5 and 10 ng/mL to reduce side effects, particularly nephrotoxicity. Although initially used in combination with other immunosuppressant agents, most commonly corticosteroids and mycophenolic acid, tacrolimus monotherapy in the later stages of liver transplant is more widely practiced. Today, tacrolimus is the primary immunosuppressive agent used in the United States, with over 85% of patients dismissed after liver transplant being on a tacrolimus-based immunosuppressive regimen [7]. Like cyclosporine, tacrolimus is metabolized by the cytochrome P450 enzyme system and is subject to blood variation when administered simultaneously with drugs known to stimulate or inhibit the cytochrome P450 enzyme system (Box 43.2). In patients with hepatitis C, the reduced incidence and severity of acute rejection episodes associated with tacrolimus appears to be associated with less severe recurrence of hepatitis C compared to cyclosporine-based immunosuppressive regimens [37].

Mycophenolic acid

Both mycophenolate mofetil (MMF) and mycophenolate sodium (MPS) undergo immediate first-past metabolism in the liver into the active compound mycophenolic acid. Mycophenolic acid was first discovered in 1893; however, the immunosuppressive properties were not recognized until the 1990s. Mycophenolic acid is a noncompetitive inhibitor of inosine 5′-monophosphate dehydrogenase (IMPDH), which is the rate-limiting enzyme in the de novo synthesis of guanine nucleotides. Inhibition of the IMPDH pathway results in selective blockade of lymphocyte proliferation. Mycophenolic acid is metabolized to mycophenolic acid glucuronide, which is excreted in bile and has an enterohepatic circulation [38,39]. It is excreted in the urine in humans and to a lesser extent in the bile. There may be larger variations of pharmacokinetics in liver transplant recipients related to fluctuations in serum albumin, unlike that seen in renal transplant recipients.

The major advantage of using mycophenolic acid is the lack of renal toxicity. In patients with preexisting renal disease [40] mycophenolic acid has been used in conjunction with low-dose calcineurin inhibitors as part of a renal-sparing protocol with promising results. The use of MMF in conjunction with corticosteroids and tacrolimus has been shown to be superior in preventing rejection and improving renal function as compared with tacrolimus and corticosteroid therapy alone [41]. Patients discharged home on immunosuppressive therapy that included MMF appear to have better long-term patient and graft survival. It is possible that the use of MMF may enable a lower dose of calcineurin inhibitor to be used in an attempt to preserve renal function. Therefore, MMF may be particularly useful in patients who may be at higher risk of rejection, such as younger patients undergoing liver transplant for fulminant liver failure and patients undergoing transplant for autoimmune liver diseases. MMF monotherapy after calcineurin inhibitor withdrawal has been associated with a high incidence of acute cellular rejection and steroid-resistant rejection

[42,43]. Therefore, the use of MMF alone may not be sufficient to prevent rejection in liver transplantation.

The usual dose is 1,000 mg administered orally twice daily. Dose reductions are made depending on toxicity. An enteric-coated preparation (Myfortic®) is available that allows delayed release of the active drug in the small intestine rather than the stomach. This may help alleviate some of the gastrointestinal side effects presently seen with MMF therapy.

Significant side effects of MMF are related to gastrointestinal disorders and bone marrow suppression. Indeed, reduction of dosage or discontinuation of MMF therapy is common in liver recipients. Diarrhea is the most common dose-limiting adverse effect, although abdominal pain, nausea, and vomiting can frequently occur. Studies have also shown an increased incidence of CMV, herpes simplex virus, *Candida* infections, and rarely progressive multifocal leukoencephalopathy with the use of mycophenolic acid. In pregnant patients, there is an increased risk of spontaneous abortions during the first trimester and serious congenital malformations have also been reported. Therefore, mycophenolic acid must be discontinued in liver transplant recipients who wish to bear children.

While we are able to measure mycophenolic acid levels, these assays are generally not employed in clinical practice in liver transplant recipients. In many instances, these side effects appear to be dose dependent. Side effects may require dose reduction or withdrawal in up to 50% of patients. Gastrointestinal side effects may be reduced by acid reduction using proton pump inhibitors. Bone marrow suppression usually responds to dose reduction, but in some instances it may require drug discontinuation or the use of granulocyte-stimulating factor.

Sirolimus

Sirolimus (rapamycin, Rapamune®) is a macrolide antibiotic isolated from the fungus *Streptomyces hygroscopicus*, first discovered in soil samples from Easter Island. It is structurally similar to the calcineurin inhibitor tacrolimus and has proved to have potent immunosuppressive properties.

Like calcineurin inhibitors cyclosporine and tacrolimus, rapamycin acts by binding to the immunophilin FKB12. However, this does not affect calcineurin activity, but instead the complex binds and inhibits the protein called mammalian target of rapamycin (mTOR). Inhibition of mTOR results in selective inhibition of synthesis of new ribosomal proteins that are essential for progression of the cells from the G1 to the S phase. In addition, rapamycin has also been associated with diminished fibroblastic activity [44,45]. While in vitro studies have suggested that sirolimus and tacrolimus might compete for FKBP12 protein and act as antagonists, studies have subsequently confirmed that sirolimus augments the immunosuppressive activity of tacrolimus.

Sirolimus is absorbed rapidly from the small intestine with mean peak blood concentrations occurring 1–2 hours after administration. Bioavailability is approximately 15% [46]. Time to maximum concentration can be reduced by the ingestion of a fatty meal or with the use of a liquid formulation. The drug is excreted in the feces (50%) with very little urinary excretion. The mean half-life is approximately 60 hours in patients with normal renal function. The long half-life has allowed once-daily administration. A loading dose of approximately three times the maintenance dose has been recommended at the initiation of therapy. Drug monitoring of trough levels is recommended. Clinical studies suggest that efficacy and toxicity are related to sirolimus concentrations, and there is high interpatient variability. Whole blood concentrations of the drug must be measured since 95% of the drug is sequestered in red blood cells. Drugs that induce or inhibit cytochrome P4503A enzymes have been shown to interact significantly with sirolimus.

Sirolimus was first reported for use in liver transplantation from the United Kingdom by Watson et al. [47]. McAllister et al. used sirolimus with low-dose tacrolimus and reported a very low incidence of acute rejection at 14% [48]. However, two international randomized controlled clinical trials combining rapamycin and cyclosporine with rapamycin with tacrolimus revealed some disturbing results [49]. In the rapamycin–cyclosporine combination group versus cyclosporine and prednisone group, rates of biopsy-confirmed rejection were lower in the sirolimus group (45.5% versus 59.6%) but there was no significant difference in patient survival. There was a significantly higher incidence of wound infections in the sirolimus group (16.2% versus 0%) and there was a higher incidence of hepatic artery/portal-venous thrombosis in the sirolimus group (12.8% versus 3.8%). In the rapamycin–tacrolimus combination group there was no difference in the incidence of rejection compared to the tacrolimus/prednisone group but there was a significantly higher incidence of graft loss (22.7% versus 8.9%; $P < 0.006$) and death (14.5% versus 5.4%; $P < 0.025$). Here again a higher incidence of hepatic artery thrombosis was found in the sirolimus group (5.4% versus 0.9%; $P < 0.06$) [50]. Both of these studies were terminated prematurely and led to a black box warning from the US Food and Drug Administration (FDA) stating that sirolimus in combination with tacrolimus and cyclosporine is associated with excess mortality and graft loss.

Other single center studies have not supported these findings [51,52]. Today, rapamycin is primarily used as an immunosuppressive agent for its renal-sparing effect in patients experiencing calcineurin nephrotoxicity.

However, recent studies have questioned the renal toxic-sparing effect of sirolimus in randomized controlled trials [53]. In addition, uncontrolled trials have suggested that rapamycin may have antineoplastic effects and may be effective in hepatocellular cancer [54–56]. While a number of studies have suggested an antineoplastic effect of rapamycin in hepatocellular carcinoma (HCC) patients, this finding has not been confirmed as yet in controlled trials [57].

Finally, rapamycin has been shown in some studies to have a positive effect on the recurrence of hepatitis C [58,59]. However, a recent analysis of the Scientific Registry of Transplant Recipients (SRTR) database shows that sirolimus use in hepatitis C patients is associated with a significantly increased risk of patient death following liver transplantation [60]. Other studies have shown that pretreatment with sirolimus attenuated the anti-hepatitis C virus (HCV) replication effect of interferon-α in the HCV replication model. It has also shown that ribavirin activates mTOR which in turn enhances the interferon signaling pathway. Rapamycin, on the other hand, is an inhibitor of mTOR. Thus, the true effect of rapamycin on hepatitis C recurrence needs further assessment.

Rapamycin has a number of side effects that currently restrict its usage in liver transplantation. Adverse effects of rapamycin include thrombocytopenia, leukopenia, anemia requiring blood transfusions, arthralgias, and pneumonitis. Rapamycin is also associated with a high incidence of hyperlipidemia with up to one third of patients requiring treatment for hyperlipidemia. Delayed wound healing and oral ulcers which are quite painful are also frequently seen and often limit continued use of this agent. In addition to the side effects noted above, there have been reports of an increased risk of nephrotoxicity when combining rapamycin with high doses of calcineurin inhibitors. Thus, the future role of sirolimus in the liver transplant recipient remains undefined, and further data with regard to its antineoplastic effect will be forthcoming [57].

Biologic immunosuppressive agents

Immunosuppression with antibody therapy in liver transplantation may consist of either polyclonal antibodies or monoclonal antibodies. Polyclonal antibodies include antithymocyte globulin and antilymphocyte globulin. Polyclonal preparations may be obtained by immunizing either a horse or rabbit with different immunogens, whereas monoclonal antibodies are produced in response to a single antigen. The advent of hybridoma technology to fuse two cell lines, one capable of specific antibody production and the other capable of permanent cell growth, was a key breakthrough in monoclonal antibody production.

Depleting antibodies

Polyclonal antithymocyte globulin is prepared by immunizing animals such as horses or rabbits with immunogens from different sources, followed by harvesting the immunoglobulin G (IgG) and absorbing out the toxic antibodies, i.e., those against platelets and erythrocytes. Antithymocyte globulin is produced by using human thymocytes as immunogens, whereas antilymphocyte globulin is produced using human lymphocytes. Polyclonal agents have been in use since the early 1960s. The initial agents, termed antilymphocyte serum, consist of unfractioned serum obtained from animals after immunization with human lymphocytes. Subsequently this preparation is purified, and the immunoglobin is concentrated since the immunosuppressive properties of the serum are contained in the immunoglobulin fraction. Various preparations of polyclonal antibodies are available throughout the world. In the United States, the commonly used polyclonal preparations are antithymocyte globulins derived either from the horse (Atgam®) or the rabbit (Thymoglublin®). The polyclonal antibodies exert their action through various mechanisms that include complement-mediated cell lysis, increased uptake of T cells by the reticuloendothelial system, and also by modulation of surface receptors of lymphocytes thus blocking their function. As an induction agent, polyclonal antithymocyte globulin is usually used for 3–10 days to produce "profound and durable" lymphopenia that can last often beyond 1 year. In addition to immunodeficiency complications, toxic effects of polyclonal antithymocyte globulin include thrombocytopenia, the cytokine release syndrome, and occasionally serum sickness or allergic reactions [61,62]. Concerns remain about an increase in infectious complications and an increase in the incidence of post-transplant lymphoproliferative disorders when these antibodies are utilized.

Monoclonal antibodies

Muromonab-CD3 (OKT3) is a mouse monoclonal antibody against the T-cell receptor (CD3), and has been used for 20 years for immunosuppressive induction and to treat rejection [62,63]. OKT3 binds to the T-cell receptor-associated CD3 complex and triggers a massive cytokine release syndrome before both depleting and functionally altering T cells. Administration of OKT3 results in rapid depletion and extravasation of most T cells from the blood stream and peripheral lymphoid organs such as lymph nodes and spleen. This depletion is secondary to both cell death and margination of the T lymphocytes into the vascular endothelial walls and redistribution to nonlymphoid organs such as the lung. More recently, OKT3 has

been used in liver transplant to treat steroid-resistant cellular rejection episodes [64].

OKT3 has been associated with a high incidence of adverse effects related to the cytokine release phenomena, and premedication with steroids, antihistamines, and analgesics is generally advised. This syndrome usually occurs within an hour of drug administration during the first two to three doses [61]. Additionally, during OKT3 administration to treat rejection, prophylaxis against infections such as with CMV, pneumocystis, and fungi is advised. The use of OKT3 has also been associated with early and severe recurrence of hepatitis C and has been associated with an increased incidence of lymphoproliferative disease in liver transplant recipients [65, 66]. The total lymphocyte counts and CD3 counts are usually monitored during therapy, and dose adjustment may be needed to ensure adequate suppression of the CD3 count. Humans can make neutralizing antibodies against OKT3 that terminate its effects and limit its use, thus the importance of following CD3 counts.

A second depleting monoclonal antibody, alemtuzumab or Campath®, is a humanized recombinant anti-CD52 monoclonal antibody. Campath produces profound depletion of circulating lymphoctyes that can last for months to up to a year. It has been approved for treating refractory B-cell chronic lymphocytic leukemia but has not been approved for immunosuppression in solid organ transplantation [67,68]. Side effects of alemtuzumab include first-dose reactions, profound neutropenia, anemia, and rarely pancytopenia and autoimmunity (i.e., hemolytic anemia, thrombocytopenia, and hyperthyroidism). The risk of immunodeficiency complications, i.e., infectious complications, is high, and severe recurrence of hepatitis C has been reported [69,70]. Currently, the use of alemtuzumab remains experimental in liver transplantation, and while initially it was thought to invoke tolerance, this theory has been not substantiated.

Nondepleting antibodies and fusion proteins

Interleukin 2 receptor antibodies (anti-CD25) daclizumab and basiliximab have been used in liver transplantation. The exact mechanism of action is still incompletely understood but likely results from their binding to the IL2 receptor on the surface of activated, but not resting, T cells. Because the expression of CD25 (IL2 receptor α-chain) requires T-cell activation, anti-CD25 antibody causes little depletion of T cells and is only moderately effective in preventing rejection. Anti-CD25 antibody has been used for induction immunosuppression, especially in patients with renal failure, to provide a window of opportunity for the kidneys to recover before commencing calcineurin inhibitors [70–72]. It has also been used for induction immunosuppression in corticosteroid-free protocols [73]. One of the two IL2 receptor antibodies, daclizumab, has been discontinued in the United States by the manufacturer. Its noted side effects are uncommon, but a high incidence of hepatic allograft rejection has been reported when these antibodies are utilized without the use of a calcineurin inhibitor. Two recent studies have questioned whether or not anti-CD25 antibody use has a renal-sparing effect [74,75].

Co-stimulation blockade

T-cell activation requires interaction of the T-cell receptor with an MHC molecule on an antigen-presenting cell and a second costimulatory signal (signal 2). One costimulatory signal is between the CD28 receptor on T cells and CD80 and CD86 on the antigen-presenting cell. Importantly, cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) is a natural homolog to CD28 that is transiently expressed on T cells and acts as a negative regulator by competing with CD28 for CD80/86 binding. As such, the immune response can be inhibited by stimulating CTLA-4 activity through therapeutic induction of soluble CTLA-4. In organ transplantation, the most well-developed soluble CTLA agent is belatacept, which is a soluble recombinant immunoglobulin fusion protein comprised of the extracellular CTLA-4 domain and the FC portion of IgG1. It is administered once a month by injection. Reports from early trials thus far have been reported in renal transplantation, and belatacept in combination with MMF, corticosteroids, and basiliximab has shown significant improvement in renal function when compared with calcineurin inhibitor use [76]. In liver transplantation, the initial assessment has been less promising with a significantly increased incidence of rejection being reported in the calcineurin-free belatacept arms as compared with the calcineurin inhibitor arms. Further studies in liver transplant will be forthcoming.

Goals of immunosuppression

Today, the administration of immunosuppression remains as much an art as a science. While we have made great strides in developing new immunosuppressive agents, the use of combination therapy remains to be refined. There are few markers of overall immunosuppression, tolerance, rejection, or degree of alloreactivity. In addition, there remains a poor correlation between rejection and degree of abnormality of liver function tests and immunosuppressive levels. Thus, today, liver biopsy remains the gold standard guide to diagnosing and treating rejection. However, in the future there remains hope of monitoring alloreactivity using transcriptional

profiling and developing diagnostic tests to assess overall immunosuppression and operational tolerance in liver transplant recipients [77].

Today we achieve excellent patient and graft survival, with an incidence of rejection of 35–40%. However, graft loss related to rejection occurs in less than 5% of patients. The main challenge is that patients continue to suffer from complications related to immunosuppression including metabolic complications such as diabetes mellitus, cardiovascular risk and coronary disease, an increase in de novo malignancies, a renal failure rate of 20% at 15 years, and severe recurrence of hepatitis C, frequently leading to graft failure and need for retransplantation. These findings all suggest liver transplant recipients are over-immunosuppressed.

The strategy for future immunosuppressive therapy appears to be changing. Today, the goal is to control alloreactivity using low-dose combination therapy that will prevent rejection yet minimize side effects. Tailoring immunosuppressive therapy in the individual transplant recipient is a concept that has evolved in recent times. Today, we are attempting to administer immunosuppression that best meets the needs of individual patients, i.e., delaying the introduction of calcineurin inhibitors to allow renal function to improve, corticosteroid avoidance for patients with osteoporosis or hepatitis C, and increased immunosuppression and continuance of corticosteroid therapies in young patients undergoing a liver transplant for acute liver failure or autoimmune liver disease where rejection rates are the highest. In addition, we know that alloreactivity is highest within the first few weeks following liver transplantation but subsides thereafter and, thus, the need for immunosuppression decreases with time (Fig. 43.3). Indeed, over 20% of patients can be completely withdrawn from immunosuppression without experiencing a detrimental effect [78,79]. Thus, the development of therapeutic strategies to promote tolerance or a state in which the allograft is specifically accepted without the need for chronic immunosuppression remains our ultimate goal [80,81].

With the advent of unlocking human DNA, new avenues have opened to true individualization based on drug metabolism. Pharmacogenetic typing offers the possibility of significant improvement in the individualization of immunosuppressive drug prescribing with reduced rates of rejection and, more importantly, in minimizing toxicity.

CHAPTER 44

The First Six Months Following Liver Transplantation

Rajender Reddy[1] *& Manuel Mendizabal*[2]

[1]Department of Hepatology, Hospital of the University of Pennsylvania, Philadelphia, PA, USA
[2]Unidad de Hígado y Trasplante Hepático, Hospital Universitario Austral, Pilar, Argentina

Key concepts

- Initial postoperative assessment of liver transplant recipients should focus on careful evaluation and management of hemodynamic stability. Assessment of renal and pulmonary function is mandatory and continuous neurologic examination is essential. Within the first few days following liver transplantation, profound graft dysfunction suggests primary nonfunction or hepatic artery thrombosis and early diagnosis is critical as this entails consideration of retransplantation.
- Throughout the first few weeks, allograft function should be monitored closely in order to recognize acute cellular rejection (ACR) so that it can be treated promptly. Full knowledge and understanding of the side effects of immunosuppressants is essential so as to avoid adverse events.
- Initial immunosuppression consists of corticosteroids associated with a calcineurin inhibitor (CNI) (tacrolimus or cyclosporine). Careful attention should be paid to potential drug–drug interactions leading to variability in the blood levels of CNIs. Not uncommonly some centers use OKT3, thymoglobulin, or interleukin 2 antibody receptors (e.g., basiliximab, dacluzimab) for induction, whereas others restrict their use to patients with renal failure.
- Common side effects related to immunosuppression agents include hypertension, renal insufficiency, diabetes, and hyperlipidemia and these have a high impact on post-transplant morbidity and mortality if left untreated.
- Biliary tract abnormalities have been described in as high as 30% of liver transplant recipients and these include biliary leak and stenosis. Diagnosis and potential treatment is best pursued with endoscopic retrograde cholangiopancreatography.
- ACR mostly occurs within the first 3 months following transplantation, but can be encountered at any time. Distinguishing it from recurrent disease, particularly hepatitis C, is crucial since management is different. In recipients transplanted for hepatitis C, prolonged or high-dose corticosteroid administration may accelerate allograft hepatitis and result in poorer long-term outcomes.

Over the past several years the postoperative care of liver transplantation (LT) has improved dramatically. Most life-threatening complications following LT occur within the perioperative period and include primary nonfunction of the allograft (PNF), acute cellular rejection (ACR), technical complications related to the surgery such as biliary leaks and hepatic artery thrombosis (HAT), and a variety of medical complications (Fig. 44.1). Better understanding of the pathophysiology of some of these complications and improved diagnostic tools has allowed us to differentiate and appropriately manage these often critically ill patients.

Intensive care unit management

Following LT, patients are transferred from the operating room to the intensive care unit (ICU), where care is provided by a multidisciplinary team including an intensivist, a transplant surgeon, a hepatologist, and an experienced nursing team. Patients with an uncomplicated transplant operation, those who have a rapid reversal of anesthetic effects, and those who have a functioning allograft and are hemodynamically stable are usually good candidates for early extubation in the recovery room. As with any patient undergoing major abdominal surgery, careful and frequent assessment of the patient's level of consciousness and hemodynamic status, including cardiopulmonary function and urinary output, is done. Periodic assessment of intra-abdominal drainage through drains is essential. The quantity and character of the drainage is determined and particular note is made of whether it is clear or bloody. In some centers, a T tube is placed at the donor–recipient anastomosis, allowing easy appraisal of bile quantity and quality with pale and low

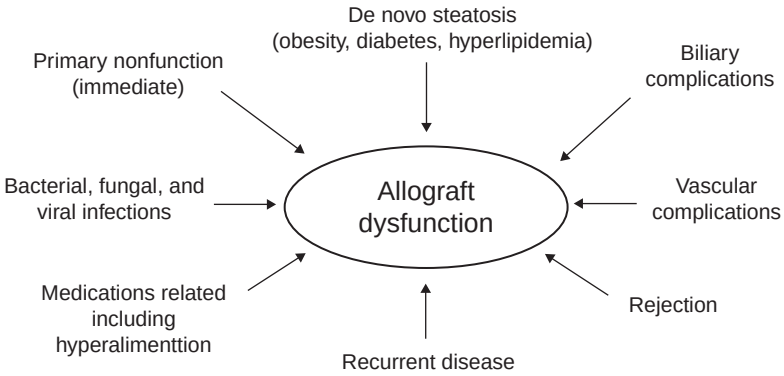

Figure 44.1 Causes for allograft dysfunction following liver transplantation.

output being associated with poor graft function. It is well described that when larger volumes of blood products are used intraoperatively, complications after transplantation increase [1]. Physicians must be aware of potential issues including pulmonary problems, infectious complications, renal failure, and cardiac complications. Neurologic abnormalities are not infrequent in the immediate postoperative period. Brachial plexus palsy as a result of compression injury secondary to the use of retractors and extremity position during the surgery can be seen. Mental status changes ranging from anxiety to delusional states and encephalopathy can be expected, but most resolve with no intervention [2,3].

General management

Assessment of the allograft function is initiated in the operating room at the time of graft reperfusion, mainly by observation of the bile production and its characteristics. The degree of elevation of serum aminotransferases levels indicates the extent of liver parenchymal injury due to a variety of factors, including reperfusion injury and graft ischemia time, defined mainly by two variables – cold ischemia time (CIT) and warm ischemia time (WIT). CIT is defined as the time interval that begins when an organ is cooled with a cold perfusion solution after organ procurement surgery and ends when the organ is implanted. On the other hand, WIT begins when the organ reaches physiologic temperature before the completion of surgical anastomosis and ends with reestablishment of the blood circulation in the graft. The duration of ischemia correlates with the degree of hepatocyte injury characterized by apoptosis, necrosis, and inflammation. Serum aminotransferase elevation peaks at 1–2 days after the transplant but should rapidly decline along with the prothrombin time if graft function is satisfactory. This may be followed by a cholestatic picture with increases in alkaline phosphatase (AP), γ-glutamyltransferase (GGT), and bilirubin; these slowly improve if the preservation injury is not severe.

Graft function

During the immediate postoperative period, three major complications can cause profound graft dysfunction, which in most cases requires prompt liver retransplantation (Table 44.1). PNF, HAT, and hyperacute rejection remain a great challenge for the transplant team and have a major impact on postoperative morbidity and mortality. PNF is an extreme form of preservation injury occurring in 3–6% of allografts. PNF manifests as acute liver failure (encephalopathy, elevated serum aminotransferases, coagulopathy, jaundice) and may be associated with multiorgan failure (renal dysfunction, pulmonary complications) [4,5]. Risk factors include donor age older than 50 years, donor liver steatosis greater than 30%, donation after cardiac death (DCD) graft, reduced size graft, severe donor hypernatremia ($[Na^+]$ greater than 170 mEq/L), severely ill recipient, and protracted CIT [4,6]. Urgent retransplantation is usually required.

HAT can occur early after transplantation or in the late postoperative period and can be a devastating

Table 44.1 Expected complications following liver transplantation.

Time	Medical complications	Surgical complications
First week	Hyperacute rejection Neurologic complications Primary nonfunction	Intra-abdominal bleeding HAT Biliary leak
Second to fourth week	ACR Neurologic complications Renal failure	HAT Portal vein thrombosis Biliary leak
First to sixth month	ACR Recurrent HCV Hypertension CMV infection Renal failure	Delayed HAT Biliary strictures/casts Portal vein thrombosis

ACR, acute cellular rejection; CMV, cytomegalovirus; HAT, hepatic artery thrombosis; HCV, hepatitis C virus.

complication. It is reported to occur in 4–15% of LT recipients and is generally more frequent after pediatric LT [7,8]. When present within the first few days to 2 weeks after transplantation, HAT manifests with profound graft dysfunction, along with biliary strictures, sepsis, and liver abscesses. Color Doppler ultrasonography is the preferred method to evaluate hepatic artery patency with a reported sensitivity of approximately 90% for acute HAT [9]. Multidetector computed tomography (CT) angiography or magnetic resonance angiography are alternative options for the diagnosis of HAT in patients with difficult or indeterminate sonographic examinations [10, 11]. Angiography provides the opportunity to administer thrombolytics and perform thrombectomy or stenting of the hepatic artery. Early diagnosis and treatment of HAT can avoid liver retransplantation [12]. On the other hand, late unrecognized HAT can lead to biliary tract problems, manifested by either leaks or obstruction, and intrahepatic bilomas. In these cases the treatment of HAT depends on the extension of the graft damage, and has included urgent revascularization or prompt liver retransplantation [12].

At the present time, hyperacute rejection is extremely rare post-LT. This type of rejection becomes apparent within hours post-transplantation and is caused by preformed humoral antibodies against the allograft endothelial cells [13]. Clinical signs and symptoms usually resemble PNF and liver biopsy is necessary for accurate diagnosis in that it reveals congestion and hemorrhagic necrosis within the graft sinusoids. Thus far, no effective treatment has been described other than retransplantation.

Infectious complications

Infectious complications are a continuous threat to every immunosuppressed patient [14]. During the early postoperative period, infections are related to a difficult and prolonged surgical procedure or technical complications of surgery, poor nutritional status, large amounts of blood products intraoperatively, prolonged ICU stay, and poor graft function [15]. Prophylactic strategies include preoperative cultures and antibiotics covering a broad spectrum of organisms, especially enteric Gram-negative and Gram-positive bacteria. Intravenous antibiotics are generally administered before transplantation in the operating room and for 24–48 hours after surgery. Bacterial infections due to an indwelling catheter source (30%), pneumonia (25%), and surgical wounds (10%) dominate the first week. Gram-negative bacteremia should prompt investigation of a biliary tract source and are more common in those with diabetes or with a poor nutritional status [16]. Viral and opportunistic infections are not a major concern during the first few weeks in uncomplicated liver transplant recipients.

Immediate surgical complications

Postoperative bleeding is the most common surgical complication following LT. Approximately 5–15% of posttransplant recipients require reoperation to control early postoperative hemorrhage [17]. However, in approximately half of the patients no specific site of bleeding is found, and after careful examination of the vascular bed is completed such bleeding is usually attributed to coagulopathy. Importantly, it has been reported that two thirds of the patients with poor graft function undergoing reoperation for hemorrhage will die within 6 months of transplantation [17]. Renal failure secondary to postoperative hemorrhage and hemodynamic instability may evolve but usually resolves after controlling the bleeding and with careful hemodynamic monitoring. Biliary complications can occur at any time after transplantation. The vast majority, however, occur within the first 3 months of transplantation, requiring reoperation in 10–20% of patients [18]. Biliary leaks and stenosis are the most common complications. In general, early bile leak is related to technical complications at the biliary anastomotic site. On the other hand, late bile leaks are caused by either ischemic injury from HAT or by removal of T tubes and poor anastomotic healing. Patients with early bile leak can present with bile in the abdominal drains, hyperbilirubinemia, and abdominal pain. Management of small, contained leaks is primarily via endoscopic retrograde cholangiopancreatography (ERCP) and internal stent placement or internal/external biliary drains by percutaneous transhepatic cholangiography (PTC). Over the long term, reoperation and surgical revision may be required for a focal stricture or one not responsive to endoscopic therapy.

Immunsuppression management

A key component of postoperative management of a liver transplant recipient is the regulation of immunosuppressant drugs and it varies widely among centers. The primary goal of immunosuppression is to avoid rejection and graft loss and a secondary objective is to diminish adverse side effects of the antirejection therapy. Significant advances have been achieved in pharmacologic immunosuppression, allowing a wide array of immunosuppressive agents to be used [19]. Induction therapy with high-dose steroids is initiated intraoperatively, and then slowly tapered off. A calcineurin inhibitor (CNI), either tacrolimus or cyclosporine, is usually introduced during the first postoperative day. However, in patients with preexisting renal insufficiency, some centers may delay CNI use and initiate OKT3 or interleukin 2 (IL2) antibody receptors (i.e., basiliximab) during the initial phase. Over the past decade, azathioprine has been substituted by mycophenolate mofetil in some centers as a CNI-sparing strategy, not only in those patients with renal

failure but in those who develop CNI-related central nervous system toxicity as well. However, in LT, the clinical benefit of mycophenolate mofetil over azathioprine is questionable [20]. During the ICU stay, rejection is generally not a concern.

Hepatitis B prophylaxis

Prior to the introduction of hyperimmune hepatitis B immunoglobulin (HBIg), patients transplanted with a diagnosis of chronic or fulminant hepatitis B virus (HBV) infection had an approximate 75% rate of recurrent HBV [21]. Recurrence of HBV infection is associated with reduced graft and patient survival [22]. Although there is extreme variation in immunoprophylaxis protocols among transplant centers, current prophylactic post-transplant strategies include HBIg and nucleos(t)ide analogs. Most protocols use HBIg intravenously initially during the anhepatic phase and for a variable period post-transplant. Thereafter, some transplant centers administer HBIg monthly and some others, as needed, maintain high and variable anti-hepatitis B surface (HBs) serum titers. With current strategies that also include effective antiviral nucleos(t)ide analogs, the HBV recurrence rate is less than 10% [23]. Newer strategies with much lower doses of HBIg have shown similar results at far less cost in patients with low viral load or HBV DNA-negative status prior to transplantation [24].

Floor care

Monitoring for rejection and treatment

Uncomplicated patients are usually ready to be transferred from the ICU to the floor 24–48 hours after transplant, where close monitoring of the hepatic function should be continued, concurrently with immunosuppression titration into the therapeutic range. Careful and thorough patient and care giver education by transplant coordinators and physicians should be clearly addressed.

Daily performance of liver function tests is used for surveillance of proper engraftment. Prothrombin time (PT) is a particular sensitive index to monitor hepatocellular function. Serum albumin is a good index of graft synthetic function but not in the immediate post-transplant period because of its prolonged half-life and unstable fluid shifts. A few variables associated with early allograft dysfunction have been described as indicators of poor long-term graft and patient survival. These include donors older than 50 years, a CIT greater than 15 hours, donor preprocurement acidosis, and recipient PT or bilirubin that stays steadily elevated [1,25]. Abnormalities of the liver function tests in this phase of the post-transplant period are frequently a manifestation of preservation injury or ACR. Preservation injury usually presents with an elevation of AP and GGT and without a significant increase in total bilirubin. In contrast, an elevation of transaminases (alanine transaminase (ALT) and aspartate transaminase (AST)) together with rising bilirubin level and/or GGT should raise concern for ACR. However, changes in hepatic biochemical tests are nonspecific and reflect injury from any cause, making liver biopsy essential for accurate diagnosis. Biopsy-proven acute rejection occurs in 50% of liver allografts within the first 6 weeks after transplantation [26]. Reported rates of rejection vary because of differences in the reason for a liver biopsy, such as a biopsy triggered by abnormal liver function tests or done routinely as per transplant center protocol. Histologic findings consistent with ACR without significant biochemical abnormalities can be seen in a third of protocol biopsies. The clinical significance of these findings remains unclear; however, most of the transplant centers performing protocol biopsies may treat rejection based solely on histology [27,28]. Rejection reveals portal inflammation with a mixed cellular infiltrate characterized by lymphocytes, neutrophils, and eosinophils (Fig. 44.2). Venous endothelium and biliary ducts are the targets of the inflammatory reaction (Tables 44.2 and 44.3) [29,30]. An adequate level of immunosuppression decreases the risk of ACR. Young and relatively healthy recipients without renal insufficiency and prolonged CIT have been described to have higher incidences of graft rejection [26].

Treatment consists of augmented immunosuppression. Milder rejection episodes may resolve by increasing the dosage of the maintenance immunosuppressant, such as

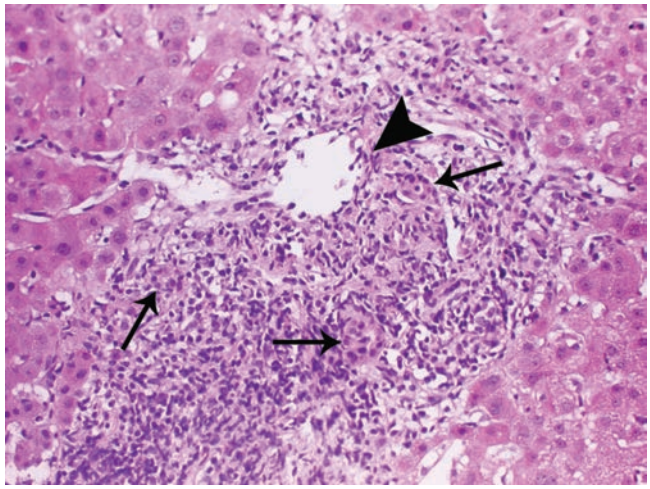

Figure 44.2 Histopathologic findings associated with acute cellular rejection. This core needle biopsy specimen shows portal inflammatory infiltrate containing lymphocytes (predominantly), eosinophils, and neutrophils. Endothelitis characterized by subendothelial localization of the inflammatory cells in a portal vein branch (arrow head) and bile duct inflammation/damage (arrows) can also be seen.

Table 44.2 Grading of acute allograft rejection. A global assessment of the rejection grade is made on a review of the biopsy and after the diagnosis of rejection has been established.

Global assessment[a]	Criteria
Indeterminate	Portal inflammatory infiltrate that fails to meet the criteria for the diagnosis of acute rejection
Mild	Rejection infiltrate in a minority of the triads that is generally mild, and confined within the portal space
Moderate	Rejection infiltrate, expanding most or all of the triads
Severe	As above for moderate to severe perivenular inflammation that extends into the hepatic parenchyma and is associated with perivenular hepatocyte necrosis

[a]Verbal description of mild, moderate, or severe acute rejection could also be labeled as grade I, II, and III, respectively.
Reproduced from Demetris et al. [29] with permission from Plenum.

a CNI, especially if trough levels are suboptimal. More severe episodes require corticosteroid pulse therapy and recycle, and in steroid-refractory cases antilymphocyte preparations or monoclonal antibodies (i.e., OKT3) may be used. In contrast to other solid organ transplants, the liver allograft might be relatively protected after an ACR episode [31]. In allograft recipients with hepatitis C virus (HCV) infection, cellular rejection can be sometimes difficult to distinguish from recurrent HCV. Liver biopsy in recurrent hepatitis C may demonstrate a few similar histologic findings to ACR such as portal inflammatory reaction and lymphocyte predominance [32]. Distinction between these two entities is essential, because the use of antirejection therapy, especially steroids, might accelerate allograft hepatitis and result in poorer long-term outcomes.

Medical complications

In those who have pretransplant ascites, the ascites present before transplantation may continue after LT but usually resolves over days to weeks with sodium restriction and conservative use of diuretics. If large ascites persists, other causes, such as venous outflow anastomosis obstruction, should be considered. Nowadays, with the piggyback technique, caval obstruction is rare and outflow obstruction usually results from suprahepatic anastomoses, manifested as acute outflow obstruction with coagulopathy, jaundice, and ascites. Late

Table 44.3 Rejection activity index using criteria that can be used to score liver allograft biopsies with acute rejection, as defined by the World Gastroenterology Consensus document.

Category	Criteria	Score
Portal inflammation	Mostly lymphocytic inflammation involving, but not noticeably expanding, a minority of the triads	1
	Expansion of most or all of the triads by a mixed infiltrate containing lymphocytes with occasional blasts, neutrophils, and eosinophils	2
	Marked expansion of most or all of the triads by a mixed infiltrate containing numerous blasts and eosinophils with inflammatory spillover into the periportal parenchyma	3
Bile duct inflammation damage	A minority of the ducts are cuffed and infiltrated by inflammatory cells and show only mild reactive changes such as an increased nuclear cytoplasmic ratio of the epithelial cells	1
	Most or all of the ducts are infiltrated by inflammatory cells. More than occasional ducts show degenerative changes such as nuclear pleomorphism, disordered polarity, and cytoplasmic vacuolization of the epithelium	2
	As above for score 2, with most or all of the ducts showing degenerative changes or focal luminal disruption	3
Venous Endothelial Inflammation	Subendothelial lymphocytic infiltration involving some, but not a majority, of the portal and/or hepatic venules	1
	Subendothelial infiltration involving most or all of the portal and/or hepatic venules	2
	As above for score 2, with moderate or severe perivenular inflammation that extends into the perivenular parenchyma and is associated with perivenular hepatocyte necrosis	3

presentation of hepatic outflow obstruction manifests as hepatomegaly and persistent ascites resistant to medical therapy. Diagnosis can be made with Doppler ultrasonography in some cases, but hepatic venography and assessment of a gradient between the pre- and postanastomotic site remains the gold standard. Findings on liver biopsy include central lobular congestion and necrosis with cholestasis and the absence of other features of rejection. Management of outflow obstruction is dictated by the severity of allograft dysfunction and the timing of presentation. Emergent revision of the outflow anastomosis and even retransplantation may be required within the first days after LT. Chronic outflow obstruction with preservation of the graft function can be handled conservatively with diuretics. However, radiologic revision of outflow anastomoses followed by venous stenting or angioplasty of the obstruction might be required.

During this phase of hospitalization, many patients develop variable degrees of psychiatric or neurologic abnormalities. Anxiety and psychosis with delusions and hallucinations are frequent, but most resolve gradually without any specific therapy. Seizures, encephalopathy, and tremors are not uncommon at this stage; they are usually multifactorial in origin. Precipitating factors associated with neurotoxicity include metabolic causes (i.e., electrolyte abnormalities, uremia), sleep deprivation, adverse effects of immunosuppressants, and infections. CNIs and steroids have known neurologic side effects; adding mycophenolate mofetil or azathioprine allows for a reduction in the dose of the CNI. LT recipients are not exempt from suffering cerebrovascular events. In the setting of thrombocytopenia and coagulopathy, intracerebral hemorrhage or subdural hematoma may occur spontaneously. Ischemic cerebrovascular events are less common in this setting. Central pontine myelinolysis (CPM) is a devastating neurologic complication associated with variable symptoms including coma, ataxia, dysarthria, and dysphagia. CPM has been classically associated with rapid serum sodium shifts in the perioperative period, potentiated by high CNI levels [33]. Treatment is supportive, with protracted neurologic rehabilitation. Patients transplanted for acute liver failure present a higher risk of neurologic complications. These patients usually present with cerebral edema, and in those cases where an intracranial pressure monitor is in place careful intraoperative monitoring is warranted to reduce the risk of pre and post-transplant neurologic complications.

Several other medical complications can occur during the course of hospitalization. These can be exacerbations of preexisting conditions, but more often are side effects of the immunosuppressive drugs (Table 44.4). Arterial hypertension is the most common cardiovascular complication and is seen in 50–60% of LT recipients [34]. Hypertension is due to a number of factors, including volume overload, preoperative stress, impaired glomerular filtration rate, glucocorticoids, and CNI administration [35]. The first line of therapy is to ensure an appropriate CNI trough level. In the absence of toxic immunosuppressant drug levels, antihypertensive pharmacotherapy is necessary. The mechanism underlying CNI-induced hypertension is vasoconstriction of renal and systemic vessels and, therefore, calcium channel blockers that do not interfere with CNI metabolism, such as amlodipine and nifedipine, are preferred over diltiazem or verapamil. Thiazide diuretics may be effective to treat volume overload. When a second agent is required, β-blockers such as atenolol can be added, but generally are less effective than amlodipine. In the early postoperative period angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers are not preferred due to their potential to aggravate hyperkalemia and renal dysfunction. Nevertheless, ACE inhibitors can be very effective in the long term, especially in patients with diabetes and/or proteinuria [36].

New-onset diabetes mellitus (DM) can be seen in approximately 15% of LT recipients [34]. HCV seropositivity and, in particular, the use of corticosteroids and CNIs (mainly tacrolimus) may predispose recipients to insulin resistance and glucose intolerance [37, 38]. Preexisting or new-onset DM is associated with an increased incidence of cardiovascular morbidity and mortality, infections, renal impairment, rejection episodes, and decreased graft survival. Corticosteroid withdrawal and switching from tacrolimus to the less diabetogenic drug cyclosporine can be effective [39]. Treatment does not differ from that for the nontransplant population. Lifestyle and diet modifications, including oral hypoglycemic agents and/or insulin administration, might be necessary. Sulfonylureas, such as glimepiride or glyburide, are preferred as the initial agent. In patients with renal dysfunction metformin is to be avoided because of the potential risk of developing lactic acidosis [36].

Cytomegalovirus and *Pneumocystis jirovecii* prophylaxis

An antiviral prophylactic regimen against cytomegalovirus (CMV) is essential in high-risk patients (CMV-positive donor for a CMV-negative recipient (D+/R–)) since CMV infection following LT is associated with poorer graft survival [40]. Other risk factors for CMV infection include the use of antilymphocyte antibodies and retransplantation. Several agents have been suggested for CMV prophylaxis although the recommended regimen in D+/R– patients is oral ganciclovir 5 mg/kg/day or valganciclovir 900 mg/day immediately after transplantation and continued for 3–6 months. These protocols reduce the risk of CMV disease in the recipient by 90–95% [41–43]. When prophylaxis is used in CMV-positive recipients (with either D+ or D–), 3 months of antiviral agents is recommended [43]. CMV infection

GI, gastrointestinal.

can be asymptomatic or manifest between 2 and 12 months after LT with one or more features of: mild increase in aminotransferases, leukopenia, thrombocytopenia, retinitis, pneumonitis, and diarrhea [40]. Diagnosis is made from tissue samples and/or blood (CMV DNA and/or CMV antigenemia). Liver biopsy findings include microabscesses, lobular hepatitis, and giant cells with viral inclusions. It is important to differentiate CMV hepatitis from ACR because treatment of CMV hepatitis involves the reduction of immunosuppression. CMV infection can also result from the reactivation of a prior infection in the recipient; in such cases, treatment again includes intravenous ganciclovir 5 mg/kg every 12 hours for 2–4 weeks with conversion to oral valganciclovir for completion of therapy [43].

Prior to the introduction of prophylactic regimens, the risk of *Pneumocystis* pneumonia (PCP) in LT recipients ranged from 5% to 15% [44]. Prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) is effective in preventing PCP [45]. In patients with sulfa allergy or TMP-SMX intolerance, pentamidine or atovaquone are also effective. The length of time of prophylaxis is for 6–12 months after transplantation, coincident with the highest immunosuppression requirements and greatest risk of infection.

Another important objective while the patient is still in the transplant unit is education of the recipient and care giver with respect to the administration of medications over the long term, and proper health care practices. A member of the transplantation team should spend time instructing the patient and family about medication side effects, signs and symptoms of infection, rejection, diet, and general rules of medical care. Patients should also be instructed in the care of the surgical wound, T tube (if one is placed), and any drains that remain. This time can also be used to emphasize the importance of communication with the liver transplant center regarding unexpected clinical situations that may occur at home. A good knowledge of medications and health care issues is vital for a successful outcome over the long run.

Clinic visits

General management

Following discharge from the hospital after LT, patients must continue medical care in the transplant clinic. The frequency of visits varies among centers but it is mostly dictated by the patient's overall condition. Usually during the first 1–2 months, visits are weekly, twice a month thereafter, and monthly up to 1 year. During clinic visits, attention is paid to nutrition, diet, medical compliance, and overall health. Patients should continue to be monitored closely for signs of graft dysfunction and a continued low threshold for suspicion of rejection needs to be maintained. Any reportable abnormal result from hepatic biochemical tests, especially serum aminotransferases, should prompt a liver biopsy to rule out ACR or other causes of ALT or AST elevation such as HCV recurrence or CMV infection. Acute rejection episodes not diagnosed in time or refractory to treatment can lead to chronic rejection, which is characterized by the disappearance of small intrahepatic bile ducts and obliterative angiopathy (Table 44.5) [46]. Chronic rejection is an uncommon complication occurring mostly after 6 months of transplantation. Left untreated, chronic rejection can

Table 44.5 Grading of chronic allograft rejection.

Structure	Early chronic rejection	Late chronic rejection
Small bile ducts (<60 μm)	Degenerative changes involving a majority of ducts; eosinophilic transformation of the cytoplasm; increased N:C ratio; nuclear hyperchromasia; uneven nuclear spacing; ducts only partially lined by biliary epithelial cells	Degenerative changes in the remaining bile ducts
	Bile duct loss in <50% of portal tracts	Loss in ≥50% of portal tracts
Terminal hepatic venules and zone 3 hepatocytes	Intimal/luminal inflammation Lytic zone 3 necrosis and inflammation Mild perivenular fibrosis	Focal obliteration Variable inflammation Severe (bridging) fibrosis
Portal tract hepatic arterioles Other	Occasional loss involving <25% of portal tracts So-called "transition" hepatitis with spotty necrosis of hepatocytes	Loss involving >25% of portal tracts Sinusoidal foam cell accumulation; marked cholestasis
Large perihilar hepatic artery branches	Intimal inflammation; focal foam cell deposition without luminal compromise	Luminal narrowing by subintimal foam cells; fibrointimal proliferation
Large perihilar bile ducts	Inflammation damage and focal foam cell deposition	Mural fibrosis

Reproduced from Demetris et al. [46] with permission from Plenum.

result in graft failure and the need for retransplantation. However, after retransplantation, the risk of recurrent chronic rejection can be as high 90% [47]. Monitoring of immunosuppression levels is necessary at every clinic visit. CNIs and mammalian target of rapamycin (mTOR) inhibitors (i.e., sirolimus) are metabolized by cytochrome P450 3A4 (CYP3A4). A large number of drugs are metabolized by CYP3A4 as well; thus, the possibility of drug–drug interactions exists, especially in the early post-transplant period when patients usually take a large number of medications (Box 44.1). A pharmacist particularly dedicated to the transplant program can help in sorting out the drug–drug interactions for the patients, families, and heath care providers, and can help facilitate proper care.

Box 44.1 Medications with significant interactions with calcineurin Inhibitors.[a]

Decreased CNI levels

Antibiotics
- Isoniazid
- Rifabutin
- Rifampicin

Anticonvulsants
- Carbamazepine
- Phenobarbital
- Phenytoin

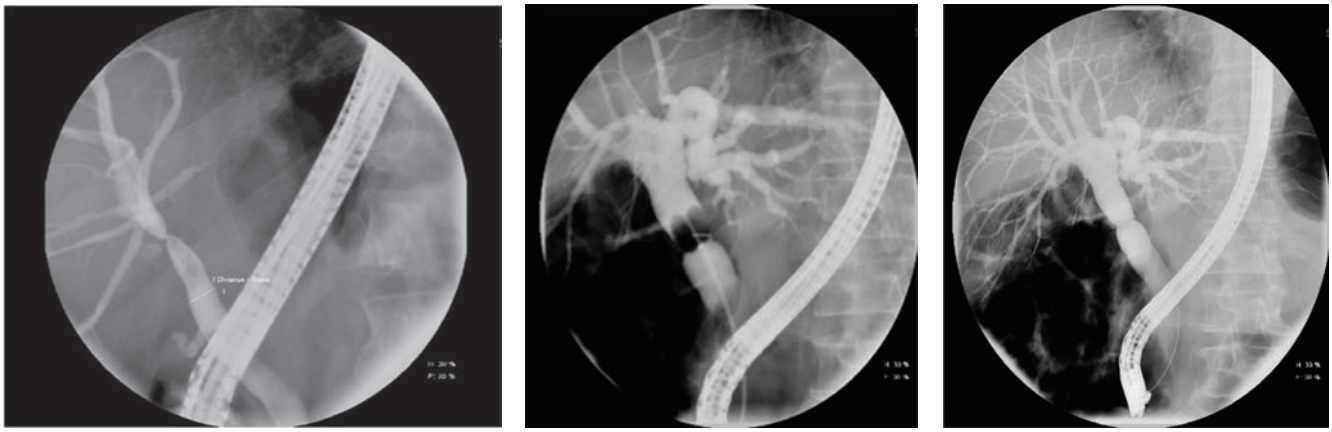
Others
- St John's wort (herbal preparation)

Increased CNI levels

Antibiotics
- Azithromycin
- Clarithromycin
- Erythromycin

Antifungals
- Caspofungin
- Fluconazole
- Itraconazole
- Ketocanzole
- Voriconazole

Calcium channel blockers
- Diltiazem
- Nicardipine
- Verapamil



Others
- Atorvastatin
- Cisapride
- Grapefruit juice
- HIV protease inhibitors

[a]This is not a complete list. The pharmacy should be consulted for other drug–drug interactions.
CNI, calcineurin inhibitor; HIV, human immunodeficiency virus.

Late surgical complications

Biliary tract complications are more frequent within the first 6 months following transplantation. Hyperbilirubinemia and GGT and/or AP elevation are usually early signs of biliary complications, and when clinically suspected a cholangiographic evaluation is indicated. If a T tube is still in place, cholangiography through the tube allows rapid diagnosis. ERCP or PTC not only permit diagnosis but potentially offer a therapeutic avenue as well. In cases where a Roux-en-Y anastomosis is performed, magnetic resonance retrograde cholangiopancreatography (MRCP) is being increasingly used. At this stage, biliary tract abnormalities include intra- or extrahepatic strictures and casts/sludge formation. First-line therapy of extrahepatic biliary strictures includes either ERCP or PTC balloon dilatation and stenting (Fig. 44.3). Surgical management with Roux-en-Y biliary reconstruction is reserved for patients who fail endoscopic or percutaneous therapy. Nonanastomotic strictures frequently develop secondary to vascular insufficiency; however in a small group the pathogenesis remains unclear. Known risk factors for nonanastomotic strictures include prolonged graft ischemia time, older donor age, recurrence of primary sclerosing cholangitis (PSC), and DCD organs [48,49]. Surgical therapy ranging from Roux-en-Y reconstruction to retransplantation may be required. Biliary stones and casts may develop late after LT, commonly presenting with cholangitis. Endoscopic treatment is usually effective in extracting stones but fails to treat biliary casts. Surgical treatment or even retransplantation may be required in such cases.

Complications of the hepatic vasculature can emerge late after LT. While early HAT has a fulminant presentation, late HAT often manifests in an indolent manner. Delayed HAT is a serious complication and patients can present with liver abscesses, bile leak or stricture, and recurrent cholangitis [50]. These patients might be eligible for vascular or biliary endoscopic treatment; however, as with early HAT, most of these patients will ultimately require retransplantation. Hepatic artery aneurysms are an infrequent complication commonly associated with fungal infections and can rupture with resultant intra-abdominal bleeding requiring surgical hepatic artery reconstruction. Portal vein thrombosis (PVT) is also an infrequent vascular complication of LT, occurring in 1–3% of the recipients [7]. As with HAT, PVT occurs primarily in the early postoperative period, but it can also manifest several months to years following transplantation. Common clinical manifestations include hepatic decompensation and complications of portal hypertension such as ascites and variceal hemorrhage. In contrast to HAT, PVT

A B C

Figure 44.3 Endoscopic retrograde cholangiopancreatography (ERCP) showing an anastomotic biliary stricture at the choledochocholedochostomy (A), followed by dilatation (B) and stenting (C).

technically challenges retransplantation. Extensive PVT might involve the superior mesenteric vein as well, making retransplantation technically more difficult [7]. Treatment for PVT is recommended for symptomatic patients. If PVT occurs in the immediate postoperative period, reoperation and thrombectomy or vascular reconstruction yields excellent results. Direct repair of the portal vein in patients with chronic PVT is particularly difficult. Decompressive shunt surgery has been used with success; however, retransplantation may be required if the various nontransplant modalities fail to alleviate complications of portal hypertension [51].

Immunosuppresion-related complications

Special attention should be paid to the potential medical complications that can emerge following LT, most of which are related to long-term use of immunosuppression. Dyslipidemia develops in up to 47% of LT recipients [52,53]. Corticosteroids, cyclosporine, and especially mTOR inhibitors have a significant effect on serum lipid levels [36]. Lowering cholesterol is an important intervention to prevent long-term cardiovascular disease. As with nontransplant patients, implementing lifestyle modifications is the first-line treatment. If serum lipids remain elevated, pharmacologic therapy with "statins" can be safely initiated. Myopathy, hepatotoxicity, and rhabdomyolysis are uncommon side effects. In patients on CNIs, hydrophilic statins (i.e., fluvastatin, pravastatin) are preferred because they are not metabolized through CYP3A4 [53]. Switching from cyclosporine or mTOR inhibitor to tacrolimus can be considered if cholesterol level remains elevated. Bile acid sequestrants, fibrates, and nicotinic acid should be avoided because of their potential interference with other drugs. Preventing the development of atherosclerotic disease is essential in the transplant recipients since cardiovascular disease is a significant cause of morbidity and mortality [54].

Early recurrent disease

Recurrence of the original liver disease is another important cause of graft dysfunction. Virtually all conditions for which a LT was done can recur; however, this is almost invariably seen with hepatitis C. HCV recurrence usually evolves during the first 6 months following LT and typically manifests with serum aminotransferase elevation. Histologic findings at times are similar to those of ACR and therefore distinction between these two entities may be challenging. A constellation of clinical and histologic features may help differentiate them, otherwise steroid boluses given for "diagnosed" ACR can promote fibrosis progression in the event the patient has recurrent HCV [55]. Importantly, there is a cholestatic variant of recurrent HCV characterized by extremely high HCV RNA levels and a cholestatic clinical picture. It occurs early in the post-transplant period in approximately 5% of transplanted patients with hepatitis C and generally results in graft failure [56]. Treatment remains uncertain; reducing immunosuppression and interferon therapy are usually ineffective. Most centers consider cholestatic HCV recurrence a contraindication for retransplantation. Reported recurrence rates for autoimmune hepatitis (AIH) after LT are approximately 20–40% [57,58]. Steroids, azathioprine, and/or mycophenolate mofetil have been successfully used to treat recurrent AIH [59]. Overall post-transplant recurrence rates of primary biliary cirrhosis can reach 50% and range from 10% to 27% for those transplanted for PSC [60,61]. Therapy with ursodeoxycholic acid in the post-transplant setting has not been defined although it is routinely used. Patients transplanted for hepatocellular carcinoma (HCC) that exceeded the Milan criteria and/or with

vascular invasion present a higher risk of recurrence [62]. Periodic and often semiannual chest CT and liver magnetic resonance imaging is recommended for surveillance for recurrence. More commonly, HCC recurrence is diagnosed beyond 6 months post-transplant.

Cancer

All transplant recipients are at higher risk than the general population of developing de novo malignancies (i.e., hematologic, skin, lung, colon, genitourinary tract, and oropharynx) [63] or having a recurrence of previous cancers. Prolonged exposure to immunosuppressive therapy has been described as the main risk factor for developing malignancies in the post-transplant period. Skin cancers, especially squamous cell carcinoma, basal cell carcinomas, and melanoma, account for 39% of malignancies that develop after LT [64]. Although, the peak incidence of cutaneous malignancies is 3–5 years after organ transplantation, patients should always be instructed to use effective sunscreen, and an annual follow-up by a dermatologist is highly recommended. Post-transplant lymphoproliferative disorder (PTLD) occurs in about 2% of LT recipients and most cases develop during the first year after transplantation [65]. Early PTLD is usually associated with Epstein–Barr virus (EBV) reactivation or primary infection. Risk factors for PTLD in LT recipients are young age, pretransplant EBV naivety, and a high degree of immunosuppression [66,67]. Symptoms include fever, weight loss, malaise, and night sweats. First-line treatment consists of immunosuppression reduction while monitoring for allograft dysfunction. Patients who do not respond or are intolerant to this first step should be treated with rituximab or chemotherapy.

Long-term follow-up

Liver transplant recipients should always be motivated to continue medical follow-up. Preventive measures must be emphatically implemented by the transplant center and primary care physician. Transplanted patients should be encouraged to maintain routine dental care, and discontinue tobacco or cannabis smoking. Vaccines are recommended in the post-transplant setting, especially inactivated vaccines such as pneumococcus, influenza, and tetanus. Immunosuppressed patients overall have lower seroconversion rates. Most centers recommend against live-attenuated vaccines. Obesity is a major problem after transplantation and approximately a fifth of patients become obese within 2 years after LT [68]. Pretransplant obese patients tend to gain more weight after LT. Patients should be counseled about lifestyle modifications, including diet and exercise programs.

Multiple choice questions

44.1 Histopathologic diagnosis of acute cellular rejection includes all except which one of the following?

- **a** Subendothelial localization of inflammatory cells in portal vein branches.
- **b** Small bile ducts inflammation and damage.
- **c** Presence of lobular microabscesses.
- **d** Portal inflammatory infiltrate including lymphocytes, eosinophils, and neutrophils.

44.2 Common complications associated with graft loss in the first few weeks after liver transplantation include all of the following except which one?

- **a** Hepatic artery thrombosis (HAT).
- **b** Primary nonfunction of graft (PNF).
- **c** Acute cellular rejection (ACR).
- **d** Cytomegalovirus (CMV) infection.

44.3 Common complications associated with immunosuppressants include all of the following except which one?

- **a** Diabetes mellitus.
- **b** Hypertension.
- **c** Infections.
- **d** Parkinson disease.
- **e** Renal insufficiency.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 45

Long-term Management of the Liver Transplant Patient

Timothy M. McCashland

Department of Hepatology, University of Nebraska Medical Center, Nebraska Medical Center, Omaha, NE, USA

Key concepts

- Preventive care is paramount in the liver transplant recipient and includes vaccination, dental care, and counseling to abstain from smoking.
- Common medical problems in the long-term liver transplant recipient include metabolic syndrome (obesity, hyperlipidemia, diabetes mellitus), osteoporosis, cardiovascular disease, and renal disease – all of which may result in increased morbidity and mortality.
- Technical-related problems of biliary complications may be corrected by endoscopic therapy. However, living related biliary complications are common both in the donor and recipient and require a multidiscipline team approach.
- Common causes of deaths in survivors of more than 1 year include development of de novo malignancy, cardiovascular causes, renal failure, and recurrent disease. Diligent surveillance for these diseases may lead to early detection and lower morbidity.
- Renal impairment is common in long-term survivors. The development of end-stage renal disease is reported up to 18%, with markedly decreased survival in these patients.
- Quality of life post liver transplantation is improved but many times does not reach the level of the general population

The traditional model of care in most transplant centers is for the transplant surgeon to manage the immediate postoperative care, with gradual incorporation of transplant hepatologists and primary care physicians [1,2]. With increasing success in liver transplantation, a major shift in the prevention and management of a patient's medical-related complications secondary to liver transplantation has become the principle management focus. Distinct differences exist among transplant centers as to who becomes the primary physician in charge of long-term management [3–5]. The majority of transplant centers rely on transplant hepatologists for the management of long-term care [3–5]. However, a recent study noted that transplant hepatologists support a shift toward incorporating primary care physicians as integral members of the transplant team to manage metabolic complications [5]. In actuality, this rarely happens and the transplant hepatologists are managing the patients. Transplant centers nevertheless do not favor primary care physicians managing immunosuppression, acute allograft rejection, recurrent disease, and biliary complications.

Several comprehensive reviews of medical complications and the management of liver transplant recipients have been published previously [6–10]. The American Society of Transplantation also has published guidelines for the long-term management of the liver transplant patient [11]. This chapter will address management of long-term care of the liver transplant patient divided into topics of quality of life, preventive care (vaccinations, dental care), metabolic complications (obesity, diabetes mellitus, cardiovascular disease, bone disease, gout), inflammatory bowel disease, renal dysfunction, transplant-related diseases (biliary complications, de novo neoplasia), and causes of death in long-term survivors,

Quality of life

The immediate goal of liver transplantation is to improve survival of the recipient. However, the secondary goal is to improve the quality of life (QOL) and return the patient to a productive life. Bownik and Saab provide a comprehensive review of this topic [12]. Health-related quality of life (HRQOL) is the measurement of a patient's self-assessment of their physical, functional, social and

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

psychological health. A recent review of instruments used to assess QOL in the adult liver transplant population noted that generic assessment questionnaires are most common and include: the Medical Outcomes Study short form 36 (SF-36), the Hospital Anxiety and Depression Scale (HADS), and the Beck Depression Inventory (BDI) [13]. The SF-36 remains the most popular instrument and has advantage of being able to compare scores with the general population and those with chronic diseases. Interestingly, Saab et al. found that the model for end-stage liver disease (MELD) score was not predictive of HRQOL scores post transplant [14]. In contrast, Castaldo et al. noted improved physical HRQOL post transplant with increasing MELD scores [15]. Early studies with follow-up of less than 2 years noted liver recipients achieve very satisfactory levels of HRQOL in the mental and physical components [16–18]. However, the HRQOL levels were below that of the general population. A prospective multicenter study assessing pretransplant and post-transplant HRQOL using the SF-36 and EuroQol (EQ-5D) instruments with follow-up of 2 years showed a significant improvement in all dimensions of the SF-36 including the role emotion dimension and the EQ-5D scores [18]. Longer survival after transplantation, younger age, and patients from larger transplant centers were independent predictive variables of higher QOL scores. A cross-sectional study from Finland with exceptional follow-up discovered that liver transplant patients had slightly worse HRQOL than the general population, especially in those with increasing age and transplantation for acute liver failure [19]. Unfortunately, with longer follow-up sustained growth in HRQOL does not happen and in fact may decrease, especially in the mental health and role emotion/anxiety domains [20]. Painter et al. however showed that patients up to 5 years after transplant who participated in physical activity and had fewer comorbid conditions improved their HRQOL [21]. Desai et al. in a single center study evaluated QOL in patients 10–30 years post transplant. Patients had an overall good QOL, but reduced physical function was associated with age >60 years, female gender, post-transplant complications, and recurrent disease [22]. A meta-analysis by Bravata et al. on HRQOL concluded improvements in general health, physical health, daily activity function, and sexual function [23]. A more recent study incorporating 44 longitudinal studies and 19 studies using the SF-36 showed the general public had higher rating in physical functioning, role physical, role emotional, social functioning, energy, and general health than liver transplant patients [20]. Therefore, improvement in QOL may be overstated by previous studies. As for specific etiology of liver disease and decreased QOL, conflicting results have been reported. Cowling et al. noted no difference in QOL between Laennec versus non-Laennec patients with follow-up to 5 years [24]. However, other studies found impaired lower global QOL and physical functioning in hepatitis C patients with recurrent disease [25].

Psychologic improvement after liver transplantation has also been shown to begin immediately after surgery. More recent long-term studies tend to show that depression coping skills, anxiety, and social environments are more relevant in liver transplant recipients' QOL than other somatic factors [26]. Not surprisingly, elevated levels of anxiety and neuroticism prior to transplant were associated with worse psychologic health after transplantation [27]. A concerning and interesting investigation by Lewis et al. using multiple tests in cognitive function in 36 patients 10 years after transplantation showed patients scored significantly lower than healthy controls across a wide range of cognitive functions [28]. Unfortunately the reason for this lower function is unknown and needs further study. Blanch et al., using the psychosocial-adjustment-to-illness scale, found that women had poorer adjustment to orthotopic liver transplantation (OLT) than men; the proportion of women with poor adjustment was higher (31.5% versus 16.7%) [26]. Women showed a greater dysfunction in health care orientation, sexual relations, extended family relationships, and psychologic distress. Therefore women may need more psychologic intervention after transplant than men. Thus, psychologic factors are important contributors to QOL issues in the long-term management of liver transplant recipients.

Return to employment after liver transplantation is achieved by 25–60% of patients within the first 6 months' post transplant [10]. Factors associated with return to work include younger age, better general health, pretransplant employment, private insurance, and higher physical conditioning [29].

Preventive care

As the concerns of allograft rejection and infections lessen in the patient with long-term survival after liver transplantation, the physician care giver still must be diligent in adherence to preventive care. This should include a yearly review of vaccinations, dental care, smoking history, and weight, and surveillance for bone disease and malignancy.

Vaccines

Influenza is a seasonal infection that disproportionately affects those who are immunocompromised. Harris et al. brought to light that solid organ transplant recipients unfortunately remain underimmunized against influenza [30]. Using a vaccine safety dataset from three large health maintence organization systems, 49% of pretransplant or post-transplant liver recipients were found to be

vaccinated for influenza. Variables associated with higher rates of vaccinations included older age (odds ratio (OR), 1.8) and prior vaccination (OR, 4.5]. Previously published studies reported influenza vaccination response in adult liver transplant recipients to be from 50% to 95% seroconversion [31,32]. Duchini et al. studied 20 post-transplant patients at baseline and 6 weeks after vaccination [33]. Side effects were well tolerated, but all had significantly lower titers than normal individuals.

Invasive pneumococcal disease has a 13-fold greater incidence in solid organ transplant recipients compared with the general population. We have previously reported on pneumococccal vaccination before transplantation with post-transplantation follow-up. Antibody levels were equal to or less than baseline at 3 months' post transplantation [34]. The American Society of Transplantation has published guidelines recommending a single dose of pneumococcal polysaccharide vaccine, with an additional dose given 3–5 years later [35]. A very interesting recent study tried to enhance immunogenicity by priming the liver transplant recipient with a 7-valent pneumoccoccal conjugate vaccine followed by boosting with the standard 23-valent vaccine [36]. At 16 weeks' post vaccination, 86% and 91% of patients in primed and unprimed groups responded to the pneumococcal vaccines. Therefore, priming with conjugated vaccine did not improve the response rate. Thus, recipients should continue with a standard single dose of 23-valent vaccine with revaccination 3–5 years later.

Inactivated vaccines are safe to administer to liver transplant patients. These include hepatitis A and B, diphtheria, *Haemophilus influenza*, human papillomavirus, pertussis, pneumococcus, meningococcus, and tetanus. Investigators have shown that the licensed live attenuated varicella-zoster virus was well tolerated, with 87% developing humoral and cellular immunity in liver transplant pediatric patients [37].

In 1996, the Advisory Committee on Immunization Practices recommended all patients with chronic liver disease be vaccinated for hepatitis A virus (HAV). Unfortunately, some patients are not vaccinated pre transplant and may require the vaccine after transplant. A Mayo Clinic study of 39 patients evaluated HAV seroconversion rates at 1 and 7 months after the first dose, utilizing two standard doses given at 6 months apart [38]. Seroconversion rates were dramatically lower in the OLT patients compared to patients with chronic liver disease and healthy controls at 1 month (8% OLT versus 83% chronic liver disease versus 93% controls) and 6 months (21% versus 97% versus 98%).

Prevention of hepatitis B after liver transplantation is evolving. Strategies include short-term use of hepatitis B immunoglobulin (HBIg) and long-term use of nucleos(t)ide analog medications. Several investigators have tried hepatitis B vaccination as another alternative tactic [39,40]. Sanchez-Fueyo et al. in a pilot trial of recombinant HBV vaccine in liver transplant patients reported anti-hepatitis B surface (HBs) titers greater than 10 IU/L in 14 of 17 patients. The Berlin group evaluated antibody response to hepatitis B surface antigen (HBsAg) in 10 patients 2 years after transplantation [39]. In contrast to other studies, patients were continued on HBIg during the study. They additionally received 20 μg of recombinant HBV antigen with a novel adjuvant (monophosphoryl lipid A) at weeks 0, 2, 4, 16, and 18. Five of ten patients developed antibody titers greater than 500 IU/L. Others have reported markedly poorer results, even with the use of double doses (40 μg in up to 12 doses) [41]. Gunther et al. reported the results of using a double dose revaccination booster 2 years after the initial vaccination. After the booster vaccination anti-HBs titers increased significantly in all patients [42]. Regrettably, at this time use of vaccination as a sole means of protection has not proven to be the strategy of choice.

Recommendations

- Vaccinate patients prior to liver transplantation if possible for HAV, hepatitis B virus (HBV), and pneumococcus.
- Give a yearly influenza vaccination to liver transplant recipients.
- All personnel associated with care of liver transplant patients should receive an annual influenza vaccination.
- If a patient is unvaccinated for HAV prior to transplantation, consider vaccination post transplant.
- The discontinuation of passive immunoprophylaxis of HBIg with HBV vaccination has not become common practice.

Dental care

A common question asked in transplant programs is if antibiotic prophylaxis is needed with any dental care in liver transplant recipients. The American Heart Association does not recommend antibiotics, unless the patient has a high-risk condition of prior endocarditis, prosthetic valves, or congenital heart disease [43].

Metabolic complications

The metabolic syndrome is the constellation of diseases related to insulin resistance and increased risk of diabetes mellitus and cardiovascular diseases (Box 45.1) [44]. The prevalence of the metabolic syndrome in post liver transplant patients has jumped to the forefront in long-term management. Two comprehensive recent reviews eloquently describe the details and management of this

Box 45.1 Metabolic syndrome.

Defined by the presence of any three of the follow five characteristics:

- Abdominal obesity, which is defined as a waist circumference in men >102 cm (40 inches) and in women >80 cm (>35 inches)
- Serum triglycerides >150 mg/dL (1.7 mmol/L) or drug treatment for elevated triglycerides
- Serum high-density lipoprotein cholesterol <40 mg/dL (1 mmol/L) in men and <50 mg/dL (1.3 mmol/L) in women or drug treatment for low high-density lipoprotein cholesterol
- Blood pressure >130/85 mmHg or drug treatment for elevated blood pressure
- Fasting plasma glucose >100 mg/dL (5.6 mmol/L) or drug treatment for elevated blood glucose

common syndrome [45,46]. The prevalence of the metabolic syndrome in several studies has reported to be 45–58% [47,48]. Each component of the syndrome will be reviewed in detail.

Obesity

Weight gain is also common after liver transplantation. Studies have detailed that by 1 and 3 years' post transplantation, 24–60% of patients had a body mass index (BMI) of >30 kg/m^2 [49,50]. Predictive factors included age >50 years and a BMI >30 kg/m^2 before transplantation. Appetite stimulation from corticosteroids, change to a less restrictive diet, lack of exercise, and higher cumulative doses of prednisone lead to increased weight. Nair et al., using the Scientific Registry of Transplant Recipients database, assessed the morbidity and mortality in obese patients after liver transplantation [51]. Primary graft nonfunction and immediate, 1-year, and 2-year mortality were significantly higher in the morbidly obese group. Five-year mortality was higher in the severely obese (28%) and morbidly obese patients (27%) mainly due to infections and cardiovascular events. These results were confirmed by a more recent study using the United Network for Organ Sharing (UNOS) database [52]. In contrast, analysis of the National Institute of Diabetes and Digestive and Kidney Diseases Liver Transplantation database, when the BMI was corrected for ascites, showed similar patient and graft survival in obese patients when compared with those of normal weight [53]. These studies have led many centers to institute weight-restriction guidelines prior to liver transplantation. Bariatric surgery for morbid obesity remains minimally documented as only a small case report of two successful patients with steatohepatitis noted improvement [54].

Recommendations

- Patients should have yearly evaluation for weight gain and evaluation of immunosuppression.
- If obesity develops, the target weight loss should be approximately 0.5–1 kg/week (1–2 lb/week). This requires multiple clinical visits and the supervision of a nutritionist.

Hyperlipidemia

Hyperlipidemia is common after liver transplantation, with an incidence in up to 50–75% of patients post transplant [55]. Mixed hyperlipidemia (types 2a, 2b, and 4) with high cholesterol and triglyceride levels is the common pattern after transplantation. The etiology of hyperlipidemia is multifactoral [55]. Immunosuppressant medications, steroids, calcineurin inhibitors, and mammalian target of rapamycin (mTOR) inhibitors all can lead to elevations of total cholesterol, low-density lipoprotein cholesterol, and triglycerides. Steriods increase the secretion of very low-density lipoproteins (VLDLs) and the conversion of low-density lipoproteins (LDLs). Cyclosporine inhibits 26-hydroxylase, reducing the transport of cholesterol into bile, and binding to LDL receptors, increasing the levels of LDL cholesterol. Sirolimus use can result in severe dyslipidemia, especially hypertriglyceridemia, in liver transplantation [56]. The proposed mechanism of sirolimus-induced hyperlipidemia is thought to be related to elevated apoCIII levels, which inhibit lipoprotein lipase activity [57]. Use of the National Cholesterol Education Program (NCEP) III lipid guideline goals should be employed for liver transplant patients: total cholesterol <200 mg/dL, LDLs <100 mg/dL, high-density lipoproteins >60 mg/dL, and triglycerides <150 mg/dL [58]. Surprisingly, few data exist on the use of statins for hyperlipidemia in liver transplant patients. In a small study of 16 patients, cerivastatin and pravastatin decreased cholesterol by 21% and 15%, and LDLs by 27% and 17%, respectively [59]. Atorvastatin and ezetimibe have been shown to be safe in renal transplant patients [60,61]. One underlining concern has been the risk of myopathy with the use of statins and calcineurin inhibitors. This potential drug–drug interaction may theoretically be reduced with the use of pravastatin, which is not extensively metabolized by cytochrome P450 3A4 (CYP3A4). The usual starting doses of statins are simvastatin 40 mg/day, atorvastatin 40 mg/day, and pravastian 20 mg/day. The addition of fenofibrates and niacin for severe hypertriglycerides may be needed to reach target triglyceride goals.

Recommendations

- Patients should have an annual evaluation of total cholesterol, low-density lipoprotein, high-density lipoprotein, and triglyceride levels.
- Use NCEP III lipid guidelines for treatment.

Hypertension

Earlier hypertension studies within the first year noted hypertension ranging from 17% to 82% [62,63]. More recent studies using a standard definition of hypertension readings of greater than 140/85, reported that the incidence at 3 months was 82% in cyclosporine patients and 32% of tacrolimus patients; at 6 months 50% of patients were hypertensive [64]. In studies with longer follow-up, from 3 to 5 years after transplant, overall incidence was around 50%. Detailed analysis in the Rabkin et al. study noted 58% required a single antihypertensive agent, 29% required two agents, and 10% needed three agents [65]. Galioto et al. found that nifedipine was effective in only 22% of patients, whereas 33% of carvedilol-treated patients after liver transplant responded favorably [66]. In a large study, Neal et al. reported 46% of patients responded to amlodipine with a decrease in systolic blood pressure from 154 to 130 mmHg [67]. Those patients unresponsive or intolerant to amlodipine were randomized to bioprolol or lisinopril. Lisinopril was successful in 84% of patients, reducing the systolic blood pressure from 154 to 130 mmHg. Galioto and colleagues compared nifedipine (30–60 mg/day) and carvedilol (12.5–25 mg/day) in 50 patients post liver transplant for up to 1 year [68]. Monotherapy therapy was successful in 21% in nifedipine patients and 29% in carvedilol patients. Carvediol was better tolerated, and the addition of an angiotensin-converting enzyme (ACE) inhibitor increased response in 20% of the cases.

Recommendations

- The early treatment of hypertension incorporates the use of diuretics, clonidine, and calcium channel blockers followed by β-blockers and ACE inhibitors.
- The target blood pressure is <140/90 mmHg.
- ACE inhibitors, especially in patients with diabetes, are a good choice for the treatment of hypertension.

Diabetes

The incidence of new-onset diabetes mellitus (NODM) remains difficult to estimate due to discrepancies in diagnostic criteria and definitions in the post-transplant setting. However, a reasonable estimate would be around 25% within 3–6 months post transplant. Consensus guidelines on the definition of NODM after transplantation have been developed based on definitions from the American Diabetes Association, World Health Organization, and American College of Endocrinology [69]. Two recent comprehensive reviews detail this topic in detail [70,71].

Immunosuppressive medications are diabetogenic. Corticosteroids induce insulin resistance. Calcineurin inhibitors decrease insulin synthesis and secretion and induce insulin resistance [72]. Cyclosporine and tacrolimus appear to increase diabetic risk, although a systematic review of multiple studies noted a higher risk with tacrolimus [73]. Other immunosuppression medications including azathioprine, myophenolate mofetil, and sirolimus do not induce diabetes. In a large study comparing tacrolimus plus steroids to those receiving tacrolimus plus daclizumab (steroid free), the incidence of NODM was 15.3% versus 5.7% [74].

Several risk factors for the development of NODM after transplantation have been characterized: family history of diabetes, African-American or Hispanic race, age over 40 years, obesity, steroid-resistant rejection, hepatitis C, alcoholic cirrhosis, and male gender [71]. Hepatitis C is the leading indication for liver transplantation and, with its higher association of diabetes mellitus (both pre and post transplantation), a planned and concerted effort of management with immunosuppression and risk of accelerated fibrosis should be discussed.

An early study by John and Thuluvath from Johns Hopkins University found that 46/435 (10.5%) of post-transplant patients developed NODM, of which 18 patients were insulin dependent and 28 patients were treated by oral hypoglycemic medications [75]. Using the UNOS database, Yoo et al. found 7.6% were insulin-dependent diabetics and another 7.6% were noninsulin-dependent diabetics at 1 year after transplant [76]. A more recent study using the UNOS database from 2004 to 2008 reported an incidence of 26.4% NODM [77]. Independent predictors were age >50 years, African-American race, BMI >25 kg/m^2, donor age >60 years, diabetic donor, tacrolimus use, and steroid use at discharge. Conversely, Ahn and colleagues have shown that patients with younger age, longer time before development of NODM, non-hepatitis C virus (HCV) patients, and use of mycophenolate were factors that predicted reversal of NODM [78].

The overall impact of NODM on morbidity and mortality in liver transplantation recipients has had mixed results, but with longer follow-up a trend is developing toward worse outcomes. Khalili et al. reported that overall infectious episodes in the presence of diabetes were five-fold higher [79]. Higher morbidity in diabetic versus nondiabetic patients from cardiac (48% versus 24%), major infective (41% versus 25%), minor infections (28% versus 5%), neurologic (22% versus 9%), and neuropsychiatric (22% versus 6%) episodes were seen a Baltimore study [75]. A UNOS database study reported that 5-year patient survival was lower in patients with type 1 (insulin-dependent) diabetes compared with those without diabetes (63% versus 75%) [76]. Patients with diet-controlled diabetes had a minimally decreased 5-year survival compared with nondiabetics. Furthermore, patients with type 1 diabetes or coronary artery disease were 40% more likely to die within 5 years compared with those without these risk factors. In agreement, investigators

from Miami in a large single center study comfirmed that patients with sustained NODM had lower survival rates at 10 years (69% versus 78%) and higher rates of death due to infection (9.5% versus 4.3 %) [80]. Veldt et al. added further concerns by illustrating that patients with hepatitis C and insulin resistance post transplant had a significantly higher probability of developing advanced fibrosis [81].

Scant information is available on the proper treatment of NODM in liver transplant patients. One study reported dismal management with less than 40% being referred to endocrinology and only 15% of patients having glycosylated hemoglobin level monitoring. Of those receiving treatment for NODM, 39% were on insulin and 39% were on oral antiglycemia medications, and 21% on both [82]. There are no studies in the transplant setting that show that tight glycemic control reduces morbidity and mortality. NODM usually resembles type 2 diabetes mellitus, thus a management approach of lifestyle modifications (weight control, exercise, proper diabetic diet) are the first line of treatment. The second step is the use of oral antidiabetic drugs with normal renal and graft function. For those still in poor control, the final management step is long-term insulin use in consultation with a diabetologist, consideration of altering the calcineurin inhibitor, and a minimal or steroid-free regimen.

Recommendations

- Standard immunosuppression is associated with a higher risk of NODM.
- The management of patients who develop NODM is similar to recommendations for patients with type 2 diabetes.
- Those with a hemoglobin A1C level >6.5% should start treatment.
- The initial treatment is lifestyle modifications (exercise, weight loss) and education (dietary and natural history).
- If glycemic control is unsuccessful with dietary modification, the use of oral diabetic agents may be considered.
- Insulin should be used if blood glucose levels do not fall below 120 mg/dL before meals or <160 mg/dL after meals.
- A liberal use of endocrinology consultation is recommended for patients difficult to control with consideration of altered immunosuppression.

Bone disease

Osteoporosis is characterized by reduced bone mass and altered architecture, increasing the risk of fracture, typically in the spine, hip, rib, or wrist areas. Risk factors pre transplantation include cholestatic liver disease, alcoholic liver disease, lower body weight, and older age [83]. Within 6 months' post transplantation, bone loss reaches the nadir of bone mass index with gradual recovery over years. Guichelaar et al. reported a gradual improvement of osteoporosis with follow-up 8 years post transplant [84]. Fractures are common in the high-risk group, most commonly in the hip, pelvis, spine, ribs, and wrist with frequently reported risks ranging from 5% to 35% [85]. Hardinger et al. from St Louis followed 153 patients over 10 years [86]. The prevalence of symptomatic fractures was 15% at a mean of 2.2 years' post transplantation. The only factor associated with risk of fracture was being female. Age, time from transplant, race, menopause, renal insufficiency, family history of osteoporosis, bone mineral density (BMD), and T score did not predict either osteoporosis or fractures after liver transplantation.

Immunosuppressive medications are also thought to contribute to osteoporosis. Glucocorticoids increase bone resorption by the inhibition of osteoblast activity even at low doses of less than 7.5 mg per day. A histomorphometric analysis of 33 patients after liver transplantation by the Mayo Clinic suggested that patients with tacrolimus therapy have an earlier recovery of bone formation and trabecular structure by 4 months compared with cyclosporine-treated patients [87]. Secondary causes of osteoporosis are common in patients with end-stage liver disease. They include hyperparathyroidism, hypogonadism, smoking, loop diuretics, low dietary calcium, and vitamin D deficiency (<30 ng/mL).

Treatment of osteoporosis after liver transplant has usually been reported in small uncontrolled series. A randomized, multicenter, Austalian, double blind trial compared infusions of zoledronic acid 4 mg versus placebo given within 7 days of transplantation and at 1, 3, 6, and 9 months. At 12 months, the BMD percentage of change in the treatment groups was +2–4% from baseline [88]. In contrast in a study from Austria, the use of prophylactic treatment with alendoronate, calcium, and vitamin D prevented further bone loss in the first 4 months after liver transplant. Continued use lead to increased BMD during up to 48 months of study [89].

Two comprehensive reviews by Crippin and Compston provide excellent guidelines on the management of bone disease in liver transplant patients [90,91].

Recommendatons

- Pretransplant evaluation should be done with a dual-energy X-ray absorptionmetry (DEXA) bone scan and serum tests of calcium, phosphorous, parathyroid hormone, testosterone (men), estradiol (women), and 25-hydroxyvitamin D levels.
- All patients should be treated with 1500 mg of calcium per day and any deficiencies corrected.
- Vitamin D deficiency should be corrected to a serum 25-hydroxyvitamin D level of >30 ng/mL.

- If severe osteoporosis is noted by a T score >2 SD below normal, then consider starting oral bisphosphanates.
- Those under treatment for osteoporosis should have yearly DEXA scans, measurement of calcium, phosphorous, 25-hydroxyvitamin D levels, and a check of thyroid function.

Inflammatory bowel disease

Conflicting results have been published on the prevalence and severity of inflammatory bowel disease (IBD) after liver transplantation [92]. Differences may be attributed to variations in immunosuppression and/or maintenance IBD medications, duration of IBD, and length of follow-up. IBD can be either the exacerbation of preexisting disease or de novo disease. Haagsma et al., in a single center study, reported 36% of patients with pre-OLT IBD experienced excerbations at a median of 1 year after transplant [93]. Additionally, 11% of patients developed de novo IBD, with risks of 4% (3 years), 11% (5 years), and 14% (10 years) after transplantation. Interestingly, none of the patients were continued on IBD medications such as aminosalicylates. A study from Nebraska reviewed 40 patients with IBD [94]. Recurrence of IBD was seen in 65% of these patients post transplant with 16% having flares that responded poorly to medical management and required colectomy. De novo IBD developed in eight patients. Overall cumulative risk for IBD was 15%, 39%, and 54% at 1, 5, and 10 years post transplant. De novo IBD has been associated with CMV infection, CMV mismatch, and transplantation of autoimmune hepatitis. Risk factors for the exacerbation of preexisting IBD post transplantation include the use of tacrolimus, active disease at transplantation, a long duration of disease, and early discontinuation of steroids. Most transplant centers now continue specific IBD medications along with immunosupressants. From a different perspective, Dvorchik from Pittsburgh analyzed 303 patients to look at the risk of colectomy after transplantation in patients with inflammatory bowel disease [95]. Twenty-two patients (7%) had a colectomy due to refractory disease in follow-up to 12 years post transplant. Surprisingly, only OLT was the significant risk factor for colectomy (hazard ratio (HR), 3.1).

Patients with primary sclerosing cholangitis (PSC) and IBD may have an increased risk of developing colorectal cancer after liver transplantation. Vera et al. from Birmingham, UK studied 82 patients with PSC and IBD to identify risk factors for colorectal cancer [96]. Colorectal cancer developed in 9.6% of these patients with a mean interval between liver transplantation and cancer of 46 months (21–68 months). The cumulative risk of developing colorectal cancer was 14% and 17%, 5 and 10 years after transplantation. Multivariate analysis identified three variables significantly related to colorectal cancer: dysplasia post transplant, duration of colitis for more than 10 years, and pancolitis. When all three variables were present the risk of colorectal cancer was 100% within 5 years post transplant. Proctocolectomy and ileal pouch–anal anastomosis for severe ulcerative colitis after liver transplantation has been reported in several small case series with excellent outcomes, and a slightly higher rate of prouchitis [97].

Recommendations

- Maintenance use of IBD medications after transplantation (i.e., aminosalicylates) is recommended.
- Patients transplanted for PSC should have yearly colonoscopy with surveillance biopsies.
- If dysplasia is found, colectomy is warranted.

Renal dysfunction

The development of renal dysfunction is becoming more of a major problem after liver transplantation coupled with greater long-term patient survival. Renal dysfunction in relationship to liver transplantation was recently reviewed by a multidisciplined group [98]. Calcineurin inhibitor (CNI) medications (cyclosporine and tacrolimus) remain the cornerstone of immunosuppression in liver transplantation; however, they remain the principle cause of renal dysfunction. A decrease in glomeruloar filtration rate of 30–50% within 6 months after transplantation is commonly seen [99]. Renal biopsies in those with chronic renal failure (CRF) associated the CNIs demonstrate interstitial fibrosis, tubular atrophy, arterioloar hyalinosis and sclerosis, and collapse of the glomeruli.

The incidence of CRF and end-stage renal disease (ESRD) after liver transplantation has been variably described, likely due to differences in definition, method of measurement, and duration of follow-up. The most frequently cited early study, by Gonwa et al. from Dallas, studied 834 patients with a follow-up of up to 13 years after liver transplant using a definition of CRF of serum creatinine >2.5 mg/dL [100]. The incidence of ESRD gradually rose from 1.6% at year 1 to 3% at year 5 and 9.5% at year 13; the total incidence of severe renal dysfunction (CRF + ESRD) at year 13 was 18.1%. A significant difference in the development of CRF and ESRD was seen in patients with pretransplant hepatorenal syndrome (HRS) compared to those without (HRS group: CRF, 8%, ESRD, 11%; versus non-HRS group: CRF, 4%, ESRD, 4%). Postoperative 1-year, 3-month, and 4-week serum creatinine levels were predictive of CRF and ESRD. Additionally, a profound difference in survival

(27% versus 71%) was noted by year 6 after transplant in patients who developed ESRD on chronic hemodialysis compared with those who received a kidney transplant. The sentinel study by Ojo et al. using registry data of transplant recipients in the United States found a 5-year risk of chronic kidney disease (glomerular filtration rate (GFR), 15–29 mL/min/1.73 m^2) at 18% in liver transplant patients [101]. Risk factors associated with CRF included advanced age, female sex, pretransplantation hepatitis C infection, hypertension, diabetes mellitus, and postoperative acute renal failure. Those that developed CRF had a five-fold greater risk of death compared with those without CRF. This study concluded that an enormous financial burden of treatment of ESRD in this population is likely in the future, if not currently. Patients who proceed to liver transplantation with HRS present a complex decision regarding the potential of renal function recovery. Patient who have been on renal replacement for more than 8 weeks due to HRS prior to transplantation will likely benefit with a combined liver–kidney transplant for long-term survival [102]. This conclusion was validated in a study of renal replacement treatment (RRT) pre transplantation and long-term results [103]. Only 11% of patients with RRT for >90 days before the transplant recovered renal function, and for those who did not recover renal function their survival was only 38% at 1 year post transplant.

What can be done to reduce this risk of CRF in liver transplant recipients? Marotta described three strategies: reduction or withdrawal of CNIs by addition of an adjuvant agent, conversion of CNI to non-CNI therapy (sirolimus/everolimus + mycophenolate mofetil (MMF)), and lastly antibody induction with delayed CNI therapy [104]. A reduction of CNIs by up to 75% and the addition of MMF led to an improvement in GFR at 1 year from 59 to 64 mL/min in a recent study [105]. In a study comparing two immunosuppression groups – those started and continued on a CNI versus those started on a CNI in combination with MMF [106] – the decrease in GFR was less in the MMF group when compared with the CNI alone group (at 3 years: –15% versus –33%, respectively). Conversion from a CNI to everolimus (mTOR inhibitor) resulted in renal function improvement; however, side effects of hyperlipidemia and proteinuria were of concern [107]. Lastly, induction therapy with daclizumab and MMF followed by delayed administration up until the fifth day post transplantation with lower dose tacrolimus was studied in a mulicenter, prospective, randomized trial compared with groups given immunosuppression of tacrolimus and corticosteroids and MMF and reduced dose tacrolimus and corticosteroids. The estimated GFR decrease at 1 year post liver transplantation was –13.6 mL/min in the induction/delayed dose tacrolimus group versus –23.6 mL/min in the tacrolimus/corticosteroid group versus –21.2 mL/min in the MMF/reduced dose tacrolimus/corticosteroid group [108]. The optimum strategy to prevent or reduce renal dysfunction remains a difficult task in liver transplantation. New immunosuppression agents will have to be discovered as CNIs continue to be the leading cause of CRF. In the United States, the number of combined liver–kidney transplantations over the last 10 years has increased by 279% (from 100 to 379) [109]. The most likely reasons for the increase in kidney transplantation are acute renal failure and HRS associated with end-stage liver disease. Those with a combined liver–kidney transplantation had a survival of 85% at 1 year.

Recommendations

- Those with a known high risk of development of CRF should be considered for nontraditional immunosuppression and careful monitoring.
- Consider a CNI-free immunosuppression regimen for patients who develop renal insufficiency.
- If progressive renal dysfunction is seen, evaluation by ultrasound and consultation by nephrology is warranted.
- Kidney transplantation offers a significant survival difference compared to chronic dialysis. Therefore patients should be counseled regarding these differences.

Transplant-related diseases

Biliary complications

Biliary tract complications remain a common postoperative complication after liver transplantation and three excellent recent review articles discuss this topic in detail [110–112]. Liver transplantation is associated with postoperative biliary complications such as biliary strictures, leaks, sludge, stone casts, mucoceles, biloma, hemobilia, and sphincter of Oddi dysfunction [112]. Endoscopic or interventional radiologic treatment is now the standard of care, replacing initial management of bile duct complications with surgical revision. The two most common categories of biliary complications are strictures (anastomotic and nonanastomotic) and leaks (T tube, anastomotic, cut edge). In addition, stricture or leaks can be classified as early (<30 days) or late and they may be associated with hepatic artery thrombosis. Risk factors for the development of biliary complications after transplantation are shown in Box 45.2. Leaks may be associated with T-tube migration or T-tube removal. Poor healing of the choledochocholedochostomy anastomosis can also result in stricturing. The use of T tubes is rapidly declining. Living-related transplantation has been reported to double biliary complications due to the challenging technical

Box 45.2 Risk factors for biliary complications.

- Roux-en-Y anastomosis
- Ischemia/reperfusion
- T tube
- Duct mismatch size
- Cytomegalovirus infection
- Hepatic artery thrombosis
- ABO mismatch
- Non-heart-beating donor
- Primary sclerosing cholangitis
- Chronic ductopenic rejection
- Older age donor
- Prolonged cold ischemic time donor
- Prolonged warm ischemic time

reconstruction of either a Roux-en-Y hepaticojejunostomy or duct-to-duct anastomosis [110]. The challenge can be an inability to traverse the stricture, complex anastomosis, or sharp angulation or "crane neck" deformed bile ducts.

Patients typically present with elevations of serum aminotransferase, bilirubin, and alkaline phosphatase. Fevers, pruritus, and right upper abdominal pain are frequent symptoms. Diagnosis of biliary complication may be made by endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiogram (PTC), or more recently magnetic resonance cholangiopancreatograpy (MRCP). The Barcelona group verified in a group of 63 patients that MRCP made the correct diagnosis of biliary complication in 91% of patients with a sensitivity of 95% and positive predictive value of 97% [113]. However, with a high incidence of abnormal findings many physicians proceed directly to ERCP with PTC reserved for unsuccessful endoscopic cases.

Overall, biliary stricture rates of 4–15% are reported for deceased donor liver transplantation and in living related transplantation of up to 30% [112]. Anastomosis strictures most often require three to five endoscopic interventions with progressively larger dilatations/stents with long-term success rates of 70–100% in OLT, but with a 25% lower success rate in living related transplantation [112]. Nonanastomotic strictures are more difficult to treat than anastomositic strictures. Only 50–70% of patients have long-term success with dilatation and stent placement and require the use of PTC more often and have a higher risk of graft loss.

Leaks are equally common (4–11%), with anastomic or T-tube leaks occurring early after transplantation. Endoscopic cholangiography with biliary sphincterotomy and stent placement are universally used, with successful outcomes of over 90% [111].

Recommendations

- Diagnosis of biliary complication may be obtained by ERCP, PTC, or MRCP.
- Biliary strictures are treated with dilatation and the placement of progressively larger stents for longer periods (>6 months).
- Biliary leaks are treated with biliary stents (usually <6 weeks' duration).
- Living related donor transplantation biliary complications requires a multidiscipline team approach.

De novo malignancy

Transplant recipients are at risk for development of de novo malignancies due to multiple factors including etiology of liver disease, viral infection, inflammatory bowel disease, behavior, age, and immunosuppression exposure. The overall risk of malignancy is two to four times higher than an age- and sex-matched population [114]. Unfortunately, more than 30% of late deaths in liver transplant recipients are due to de novo malignancy [115]. The most frequently diagnosed cancers are non-melanoma skin cancer, post-transplant lymphoproliferative disease (Epstein–Barr virus (EBV) driven), colorectal cancer, lung cancer, oropharyngeal cancer, Kaposi sarcoma, and urologic tumors. Breast, cervical, and prostate cancers seem to have similar rates as found in the general population [115]. The relative risk of neoplasia in this patient population is illustrated in Table 45.1. Earlier studies showed that liver transplant recipients have a high rate of lymphoma occurrence. These are commonly EBV-driven lymphomas, predominately of B-cell origin. Higher risks of oropharyngeal and lung cancers are noted in patients transplanted for alcoholic cirrhosis and who smoke. Watt et al. have provided the most recent comprehensive study of long-term probability and mortality of de novo malignancy after

Table 45.1 Relative risks of de novo malignancy after liver transplantation.

Malignancy	Relative risk
Skin (basal/squamous)	20–70
Lymphoma	10–30
Kaposi sarcoma	100
Head and neck	4–7
Lung	1.5–2.5
Colorectal overall	3–12
Colorectal in ulcerative colitis	25–30
Kidney	5–30
Hepatocellular	3.5
Breast	1
Prostate	1
Cervical	1

transplantation using a multicenter dataset with greater than 10-year follow-up [116]. One hundred and seventy-one patients were studied, who developed 271 malignancies (147 skin, 92 solid organ, and 29 hematologic). Patients transplanted for primary sclerosing cholangitis (22% at 10 years) and alcoholic liver disease (18% at 10 years) had the highest risks. Risk factors for de novo malignancy were age by decade (HR, 1.33), history of smoking (HR, 1.6), PSC (HR, 2.5), and alcoholic liver disease (HR, 2.1). The long-term prognosis was extremely poor for solitary organ cancers, with death rates at 1 year of 40% and 55% at 5 years after diagnosis.

The role of immunosuppression influence on de novo malignancy remains uncertain. Antilymphocyte antiglobulin therapy increases lymphoproliferative disorders and azathiprine may increase cutaneous cancers. The risk of de novo cancers with newer immunosuppressant medications such as mycophenolate or rapamycin remains unknown, but may lower the risk due to its antiproliferative effects. However, Toso et al., using the Scientific Registry of Transplant Recipients, evaluated maintenance immunosuppression for at least 6 months comparing sirolimus versus CNI in patients transplanted for hepatocellular carcinoma [117]. Anti-CD25 antibody induction and sirolimus-based maintenance therapy was associated with higher survival due to lower hepatocellular carcinoma recurrence in this study.

Screening recommendation strategies have not been studied in this population and recommendations are inferred by screening of the general public. However, an alarming study reported only 40% of patients had dermatologic and oral examinations or mammograms within 2 years of transplant [118]. Eleven percent had a gynecologic examination in the follow-up period and only 50% had either sigmoidoscopy or colonoscopy.

Recommendations

- Patients should cease smoking and using alcohol.
- Similar screening protocols to those used in the general population should be utilized.
- There should be an annual examination for skin cancer and the use of sunscreen lotion of SP 50 or greater when exposed to sunlight.
- Mammograms and gynecological evaluation should be biannual for women.
- A yearly measurement of prostate-specific antigen in males more than 50 years of age is recommended
- Patients transplanted for alcoholic cirrhosis may benefit from an annual examination of the mouth and throat combined with a chest X-ray.
- Patients with inflammatory bowel disease must have annual colonoscopy with surveillance biopsies for dysplasia. Colonoscopy every 5–10 years for liver transplant recipients without inflammatory bowel disease is recommended.

Causes of mortality

The most comprehensive recent study evaluating the long-term causes of death was analyzed by Watt et al. noting a shift at more than 1 year post transplant: 28% hepatic, 22% malignancy, 11% cardiovascular, 9% infectious, and 6% renal related [119]. Risk factors for a higher risk of death beyond 1 year were age in decades (HR, 1.23), diabetes prior to liver transplant (HR, 1.48), renal dysfunction (HR, 3.59), cholangiocarcinoma (HR, 3.22), hepatocellular carcinoma (HR, 1.79), and retransplantation (HR, 4.79). This study illustrated the shift in hepatic- and renal-related deaths as main causes of late mortality. The authors proposed that diligent medical management of diabetes, hypertension, and renal insufficiency, treatment of viral hepatitis, and improved immunosuppression may impact long-term mortality.

In summary, with a longer survival of patients after transplant there are more frequent complications related to medical, immunosuppression, and surgical treatment of these patients. However, the quality of life appears to improve in the long-term survivor. Common complications secondary to the transplantation procedure include the development of de novo malignancy and metabolic syndrome (cardiovascular disease or diabetes) and these require annual evaluations and surveillance to prevent or lower the risk of morbidity or mortality. Renal dysfunction appears to be increasing with often dire consequences.

CHAPTER 46

The Liver Transplant Procedure

Bijan Eghtesad & John J. Fung
Department of General Surgery, The Cleveland Clinic, Cleveland, OH, USA

Key concepts

- The transplant operation has been standardized in the past 25 years. However, technical refinements continue to be introduced.
- The biliary anastomosis remains the Achilles heel of the recipient operation.
- Donor graft shortage remains a critical issue. Extended criteria donors have been increasingly utilized.
- Major complications after liver transplantation include: primary nonfunction, portal vein thrombosis, bleeding, hepatic artery thrombosis, and hepatic outflow obstruction.
- Biliary complications continue to be a major problem with an incidence of about 15–20%.

Orthotopic liver transplantation (LTX) has become an accepted means for the treatment of end-stage liver disease (ESLD). Although the technique of LTX has been refined to a relatively standardized approach, the operation still remains a formidable surgical challenge. As such, LTX is associated with numerous potential surgical complications, in which the recipient's pretransplant condition, anatomy, and diagnosis, as well as donor and immunologic factors, may all contribute. These risks can be minimized by fully appreciating anomalous anatomic variations, performing appropriate ABO matching, size matching of the donor liver to the recipient habitus, adequate maintenance of donor liver function, attention to organ procurement, and minimization of cold ischemic time. The purpose of this chapter is to review the operative procedure and to highlight some of the more important intraoperative and early and late postoperative complications.

Historical background

Although attempts at orthotopic liver transplantation were performed in large animals as early as 1956 [1], the technical aspects of the operation, including the critical need for portal-venous blood flow, were elucidated by Thomas Starzl in 1960 [2] prior to the first attempt at clinical LTX in 1963 [3]. The 3-year-old boy with biliary atresia ultimately died of hemorrhage and coagulopathy. This was followed by six more unsuccessful LTXs in Denver, Boston, and Paris [3–5]. The poor outcomes of the first human LTX attempts resulted in a moratorium that extended into the summer of 1967 when a child finally underwent successful LTX in Denver [6]. This was followed in 1968 by the opening of a LTX unit in Cambridge, United Kingdom by Roy Calne [7]. The first 33 LTX, of which 25 were performed in Denver and four in Cambridge, were later described in 1969 in a book entitled *Experience in Hepatic Transplantation* [8].

Terminology

Orthotopic LTX replaces the removed liver with the transplanted allograft liver in the anatomically correct position. Heterotopic LTX places the liver allograft in an extrahepatic site, usually at the root of the mesentery, but is of historical significance only due to poor outcomes. Auxiliary LTX is the placement of the donor liver in the presence of the native liver. Such transplants can be either orthotopic, after removal of part of the native liver, or heterotopic, with placement of a portion of the donor liver in a heterotopic position.

Segmental LTX places only a portion of the donor liver into the recipient – this utilizes a reduced size liver allograft, sometimes referred to as a "technical variant" liver allograft. The source of segmental grafts can be cadaveric, living donor, or both (in the case of dual donor segmental

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

transplants). In the case of cadaveric segments, the graft can be a split liver graft, where the cadaveric whole liver is reduced to one or two smaller grafts. In each case, the segmental allograft maintains its own venous drainage, portal-venous inflow, hepatic artery inflow, and biliary drainage. In practice, these structures must be partitioned in a way so as to maximize the likelihood of survival, but this entails added risk compared with a whole cadaveric graft. Living donor segmental LTX is similar to split livers in terms of technical issues and complications.

Donor considerations

As noted above, the source for donor organs can be from living donors or deceased donors. The nuances of options in both are complex; for example, living donor allografts can be segmental (as noted above) or whole grafts (in the case of a domino liver transplant). The options for sources of liver allografts will differ according to the age and size of the recipient, diagnosis, geographic location, waiting list size, and technical expertise. The use of a living donor segmental graft (living adult-to-child left lateral segment) for a pediatric recipient was first successfully reported by the transplant team from Brisbane, Australia in 1989 [9]. The adoption of this innovative approach, along with other technical variant livers, to addressing the organ shortage in the pediatric ESLD population has significantly reduced waiting list deaths in this historically high mortality while-waiting group with outcomes that match those of using whole pediatric grafts [10]. However, with the increasing mortality in adult candidates, the development of living adult-to-adult lobar donation has generated greater interest due to a potentially larger beneficiary pool. The principal concern is the demand for a larger volume of functional transplanted liver and the added technical skill and experience needed to minimize the substantially greater risk to the donor and recipient. Since the first report of an adult-to-adult living donor lobar liver transplant in Japan [11], an increasingly clearer assessment of the risk to the donor, using a standardized approach to the collection and categorization of complications, has been achieved.

In spite of dependence on the use of living donors in many parts of Asia, the overwhelming contribution of liver allografts in Europe and North and South America are from deceased donors. The majority of livers are from brain-dead donors (referred to as donation after brain death or DBD), although the use of classic, nonheart-beating donors (currently referred to as donation after cardiac death or DCD) is increasing. For DBD, following the declaration of death and consent for donation, careful management of donor physiologic parameters optimizes allograft function and thus recipient outcomes following LTX. The goal is to maintain adequate circulation, oxygenation, and metabolism prior to organ procurement [12]. This can be difficult in the face of cardiac instability, neurogenic shock, volatile intravascular fluid status, loss of the normal hormonal milieu, and depletion of high-energy stores for liver function.

As the number of waiting list patients exceeds the number of livers available for transplantation, the utilization of donors that in the past were not considered has been reassessed. An "expanded criteria donor" (ECD) is one in whom certain characteristics impart either real or perceived short- and/or long-term risks to the recipient. In particular, efforts have focused on identifying and defining ECDs [13]. Although there is no universally accepted definition of an ECD liver, the following is a brief list of some possible characteristics of an expanded criteria liver donor:

- A medical history of systemic malignancy in the donor, particularly lung, central nervous system, and melanoma.
- A predonation course of hemodynamic instability, reflected by high donor serum sodium and high levels of vasopressor use.
- Serologic and molecular evidence of active viral infection, e.g. rabies, West Nile virus.
- Evidence of less than optimal liver function prior to surgical recovery, including liver biopsy findings of steatosis.
- Adverse intraoperative recovery events, including iatrogenic surgical injury during procurement.
- Advanced donor age.
- Cause of death other than traumatic.

Donor operation

The key to successful LTX starts with the procurement of an optimally functioning donor liver allograft. In general, maximizing the number of organs procured and transplanted for each donor, while maintaining optimal function of those organs, is the goal to donor management and selection. Since wide exposure to the abdominal and thoracic organs is required, as well as access to the aorta and the provision of sufficient venous venting, a long midline incision, including median sternotomy, is generally preferred and allows for inspection of all organs that are to be procured (Fig. 46.1). The decision regarding the division of the vasculature should be decided prior to procurement and must be coordinated with the multi-organ donor team to prevent conflicts during the actual procedure.

As the basic principle of current organ preservation is as rapid as possible exsanguination and core cooling at the time of circulation cessation, early access to the

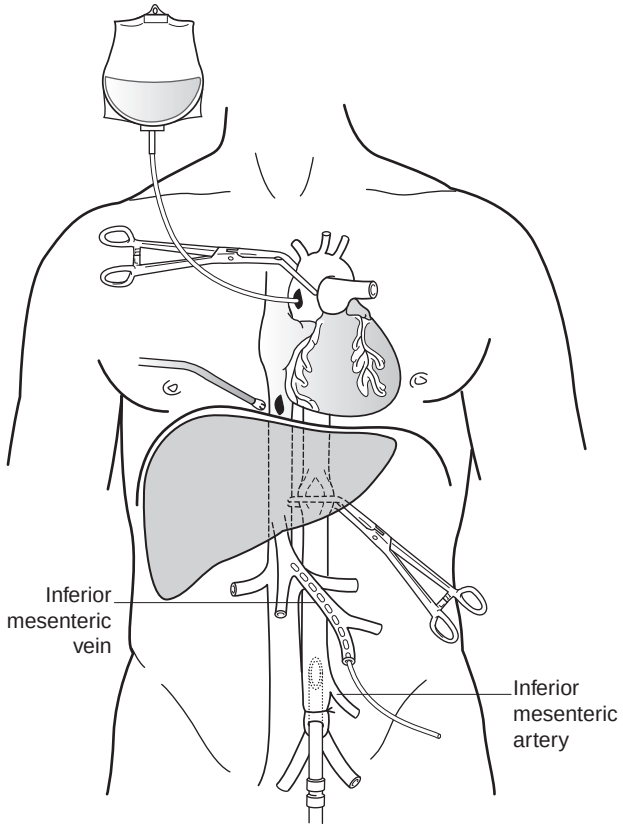

Figure 46.1 Classic multiorgan procurement in a DBD donor as described by Starzl et al. [14]. (Reproduced from Starzl et al. [14] with pemission from Elsevier.)

aorta (infrarenal aorta for abdominal organs and arch of the aorta for thoracic organs) is critical, particularly in an unstable patient or when immediate procurement is necessary. Simultaneously, preparing a site for venting of the venous blood and preservation solution can be achieved by preparing the vena cava for transection. The type of preservation solution has evolved, initially from lactated Ringer solution, to Collins solution, to University of Wisconsin solution (Viaspan®), to histidine-ketogluterate-tryptophan (Custodial®) and others, which has extended preservation times while maintaining optimal structural and metabolic functions of the liver. In addition, the practice of meticulous in vivo dissection has given way to more rapid techniques, designed to shorten the time in the operating room, reducing the risk of hemodynamic instability and bleeding and increasing the likelihood of multiorgan utilization. This is particularly important in situations where rapid exsanguination and core cooling is necessary in an uncontrolled fashion, e.g., DCD donors.

Once the liver is visualized and the decision is made to move forward with procurement, the liver is separated from its ligamentous attachments by division of the falciform, round, and triangular ligaments. At this point, the insertion of the diaphragmatic crux should be divided, exposing the celiac trunk and aorta. The aorta should be encircled at this point to allow for clamping to optimize flushing of abdominal organs. Care should be given before division of the hepatogastric ligament – inspection of the arterial supply of the liver can be performed at this time, paying close attention to anatomic variants, such as an accessory or aberrant right hepatic artery from the superior mesenteric artery (10% incidence) or an accessory left hepatic artery from the left gastric artery (13% incidence). In addition, after identification of the gastroduodenal artery, a trial clamp should be performed before division, in the event that there is significant celiac stenosis due to atherosclerotic disease or from median arcuate ligament syndrome, in which case the gastroduodenal artery should not be transected until aortic perfusion is completed. The gallbladder is incised and irrigated and the distal common bile duct is transected close to the pancreatic head. The aorta is encircled above the iliac artery bifurcation and cannulated. Some centers will choose to cannulate the inferior mesenteric vein at this point for simultaneous portal-venous perfusion. At this point, the liver is ready for exsanguination. Shortly before infusion of preservation solution, a dose of 300–500 U/kg of heparin should be given intravenously. Immediately before the infusion of preservation solution, the aorta at the diaphragmatic crux should be clamped and cold preservation solution infused under some pressure. The vena cava should be transected, either through an incision in the abdominal vena cava or immediately above the diaphragm (depending on whether thoracic organs are to be procured or not). If the heart is to be procured, cardioplegia infusion is started simultaneously. Ice-cold saline slush, prepared earlier, is then used topically to cool the organs in situ. After the allotted amount of preservation solution is used, the organs are then removed in order of heart, lungs, liver/pancreas/intestine, and finally kidneys. The organs are then placed into separate basins and further divided, characterized, and bagged for transport. It is usual practice to send a segment of donor iliac or carotid artery and donor iliac vein, in case of the need for alternative revascularization (see below).

Recipient operation

The technique of LTX has been progressively refined since its introduction in humans in 1963, with several variations that are applied selectively according to the patient's specific situation and/or the transplant center's routine practice. The initially described conventional LTX involves resection of the recipient native liver (hepatectomy) along with the retrohepatic inferior vena cava (IVC) and a short

anhepatic phase, followed by the implantation of a whole deceased donor liver graft with the interposed donor IVC. Restoration of venous continuity during the implantation is achieved by an upper subdiaphragmatic and a lower suprarenal end-to-end donor-to-recipient IVC anastomosis. The donor-to-recipient portal vein and hepatic artery anastomoses are also performed in an end-to-end fashion. The biliary continuity is reestablished using either a primary duct-to-duct technique or the performance of a hepaticojejunostomy.

Hepatectomy

The "standard incision" for LTX has historically been a bilateral subcostal incision with an upper midline extension to the xiphoid (sometimes called an inverted Y or Mercedes incision) (Fig. 46.2). Other incisions have been used, however the principle in determining the type of incision is to gain adequate exposure to the liver and to other intra-abdominal structures, such as the infrarenal aorta, should the need arise. The type of incision is of paramount importance and choosing the wrong incision can make the operation difficult. The presence of previous incisions may require modifications to the planned incision in order to avoid flap necrosis from devascularization. In the case of preceding surgery in the LTX recipient, particular attention must be paid upon entering the abdominal cavity, as the presence of vascular adhesions can lead to both significant blood loss and/or violation of the gastrointestinal tract.

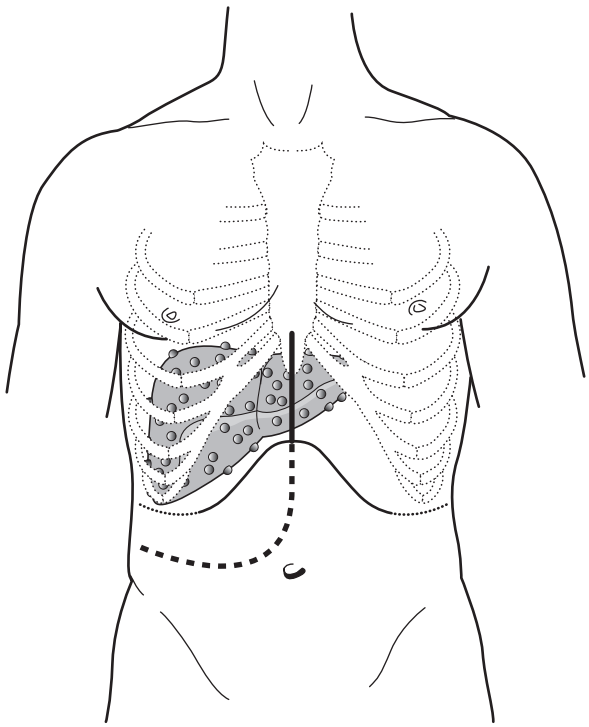

Figure 46.2 Types of incisions utilized in liver transplantation, classically utilizing a bilateral subcostal incision with an upper midline incision. Alternatively, a bilateral subcostal incision without an upper midline incision, or right subcostal with an upper midline extension, can be utilized.

Usually, the hepatectomy is the most difficult part the LTX procedure. Consequently, technical misadventures during this phase of the operation may result in significant complications. This is particularly true during the hepatectomy in patients with previous upper abdominal surgery. Excessive bleeding is the most common complication. This can be the result of carelessness, massive portal hypertension, and the presence of unusual collaterals (especially in the presence of portal vein thrombosis) and/or vascularized adhesions. Deliberate, methodic, and bloodless dissection translates to a much smoother operation and, ironically, a considerably shorter total case time. It is particularly difficult to perform surgical hemostasis once the allograft is in place, especially if there is any degree of post-reperfusion coagulopathy and if the graft is relatively large compared with the recipient abdominal compartment. In addition, early portal decompression with the veno-venous by-pass (see below) may aid in reducing the risk of massive bleeding.

Careful dissection of the hilum of the liver is critical during the hepatectomy. This is true especially in case of hepatectomy for segmental LTX, in cases of previous surgical procedures in the hilum of the liver, and in cases where there are anatomic variants. The goal in hepatectomy is preservation of the hilar structures, especially the hepatic artery and portal vein needed to revascularize the new liver allograft, as well as preservation of a sufficient length of the common bile and hepatic ducts for biliary reconstruction. Approaches to the hilum can commence either from the right side with dissection of the cystic duct and common bile duct or from the left with dissection of the hepatic artery. After identification of the common bile duct, it is good practice to preserve the surrounding soft tissue so as not to cause damage to the bile duct blood supply (Fig. 46.3). This is important to prevent postoperative bile duct ischemia and necrosis or stricture formation. An important technical issue in dissection of the hepatic artery is to start dissection of the artery at the level of the right and left branches and to proceed to the confluence and then to the gastroduodenal artery, and finally to the common hepatic artery. The surgeon should avoid too much traction of the artery to prevent intimal dissection in the artery, which can predispose the artery to postoperative thrombosis. Dissection of the branches of the common hepatic artery will allow the surgeon to select which part of the artery will provide a better size match with the donor hepatic artery. In addition, recognition of variations in the recipient anatomy of the hepatic artery is

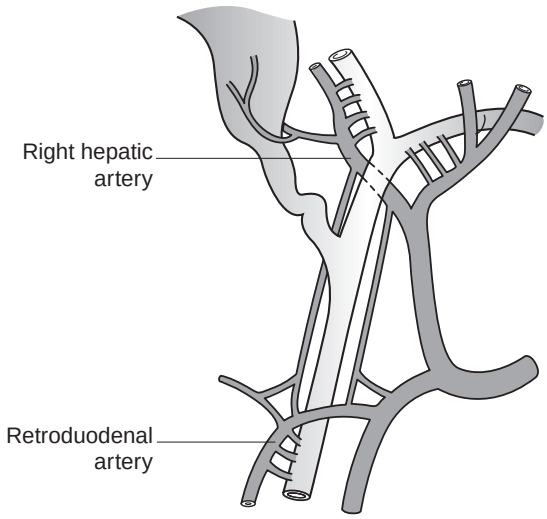

Figure 46.3 Blood supply of the biliary system. The unique nature of the blood supply for the bile duct depends solely on a hepatic artery blood supply via a vascular plexus to assure bile duct viability.

helpful to prevent the possibility of damage to the artery at the time of dissection.

Portal vein dissection is usually done after division of the hepatic artery and bile duct. All the soft tissue around the portal vein should be dissected and removed from the hilar plate to the level of the head of the pancreas. The avulsion of small pancreatic branches entering the portal vein or injury to the left gastric vein can cause massive bleeding in light of portal hypertension.

A potentially serious complication during hepatectomy is injury to the right adrenal gland, which results in severe bleeding, that is difficult to control and may require adrenalectomy. Another feared complication is injury to the right renal vein during mobilization of the infrahepatic vena cava. Dissection of the vena cava at too low a level must be avoided. Injury of the suprahepatic vena cava is an uncommon but potentially disastrous complication. Rarely, injury of the suprahepatic vena cava, with a resulting cuff that is too short, in patients with Budd–Chiari syndrome or in patients undergoing liver retransplantation in the face of a previous suprahepatic vena caval stenosis, may require control of the vena cava at the level of the diaphragm or within the pericardium. This allows placement of the vascular clamp close to or at the level of the right heart atrium. If necessary, the suprahepatic vena cava may need to be sutured closed, and venous outflow of the hepatic allograft may require a caval–atrial anastomosis.

Another potential complication is injury to the right phrenic nerve. This occurs when an excessive amount of diaphragm is included in the suprahepatic vascular clamp, particularly in the pediatric patient. This injury is usually reversible, but on occasion it can lead to permanent paralysis of the right hemidiaphragm. In addition, excessive diathermy to the right diaphragm may lead to necrosis and subsequently a diaphragmatic hernia.

Anhepatic phase

During classic LTX simultaneous complete occlusion of the recipient IVC and portal vein can lead to hemodynamic instability (Fig. 46.4). As a result, veno-venous by-pass was developed to allow diversion of blood from the recipient IVC and portal vein directly to the patient's superior vena cava during the anhepatic phase, using heparin-bonded cannulae and a motor-driven by-pass system (Fig. 46.5) [14]. Veno-venous by-pass can be used either routinely or selectively in patients showing hemodynamic instability after a trial of clamping the IVC and portal vein, prior to the total removal of the recipient liver [15,16]. Advantages of veno-venous by-pass include the following:

- The avoidance of cardiovascular instability resulting from reduced venous return to the heart during venous cross-clamping, particularly in patients with acute liver failure or in patients with noncirrhotic indications for LTX who have not developed portosystemic venous collaterals.
- The reduction of blood loss due to decompression of the portal circulation, minimizing transfusion and volume requirements.

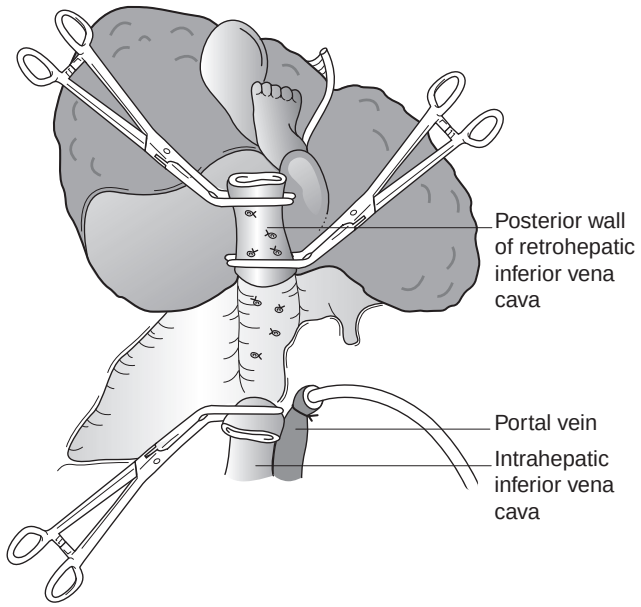

Figure 46.4 Requirement for infrahepatic vena cava and portal vein clamping during classic standard liver transplantation. In this case a veno-venous by-pass is being utilized, as evidenced by the portal-venous cannulae in place to decompress the mesenteric venous system.

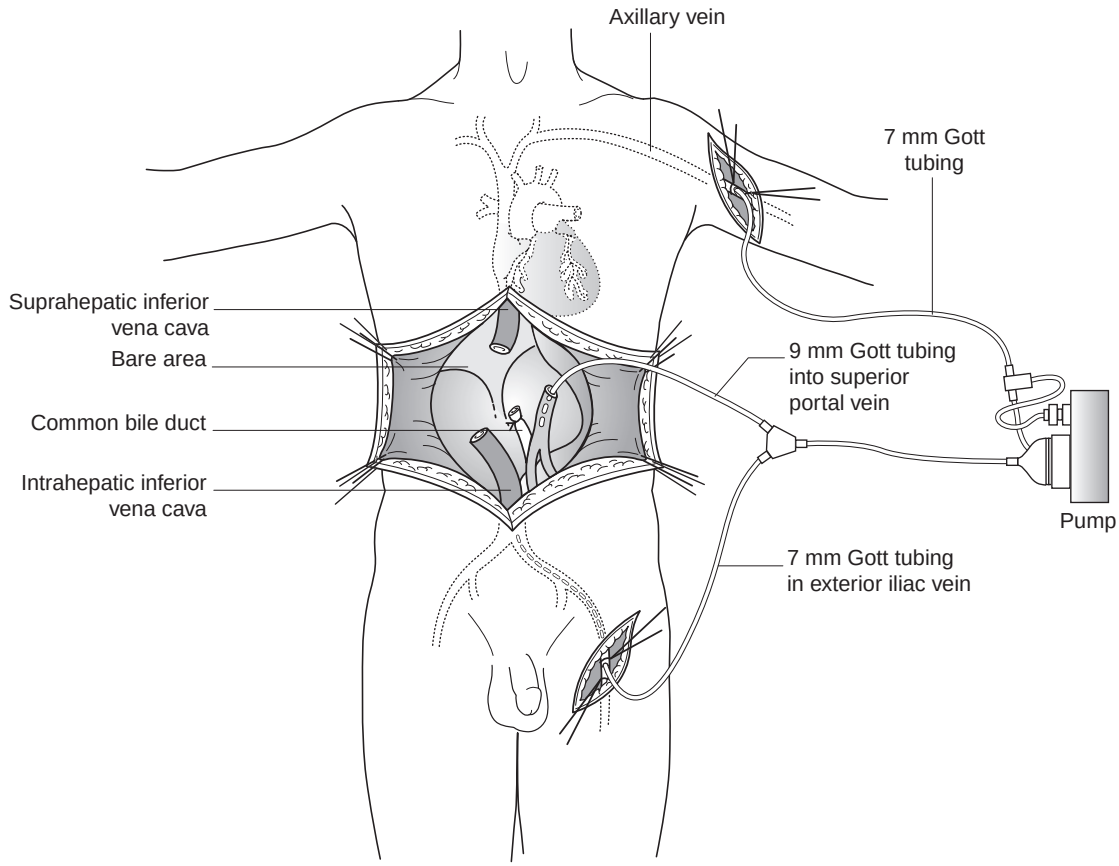

Figure 46.5 Veno-venous by-pass in liver transplantation, shown in the anhepatic phase with removal of the recipient vena cava, using the right axillary vein as the inflow. Alternatively, the by-pass may utilize percutaneously placed cannulae through the femoral vein and jugular vein.

- The avoidance of mesenteric stasis and bowel edema, and the subsequent development and release of anaerobic metabolic products and bacterial translocation into the circulation after reperfusion.
- The protection of renal function by avoiding renal-venous hypertension with a reduction of renal perfusion.
- Decompression of the portal system pressures and the avoidance of hemodynamic instability, thus allowing a safe prolongation of the anhepatic phase. This allows meticulous hemostasis and any necessary dissection as well as facilitating the correction of any complications arising during this phase of the operation.

Another advantage of the veno-venous by-pass is to allow a methodic approach to teaching trainees the complex procedure of LTX. However, the veno-venous by-pass can cause complications, some of them fatal. Complications associated with veno-venous by-pass have been described as occurring in 10–30% of cases [17–19]. These include seroma at the site of cannulae insertion, hematoma, wound infection, deep venous thrombosis, and nerve injury. The most frequent complications are wound lymphocoeles, both in the inguinal and axillary incisions. They can be avoided by careful dissection and ligation of all lymphatics. Lymphocoeles are usually self-limiting and self-healing, but occasionally chronic lymphorrhea can be quite disabling and requires surgical correction. Newer approaches to percutaneous cannulation of the femoral vein and internal jugular vein may obviate wound complications associated with cutdowns [20], however the risk of hematoma formation or venous perforation exists with these techniques. Mortality has also been described with an air embolus at the time of decannulation as well as intracircuit clots and a subsequent pulmonary embolus, the latter having occurred mainly when nonheparin-bonded tubing was used [21].

Over the past two decades there has been a trend towards avoiding the use of veno-venous by-pass, with an increasing number of transplant surgeons questioning its need [22,23]. This is due in part to the improved intraoperative hemodynamic management of the patient by the anesthesiology team and in part to the improved technical skills of the surgeons. The preservation of the entire retrohepatic vena cava and anastomosis of the new liver to a cuff formed from one or more of the main suprahepatic veins, has been advocated as a method of

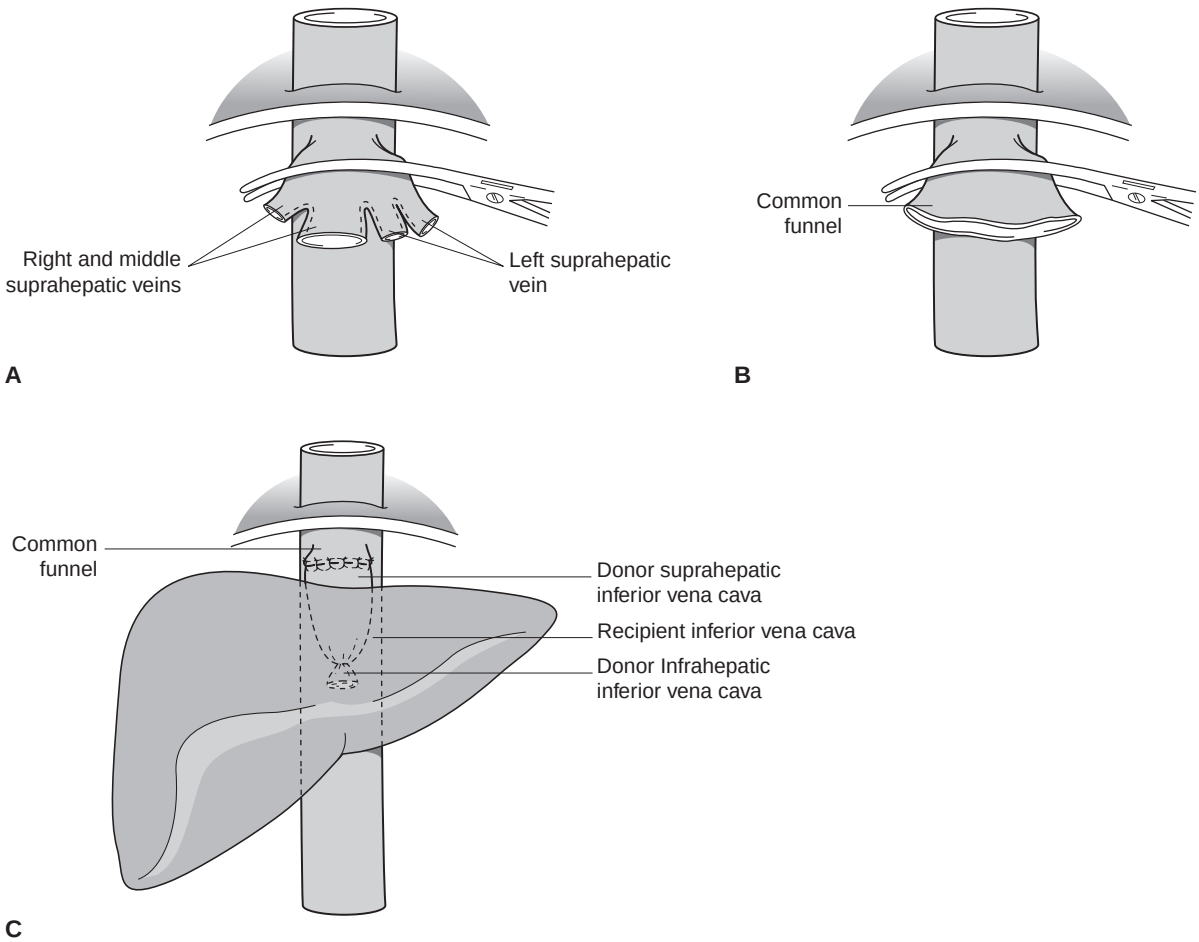

Figure 46.6 Piggyback method of recipient hepatectomy preserving the intrahepatic vena cava for liver allograft implantation utilizing end-to-side cavo-hepatic venous anastomosis. A. Following removal of liver with origins of individual hepatic veins; B. creating a common orifice by dividing the septa between individual hepatic veins; C. end-to-side cavo-cavostomy using suprahepatic vena cava of donor to common funnel orifice of recipient hepatic veins.

avoiding veno-venous by-pass. The advantages of preserving the vena cava can be significant, but this technique (also known as the "piggyback technique") requires additional skills and complete knowledge of and confidence with standard LTX with veno-venous by-pass [24]. Essentially, the technique consists of the dissection of the caudate process and right lobe of the liver from the retrohepatic vena cava, until only the right, middle, and left hepatic veins remain. Subsequently, the major hepatic veins are clamped and interconnected, thus forming a cuff that can then be anastomosed to the suprahepatic vena cava of the donor liver, in an end-to-side fashion (Fig. 46.6). After flushing the liver to clear the preserving solution, the infrahepatic cava of the allograft can be simply ligated. The new liver will then lie on top of the recipient's vena cava, but can also result in compression of the recipient's vena cava with the development of thrombosis [25,26].

There are several potential advantages of the piggyback technique, including less bleeding, less chance of adrenal gland and renal vein injury, shortening the anhepatic phase by eliminating the lower caval anastomosis, protection of the renal-venous outflow and function, and potentially less hemodynamic instability. In this situation, if portal cross-clamping in the patient with existing portal hypertension is well tolerated, it may be appropriate not to utilize a veno-venous by-pass. There have been many modifications to the caval-preserving methods used in different conditions and indications at the time of transplantation. The essential part of all these methods is to preserve the inferior vena cava with or without the use of veno-venous by-pass. In cases without preexisting portal hypertension (e.g., fulminant hepatitis), a temporary portacaval shunt can be fashioned during the initiation of the anhepatic phase to achieve mesenteric vein decompression without veno-venous by-pass (Fig. 46.7) [27]. In addition, modifications to implantation, using a side-to-side cavo-cavostomy, either handsewn [28,29] or by stapler [30], have been described.

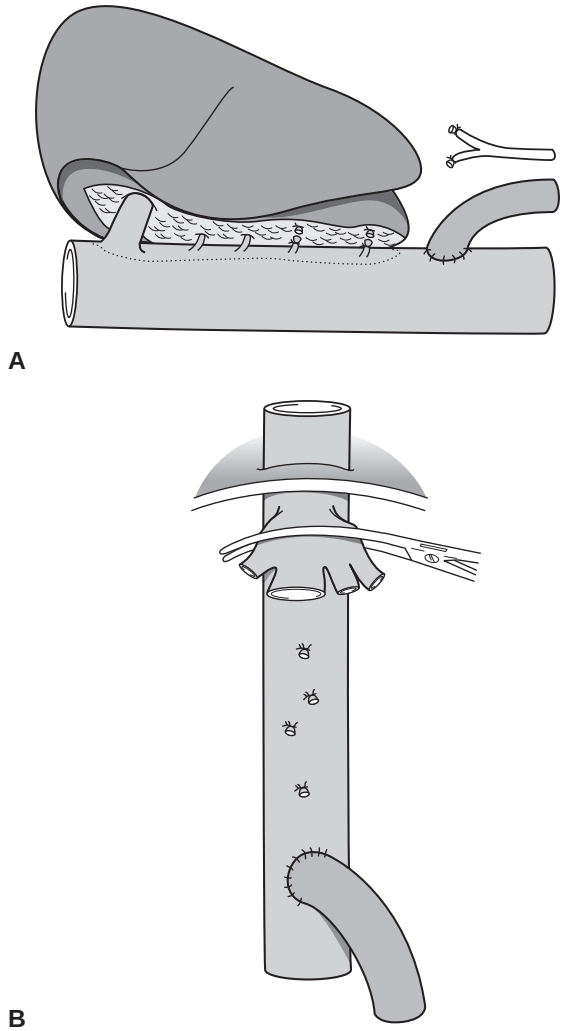

Figure 46.7 Use of a temporary portacaval shunt with piggyback vena cava preservation. A. Lateral view of portocaval shunt prior to mobilization of liver from short hepatic veins; B. frontal illustration of recipient inferior vena cava with portocaval shunt after removal of liver.

It is important to take advantage of the anhepatic phase and perform a thorough hemostasis of the operative area. At times, after the implantation of the new liver, there is not enough exposure to get a good hemostasis in the retrohepatic space. This is especially true in cases when the allograft is large and difficult to mobilize.

Implantation

Implantation of the new liver consists of several vascular anastomoses, reperfusion of the liver with the recipient blood, and biliary reconstruction. The conventional method of implanting the new liver consists of end-to end anastomoses of the supra- and infrahepatic vena cava of the donor liver to the corresponding vena caval cuffs in the recipient, followed by end-to-end anastomosis of the portal vein of the donor liver to the recipient portal vein. Usually, after completion of these anastomoses, the liver is reperfused with the recipient's blood and the clamps are removed and the recipient's venous circulation is reestablished through the new liver. Reperfusion of the liver can be one of the more unstable parts of the procedure. This is mainly due to the potential risk of cardiac arrhythmias, hypotension, and pulmonary edema secondary to the release of effluent from the liver allograft, which contains relatively high concentrations of potassium, necrotic debris, and cytokines, into the circulation. The use of preservative solutions with a high potassium content, such as the University of Wisconsin solution, and the use of livers from expanded criteria donors or livers with a prolonged cold ischemia time can exaggerate the magnitude of these complications. To potentially lessen or prevent these problems many surgeons flush the liver with lactated Ringer solution, 5% albumin, or recipient portal blood before full reperfusion.

In describing the surgical techniques involved in LTX, variations in the approach to recipients with preexisting underlying portal vein thrombosis should be mentioned. The incidence of portal vein thrombosis in patients with cirrhosis has been reported to vary between 0.6% and 64.1% depending upon the diagnostic study used and on patient selection [31,32]. The presence of portal vein thrombosis was previously considered a relative contraindication for LTX, a viewpoint that has since changed. Therapeutic options in the approach during LTX to preexisting portal vein thrombosis include eversion thromboendartectomy of the recipient portal vein (Fig. 46.8), the use of either interposition or jump venous grafts between the donor portal vein and the recipient portal or superior mesenteric vein (Fig. 46.9), cavoportal hemitransposition [33], anastomosis of the donor portal vein to an alternative recipient vein or venous collateral, and rarely arterialization of the portal vein [34]. Cavoportal hemitransposition is an option utilized when extensive thrombosis of the recipient portomesenteric venous system is present and its use is rarely indicated [35].

Arterial anastomosis between the donor and recipient arteries is usually end-to-end and the site usually varies depending on the arterial anatomy of the donor and recipient and the surgeon's preference. One must recognize that patients with an anomalous hepatic arterial anatomy may not have a large enough common hepatic artery to use as inflow. Patients with celiac axis stenosis may also have inadequate inflow. The median arcuate ligament syndrome has been described as affecting arterial inflow in LTX [36]. In these circumstances, the use of a donor iliac arterial conduit from the infrarenal (Fig. 46.10) (or occasionally supraceliac) (Fig. 46.11) aorta to the allograft may be necessary. Artificial conduits, e.g., polytetrafluoroethylene (PTFE) (Gortex®) grafts, should be avoided due to the risk of thrombosis and infection.

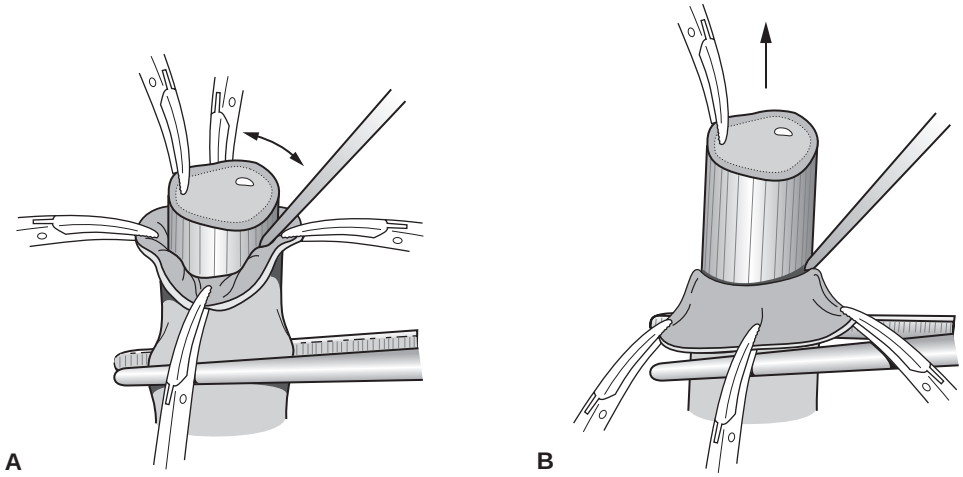

Figure 46.8 Eversion portal-venous thromboendarterectomy to reestablish the blood flow in portal vein thrombosis.

The biliary anastomosis has been referred to as the "Achilles heel" of the LTX operation [37]. There are currently two commonly practised biliary reconstructions after LTX. The most common is the choledochocholedochostomy (duct-to-duct anastomosis) and the other is the choledochojejunostomy (to a Roux-en-Y defunctionalized intestinal loop) (Fig. 46.12). The duct-to-duct anastomosis is usually done over a T tube, which remains as a stent in the duct for a few months (Fig. 46.12, insert). The advantages of leaving a T tube are the ability to quantify and characterize bile production as an early sign of hepatic allograft function; and to provide ready cholangiographic access to the biliary system in cases of abnormal liver function tests to rule out biliary problems. The disadvantage of the T tube is the risk of bile leak after removal of the tube, requiring emergent endoscopic retrograde cholangiopancreatography (ERCP) and decompression of the duct. Recently some transplant surgeons have questioned the need for a T tube in duct-to-duct anastomosis [38–40]. The use of stents in Roux-en-Y choledochojejunostomy is also a matter of controversy and some surgeons have stopped using them because of complications such as retention of the stent and obstruction of the biliary system. Other "historic" types

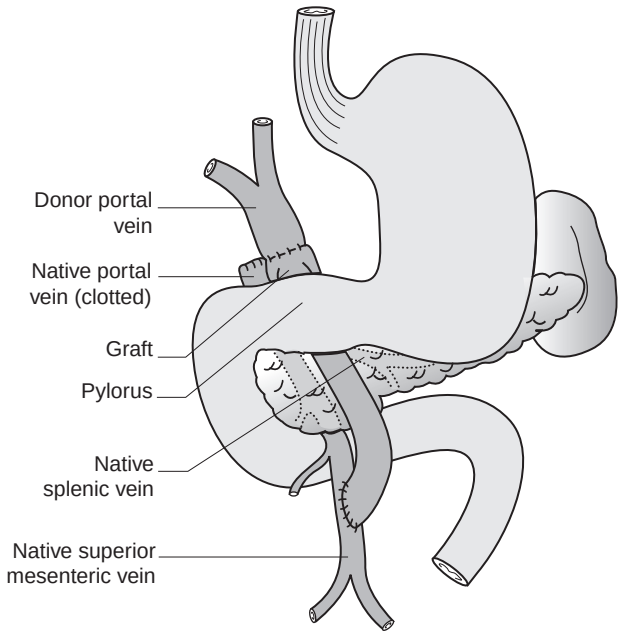

Figure 46.9 Use of an interposition vein graft from the recipient's superior mesenteric vein to the allograft portal vein in the setting of portal vein thrombosis.

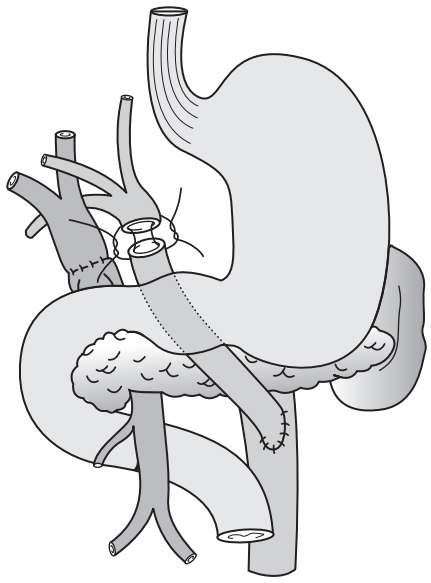

Figure 46.10 Use of an interposition arterial graft from the infrarenal aorta to the allograft hepatic artery in the setting of inadequate recipient hepatic artery inflow.

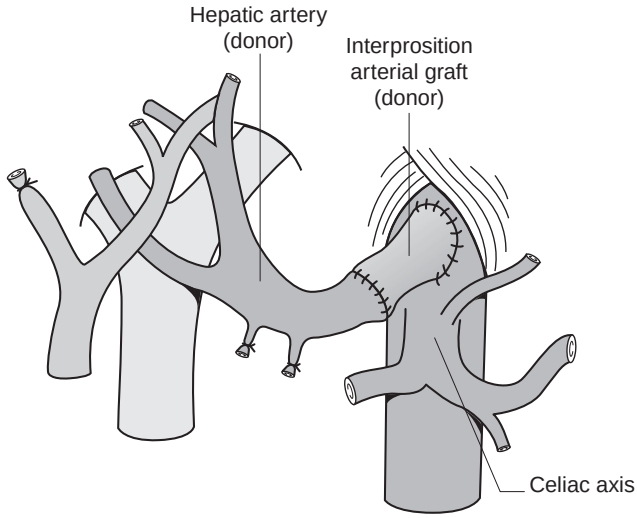

Figure 46.11 Use of an interposition arterial graft from the supraceliac aorta to the allograft hepatic artery in the setting of inadequate recipient hepatic artery inflow.

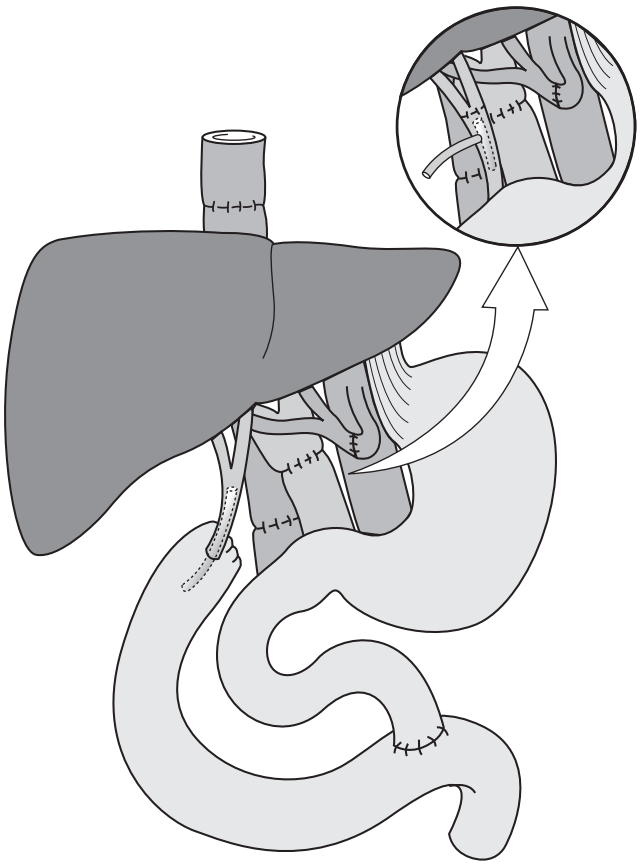

Figure 46.12 Options for establishing biliary continuity using a hepaticojejunostomy over a temporary indwelling biliary stent or alternatively a primary duct-to-duct technique over a T tube (insert).

of biliary reconstructions include choledochoduodenostomy and the now defunct cholecystoduodenostomy (the "Wadell–Calne" biliary reconstruction) [37].

Complications

Complications after LTX have a significant impact on outcome and cost of the procedure. The postoperative course in patients can range from straightforward to extremely complicated, and the outcome depends on the status of the recipient, the donor organ, and technical issues in the operation. Timely diagnosis of alterations in the normal postoperative course is the critical factor to minimize morbidity and mortality and to have a better outcome.

Primary nonfunction

Primary nonfunction (PNF) is characterized by encephalopathy, coagulopathy, minimal bile output, and progressive renal and multisystem failure with increasing serum lactate levels and rapidly rising liver enzymes and histologic evidence of hepatocyte necrosis in the absence of any vascular complications. With better donor management and selection, improved operative techniques, and newer preservation solutions, the risk of PNF has decreased but still occurs in somewhere between 4% and 6% of LTX procedures. Various donor risk factors can be implicated in primary graft dysfunction; these include prolonged cold ischemia time, an unstable donor, high level of steatosis in the liver allograft, older donor, high serum sodium level in the donor, preformed lymphocytotoxic antibodies, ABO incompatibility, and recovered organs from DCD donors. Patients with initial dysfunction may recover with support but those who progress to show evidence of extrahepatic complications such as hemodynamic instability, renal failure, or other organ system dysfunction may require urgent retransplantation [41–43].

Hepatic artery stenosis/thrombosis

Angiographic evidence of a greater than 50% reduction in the caliber of the lumen of the hepatic artery is defined as hepatic artery stenosis. This occurs in about 5% of cases after LTX. Clinically, these patients may show an increase in liver numbers or no sign at all. Sonographically, the presence of a low resistive index of less than 0.5 with an increase in focal peak velocity is suggestive of the pathology [44–46]. The detection of hepatic artery stenosis early after LTX can usually be managed by surgical intervention, when the risk for anastomotic disruption by angioplasty is highest [47]. Percutaneous angioplasty is generally reserved for stenosis occurring several weeks after the transplant procedure with an over 90% success rate [48,49].

Intimal dissection of the artery can result from too vigorous manipulation during surgery, either in the donor or the recipient, or from direct trauma to the artery from too forceful clamping. If not recognized early, intimal flaps will lead to arterial thrombosis. Complete thrombosis of the hepatic artery (HAT) is usually more symptomatic and dramatic when it occurs early in the post-transplant period and it occurs more often in adults than in children. It can lead to acute, massive necrosis, the formation of a central biloma secondary to intrahepatic duct necrosis, multiple biliary structures, or intermittent bacteremia [50–52]. Occasionally, rarely in adults but more often in children, HAT can be asymptomatic. The factors that determine whether a liver fails or survives in the face of complete HAT are not known, however the presence of collateral circulation (e.g., from the phrenic artery via vascularized adhesions to the liver) is usually associated with a more benign course after HAT. Segmental or lobar HAT has also been described. Left HAT (usually associated with an injury to an unrecognized anomalous left hepatic artery arising from the left gastric artery) is generally benign. However, right HAT (usually associated with an injury to an unrecognized anomalous right hepatic artery arising from the superior mesenteric artery, or from technically imperfect reconstruction of the anomalous right hepatic artery at the back table) is associated with the development of biliary strictures, due to the dependence of biliary viability on hepatic artery blood flow. Angiography is the gold standard for diagnosis, and in the case of early documentation of HAT urgent revascularization may result in restoration of arterial patency [47,53,54]. However, a significant number of patients treated in this manner may still require retransplantation due to biliary complications and persistent biliary sepsis [55,56].

Portal vein stenosis/thrombosis

Portal vein strictures can present shortly after LTX characterized by an increased production of ascites and liver allograft dysfunction. Ultrasonography and computed tomography (CT) angiography are usually diagnostic, while superior mesenteric artery angiography with late films is the confirmatory test [57]. Treatment is by surgical intervention in early post transplantation and by percutaneous transhepatic dilatation or stenting of the stricture later after LTX. If left untreated, it can progress to complete thrombosis of the vein or severe graft dysfunction and hemodynamic instability secondary to a massive production of ascites.

Portal vein thrombosis is an uncommon but significant complication after adult LTX, but is more common following pediatric LTX. It can manifest by rapid graft dysfunction with production of massive ascites. The differential diagnosis of portal-venous insufficiency includes technical errors such as kinking or redundancy of the vein, poor mesenteric flow secondary to the open collateral venous system (steal syndrome), and anastomotic stricture or twist. Treatment is immediate surgical revascularization of the graft by thrombectomy and correction of the technical problem, ligation of large collaterals in the portal-venous system, by-pass grafting via the superior mesenteric vein, or percutaneous portal vein stenting. Otherwise, retransplantation may be the only therapeutic option.

Hepatic outflow obstruction

Complications associated with vena cava stenosis include a 2.5–6% incidence of venous outflow obstruction (iatrogenic Budd–Chiari syndrome), caused by either rotation of the liver graft or anastomotic stricture [58]. Stenosis of the suprahepatic cava anastomosis can present with hepatic outflow obstruction in the form of liver allograft dysfunction, ascites formation, and impairment of renal function. The problem carries a high risk for morbidity and mortality. Although hepatic outflow obstruction occurs following both standard and piggyback techniques, it is more common with the piggyback procedure. One study showed a reduction in the incidence of venous outflow obstruction from 6% to 1% when the caval anastomosis was performed using the termination of the three native hepatic veins rather than only two hepatic veins [26]. Others have adapted a side-to-side cavo-cavoplasty in order to reduce the risk of stenosis [25,26].

Diagnosis can be made by cavagram and measurements of the venous pressure gradients proximal and distal to the anastomosis. Treatment options are by angioplasty, stent placement, or surgical correction of the strictured area [59–61]. Anastomosis between the infrahepatic donor cava and the recipient cava with the piggyback technique can decompress the liver in patients with outflow obstruction secondary to anastomotic narrowing between the suprahepatic donor cava and the confluence of the hepatic vein in the recipient [62]. When all these measures fail, retransplantation may be the only option.

Biliary complications

Biliary complications continue to be a major problem after LTX with an overall incidence of about 15–20% [63–65]. These complications range from early anastomotic leak to late stricture and obstruction, both in the extrahepatic or intrahepatic biliary system. The associated mortality rate with biliary complications is about 10% and this is mainly due to delays in diagnosis or misdiagnosis of the problem and secondary infectious complications and graft dysfunction [66]. The biochemical abnormalities with elevation of bilirubin and canalicular enzymes (alkaline phosphatase and γ-glutamyltransferase) are not specific. These indicators of biliary obstruction are also seen in ischemic graft injury, rejection, recurrent

hepatitis C virus (HCV), and sepsis. In order to make an accurate diagnosis, it is helpful to use imaging modalities like cholangiography, both transhepatic and endoscopic, to evaluate strictures, obstruction, or leak; ultrasonography for the detection of biliary dilatation; and radioisotope studies to evaluate anastomotic or cut surface leaks [67–69].

The most common biliary complication is biliary stenosis. This is the result of either an imperfect anastomotic technique or ischemia of the bile duct, which as it heals leads to a stenotic area in the common bile duct, either at or slightly proximal to the biliary anastomosis, with proximal biliary dilatation. Recurrent bouts of cholangitis or persistent abnormal liver function tests may indicate an obstruction to bile outflow. In these cases, endoscopic or percutaneous balloon dilatation of the bile duct stricture and stenting have been successful. In cases with no response, revision of the choledochojejunostomy or conversion of the duct-to-duct anastomosis to a choledochojejunostomy with a Roux-en-Y loop is the treatment of choice [70–72].

It has been hypothesized that the papilla of Vater is innervated by fibers coursing through the hepatic branch of the vagus, and that the hepatectomy can result in a syndrome known as "ampullary dysfunction" [66]. The radiologic examination of the biliary tree reveals dilatation of both the donor and recipient bile ducts, distal to the choledochocholedochostomy. The treatment consists of conversion to a choledochojejunostomy, although the alternative treatment, endoscopic papillotomy, has been attempted with some success.

Multiple intrahepatic strictures of the biliary tree have been described by various groups [73]. The causes and pathophysiology of these intrahepatic strictures have not been clearly elucidated. In many cases, the strictures seem to be associated with a hepatic artery thrombosis or stenosis, and ischemia of the biliary tree is probably the etiology, especially in nonheart-beating donors [74]. Preservation damage of the allograft may result in multiple intrahepatic biliary strictures, with or without biliary sludge and casts [73]. An immunologic association to a positive lymphocytotoxic-positive crossmatch has also been hypothesized. In some patients who were originally transplanted for primary sclerosing cholangitis, recurrence of the disease seems a possibility [75–79]. While some patients with multiple intrahepatic strictures eventually need to be retransplanted, others can live for years with minimal difficulties, especially if they receive chronic antibiotic prophylaxis. Recently, a grading system for intrahepatic biliary strictures and their projections for outcomes based on a large number of DCD liver transplant recipients was described [80].

The most feared complication of the biliary anastomosis is an anastomotic biliary leak. This complication is particularly lethal in choledochojejunostomies since the bile collection is rapidly infected with enteric organisms, which results in an inflamed and friable operative site during attempted repair. The presence of continued enteric leak may result in mycotic rupture of the hepatic artery anastomosis. In choledochocholedochostomies the leaks usually occur at the exit site of the T tube. In order to avoid this, a purse-string suture should be placed around the exit site. Leakage at the T-tube exit site is usually self-containing and no treatment is necessary so long as the distal bile duct empties well. Some surgeons have advocated not using any stenting following choledochocholedochostomy in an attempt to avoid the risk of T-tube site leakage [81–83].

When a Roux-en-Y loop is used, bleeding can occur at the jejunojejunostomy. In about half of the cases this is a self-limiting problem. In the other half, endoscopic intervention with a pediatric colonoscope with a heater probe or epinephrine injection or the need for surgical exploration for hemostasis may be necessary. This can be avoided by using a hemostatic running suture to approximate the mucosa and submucosa. A potentially lethal complication of Roux-en-Y biliary drainage is an unrecognized internal hernia through the mesentery at the jejunojejunostomy, unexplained abdominal distention, and vomiting due to small bowel volvulus that can progress to vascular compromise and loss of intestinal viability. Prompt recognition is critical and CT scans may reveal findings of a closed loop obstruction. Careful closure of the defect in the mesentery can reduce this complication [84].

Bleeding

Poor graft function, coagulopathy, imperfect hemostasis, or slippage of a tie may result in postoperative bleeding requiring reexploration. Postoperative bleeding is reported in between 7% and 15% of patients and requires reexploration in approximately half of them [85]. Even if easily controlled, postoperative bleeding leads to increased cost, morbidity, and mortality. Thus meticulous attention to intraoperative hemostasis and correction of coagulopathy will reduce the likelihood of postoperative hemorrhage. Early reexploration is indicated when the volume of blood transfusions exceeds 4 units within 24 hours.

Survey of liver transplantation practices

Recently, an international survey of the practice of performing deceased donor LTX was conducted by Alexis Laurent, Riccardo Memeo, and Daniel Cherqui

Table 46.1 Summary of the SALT survey on the practice of liver transplantation.

Technique used	World	United States	Europe
IVC preservation (piggyback):			
Always		4%	29%
Never		0%	4%
Selectively		4%	18%
Temporary portacaval shunt used:			
Yes		0%	58%
Type of caval anastomosis:			
Piggyback – three hepatic veins		22%	36%
Piggyback – two hepatic veins		33%	13%
Side-to-side		22%	38%
Other		23%	13%
Placement of aortic conduit:			
Supraceliac		17%	30%
Infrarenal		33%	49%
Either		50%	41%
Biliary anastomosis			
Use of stents			
Duct-to-duct without T tube	75%	86%	72%
Duct-to-duct with T tube	24%	14%	26%
Suture technique:			
Posterior running & anterior interrupted	16%	10%	14%
Interrupted	47%	50%	46%
Running	37%	40%	40%
Use of drains:			
None	10%		
One drain	20%		
Two drains	43%		
Three drains	18%		
Other	9%		
Closure:			
Full thickness		25%	10%
By layer		75%	90%

(http://hopital-mondor.imadiff.net/fmi/iwp/res/iwp_auth.html). This survey, Survey on Adult Liver Transplantation (SALT), encompassed 50 centers in Europe, eight centers in North America, two in South America, one in South Africa, and three in the Middle East. As shown in Table 46.1, there is considerable intercontinental variation in some specific aspects of the LTX procedure outlined in this chapter.

Of note was that preservation of the IVC (for piggyback implantation) was the most frequently used technique, used routinely by 57% of the teams and selectively by 38%. The use of venous by-pass was in 15% of cases of IVC preservation and in 58% when the IVC was resected. Several types of venous outflow reconstruction were used – the most common being piggyback on the stump of two or three hepatic veins followed by a side-to-side caval anastomosis. Lastly, the duct-to-duct biliary anastomosis was most often used as the standard biliary reconstructive technique, with a T tube being used in 25% of the programs on a routine basis.

Given the excellent outcomes obtained around the world, it suggests that these modifications are rather insignificant in the hands of experienced surgeons in the current era of LTX.

Conclusions

While the results of LTX have improved dramatically over the past 50 years, many of the same technical considerations have plagued the procedure since its inception. With the increasing complexity of candidates undergoing LTX, an improved understanding of the pathophysiology of donor organ preservation, reperfusion injury, improved immunosuppression, more effective diagnostic tools, and new anti-infective agents, have all contributed to a smoother post-transplant course. Nevertheless, all of these advances cannot negate a poorly performed technical procedure.

CHAPTER 47

Recurrent Disease Following Liver Transplantation

Kymberly D. S. Watt[1] *& Marie A. Laryea*[2]

[1]Division of Gastroenterology and Hepatology, Mayo Clinic Rochester, MN, USA
[2]Hepatology/Multi-Organ Transplant Program, Dalhousie University, Halifax Nova Scotia, Canada

Key concepts

- Recurrent liver disease can occur for virtually all indications of liver transplantation.
- Hepatitis C virus (HCV) recurrence is almost universal, with up to 30% developing allograft cirrhosis by the fifth year post transplant.
- HCV-related allograft cirrhosis is associated with a high risk of decompensation and death.
- Hepatitis B virus recurrence is less common and the outcome of recurrence is substantially improved by the use of human immunoglobulin and nucleos(t)ide analogs.
- Recurrent primary biliary cirrhosis and autoimmune hepatitis do not have a substantial impact on patient and graft survival rates; however, recurrent primary sclerosing cholangitis is associated with reduced graft survival.
- Although recurrent alcohol use after transplantation for alcoholic liver disease is common, direct or indirect negative effects of recurrent alcohol use on the allograft is uncommon.
- Recurrent nonalcoholic fatty liver disease is common, but only 2.5–5% of patients experience graft loss due to recurrence.
- Recurrent Budd–Chiari syndrome can occur days to years after transplantation, despite adequate anticoagulation.

Recurrence of liver disease can occur for many of the primary indications for liver transplantation (LTX) (Table 47.1). The timing and natural history of recurrent disease can vary depending on the underlying disease and its course may differ from the original disease. A subset of patients with recurrent disease will develop allograft failure and may require retransplantation. Survival after LTX continues to improve. With this, it is anticipated that the proportion of patients requiring retransplantation will grow and concern exists that the need may outgrow the current donor supply. This chapter will review recurrent diseases after transplantation with a focus on recurrent viral hepatitis as it is the most clinically relevant recurrent disease in the transplant population. Retransplantation and recurrent malignancies will be covered in their respective chapters.

Recurrent hepatitis C

Hepatitis C virus (HCV) associated liver failure is the most common indication for liver transplantation and the infection recurs nearly universally following transplantation. Although the impact of HCV infection on the allograft varies substantially between recipients, allograft failure secondary to recurrence of HCV infection is a common cause of death and retransplantation among recipients with HCV infection [1–3]. In a large multicentered cohort study with over 10 years of follow-up, HCV infection was a specific risk factor for long-term liver-related mortality [4]. Recurrent HCV is a common indication for late retransplant (>3 months after primary transplant) and is a factor in up to 40% of retransplants [5]. Survival after retransplant may be lower for HCV patients but many variables interplay to make these survival rates lower [3].

Natural history

Hepatitis C virus infection of the allograft occurs at the time of transplantation [6]. HCV RNA is cleared rapidly from serum during the anhepatic phase and following reperfusion the rate of decrease in HCV RNA accelerates, believed to be related to intrahepatic uptake of

Table 47.1 Recurrent disease rates following liver transplantation

Disease	Recurrence rate (5 years)
Hepatitis C	100%
Hepatitis B	9–10%
Autoimmune hepatitis	20–25%
Primary biliary cirrhosis	30–35%
Primary sclerosing cholangitis	9–30%
Alcoholic liver disease	Up to 24%
Nonalcoholic steatohepatitis	30–50%
Budd–Chiari syndrome	1–7%
Metabolic disease	None/unknown

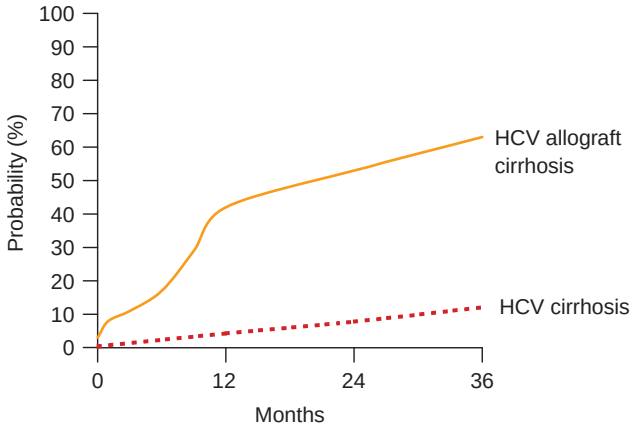

Figure 47.1 Probability of developing decompensated cirrhosis (ascites, encephalopathy, or variceal hemorrhage) from the time of diagnosis of hepatitis C virus (HCV) cirrhosis (pre transplant) and HCV allograft cirrhosis (post transplant). (Adapted from Berenguer et al. [13] and Fattovich et al. [130].)

the virus particles. Unfortunately, hepatocellular production of virions increases thereafter and HCV RNA levels increase rapidly from week 2 post transplantation, peaking by the fourth postoperative month. At the end of the first postoperative year HCV RNA levels are, on average, 10–20-fold greater than pretransplant levels [7]. Acute lobular hepatitis develops in approximately 75% of HCV recipients in the first 6–12 months following liver transplantation and generally (but not always) manifests as increased serum aminotransferase levels. By the fifth postoperative year, 80–100% of HCV-infected liver transplant recipients will have histologic evidence of chronic allograft injury secondary to hepatitis C [7].

Recurrent viral hepatitis is of limited significance unless associated with the development of fibrosis within the allograft. Neither the viral load nor liver enzyme abnormalities are predictive of intrahepatic injury or fibrosis progression. Liver biopsy is required to determine accurate grading of inflammation and staging of fibrosis. A median fibrosis progression rate of 0.8 units of fibrosis stage per year has been suggested [8], but is not applicable to individual patients. Predictors of more rapid progression (>0.8 units fibrosis per year) include warm ischemic time >60 minutes and donor age >55 years. Other studies suggest fibrosis progression is not linear over time, but shows a rapid and exponential increase during the first 3 years after LTX. After this period, progression slows and is nearly linear [9,10]. A 12-month protocol biopsy allows for stratification of fibrosis progression. Twenty-one percent of patients with Ishak fibrosis scores of 2–3, and 36% of patients with a hepatitis activity index score >4, at the 12-month biopsy progressed to cirrhosis within 3–5 years in one study [8]. A fibrosis stage greater than 2 confers a 15-fold increased risk of HCV-related graft loss, with a graft survival of only 55% at 5 years in another study [9]. Fibrosis progression has been shown to decrease, and established fibrosis improve, in transplant patients treated with antiviral medications with a sustained virologic response to treatment [10–12].

The natural history of recurrent HCV is greatly accelerated in some patients when compared with that of immunocompetent patients, whereby a disease course of decades is frequently telescoped to a few years. Up to 30% of patients can develop cirrhosis within 5 years, compared with 30% developing cirrhosis over 20–30 years in the immunocompetent population [7]. Once cirrhosis has developed in the allograft, 30–40% decompensate within 1 year and up to 60–70% by 3 years, compared with the nontransplant cirrhotic population where only 10% decompensate within 3 years (Fig. 47.1) [13,14]. Once a patient decompensates with HCV allograft cirrhosis, 54% die within 1 year and less than 10% survive 3 years (Fig. 47.2) [13,14]. Thus intervention early in the course of recurrent advanced fibrosis is needed to change this bleak natural history. Interventions may include antiviral medication or retransplantation.

A small proportion of HCV transplant patients (4–7%), develop an even more accelerated course of liver injury (fibrosing cholestatic hepatitis C) with subsequent rapid allograft failure, generally within 3–6 months. These patients are notable for very high HCV RNA levels with a predominantly cholestatic liver profile (bilirubin typically >6 mg/dL and alkaline phosphatase > 5 times normal). Bilirubin levels tend to be disproportionately elevated relative to serum alkaline phosphatase. Histologic confirmation is required and is depicted by ballooning hepatocytes (with preponderance to the perivenular region), sinusoidal fibrosis, paucity of inflammation with bile ductular proliferation, and cholestasis [15]. Once the diagnosis is established, prompt establishment of antivirals *may* be associated with improved clinical status but no data exist to confirm this.

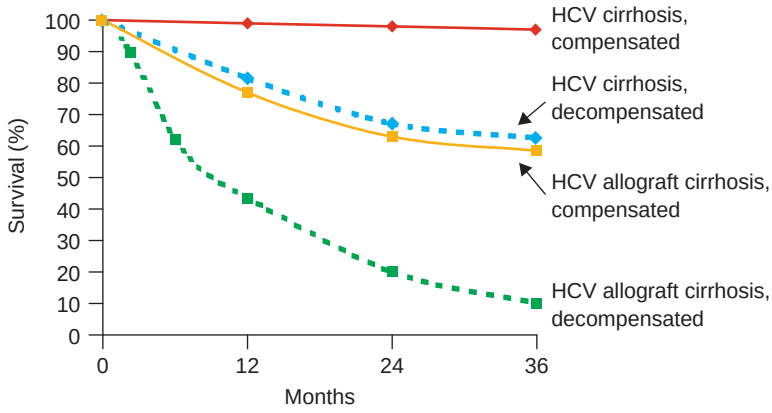

Figure 47.2 Survival rates for compensated and decompensated hepatitis C virus (HCV) cirrhosis and HCV allograft cirrhosis. (Adapted from Berenguer et al. [13] and Fattovich et al. [130].)

Risk factors

Many risk factors associated with severe recurrence and accelerated fibrosis progression have been identified (Fig. 47.3). Viral factors that impact disease progression include higher viral load both pre and post transplant. The impact of genotype is less clear. Recent data by Charlton et al. [16] demonstrated the TT haplotype of the interleukin 28b (IL28b) gene polymorphism, rs12979860, to be associated with worse outcomes post transplant. The likelihood of viral response to interferon-based treatment is also impaired in those patients with a TT genotype conferring a higher likelihood of failed treatment response both pre and post transplant. It is likely that the transplant population will predominantly have a TT genotype in the future, as they are less likely to respond to antiviral medication in the pretransplant phase and thus more likely to progress to end-stage liver disease and transplant need. Post-transplant tracking of HCV quasi-species emergence has suggested a strong correlation between genetic diversification in the viral envelope region and asymptomatic or mild disease patterns [17].

Recipient variables have been associated with more severe recurrence of HCV, and include increased age, non-Caucasian race, and female gender but the data have not been compelling enough to alter clinical practice. Data on human leucocyte antigen (HLA) compatibility between donor and recipient has been conflicting and more study is needed to determine its true impact. Insulin resistance and diabetes have been shown to be associated with more rapid fibrosis progression and worse patient and graft outcomes [18]. Combining other known risk factors with diabetes will increase the risk of allograft cirrhosis exponentially. In one study, the combination of receiving a donor liver older than 55 years and having diabetes post transplant was associated with an 8.38-fold risk of progression to severe fibrosis ($P = 0.000124$) when compared with patients not diabetic post transplant who received livers from donors aged <55 years [19]. Cytomegalovirus (CMV) infection in the HCV patient is a known risk for worse outcomes and most centers now administer antiviral prophylaxis to prevent CMV infection.

Human immunodeficiency virus (HIV) coinfection has been associated with poor survival among liver transplant recipients with HCV infection. One year patient mortality in coinfected recipients ranges between 27% and 54% [20]. Reduced response rates to treatment

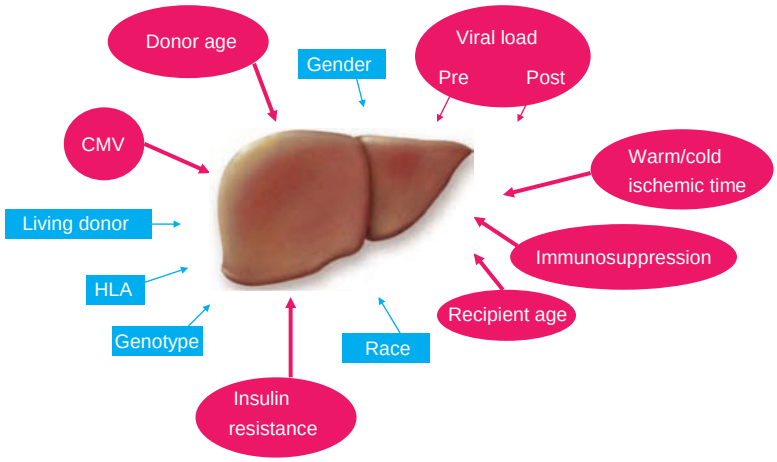

Figure 47.3 Risk factors for progressive fibrosis and worse outcomes in HCV patients after liver transplantation. *Note:* circles indicate factors with significant supporting evidence; squares indicate factors with conflicting or limited substantiating evidence. CMV, cytomegalovirus; HLA, human leucocyte antigen.

of HCV with interferon and ribavirin attenuate post-transplant outcomes in HIV-HCV coinfected liver transplant recipients. Strategies for improving outcomes in this fragile population are evolving.

Donor factors and operative factors also impact the severity of recurrence of HCV. Donor age is irrefutably linked to HCV recurrence. The exact donor age whereby the risk increases is unclear. Donor age >55–65 years are most frequently cited, but donor age >40 years is the lower range that has been implicated in worse outcomes in numerous studies [21]. Donor race in general has not been a factor in liver transplant outcomes, but when specifically analyzed in HCV recipients, if a donor: recipient race mismatch exists it may impact HCV recurrence and outcomes [22]. More study into this recent finding is needed to definitively alter practice specifically for HCV recipients. Donor liver steatosis has been inconsistently associated with HCV recurrence and the degree above which the risk increases is unclear. Warm and cold ischemic time, as reflected by preservation injury in the allograft, has important implications in the severity of HCV recurrence and has been associated with worse outcomes [23]. Living donor liver transplantation reduces the impact of ischemic time, donor age, and donor steatosis. The outcomes for living donor recipients in the recent era demonstrate at least equivalent outcomes as cadaveric donor recipients, and in some centers living donor recipients may experience less fibrosis progression than deceased donor recipients [24].

Immunosuppression impacts viral recurrence and progression of disease. The use of bolus steroid treatment for acute cellular rejection is associated with transient 1–2 log increases in HCV RNA levels [7]. In addition to being proviral, treatment of acute cellular rejection with corticosteroids is associated with increased mortality and graft loss in LTX recipients with HCV infection (relative risk, 2.9; $P = 0.04$) [25]. It has been suggested, though not proven, that a slow steroid taper is better than a rapid taper [26]. Although steroid-sparing regimens appear to be safe, a large randomized controlled study has found no difference in the rate of recurrence of HCV nor in patient or graft survival between steroid-free and steroid-utilizing arms, thus there is no compelling basis for avoiding corticosteroids in the early postoperative period [27].

Antilymphocyte agents, in particular muromonab (OKT3, a monoclonal anti-CD3 antibody) and alemtuzumab (a monoclonal anti-CD52 antibody), are strong T-cell-depleting agents associated with severe recurrence of HCV and worse short-term survival in HCV patients and are not recommended in this patient population [28, 29]. Polyclonal antilymphocyte agents and IL2 receptor blockers appear to have minimal impact on the severity of HCV recurrence in the allograft, but these studies are limited to retrospective analysis of induction regimens, which may reduce acute cellular rejection, thus interpretation on the direct effects on HCV disease cannot be made.

Conflicting data exist for the risk of worse outcomes based on calcineurin inhibitor use. Overall, there has been no major difference in outcomes of HCV patients using tacrolimus as first-line immunosuppression compared with cyclosporine use. A clinically relevant effect associated with mycophenolate mofetil in the HCV patient has not been found either. Sirolimus has conflicting data relating specifically to HCV patients and more study into the risks and benefits of the mammalian target of rapamycin (mTOR) inhibitors as a class is needed before any definitive recommendations can be made.

Treatment

Treatment regimens for recurrent HCV continue to be centered on pegylated interferons and ribavirin. Protease inhibitors have yet to be studied in the transplant population but can be expected to have drug interactions with the immunosuppressive drugs. Sustained virologic response (SVR) rates are less frequent in the transplant population than the general hepatology population, with an average response rate of approximately 30% in most studies [30]. SVR has been associated with histologic improvement and improved long-term outcomes [12,31]. Renal insufficiency and cytopenias limit doses in many instances and growth factors are frequently employed during antiviral treatment. Although uncommon, antiviral treatment has been associated with precipitating immune dysfunction, which can manifest as acute cellular rejection, chronic rejection, or autoimmune hepatitis [32–34]. These events appear to occur more commonly after seroconversion to a HCV RNA-negative state. The true frequency of this is presently being investigated in a multicentered study.

Optimal timing for antiviral medications is unclear but a fibrosis score of 2 or greater is a frequent starting point. Patients with high grades of inflammation early post transplant with stage 1 fibrosis may benefit from earlier initiation of treatment, but no definitive guideline exists. Achieving SVR prior to transplant is the ideal circumstance but is difficult to achieve in cirrhotic patients, and unsafe to attempt in decompensated patients. Attempts at treating HCV using a low accelerated dosing schedule prior to transplant have resulted in an SVR rate of 24%, but only 13% in genotype 1 patients (50% in genotypes 2 and 3) [35]. Significant adverse events and even death were documented, particularly in patients with decompensated liver disease. In patients able to achieve SVR in this study, 12/15 remained virus-negative by 6 months post transplant. The risk : benefit ratio must be weighed for each individual cirrhotic patient, before proceeding

with antiviral treatment. Consensus guidelines recommend attempting treatment only in patients with a model for end-stage liver disease (MELD) score of less than 19, or in select cases when the MELD score ranges from 19 to 25 [36].

Unlike in hepatitis B management, the development of an effective immunoglobulin has been unsuccessful to date, but studies are ongoing. Preemptive treatment with interferon and ribavirin (within the first 3–4 weeks of transplant), is fraught with difficulty and adverse side effects without any real advantage, as only 8% SVR has been documented [37]. These investigators did demonstrate reduced histologic scores at 72 weeks but, due to the small numbers of biopsies obtained, no statistical significance was found. Prophylactic therapy (treatment initiated within 6–12 weeks of transplant) has been attempted as well, but once again proved difficult with poor treatment tolerance and no histologic improvement or significant benefit in SVR [37,38]. Cases of fibrosing cholestatic hepatitis or rapidly progressive HCV may warrant attempted preemptive or prophylactic treatment, but data to support this recommendation do not exist.

Treating patients later after transplant, once histologic evidence of advancing disease is apparent, is the standard approach to treating recurrent HCV. General recommendations are for treatment once stage 2 (periportal) fibrosis has been reached. A meta-analysis of four randomized (two only in abstract form) and two nonrandomized controlled trials of antiviral treatment in liver transplant recipients found an SVR of approximately 40% [39]. These trials are quite heterogeneous and difficult to compare. The two published randomized controlled trials of pegylated interferon and ribavirin performed in liver transplant recipients demonstrated an SVR rate between 33% and 48% [40,41]. These trials had suboptimal dosing of ribavirin, but so few transplant patients achieve optimal dosing it is likely closer to "real world" treatment. Studies have demonstrated an improvement in long-term survival in patients achieving SVR compared with those patients who do not [26,42]. In addition, interferon/ribavirin therapy, whether a remission was achieved or not, may also confer potential improvement in patient survival [31].

Baseline immunosuppression may impact the likelihood of SVR on antiviral treatment, with cyclosporine possibly associated with an increased SVR compared with tacrolimus. Small case series studies suggest higher rates of SVR in patients treated with antiviral medications and cyclosporine compared with those on tacrolimus. However, a small, pilot, randomized controlled trial showed only a trend toward improved SVR rates in cyclosporine-treated patients undergoing antiviral therapy (but was not powered for statistical significance) [43]. There is a large multicentered study now underway to answer this important question.

Recurrent hepatitis B

In the United States, 2,000–4,000 deaths each year are directly related to hepatitis B virus (HBV) infection. One million US residents are chronically infected and therefore at risk for cirrhosis, end-stage liver disease, and hepatocellular carcinoma. These manifestations of HBV infection, along with fulminant hepatic failure, can be cured by liver transplantation and account for approximately 4% of liver transplants in the United States. Historically, HBV infection carried a worse prognosis post-LTX than other indications, with a 5-year survival of 53% in US patients transplanted between 1987 and 1991 [44]. Preventing the recurrence of HBV infection in the graft has lead to dramatically improved outcomes, with 5-year survival greater than 80% globally [45–47].

Before the advent of prophylaxis and highly effective antiviral agents against hepatitis B, recurrence was nearly universal, frequently leading to rapid graft failure [48,49]. The publication of the seminal work by the European Concerted Action on Viral Hepatitis (EuroHep) in 1993 marked a turning point in transplantation for HBV-related disease by demonstrating that long-term (defined as greater than 6 months) immunoprophylaxis with hepatitis B immunoglobulin (HBIg) was associated with lower rates of recurrence when compared with patients who received short-term HBIg and those who received none (~36% and 75%, respectively) [50]. More importantly, this study showed that, with proper prophylaxis, HBV recurrence was not inevitable and good outcomes were possible for these patients.

When post-transplantation prophylaxis is used rates of recurrence are consistently below 10% [45,47,51,52] even though regimens vary widely amongst centers. In 2010 the National Institutes of Health (NIH) Hepatitis B Virus Orthotopic Liver Transplantation (NIH HBV-OLT) Study Group reported the overall probability of post-transplant HBV recurrence in 15 US transplant centers to be 3%, 7%, and 9% at 1, 3, and 5 years respectively [45]. The study centers represented the spectrum of prophylaxis regimens currently in use, giving a real-life evaluation of HBV recurrence in the United States. A lower rate of recurrence had been found previously in an Australasian study of low-dose intramuscular HBIg and lamivudine (LAM), where 4% of patients were affected by recurrent HBV at 5 years [47]. The difference is unlikely to be due to superiority of the prophylaxis regimen but to differences in study populations, notably length of treatment with LAM prior to LTX and the number of patients with detectable HBV DNA at the time of LTX

(64% in the NIH study versus 0% in the Australasian study).

Definitions and diagnosis

It is crucial when reviewing literature on recurrent HBV post-LTX to understand how it is defined by the authors. Differences in assays and their limit of detection also need to be taken into account. The term *recurrence* is most often used to describe infection of an HBV-naïve graft once implanted in a hepatitis B surface antigen (HBsAg) positive patient. Given the current standard of care in HBV-positive recipients, recurrence is defined as failure of prophylaxis.

Recurrence of HBV is different from *reactivation*, where viral replication resumes after a graft containing HBV DNA (anti-hepatitis B core (HBc) positive donor) is transplanted into a recipient without immune mechanisms capable of keeping the virus in check. It is also different from *de novo infection* in a transplant recipient. Reactivation and de novo HBV infection are beyond the scope of this chapter.

A diagnosis of recurrent HBV is made when circulating HBsAg is detected in the serum after transplantation, even in the absence of hepatic inflammation or abnormal liver enzymes. *Viral breakthrough* occurs when HBV DNA is detected in the serum, even in the absence of a positive HBsAg. Patients with detectable HBV DNA and negative HBsAg do not have true recurrence as low level viral replication can occur even with prophylaxis. Viral breakthrough can herald significant viral replication but is often transient, with viral loads promptly returning to undetectable levels without intervention.

Prophylaxis is the term used to describe measures put in place post-LTX to avoid graft infection and recurrent HBV liver disease. It can involve passive immunization with HBIg, antiviral treatment with nucleos(t)ide analogs or, most commonly, a combination of measures.

Pathophysiology

One postulated mechanism for HBV recurrence is infection of the allograft by circulating viral particles present at the time of transplantation. HBV virions have a half-life between 24 seconds and 224 minutes [53]. There is therefore a period, however brief, where preformed circulating virions can infect the new graft. However, recurrence that emerges later, post transplant, is thought to be caused by virions stored in extrahepatic sites, particularly peripheral blood mononuclear cells that are released and lead to graft infection. These extrahepatic reservoirs may also cause recurrence in patients with active viral replication at the time of transplantation [54,55]. They are known to persist up to 10 years post-LTX and explain why prophylaxis must be continued long term [56].

After transplantation, additional mechanisms enhance the ability of HBV to infect the graft. Immunosuppression makes virus clearance more difficult by blunting or eliminating the immune response. Use of corticosteroids in particular appears to enhance replication, presumably by binding to a steroid-responsive nuclear element [57].

In the era of universal prophylaxis post-LTX, recurrent HBV is almost always a failure of prophylaxis, although imperfect patient adherence to prescribed therapeutic measures can render otherwise adequate prophylaxis ineffective. In compliant patients, failure is due to the emergence of viral escape mutants or inadequate dose and/or duration of prophylaxis.

When HBIg was used as monotherapy for prophylaxis, escape preS/S HBsAg mutants emerged in some patients and eventually led to viral breakthrough and HBV recurrence. With LAM monotherapy, LAM-resistant mutants at the tyrosine, methionine, aspartate, aspartate (YMDD) nucleotide-binding locus of the HBV DNA polymerase can emerge and lead to recurrence [58]. Combination therapy minimizes the selection pressure exerted on the HBV and thereby minimizes recurrence. However, mutants carrying both the preS/S and YMDD mutations have been isolated in patients with recurrent HBV receiving HBIg and LAM [45,58]. Mutants resistant to adefovir have also been seen post transplant and this resistance can be associated with recurrence as well [59]. In fact, mutants resistant to all three agents (HBIg, LAM, and adefovir) have been detected [60].

Risk factors

In the era of HBIg and highly effective nucleos(t)ide analogs, the literature defines two groups of patients: those at high risk of HBV recurrence and those at low risk (Table 47.2). This separation allows for the tailoring of post-transplantation prophylaxis relative to viral and patient factors [61].

Table 47.2 Patient characteristics associated with a high or low rate of recurrent hepatitis B virus (HBV) infection after liver transplantation.

High risk for recurrence	Low risk for recurrence
Viral load ≥100,000 copies/mL at time of LTX [45,63]	Undetectable HBV DNA at time of LTX [45,50,62]
HBeAg-positive at LTX [45,52]	HBeAg-negative at LTX [45] Hepatitis D coinfection [45,50,63] Acute hepatitis B [45,50,63]

HBeAg, hepatitis B e antigen; LTX, liver transplantation.
Data from references [45,50,52,62,63].

High-risk patients

One of the earliest studies looking at passive immunization post-LTX for HBV found that patients HBV DNA-positive at the time of LTX had higher rates of recurrence than HBV DNA-negative patients (96% versus 29% at 2 years) [62]. Although subsequent studies found various factors associated with post-LTX HBV recurrence, these are largely surrogate markers for active viral replication at the time of transplantation (Table 46.2) [63]. The NIH HBV-OLT Study Group has published studies where the presence of hepatitis B e antigen (HBeAg) at listing [44] and serum HBV DNA $>10^5$ copies/mL at the time of transplant [45,52] were the only factors associated with post-transplant HBV recurrence.

When LAM was the only antiviral medication available for treatment of HBV, pretransplant resistance to LAM was a risk factor for HBV recurrence [64,65]. These patients tended to have higher viral loads at the time of transplant, which was thought to explain the higher rate of recurrence. However, a recent study of 160 patients found the detection of the YMDD mutation after LTX to be the only significant risk factor for recurrence, irrespective of the degree of viral replication at the time of LTX [66]. Even so, other studies have shown that when adefovir is given to patients with LAM resistance prior to transplant as rescue therapy [45,67], or as prophylaxis at time of transplant [68], the risk of recurrence is low.

Low-risk patients

In the 1993 EuroHep study, independent predictors of a lower risk of HBV recurrence after liver transplantation by multivariate analysis were hepatitis D virus superinfection, acute HBV, and long-term prophylaxis [50]. These are the most likely surrogate markers for low HBV viral loads at the time of LTX, as patients with an undetectable viral load at the time of transplant are known to have less recurrence as well. Hepatitis D infection is usually accompanied by a suppression of HBV replication due to unknown interference mechanisms. Fulminant HBV is caused by immune-mediated hepatolysis and most patients do not have obvious viral replication at the time of presentation. Many studies have since confirmed these to be predictive of low rates of recurrence along with other patient factors (Table 46.2).

Prevention

Analysis of early experiences in liver transplantation for HBV-related disease was crucial in proving the effectiveness of passive immunization with HBIg in preventing post-transplantation recurrence, allowing experts to advocate transplantation for HBV in the face of great reticence in the liver transplant community [69]. The prevention of HBV recurrence involves pretransplantation, intraoperative, and post-transplantation measures that help minimize risk to the graft.

Treatment of hepatitis B virus before liver transplantation

As previously mentioned, early studies proved that HBV-infected patients with undetectable levels of HBV DNA at the time of liver transplantation had better outcomes. This is the rational for treating patients with antiviral therapy prior to transplantation [70]. This is usually done by administering long-term oral nucleos(t)ide analogs, as these are very effective and well tolerated by decompensated patients. Pre-LTX interferon therapy has been attempted but is poorly tolerated by cirrhotic patients [71] and is contraindicated in decompensated patients [72,73]. In patients with hepatic dysfunction as the principal indication for transplantation, treatment with a nucleos(t)ide analog can also lead to regression of disease and significant improvement in liver function to the point where LTX may no longer be necessary [72].

The choice of nucleos(t)ide analog pretransplantation can be a difficult one but treatment guidelines for chronic hepatitis B should be followed when possible. Given that life-long prophylaxis post-LTX is recommended, and that patients may be treated for extended periods pre transplantation, entecavir and tenofovir are highly potent agents with a high genetic barrier to resistance and are recommended as first-line treatment [72–74]. The high rates of resistance associated with LAM (50% at 5 years in chronic hepatitis B and 50% at 2 years in LTX patients) make it a lesser choice in this context. However, LAM is less expensive and is best studied in advanced liver disease. It still has a role pre transplantation when and where resources are limited. Renal fragility in cirrhotic patients awaiting transplantation make adefovir, with its known nephrotoxicity, a less appealing choice than LAM, entecavir, or tenofovir.

Studies show that if virologic breakthrough occurs on therapy prior to LTX, rescue therapy should be started at least perioperatively to minimize recurrence [45,59,67,68].

Post-transplantation prophylaxis

Prophylaxis against recurrent HBV was initially based on HBIg alone [75]. It has evolved in parallel with treatment for chronic HBV, first with the advent of LAM approved in 1998, then with adefovir in 2002. Entecavir, a cyclopentyl guanosine analog, and the nucleotide reverse transcriptase inhibitor tenofovir, both highly potent antivirals, promise to further change standard practice in LTX.

Monotherapy with HBIg is associated with high rates of recurrence long term, especially in patients with ongoing viral replication at the time of transplant [62]. This is in large part due to the emergence over time of preS/S

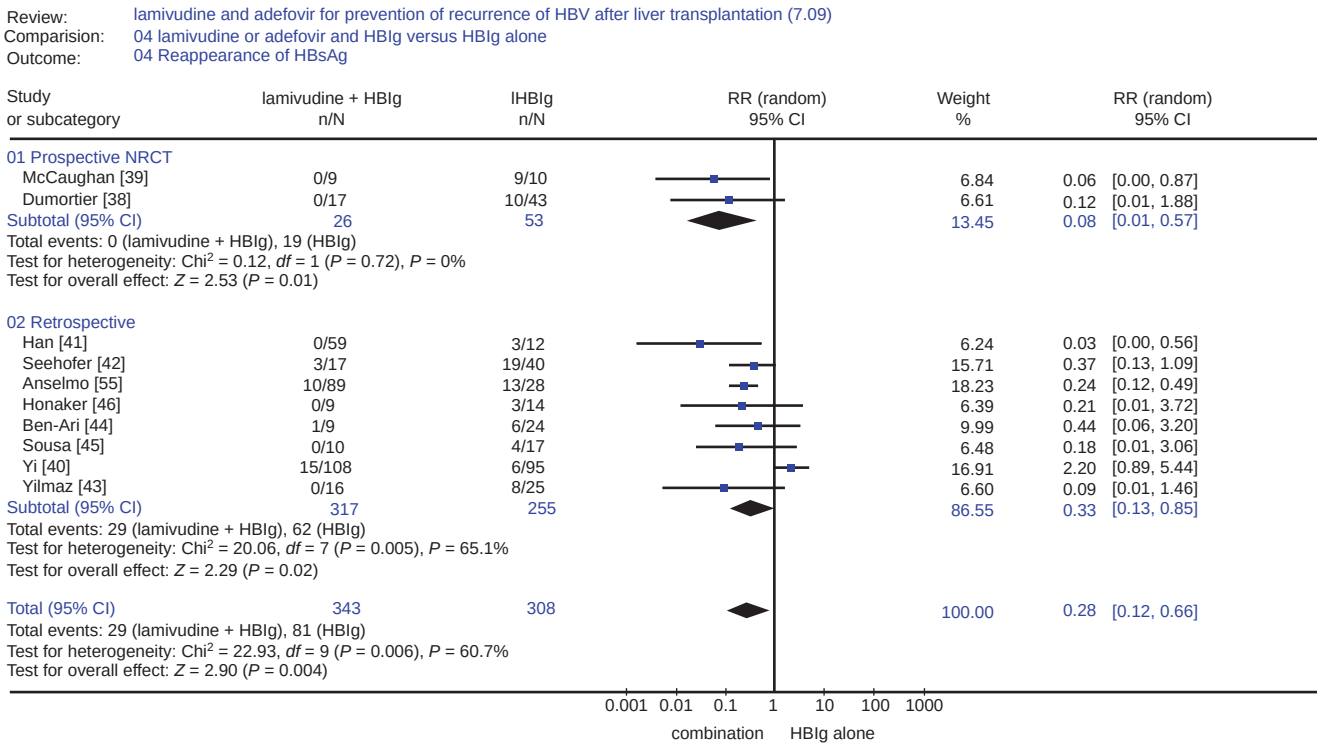

Figure 47.4 Reappearance of hepatitis B surface antigen (HbsAg) in studies that compared patients who had received combination treatment (hepatitis B immunoglobulin (HBIg) plus nucleos(t)ide analog) versus HBIg alone. CI, confidence interval; HBV, hepatitis B virus; NRCT, nonrandomized clinical trial; RR, relative risk. Original references can be obtained from Katz et al. [48]. (Reproduced from Katz et al. [48] with permission from Wiley.)

mutants [76]. For this reason, monotherapy with HBIg is no longer recommended in liver transplantation [74,77].

Standard practice for the first year post-LTX involves the use of nucleos(t)ide analogs, most commonly in combination therapy with HBIg, or, less commonly, as monotherapy or in combination with a second nucleos(t)ide analog. Combined HBIg and nucleos(t)ide analog prophylaxis is most often used long term, but some centers withdraw HBIg and transition patients to monotherapy with a nucleos(t)ide analog at a set interval that varies according to center [45]. A meta-analysis published in 2010 showed that few randomized controlled trials exist to show superiority of one regimen over the other, and highlighted the fact that practice in this area cannot truly be evidence-based [48]. However, nonrandomized trials favor combination therapy with HBIg and nucleos(t)ide analogs over nucleos(t)ide analog monotherapy (Figs 47.4 and 47.5).

Hepatitis B immunoglobulin

Passive immunization with HBIg has long been used in postexposure prophylaxis, most notably peripartum in the offspring of HBV-infected mothers. HBIg has also been the cornerstone of prevention of HBV recurrence in LTX for decades.

It is well documented that hepatitis B polyclonal immunoglobulins protect the graft from HBV infection. However, the exact mechanism is poorly understood. One hypothesis is that HBIg protects naïve hepatocytes from extrahepatic reservoirs of HBV by blocking a putative HBV receptor. Hepatits B surface antibodies (anti-HBs) help clear circulating viral particles and induce lysis of infected hepatocytes via cell-mediated immunity [78]. HBIg does not, however, eradicate HBV infection and HBV DNA is detectable in the tissues, including liver biopsies, of patients long after transplantation [56] but may neutralize circulating virions through the formation of immune complexes and immune precipitation [79].

The use of HBIg varies widely between and within LTX centers. The original approach was to use a loading dose in the anhepatic phase with 10,000 units of HBIg IV followed by 10,000 units IV daily for the first 7 days post-LTX [45]. This phase helped clear circulating virions and rendered all patients HBsAg-negative after 7 days [75]. However, centers now opt for daily low-dose IV or low-dose IM HBIg from the time of transplant onward, especially in patients on nucleos(t)ide analogs at the time of transplant and at a low risk of recurrence [45,80].

HBIg is usually well tolerated with few side effects. Reports of osmotic nephrosis associated with some HBIg

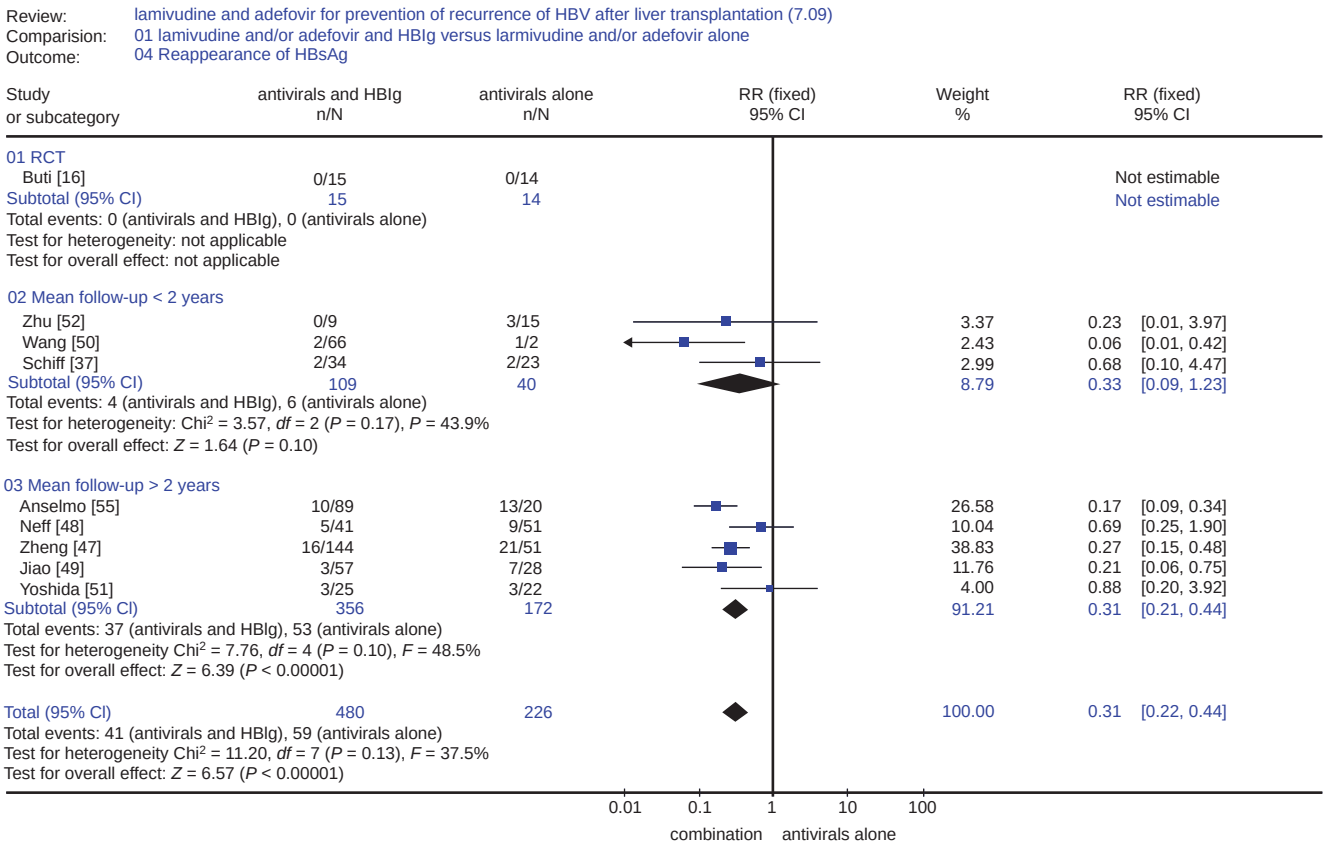

Figure 47.5 Reappearance of hepatitis B surface antigen (HbsAg) in studies that compared patients who had received combination treatment (hepatitis B immunoglobulin (HBIg) plus nucleos(t)ide analog) versus nucleos(t)ide analog alone. CI, confidence interval; HBV, hepatitis B virus; RCT, randomized clinical trial; RR, relative risk. Original references can be obtained from Katz et al. [47]. (Reproduced from Katz et al. [48] with permission from Wiley.)

preparations are unconfirmed but have raised some concern in the transplant population already at risk for renal injury [81]. To maintain anti-HBs levels, HBIg can be administered intravenously, intramuscularly and, as recently shown, subcutaneously (SC) [82]. SC administration of HBIg requires higher doses to achieve the desired titers, as absorption is decreased by 20% when compared with IM administration [83]. However, SC injections may be better tolerated by patients. HBIg can be administered at fixed intervals regardless of anti-HBs titers, or on demand according to antibody levels. Different protocols aim for different titers where higher titers (>500 IU/L) may protect more patients from recurrence but at greater cost. Most protocols aim for titers greater than 100 IU/L long term [45,83]. Lower titers of anti-HBs may be sufficient and trials in this area are necessary.

Since all combination prophylaxis regimens are associated with similar rates of HBV recurrence [45,51], choice of therapy is often driven by cost. The current trend is to minimize HBIg to reduce cost, first by lowering the dose, then the target anti-HBs titers, and now by HBIg-withdrawal strategies. By decreasing the amount of HBIg given and negating the charge associated with IV administration, low-dose IM HBIg offers significant cost savings [47]. Another cost-cutting measure is finite duration HBIg, where the transition to nucleos(t)ide analog-only prophylaxis usually takes place well after the first year post transplantation [45,46,84,85]. Some centers withdraw HBIg as early as 7 days post-LTX in low-risk patients (as defined in Table 47.2) [84,85]. More data on this approach are needed.

Nucleos(t)ide analogs

While HBIg is thought to prevent infection of hepatocytes and help in immune clearance of circulating virions, it has no impact on viral replication, specifically on extrahepatic reservoirs of HBV. Alternatively, nucleos(t)ide analogs (NAs) inhibit extrahepatic viral replication, thereby reducing and sometimes eradicating circulating virions capable of infecting hepatocytes and triggering an inflammatory response in the graft [77].

Most of the literature on NAs in liver transplantation focuses on LAM, the first agent found to be effective against HBV. The advantages of LAM are its safety profile in liver patients and the relatively low cost. Its greatest pitfall is the high rate of recurrence at (25% at 1 year

in chronic hepatitis B), making it an imperfect choice in patients likely to require prolonged treatment. Although some centers use LAM monoprophylaxis in patients who are HBV DNA-negative at the time of transplant with good results [84], resistance must be cause for concern in the long-term management of these patients. Close follow-up and prompt administration of rescue therapy when mutants emerge are essential.

Adefovir has also been studied, mostly as a rescue agent when LAM resistance emerges [67,68,74]. It has a lower rate of resistance than LAM (2% at 1 year) and is effective in treating viral breakthrough secondary to LAM-resistant mutants [59,74]. Its pitfalls are potential resistance and nephrotoxicity. Combination therapy adefovir/LAM without HBIg was found to be equivalent to LAM/HBIg therapy in patients at least 12 months post-LTX without HBV recurrence. This randomized open-label trial also showed the combination of adefovir/LAM to be the more cost-effective measure.

Entecavir and tenofovir (along with the tenofovir/emtricitabine combination Truvada®) are highly effective antiviral agents that have very favorable resistance profiles and are recommended as first-line monotherapy in chronic hepatitis B [72,73]. Their role in post-LTX prophylaxis has been demonstrated in small studies that confirm their safety and efficacy [86]. Current practice guidelines recommend these agents be considered for prophylaxis given their profound viral suppression and low rates of resistance (B1 recommendation) [73]. However, few data currently exist to truly argue for superiority of these agents in LTX. These agents may become the backbone of HBIg-free prophylaxis, with HBIg-withdrawal strategies, NA monoprophylaxis regimens, and dual NA therapy all currently under investigation.

Vaccines

Many studies have looked at triggering active immunization in transplant recipients with purified recombinant HBsAg vaccines, with mixed results. In the general population, anti-HBs titers of >10 IU/L are sufficient to confer immunity. However, in transplantation, current goals are to maintain titers >100 IU/L long term to minimize recurrence. The failure of early vaccination strategies was two-fold: most patients failed to respond due to a blunted immune reaction from immunosuppression, and those that did were unable to maintain appropriate titers long term [87]. Adjuvants and concomitant HBIg were felt to be necessary to ensure response to vaccination. A novel strategy of combining recombinant vaccine and immune-modulating agents has shown promise in a trial published in 2010 whereby patients received HBIg, LAM, and monthly vaccination for 6 months, followed by LAM and monthly vaccination for 6 months, and then LAM alone for 12 months of follow-up [88]. Twelve months after vaccination, 44% of patients continued to have titers >100 IU/L and no recurrence of HBV had been detected.

Treatment

The goal of treatment is to maintain graft function and arrest the progression of chronic HBV hepatitis. Once recurrence occurs and HBsAg is once again detected in the patient's serum post-LTX, HBIg can be discontinued, as its role is to prevent but not treat recurrence.

In chronic HBV, some advocate interferon-α therapy. However, in LTX, it is poorly tolerated and associated with an increased risk of rejection [70]. Recurrence is most commonly triggered by emerging resistance in adherent patients and treatment should be guided by known principles of HBV treatment (see Chapter 24). Rapid suppression of viral replication is desirable, and therefore tenofovir and entecavir are better rescue agents in recurrence, although adefovir has been shown effective when used to treat YMDD-mediated recurrence post-LTX [59,67,74]. With effective rescue therapy, HBV recurrence has a much more benign course than historically. Most patients respond promptly to therapy with no long-term graft-related issues.

Recurrent HBV should not be an absolute contraindication to retransplantation [70]. Should graft dysfunction arise and retransplantation be deemed necessary, the cause of HBV recurrence must be identified to determine whether retransplantation is an option. In cases where nonadherence is the main issue, candidates would need in-depth evaluation to ensure improved adherence with the next transplantation. In cases where prophylaxis failed, transplant physicians must carefully analyze the cause and determine if it is remediable. More powerful agents, longer use of HBIg with higher titers, or other novel strategies may be necessary to protect the new allograft from recurrent HBV disease.

Recurrent primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a disease characterized by progressive cholestasis secondary to immune-mediated destruction of cholangiocytes in the interlobular bile ducts. It accounts for 5% of all transplants in the United States.

In 1982, three UK patients who had undergone liver transplantation for PBC developed recurrent pruritus and jaundice post-LTX and were found to have histologic changes consistent with PBC [89]. Since then, recurrent PBC (rPBC) has become a well-recognized entity with a reported recurrence rate of 18% post-LTX [90,91]. Transplant centers that do not perform protocol post-LTX biopsies underestimate the prevalence of rPBC, leading to a

variation in reported recurrence rates. The expansion of histologic criteria to include more subtle changes has also lead to more diagnosis of recurrence. Given the cumulative incidence of rPBC, studies with longer follow-up periods tend to report more recurrence, with rates as high as 30–35% [92,93]. In spite of significant recurrence, patients transplanted for PBC have the best outcomes after LTX [94].

Diagnosis

Whereas the diagnosis of native-liver PBC is supported by a clinical picture of classic symptoms, cholestasis, pathognomonic serology, and well-defined histologic findings, rPBC can be a much more subtle disease entity. The usual symptoms of pruritus, fatigue, and sicca are often absent, affecting only 12% of patients [94]. Recurrent disease can also be seen in patients with normal liver enzymes, further complicating diagnosis [95], although approximately one half will have an elevated alkaline phosphatase [91,93,96]. Antimitochondrial antibodies (AMAs), the serologic marker of PBC, are unhelpful in detecting rPBC as their presence or measured titers fail to predict recurrence [96]. Titers often fall after LTX only to reappear later in the post-LTX course, even in patients without histologic evidence of disease recurrence.

Recurrent PBC is therefore a histologic diagnosis best described in studies conducted in centers with protocol biopsies post-LTX. The presence of a *florid duct lesion* (granulomatous cholangitis) is the major diagnostic criteria for rPBC and is present in two thirds of patients at diagnosis [93]. Some degree of fibrosis is often present on the index biopsy, though it tends to be early stage [93,95]. Often more subtle inflammatory changes are seen in patients that either had, or went on to develop, the florid duct lesion [96]. Almost one third of rPBC patients have a dense lymphoplasmacytic infiltrate, defined as "a mononuclear infiltrate that filled at least one of the portal tracts, with or without expansion of the portal tract, containing $\geq$4 plasma cells," while none of the controls had this infiltrate. With this histologic finding included in the diagnostic criterion, rPBC prevalence may be as high as 30–35% [96,97]. By using set diagnostic criteria for rPBC, a diagnosis of definite or probable rPBC can be made relatively easily (Table 47.3). It should be noted, however, that similar to native-liver PBC, rPBC is patchy, leading to sampling errors and false-negative biopsies.

Natural history

Recurrent PBC is a progressive disease that can lead in some patients to advanced fibrosis, cirrhosis, eventual graft failure, and death [92,93,97] though most patients with rPBC do not develop graft dysfunction. Although early data failed to show the clinical impact of rPBC [98], one study with longer follow-up revealed a negative effect on graft and patient survival with up to 22% of patients with rPBC decompensating or dying of their disease during 6 years of follow-up post diagnosis [92]. However, not all patients experience recurrence, and only 1.3% of all PBC patients lost their graft to disease recurrence in a study with 22 years of follow-up [99]. In general, time to rPBC-related graft loss is around 7 years. When compared with other recurrent diseases post-LTX, it progresses more slowly and carries the lowest risk of graft failure [92,99]. Retransplantation for rPBC is still a rare occurrence [92,93,98]. Recurrent PBC in the second graft has been described but does not necessarily follow the same course as rPBC in the first graft [90].

Risk factors

As post-LTX survival lengthens, and recurrent disease becomes a greater threat to graft survival, identifying modifiable donor and recipient risk factors for rPBC may lead to even better outcomes in this patient population.

Conflicting data on the influence of recipient age and HLA status exist in the literature and more work is needed to determine whether or not these are true risk factors for recurrence [100]. Some studies have shown longer cold ischemia time and donor age >65 years to be associated with higher rates of rPBC [94] but other studies failed to confirm these findings. Overall, no recipient or donor factors have consistently been shown to be associated with rPBC, largely due to a lack of available data rather than true epidemiologic evidence.

Recurrent PBC occurs regardless of immunosuppression regimen used, although rates of recurrence and time to rPBC appear affected by the agents chosen. The first hint that immunosuppression affected recurrence rates in PBC came in 1996 when a prospective trial comparing tacrolimus with cyclosporine head-to-head found higher rates of recurrence with shorter times to recurrence in patients on tacrolimus [101]. Later trials confirmed this finding while others failed to show an association between tacrolimus and increased rates of recurrence. A systematic review of four trials that had data on immunosuppression found no difference between the two agents, although a nonsignificant trend towards less rPBC in the cyclosporine group was found. A more recent retrospective study published in 2010 looking at 103 consecutive transplants for PBC found no difference in recurrence when tacrolimus or cyclosporine was used alone. By multivariate analysis, less recurrence occurred in patients receiving combination immunosuppression with azathioprine, with the lowest rates of rPBC in patients receiving cyclosporine and azathioprine [92]. No clear mechanism for this difference has been identified and prospective studies are needed to further determine the effect of immunosuppression on rPBC.

Table 47.3 Diagnostic criteria for recurrent autoimmune diseases after liver transplantation.

Disease	Diagnostic criteria
Recurrent autoimmune hepatitis (AIH)	Patient transplanted for AIH Autoantibodies in titers >1 : 80 Chronic elevation of transaminases Elevated serum IgG immunoglobulins Corticosteroid dependency Rule out rejection, viral or drug-induced hepatitis Diagnostic or compatible histology: Plasma cell-rich inflammation in portal tracts and the parenchyma Interface hepatitis Confluent/bridging necrosis (in more severe cases)
Recurrent primary biliary cirrhosis (PBC)	Patient transplanted for PBC AMA seropositivity after LTX Diagnostic or compatible histology:* Mononuclear inflammatory infiltrate Lymphoid aggregates Epithelioid granuloma formation Florid duct lesion
Recurrent primary sclerosing cholangitis (PSC)	Patient transplanted for PSC Multiple nonanastomotic biliary stricturing on cholangiography Diagnostic or compatible liver histology: Fibrous cholangitis with bile duct obliteration Ductopenia Secondary features of chronic cholestasis

*Three of four portal tract lesions: definite recurrent PBC. Two of four portal tract lesions: probable recurrent PBC.
AMA, antimitochondrial antibody; IgG, immunoglobulin G; LTX, liver transplantation.
Adapted from Schreuder et al. 2009 [90].

Treatment

The cornerstone of treatment in native-liver PBC is ursodeoxycholic acid (UDCA) and its use has been credited for the decreased number of PBC patients requiring transplantation [102]. UDCA has the greatest impact when used in patients with early disease. Given that most rPBC is diagnosed at an early stage in centers with post-LTX biopsy protocols, one can reasonably assume UDCA has a role to play in this population. However, UDCA in rPBC has not been studied in large randomized controlled trials. Some centers empirically treat patients with UDCA and retrospective analysis of their experience offers some data on efficacy. One of these retrospective studies demonstrated improved liver enzymes with no impact on liver function in 52% of UDCA-treated patients, where only 22% of untreated patients had improved enzymes [93]. No improvement in histologic progression, death, or need for retransplantation was seen in the treated groups, but follow-up in this study was relatively short (36 months) given the slow progression of rPBC. Furthermore, the patchy nature of rPBC makes assessing histologic regression challenging and prone to sampling errors. The efficacy of UDCA needs to be studied in long randomized prospective studies with hard clinical end-points (jaundice, death, decompensation, and retransplantation).

Given the apparent effect of immunosuppression on the natural history of rPBC, patients' drug regimens are sometimes modified upon diagnosis of rPBC. These strategies have not been systematically studied and are not yet supported by randomized clinical trial data.

Recurrent primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is thought to be an immunologically mediated chronic disease marked by progressive scarring of the intra- and extrahepatic bile ducts, leading to end-stage liver disease requiring liver transplantation. PSC accounts for approximately 6% of all transplants in the United States. Unfortunately, the disease recurs in 9–30% of patients transplanted for PSC by 3–5 years [91,103–105], with six times the risk of graft

loss due to recurrent disease compared with the risk of graft loss for rPBC [99]. Recurrence of PSC has been described before 3 months post transplant but usually ranges between 6 and 120 months after transplant. The difficulty with assessing recurrent disease timing and frequency is the lack of protocol biopsies in most studies. In many circumstances histologic disease may occur earlier than clinical disease is picked up. Patients having received a transplant for PSC generally have a hepaticojejunostomy (Roux-en-Y anastomosis) for near complete removal of the native bile duct, and thus are prone to biliary reflux and intermittent fluctuating liver enzyme abnormalities. In patients with a sustained alkaline phosphatase level greater than 250 U/L after 1 year, recurrent PSC should be considered and a cholangiogram and/or liver biopsy obtained [104].

Diagnosis

Imaging studies and/or histology are required for the diagnosis of recurrent disease. Cholangiographic features of intrahepatic and/or extrahepatic strictures and beading along with histologic findings including biliary fibrosis, fibro-obliterative lesions, cholangitis, and ductopenia are required for an accurate diagnosis of recurrent PSC (Table 47.3) [105,106]. The diagnosis of recurrent PSC requires the exclusion of other causes of biliary stricturing including ABO incompatibility, early and late hepatic artery thrombosis, prolonged cold ischemic time, and infectious causes. Differentiating recurrent disease from other biliary complications is dependent on the clinical picture and the timing and location of the biliary strictures (Box 47.1). Recurrent intrahepatic PSC is difficult to discern from chronic rejection and it is not clear that the two entities are mutually exclusive [107,108]. The diagnosis requires experienced pathologists and supporting clinical and radiographic evidence.

Risk factors

Risk factors for recurrent disease have not been well established, but are thought to include age, male gender, gender mismatch, inflammatory bowel disease (IBD), presence of an intact colon, presence of cholangiocarcinoma prior to transplant, steroid exposure, and acute cellular rejection [103,109]. It has been suggested that patients who receive maintenance corticosteroids or orthoclone (OKT3) post transplant appear to be at higher risk of recurrent PSC, but recurrence does not appear related to other immunosuppressant medications [110]. The risk associated with steroid use, however, may reflect active IBD, which has been thought to be associated with recurrent disease. A meta-analysis of 18 published studies, however, could not confirm IBD as a risk factor for the recurrence of PSC after liver transplantation [91], but these studies were quite heterogenous. Since that meta-analysis, however, further data have suggested that the absence of ulcerative colitis post transplant (whether there was pretransplant colectomy or not) was protective for recurrent PSC, and the presence of severe or de novo ulcerative colitis was associated with recurrent PSC [109]. Pre- or post-transplant colectomy appears to be associated with fewer cases of recurrent PSC [109,111]. PSC is a risk factor for cholangiocarcinoma but the risk in recurrent PSC, although reported, is unknown [112]. Although the recipient bile duct is resected at transplant, a tiny residual native bile duct is frequently retained within the pancreas. The risk of malignancy in this retained duct has not been studied.

Box 47.1 Differential diagnosis for recurrent primary sclerosing cholangitis.

- ABO incompatibility
- Preservation/reperfusion injury
- Hepatic artery thrombosis
- Anastomotic stricture
- Malignant stricture
- Chronic rejection
- Cytomegalovirus infection
- Cryptosporidium infection

Treatment

As in the nontransplant population, no effective treatments exist for PSC recurrence in the allograft. A randomized controlled trial of high-dose UDCA in nontransplant patients demonstrated worse outcomes [113]. Trials of moderate-dose ursodiol did not show significant benefit to patients, thus consensus guidelines do not advocate ursodiol use in nontransplant patients (and this has been extrapolated to include transplant patients).

Recurrent autoimmune hepatitis

Autoimmune hepatitis (AIH) is an inflammatory condition that may lead to cirrhosis and liver failure. Autoimmune cirrhosis, and less commonly fulminant AIH, account for around 5% of liver transplants worldwide. Like PBC, it is associated with excellent outcomes post-LTX. However, recurrence of disease post-LTX can lead to graft loss, retransplantation, or death in those affected. Patients transplanted for other indications can develop de novo AIH post-LTX but this is beyond the scope of this chapter.

The recurrence rate of AIH post-LTX is approximately 22% [91]. As in rPBC, centers that perform protocol biopsies have higher rates of recurrent AIH, detecting biochemically silent cases. Whether or not these cases are clinically relevant is still unclear. Median time to recurrence is approximately 2 years [114]. Graft loss due to

recurrent disease has been demonstrated in 6% of patients in one study [99]. In general, however, recurrent AIH does not impact on overall patient survival, with survival rates similar to those of patients without recurrence at 5 and 10 years [115].

Diagnosis

The diagnosis of recurrent AIH depends heavily on histology, but serologic and biochemical markers must be taken into account as well (Table 47.3). In a patient transplanted for AIH, increased serum transaminases, autoantibodies, and γ-globulins, as well as histologic evidence of lobular and/or periportal hepatitis (in the absence of rejection, viral infection, or drug-induced hepatitis), are features consistent with a diagnosis of recurrent AIH [91]. Some have also suggested steroid dependence as a marker for recurrent disease [116] but this is unhelpful in distinguishing it from steroid-responsive entities that mimic recurrent AIH such as late cellular rejection and alloimmune hepatitis.

Risk factors

Most studies have failed to find any clear donor factors that influence the rate of recurrence. There are conflicting data on whether HLA status (particularly HLA-DR3 positivity in recipients) is associated with recurrent AIH [91] and further studies are needed to evaluate this risk factor definitively. A recent study in a center without protocolized post-LTX biopsies found by multivariate analysis that the presence of moderate to severe inflammation in the explanted liver and high immunoglobulin G (IgG) levels before LTX were both independently associated with recurrent AIH [115]. Whether the immunosuppression regimen used is tacrolimus or cyclosporine based does not appear to have an impact on the rate of recurrence post-LTX [115].

Treatment

The goal of treatment in recurrent AIH is to intensify immunosuppression. Increasing or reinstating steroids, adding mycophenolate, or increasing calcineurin-inhibitor levels are all rational approaches that have been successful [90]. With increased immunosuppression, biochemical abnormalities and histologic features of recurrence quickly resolve in most patients with minimal impact on graft survival. Severe, refractory, or untreated cases can lead to graft failure and retransplantation may be necessary [116].

Recurrent nonalcoholic steatohepatitis

Nonalcoholic steatohepatitis (NASH) is increasingly common in patients undergoing liver transplantation. It may even overtake hepatitis C as the leading indication for transplantation in the coming decades. NASH is associated strongly with the metabolic syndrome (hypertension, diabetes, hyperlipidemia, and truncal obesity), which is highly prevalent in the post liver transplant population. These metabolic parameters infrequently resolve after transplant and in fact the prevalence increases dramatically after transplant. Diabetes is present in 30–40% of patients after transplantation, with hypertension affecting 60–70% and hyperlipidemia found in 50–70% of patients after transplant [4]. Metabolic syndrome has been described in 44–58% of patients after transplantation [117] whether transplanted for NASH or not. It is thus not surprising that NASH recurs after transplantation.

Approximately 60% of transplant patients with NASH developed steatosis grade 2 or higher within 1–2 years post transplant [118,119]. The probability of steatosis at 5 years post-LTX was 100% in comparison to 25% probability observed in patients of similar age and weight with PBC or alcoholic liver disease [119]. Of the NASH recipients with recurrent steatosis, >50% developed overt recurrent NASH within 2 years post transplant [118]. Between 5% and 10% of patients undergoing liver transplantation for NASH had recurrence that progressed to cirrhosis in long-term follow-up, with graft failure reported in about half of patients with cirrhotic stage recurrence (i.e., long-term absolute NASH recurrence-associated graft loss rate of 2.5–5%) [118]. A more recent retrospective analysis had similar overall findings but observed no NASH recurrence-associated graft loss [120].

Metabolic syndrome may not be the only risk factor for recurrent steatosis. Certainly steroid treatment can have direct and indirect effects. Steroids are known to promote fatty changes within the hepatocytes, as well as increase insulin resistance and worsen diabetes. Steroid-free protocols reduce the frequency of diabetes after transplant, but the effect on steatosis post transplant has not been adequately studied.

As in the pretransplant patient population there is no treatment other than weight loss and medical management of hypertension, diabetes, and hyperlipidemia.

Recurrent alcohol-related liver disease

Alcohol is not only the cause of end-stage liver disease in genetically susceptible individuals but can act as a cofactor accelerating the disease progression of other liver disease. Although liver transplantation can successfully cure alcohol-related liver disease (ALD), alcoholism, when present, remains after transplantation. However, the allograft may no longer have the same susceptibility to alcohol-induced liver injury, thereby making recurrent ALD a separate, rarer entity than post-LTX recidivism of alcohol use and abuse. Patient selection for LTX and treatment of alcoholism is beyond the scope of this chapter.

It is difficult to determine the true rate of recurrent alcohol use/abuse post-LTX given the absence of a reliable marker of alcohol consumption with a long half-life. Recurrent alcohol use is estimated to be 20%, but definitions generally include "any use" even if infrequent or of small quantity [121]. Recurrent ALD, defined as patients actively consuming alcohol and the presence of steatosis or graft injury (as a direct alcohol effect or secondary to chronic rejection due to documented noncompliance), resulted in a rate of recurrent ALD of 24% over 22 years of follow-up [99]. Three percent of patients transplanted for ALD lost their graft to recurrent disease with a median time to graft loss of nearly 7 years in this study.

Recurrent alcohol use/abuse impacts long-term patient survival, with 5- and 10-year survival rtes of 92% and 45%, respectively, in recidivistic patients compared with 92% and 86% in abstinent patients [122]. The increased mortality at 10 years in these patients may be due to higher rates of cardiovascular events and cancers in patients that consume significant amounts of alcohol. Patients transplanted for ALD are also more likely to smoke pre and post-LTX [123] and suffer from higher rates of tobacco-associated malignancies after transplant [124].

It is clear that severe recurrent ALD can occur in recidivistic patients, leading to alcoholic hepatitis, cirrhosis, and liver failure, sometimes very soon after the transplant. These patients are usually not considered candidates for retransplantation and die of their disease. Abstinence really is the only hope for most of these patients. Treatment of alcoholic hepatitis in the allograft is similar to that in nontransplant patients, but no studies exist specifically addressing the transplant patient.

Recurrent vascular diseases

Hepatic venous outflow obstruction can be due to thrombosis (Budd–Chiari syndrome), right heart failure, and sinusoidal obstruction syndrome (SOS, or previously known as venoocclusive disease). As patients with right heart failure and SOS rarely receive a liver transplant, the discussion on recurrent vascular disease will focus on recurrent Budd–Chiari syndrome.

Budd–Chiari syndrome

Budd–Chiari syndrome can include thrombosis along any portion of the venous outflow tract and is usually attributed to a prothrombotic disorder requiring lifelong anticoagulation (although transplant is curative for protein C, protein S, and antithrombin III deficiency). Despite anticoagulation, Budd–Chiari syndrome has been reported to recur in up to 2–27% percent of patients [125–128]. One study [125], suggested a high rate of thrombus post transplant in patients transplanted for Budd–Chiari despite early post-transplant anticoagulation. Three of 11 patients (27%) developed early recurrent thrombus of the hepatic veins and an additional three patients developed other major vessel thrombi, whereas most other larger studies demonstrated much lower recurrence rates (1–7%) [127,128]. An alternative to anticoagulation in patients with Budd–Chiari syndrome secondary to myeloproliferative disease is the use of antiplatelet agents and hydroxyurea, since patients experienced equally low recurrence rates (1/10 patients, 10%) on this regimen [126].

Recurrent metabolic disease

Metabolic diseases comprise approximately 3–5% of all transplants performed in the United States (http://www.ustransplant.org/annual_reports/). The majority of metabolic diseases (tyrosinemia, urea cycle disorders, α_1-antitrypsin deficiency, etc.) are cured by transplantation. Hereditary hemochromatosis is a metabolic disorder of iron accumulation. A genetic predisposition underlies this iron accumulation, as described elsewhere in this textbook (see Chapters 29–31). It is unknown if the inadequate hepcidin response to iron levels is purely liver related, in which case transplantation can offer a cure. If the abnormal hepcidin response is a secondary reaction to a genetically predetermined trigger elsewhere in the iron metabolism event series, then transplantation would simply reset the clock, without altering the disease course. A recent study suggests the latter is more likely [129], but more data are needed. Recurrent disease, as defined by the iron accumulation within the liver, would then take decades to accumulate. Continued iron accumulation within other organs would be unaffected by transplantation, and thus more likely to impact longevity. Further ferritin and iron studies are recommended in these patients.

Conclusions

In summary, many of the most common indications for liver transplantation can recur following transplantation. The natural history of the disease in the allograft is not always the same as in the immunocompetent patient. Risk factors may help identify those patients at highest risk of recurrence, but we cannot reliably predict who will have a worse outcome relating to this recurrence. Recurrent disease, particularly hepatitis C, PSC, and possibly NASH, may increase the burden on liver retransplantation. With the limit on organ availability, more study into the prevention and management of recurrent disease is needed.

Multiple choice questions

47.1 An individual patient undergoing liver transplantation for hepatitis C virus (HCV)-related end-stage liver disease has a risk of cirrhosis by 5 years after transplant of how much?

a 1–2%.
b 3–5%.
c 10–15%.
d 20–30%.
e 40–50%.

47.2 A patient with hepatitis B end-stage liver disease has a liver transplant. The hepatitis B virus (HBV) DNA level is detectable at 10,000 copies/mL at the time of transplant. Management prophylaxis is initiated to prevent recurrence of HBV after transplant. You would recommend which of the following prophylactic regimens?

a Hepatitis B immunoglobulin (HBIg) monotherapy.
b Lamivudine monotherapy.
c HBIg × 1 month with indefinite lamivudine.
d HBIg and tenofovir combination therapy.
e Tenofovir monotherapy.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 48
The Role of Retransplantation

Peter L. Abt & Kim M. Olthoff
Department of Surgery, Division of Transplant Surgery, The Hospital of the University of Pennsylvania, Philadelphia, PA, USA

Key concepts

- Retransplantation after primary orthotopic liver transplantation (OLT) accounts for approximately 7–10% of all liver transplants in the United States.
- Overall graft and patient survival is lower following retransplantation compared with results after one transplant. The best outcome is achieved if retransplantation is undertaken immediately in the first week or at a much later stage after transplantation.
- Care should be taken in the decision to retransplant for recurrent disease. Severely decompensated patients who have poor functional status, high model for end-stage liver disease scores, advanced age, ventilator dependence, or require dialysis have relatively poor outcomes with retransplantation.
- Retransplantation for recurrent hepatitis C remains controversial; however the presence of hepatitis C virus in and of itself should not be a contraindication to retransplantation.
- Models to predict the outcome after retransplantation that take into account patient status, disease severity, and donor graft characteristics should be further developed and validated.
- Although retransplantation offers outcomes that are inferior to primary transplantation, it should still be offered as potential life-saving therapy in cases of acute graft dysfunction, and in well-selected cases of recurrent disease and chronic graft failure.

The great success of liver transplantation since the 1980s led to a rapid increase in the number of patients on the waiting list during the 1990s, with an unmatched increase in the number of deceased donor or living donors available. With the introduction of the model for end-stage liver disease (MELD) scoring system for organ allocation, the importance of waiting time for recipient priority was removed. Subsequently the waiting list size has stabilized, with slightly more than 26,000 patients alive on the waiting list at any time during the year for each of the last 8 years. The number of liver transplants performed each year in the United States peaked in 2006 at 6,363 and for the last published year (2008) was 6,069. Unfortunately wait list mortality, defined as dropout rate due to death or illness, has remained stable at 160 per 1,000 patient-years at risk since the inception of MELD [1]. Because of this disparity, the process of prioritizing individual patients for organ allocation is a constant source of debate, and is critical in the discussion of appropriate allocation of livers to patients with a failed first graft.

Despite increasing improvements in medical decision making, surgical technique, intensive care, and immunosuppression, a certain percentage of patients still experience acute or chronic graft failure and therefore require retransplantation – accounting for approximately 8–10% of all transplants performed in the United States per year. For the 12 months between July 2008 and June 2009, 7.5% of 11,089 new wait list registrants had a previous liver transplant and 8.4% of liver transplants were performed in patients with a prior transplant. The outcome after retransplantation in general is not as successful as with primary transplantation, with long-term survival decreasing with each successive transplant (Table 48.1 and Fig. 48.1) [2]. When considering retransplantation, it should be recognized that 7.7% of the newly listed patients from July 2008 to June 2009 died awaiting a transplant [3].

Liver retransplantation not only poses a clinical and technical challenge, but also brings to bear serious financial and ethical issues because of increased costs and a finite number of available donors. Hospital charges are significantly higher and the length of stay is longer for patients receiving a second transplant and there is an obligatory net loss from the donor organ pool for patients who may have a greater chance of survival [4,5]. In this chapter we will address the reasons for retransplantation,

technical considerations, factors that contribute to the outcome after retransplantation, and also briefly explore the ethics of retransplantation.

Rate of retransplantation and indications

The overall reported rate of retransplantation in individual centers seems to vary between 7% and 17% [2,5–14]. These rates have not remained constant over the years. The University of Pittsburgh studied the rates and causes of retransplantation in three eras – the early eighties, late eighties, and nineties. The overall rate of retransplantation declined significantly over time: from 33% in the early 1980s to 13% in the 1990s [11], likely the result of improved clinical judgment, immunosuppression, advanced technical skills, and better antiviral medications. The overall rate of retransplantation in the United States is decreasing, from 9.6% to 7.6% from 1999 to 2008 [1].

Just as the overall rate of retransplantation has changed over time, so have the indications for it. There has been a marked decrease in the rate of retransplantation for acute and chronic rejection. According to a series of 114 retransplants performed in Germany, the major causes of retransplantation during the early 1980s were acute and chronic rejection, with an incidence of 27% in each [15]. However, in a more recent series, the University of California at Los Angeles (UCLA) identified primary nonfunction (PNF) as the main cause, accounting for over 25% of all retransplantation cases [16]. According to data from a retrospective study of retransplantation at Pittsburgh over a 19-year period, the rate of retransplantation for rejection declined from 13.2% to 1%, and the rate of retransplantation for hepatic artery thrombosis (HAT) declined from 8.1% to 3.8%, with the rate for PNF increasing from 4.6% to 6.0% [11].

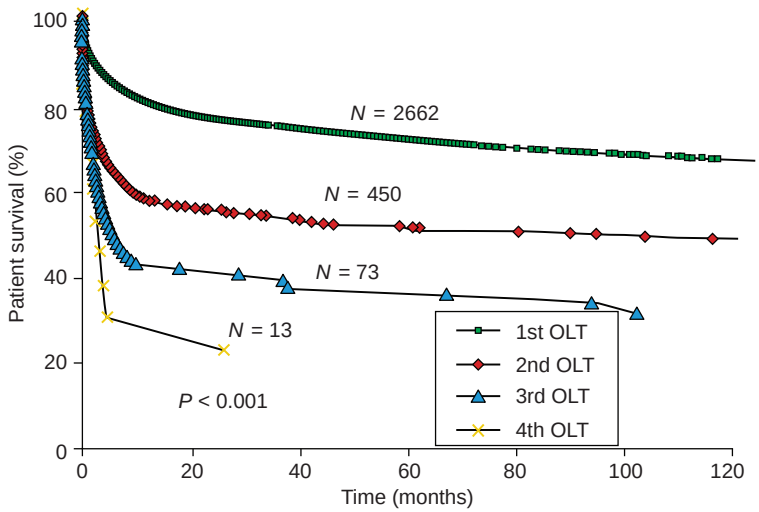

Figure 48.1 Survival estimates of recipients undergoing multiple liver transplantations. Recipient survival after primary orthotopic liver transplantation (OLT) was compared with survival after transplantation with second, third, or fourth OLTs in a single center series from the University of California at Los Angeles (UCLA) spanning two decades [2]. [a]Cause of graft failure of the primary transplant. Some patients may have multiple causes of graft failure.
Reproduced from Thuluvath et al. [1] with permission from Wiley-Blackwell.

There are several recipient characteristics that have been identified that predict a greater likelihood for retransplantation. Over the past 10 years the highest rate of retransplantation was observed in African-American recipients, who have a ratio of primary liver transplants to liver retransplants of 7.8 : 1. Asian recipients have the greatest utility of liver use, with one retransplant for every 15.1 allografts used. Woman have a slightly higher rate of retransplant of 1 : 10.5 compared with 1 : 11.6 livers utilized in males. The ratio of primary liver transplants to liver retransplants was lowest for acute hepatic necrosis where one of every 6.2 grafts were used for a retransplant and was greatest for malignant neoplasms where one of 40.1 grafts was used for retransplant. Interestingly, over the last 10 years there has been almost a three-fold difference in the rate of retransplantation among United Network for Organ Sharing (UNOS) regions. The region with the greatest risk of retransplantation was region 7, with one of 7.3 grafts being used for retransplant. Region 6 had the lowest rate of retransplant at a ratio of 1 : 20.4. The reasons for the disparity between geographic regions are unknown, but may reflect regional imbalances between the number of individuals awaiting transplant and the number of donors [1].

Retransplantation is also a significant event after pediatric liver transplantation, usually for different indications than adults, and often for technical reasons. The incidence of retransplantation in children is higher than in adults, with a range of 14–29% [17–20]. The use of split and reduced size grafts, the small size of donors and recipients, and noncompliance in the teen years are predisposing factors for an increased retransplantation rate in this population. The willingness of transplant surgeons and hepatologists to give more than one graft to children, or even more than two grafts, is greater, and, fortunately, outcome is significantly better in the pediatric population as well.

The indications for retransplantation for adults and children can essentially be divided into two groups – those patients needing emergent retransplantation in the early days and weeks following transplant due to graft failure secondary to graft dysfunction or technical complications, and those requiring late retransplantation due to chronic rejection, recurrence of disease, or late technical complications from vascular or biliary issues (Table 48.2).

Indications for early retransplantation

Primary graft dysfunction

Early graft dysfunction is a term that is used to describe a spectrum of clinical conditions in which the transplanted allograft fails to provide adequate metabolic and/or synthetic function. These patients present with various degrees of hemodynamic and metabolic instability, and the potential for the development of multiorgan system failure. The severity of global hepatic dysfunction may be assessed by biochemical and metabolic markers including elevated transaminases, persistence of metabolic acidosis, an elevated international normalized ratio (INR),

and rising bilirubin. A diagnosis of PNF is a diagnosis of exclusion made if a graft shows complete lack of initial function and its dysfunction cannot be attributed to technical or other recipient causes, and is the most common cause of retransplantation in the initial days after orthotopic liver transplantation (OLT). A more stringent definition is used for the allocation of a second organ, where PNF is defined as graft dysfunction within the first week post transplant leading to the death of the patient or retransplantation. Requirements include an aspartate aminotransferase (AST) of 3,000 U/L or more, and either an INR of 2.5 or more, a pH of less than 7.3, or a lactate value of 4.0 mmol/L or more. This allows for the rapid relisting of patients as status 1, which places the patient at the top of the allocation list. Other grafts may present with a less dramatic picture, demonstrating prolonged cholestasis, evidence of ischemic/harvest injury on biopsy, and slow or inadequate restoration of function. Termed *early allograft dysfunction* (EAD) or delayed nonfunction (DNF) these grafts may require retransplantation if they fail to recover, although they often do not meet status 1 criteria. These patients often have prolonged intensive care unit stays with an increased risk of serious infectious complications [21,22]. While many of these grafts recover, approximately one quarter of grafts exhibiting EAD criteria (high transaminases, prolonged cholestasis or coagulapathy) are lost in the first 6 months [23].

The use of "marginal" or extended criteria donor (ECD) grafts – that is, grafts from higher risk donors based on demographic, clinical, laboratory, or histologic data – may increase the risk for early graft dysfunction. Although the definition of ECD is not clearly defined, grafts that may have an increased risk of graft dysfunction usually include livers from older donors, donation after cardiac death (DCD) donors, steatotic livers, split liver grafts, and those with prolonged cold ischemic times. Each of these factors has been associated with decreased graft survival, thereby leading to an increased potential need for retransplantation. The donor risk index (DRI) is a more recent measure of donor quality assessed in terms of the risk of graft loss, which incorporates these and other donor variables [24]. There is an increasing risk of retransplantation as DRI increases [1].

Over the last decade there has been a 36% increase in the use of donors with a higher DRI value (>1.8) (Fig. 48.2). For example, there were 663 donor liver grafts from persons over 65 years (9.6% of all liver grafts) in 2007, compared with only 164 older grafts (4% of all grafts) in 1994. An increased rate of PNF has been associated with an increase in the utilization of donor organs from donors above 50 years of age [11]. There has also been an increase in the number of DCD livers over the last decade. In 1998, 24 (0.54%) deceased donor liver transplants were DCD, in 2009 this had increased to 290 (4.75%) (data from UNOS). Recipients of a DCD organ have a 13.0% risk of retransplant compared with 7.1% for donation after brain death (DBD) organ recipients. From an ethical perspective, it is precisely the availability of retransplantation organs of a high status that allows the use of these ECD donors by providing a safety net if the ECD liver does not function properly. Previously, these grafts were used in patients in desperate situations and

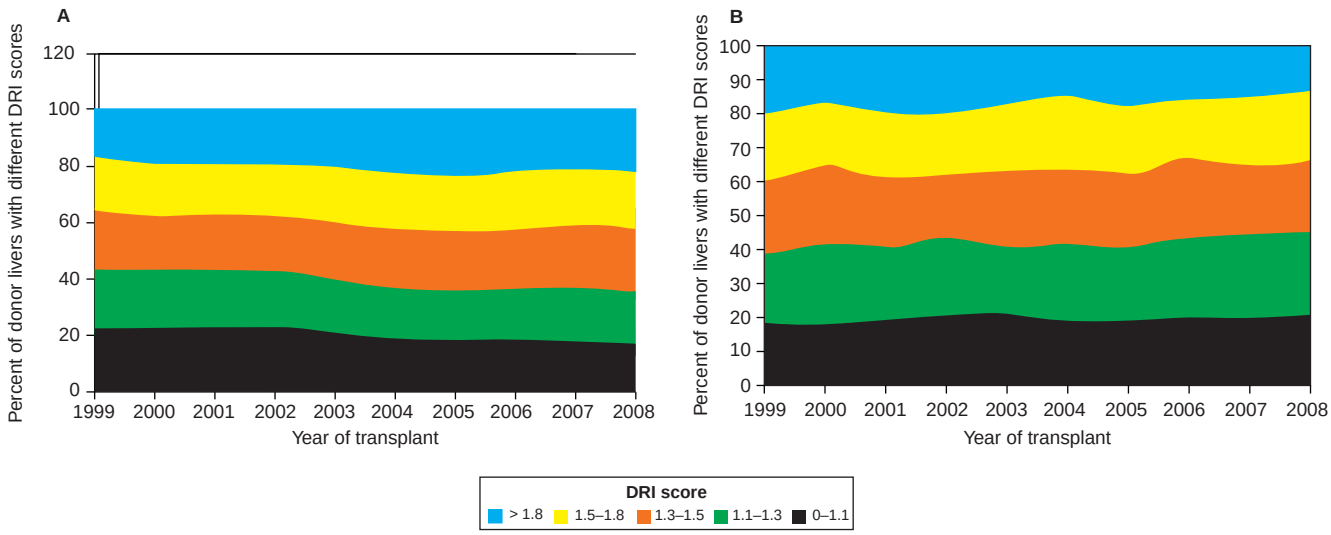

Figure 48.2 The donor risk index (DRI) for livers used for primary transplant (A) and retransplantation (B) for transplants performed between 1999 and 2008. (A) There has been a decrease in the percentage of donors with a DRI of <1.3 (17% decrease) and an increase in donors with a DRI of >1.8 (36% increase). (B) The DRI of livers used for retransplantation decreased with an 18% increase in donors with a DRI of <1.3 and a decrease in donors with a DRI of >1.8 (36%). (Reproduced from Thuluvath [1] with permission from Wiley-Blackwell. Data as of May 2009 from the Scientific Registry of Transplant Recipient (SRTR) database.)

were associated with dismal graft and patient survival. There is some debate as to which patients are acceptable candidates for these grafts, but in general less critically ill recipients are appropriate, as more stable patients may be able to better tolerate a period of relative graft dysfunction or the need for a retransplant procedure [25]. Although this matching of donor to recipient is ideal, it is often not possible with our current allocation system, which does not factor in graft quality.

Hepatic artery thrombosis

Acute HAT, despite a decreasing incidence (approximately 5%), is still a devastating problem that often requires retransplantation and is associated with markedly increased morbidity and mortality. In a review of 15 European liver transplant centers, the incidence of HAT was less than 5% but the mortality rate was as high as 55% and the retransplantation rate was approximately 80% [26]. The use of fibrinolysis, surgical thrombectomy, and immediate revascularization may avoid the necessity of retransplantation in some instances, but most patients still need a second graft. Previously, patients with HAT were designated as status 1 if diagnosed in the first week. However, recent data have shown that patients with HAT have a significantly lower risk of death while awaiting retransplantation than those requiring transplantation for other status 1 designations (fulminant failure or PNF) [27]. Therefore, HAT can only be given status 1A in adults if associated with a fulminant type of hepatic failure in the first 7 days (up to 14 days in children). In those not expressing signs of fulminant failure and those diagnosed beyond 7 days, increased MELD exception points up to 40 may be requested.

Indications for late retransplantation

Chronic rejection

Current modalities in immunosuppression have essentially eliminated the need for retransplantation for acute rejection, and the incidence of retransplantation for chronic rejection has declined significantly. However, it still remains a significant cause in the late retransplant group. In a large series from Gainesville, Florida, 27% of late retransplants in both children and adults were for chronic rejection [4], and the Kyoto group reported a 35% rate of chronic rejection in a series of living donor liver transplants as a cause for primary graft loss requiring retransplantation [28].

Primary biliary cirrhosis

Although there was initially some controversy, the recurrence of primary biliary cirrhosis (PBC) has been reported and is estimated at about 10–20%, occurring on average 3–6 years after transplantation. Pathology is considered the gold standard to diagnose recurrent PBC with the hallmark feature of granulomatous bile duct destruction. There is no correlation between antimitochondrial antibody (AMA) titer and clinical or histologic recurrence of PBC [29]. Progression of recurrent PBC is often slow and may not necessitate retransplantation [30]. In a series from the University of California, San Francisco (UCSF), recurrence of PBC was seen in eight patients with three graft failures that resulted in one death, one relisting for transplant, and one successful retransplant [31]. Ursodeoxycholic acid therapy for recurrent PBC is associated with biochemical improvement, but its role in delaying histologic progression remains unknown. [32].

Primary sclerosing cholangitis

Evidence of the recurrence of primary sclerosing cholangitis (PSC) has been documented with rates ranging from 14% to 41% post-OLT [33]. Cholangiographic and biochemical evidence along with histologic findings support the diagnosis of recurrence. Injury to the bile ducts due to anastomotic, ischemic, and infection-related strictures may present similarly to PSC, therefore these causes of bile duct damage must first be ruled out. In a study of the UNOS database of 2,154 patients with PSC, 315 (14.6%) required retransplantation [34]. It was postulated that the reasons behind this were not just disease recurrence, but also a high rate of biliary complications and chronic rejection.

Autoimmune hepatitis

Liver transplantation for autoimmune hepatitis (AIH) is highly successful; however, there is a high risk of rejection and severe recurrent AIH. Recurrence rates range from 16% to 46%. Recurrence is characterized by clinical deterioration, histology, elevated transaminases, and increased immunoglobulins. Treatment with steroids and increased immunosuppression may control disease progression, but a significant number of patients may require retransplantation [35].

Nonalcoholic steatohepatitis

Small case series have demonstrated recurrent nonalcoholic steatohepatitis (NASH) in 10–47% of patients post-OLT [36,37]. Diabetes mellitus, hyperlipidemia, and obesity, often associated with NASH, are common after transplantation and progression from fatty liver to cirrhosis post-OLT has been documented in serial biopsies, with cumulative steroid use being a potential risk factor [37]. There are very few, if any, data on retransplantation for recurrent NASH, but as the percentage of patients that are transplanted for this disease increases in the United States it may become a very significant concern.

Alcoholic liver disease

Alcoholic liver disease is the second most common cause of liver failure leading to OLT. Multiple studies have looked at recidivism rates that may be as high as 30–40%, but the recurrence of alcohol-induced cirrhosis and liver failure is rare [38]. Earlier arguments that suggested that alcohol recidivism would lead to poor adherence to immunosuppressive regimens and premature graft loss have also been proven false [39]. Obviously, resumption of alcohol use would be a contraindication for re-OLT and careful assessment of the psychosocial situation is necessary before approval in this patient group.

Hepatitis B virus

Historically, recurrent hepatitis B virus (HBV) after OLT resulted in rapidly progressive hepatic deterioration and extremely high mortality rates [40]. Prophylaxis with hepatitis B immunoglobulin (HBIg) and oral nucleoside therapy has greatly decreased the recurrence rate and made survival following OLT for patients with hepatitis B comparable to those with other causes of liver disease [41]. However, occasional recurrence evolves (approximately 5%), mainly due to acquired HBV mutations [42], although retransplantation for recurrent disease is now rare.

Hepatitis C virus

Cirrhosis from hepatitis C virus (HCV) is now the most common indication for liver transplantation in the United States [43]. After liver transplantation, HCV can be detected in the serum of nearly all patients who had HCV before transplant, although the degree of histologic recurrence is highly variable [44]. Hepatitis C viral RNA levels may increase to up to ten times those of pre-OLT levels at 4 weeks after transplantation and hepatic fibrosis may have an accelerated course [45–48]. Unlike HBV, no therapy has been conclusively shown to alter HCV recurrence or disease progression, although some progress has been made in antiviral therapy [49,50]. The natural history of post-transplant HCV infection is generally indolent but approximately 10–30% may have continuing graft damage progressing to cirrhosis in 5–10 years, and this percentage may be increasing [51,52]. However, once cirrhosis develops complications are common. Within 1 year of the finding of recurrent cirrhosis, 40% of patients develop evidence of hepatic decompensation and less than 50% survive a year from the time of decompensation [53].

Results of retransplantation

Comparison with primary transplantation

Early studies in liver transplantation showed significantly worse patient and graft survival after retransplantation when compared with primary transplants. Improvements in the results of primary grafting as well as the outcome of retransplantation have been noted. Between 1999 and 2008, the 1-year primary liver transplant survival rate improved by 4.1%, but the survival for first retransplants increased by 13% [1] (Fig. 48.3). However, when all patients are included, the results with retransplantation still fall short of primary grafting [54,55].

Timing of retransplantation

Several analyses have shown that timing plays an important role in the outcome of retransplantation [6,54,56,57]. The series from UCLA demonstrated that the survival of patients who underwent transplantation within 1 week is nearly equivalent to that seen in patients who underwent retransplantation at a much later date. It was the patients who underwent retransplantation in the period between 8 and 30 days who had a significantly worse outcome, emphasizing the need for early recognition of patients who require early retransplantation.

There is a clear differential outcome between those requiring early urgent retransplantation and those who require an "elective" second graft. In some cases, patients who underwent retransplantation many months after the primary transplant exhibited survival curves similar to those receiving a single transplant. For urgent retransplantation, which likely coincides with the first 30 days after surgery and is likely due to primary graft dysfunction, hospital charges are higher, the length of stay longer, and survival worse [5]. Although easier from a technical point of view, the mortality is likely high because of the poor clinical condition of the recipient [10].

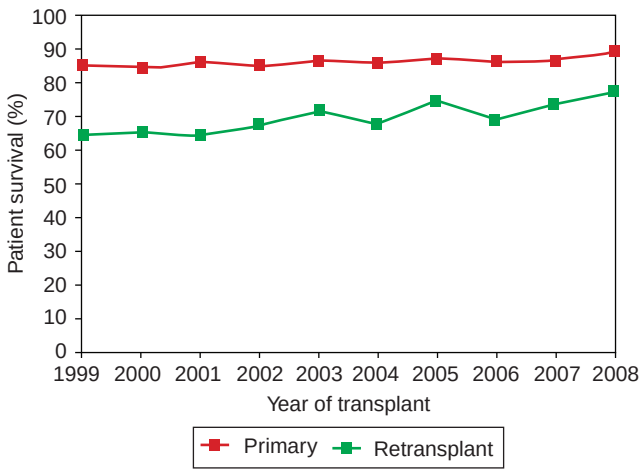

Figure 48.3 One-year patient survival for primary and retransplantation by year of transplant. (Reproduced from Thuluvath et al. [1] with permission from Wiley-Blackwell.)

Outcomes of retransplantation in hepatitis C virus patients

This remains a controversial subject with a great difference of opinion between centers. Early reports suggested that retransplant in HCV patients had a significantly worse outcome compared with other diseases, with the presence of HCV being an independent risk factor for increased mortality [47,58–61]. The presence of early fibrosing cholestatic hepatitis was considered a contraindication for retransplantation by many centers. Looking carefully at some of the earlier reports, it is found that many of the postoperative deaths were in the first 90 days, perhaps reflecting not just death from severe recurrent HCV, but also the poor perioperative condition of patients with recurrent HCV undergoing retransplantation. Some centers have supported retransplantation for recurrent HCV if retransplantation was performed early in the course of the recurrent disease [58]. Others have reported that it is the physical condition of the HCV-infected patient at the time of retransplantation that is most predictive of outcome [62]. An analysis with data from the Scientific Registry of Transplant Recipients (SRTR) assessed the relative effect of HCV diagnosis on mortality after retransplantation, demonstrating that retransplant recipients with HCV had a 30% higher covariate-adjusted mortality risk than those without HCV (Fig. 48.4) [63]. Of concern was the fact that the increased risk associated with mortality was concentrated in younger patients (age 18–39 years) and in patients transplanted in more recent years (2000 to 2002), perhaps reflecting a willingness of transplant centers to perform retransplantation in younger patients who may be more severely ill. This study, however, did not compare outcomes between recipients with HCV and other specific disorders, and inherent differences between cohorts may have less importance than the degree of illness at the time of re-OLT [64].

Positive HCV status is the most common diagnosis in retransplant patients, with an increase from 36% to 40.6% of all retransplant patients between 1994 and 2005 [1]. Survival among HCV patients who undergo retransplant is increasing, with a 1-year survival of 70.7% [65]. In some reports there appears to be little difference in the survival rate for HCV patients undergoing re-OLT when compared with other causes of re-OLT, if all other variables are kept equal [66,67], and therefore retransplantation should be considered a potential option for the treatment of recurrent disease [68]. A more recent analysis with national data demonstrated the importance of timing of retransplant in HCV. Patients with HCV who undergo retransplant within 90 days have similar survival rates as those with other diagnoses undergoing retransplant. However beyond 90 days, patients with HCV continue to have inferior outcomes (Fig. 48.5). The equivalent survival for those who undergo retransplantation within a short interval from the primary transplant likely reflects non-HCV causes of graft dysfunction as compared with those who undergo retransplant beyond 90 days [65]. HCV patients require a more careful decision-making process when compared with non-HCV patients, and re-OLT is best performed before severe decompensation

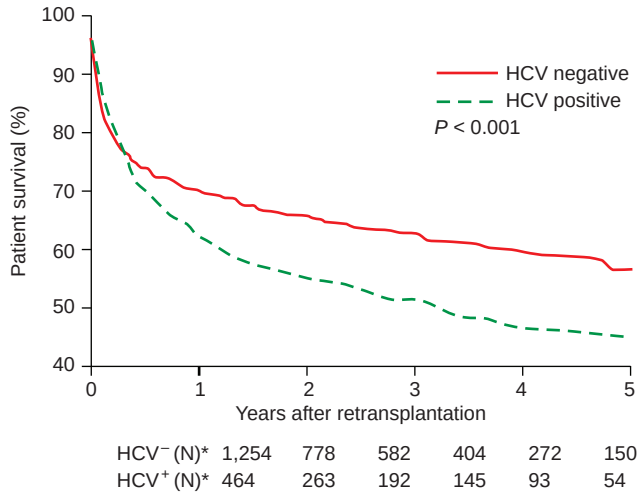

Figure 48.4 Kaplan–Meier curves comparing unadjusted mortality between hepatitis C virus (HCV) positive and HCV-negative liver retransplant recipients in a cohort of patients who underwent retransplantation between 1997 and 2002 using the Scientific Registry of Transplant Recipient (SRTR) database. (Reproduced from Pelletier et al. [63] with permission from American Association for the Study of Liver Diseases.)

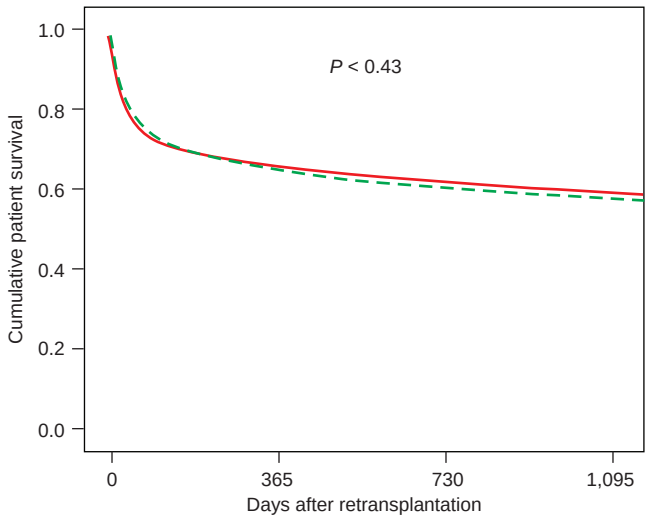

Figure 48.5 Kaplan–Meier curves comparing patient mortality between hepatitis C virus (HCV) positive and HCV-negative liver retransplant recipients from 1994 and 2005 using OPTN (Organ Procurement and Transplantation Network) data. There is no difference in survival for HCV-positive (dashed line) and HCV-negative (solid line) patients if the retransplant is performed within 90 days of the prior transplant. (Reproduced from Ghabril et al. [65] with permission from Wiley-Blackwell.)

[55,69]. This can be a difficult task in the current system of liver allocation that provides grafts to the "sickest first."

Cause of death following retransplantation

The development of sepsis and multiorgan failure accounts for most of the deaths in patients undergoing retransplantation, and the largest proportion of deaths occur in the first few weeks after transplant [70]. The incidence of death secondary to sepsis is twice as high in patients undergoing retransplantation compared with those receiving just one graft, with a 50% incidence of fungal infection [59,71]. In a series from UCSF, 28% of patients who underwent retransplantation experienced serious infections in the first month, and 17.5% died within the first 6 months from multiorgan dysfunction associated with sepsis or poor graft function [72]. Roayaie et al. reported that approximately two thirds of deaths after retransplant for HCV recurrence were associated with infection [61]. The high incidence of graft loss due to sepsis in these patients may reflect the immunosuppressed status of the patients prior to retransplantation, as well as their deteriorated functional status. In light of these findings, it may be prudent to reduce immunosuppression perioperatively and initiate more effective antimicrobial prophylaxis for patients undergoing retransplantation. Less frequent causes of death following retransplantation include technical problems such as intraoperative mortality, arterial and portal vein thrombosis, and postoperative complications such as cardiac events, neurologic complications, recurrent disease, and persistent liver failure.

Predictors of mortality after retransplantation

In an attempt to maximize the use of valuable organs, there have been many efforts to determine which factors are associated with the outcome in order to develop a model that might accurately predict survival in patients undergoing liver retransplantation. It has become increasingly apparent that it is not just the quality of the donor but also the status of the recipient that contributes most to the outcome after retransplantation. A multivariate analysis performed at UCLA determined that donor cold ischemia time over 12 hours, preoperative mechanical ventilator requirement, preoperative serum creatinine greater than 1.6 mg/dL, and serum total bilirubin over 13 mg/dL were all independent risk factors predictive of a patient's poor outcome [57,71]. Rosen and Martin identified bilirubin and creatinine as predictive of poor outcome in HCV patients [60]. The University of Pittsburgh identified older donor age, gender, and choice of immunosuppression as predictive of poor outcome [56]. In a series from Mount Sinai Medical Center, recipient age over 50 years, a preoperative creatinine greater than 2 mg/dL, and the use of intraoperative blood products significantly impacted the survival of those patients requiring retransplantation within 6 months of the primary transplant [59].

Models to predict survival after retransplantation

The critical shortage of donor organs and the resultant prolonged patient waiting periods before transplantation have prompted many to define a mathematic model that adequately predicts survival after retransplantation. Rosen et al. assigned a mortality risk score based on preoperative variables in patients undergoing retransplantation, which included recipient age, creatinine, bilirubin, non-PNF diagnosis, and UNOS status [73]. Individual patients were then stratified into low-, medium-, and high-risk groups, in an attempt to predict survival; recipient age, creatinine and bilirubin levels, and timing of transplant between 15 and 60 days were found to be predictive of outcome. These findings were validated in a multicenter international study [74]. Another model put forward by Markmann et al. from the UCLA database similarly employed a scoring system utilizing five noninvasive and readily available clinical parameters: recipient age, creatinine, bilirubin, cold ischemia time, and ventilatory status [71]. Patients having four out of a possible five points had a 1-year survival of only 27%. This classification system adequately discriminated high-risk and low-survival patients in three databases to which it was applied. A universal model for predicting survival was proposed by Ghobrial et al. for both primary transplants and retransplants, hoping to provide guidance for tailoring specific organ needs to specific recipients on the basis of the severity of disease and expected outcomes. The model incorporated MELD score, recipient age, and timing of transplantation [69].

Interestingly, none of these models found the diagnosis of HCV as a poor prognostic indicator in multivariate analysis. More recent work has focused on the importance of donor factors to recipient survival after retransplant. The addition of the cause of graft failure to the DRI to create the retransplant donor risk index was highly predictive of death after retransplant [75]. Applications of models such as these can theoretically result in better decision making, improved survival, and an increased efficacy in organ utilization.

MELD score and retransplantation

In primary transplantation, MELD score has not correlated with post-transplant outcome except at the very highest MELD scores [76]. However, in the population who undergo retransplantation, MELD score may have a more significant impact, although there is some disagreement here as well (Table 48.3) [67,77]. MELD scores

Table 48.3 Survival after liver retransplantation based upon MELD score.

MELD score	1 year	5 year
<10	83%	55%
11–20	65%	55%
21–25	62%	47%
26–30	57%	37%
>30	42%	21%

Adapted from Zimmerman and Ghobrial [81] and Watt et al. [67].

correlated with survival outcome in patients who underwent retransplantation at the University of Nebraska [78]. In the multicenter study by Rosen, the MELD score was predictive of survival in patients undergoing retransplantation after 15 days [74]. Yao et al. noted a trend for a correlation between the Child–Turcotte–Pugh (CTP) and MELD scores with 1-year post-OLT mortality, with CTP values of 10+ and MELD scores of 25+ having worse outcomes at 1 and 5 years [72]. These studies demonstrate that using MELD scores for liver allocation in this patient population may have distinct disadvantages, because patients undergoing retransplantation would need to be quite ill before reaching the top of the allocation list, thereby losing their "window of opportunity" to have a good outcome after retransplantation. Other models have been proposed to determine which MELD score is associated with the greatest utility for retransplantation in patients with HCV and those without HCV. The optimal outcome for retransplantation appears to be achieved at MELD scores of less than 28, with the maximal utility achieved at a MELD score of 21 for patients with HCV, and a MELD score of 24 for patients without HCV [79]. Unfortunately, this is not an option in many parts of the United States where the mean MELD score at transplant is significantly higher.

Living donor liver transplantation and retransplantation

With the use of right lobe grafts for adult liver transplants, transplant surgeons and hepatologists are faced with technical decisions regarding the use of living donors for retransplants, and ethical issues whether retransplantation should be performed in living donor recipients transplanted outside UNOS criteria, such as for large hepatocellular carcinoma. In a series of living donor liver transplants (LDLTs) from the A2ALL consortium, 37 of 385 (9.6%) recipients of adult to adult LDLTs required retransplantation, mostly for technical reasons [80]. These technical issues markedly decreased as experience improved, and it may be that there will be less retransplantation in this group as technical complications decrease.

The vast majority of retransplants are done with whole deceased donor grafts due to the technical demands of retransplantation and anatomic limitations of LDLTs. Data provided from UNOS demonstrated that from January 1999 until December of 2009 4,656 retransplants were performed in adults, and only 45 (0.97%) were with living donor liver allografts. During the same period of time, 758 retransplants were performed in children, 57 (7.5%) of whom received a living donor allograft.

Conclusions

The outcome of retransplantation is improving; however, survival after retransplantation is currently less than after primary OLT. Certain clinical criteria have been found to affect the outcome of retransplantation. The most important factors appear to be the preoperative status of the recipient as indicated by ventilator dependence, renal failure, physical condition, age, and MELD score. The time interval to retransplantation, donor cold ischemia time, and donor quality also contribute to the overall outcome. The overall impact of retransplantation on the survival of all patients awaiting liver transplantation and the cost-effectiveness of this procedure are issues of current debate. What also remains controversial and unanswered is retransplantation for recurrent HCV. National data demonstrate poorer outcomes when retransplantation is done beyond 90 days of the primary transplant, but other studies have demonstrated similar outcomes compared with other diagnoses [68]. Patient medical status is predictive in this population, and it may be that improved judgment ensures better outcomes in this patient population [64].

Despite continued improvements, the generally inferior outcome has prompted many to question the appropriateness of hepatic retransplantation on both economic and ethical grounds. On the other hand, an outright prohibition of hepatic retransplantation raises its own ethical questions of patient abandonment. In addition, limiting retransplantation would impede current efforts to expand the organ pool by the utilization of marginal donors. The safety net of retransplantation is needed if an aggressive donor organ acceptance strategy is to be adopted by all transplant centers. Retransplantation is an essential treatment for patients undergoing liver transplant who experience liver failure after their primary transplant. However, it must be applied with some discretion and careful decision making so that futility is avoided and maximal utility is achieved. Relying on the MELD score alone to allocate organs seems insufficient in this patient population and needs to be studied. Futile transplants

and retransplantation in subgroups of patients with little chance of successful outcome should be avoided.

CHAPTER 49

Controversies in Liver Transplantation

James F. Trotter

Division of Transplant Hepatology, Baylor University Medical Center, Dallas, TX, USA

Key concepts

- The institution of liver allocation based on the model for end-stage liver disease (MELD) score was created to alleviate problems that developed under previous liver allocation schemes.
- Liver allocation based on the MELD score has improved the triage of liver candidates by reducing the waiting list mortality rate.
- Despite these improvements, problems remain with regard to liver allocation and distribution.
- While the MELD score is an objective scoring system, relevant variation in the MELD score exists related largely to interlaboratory variation in measuring the serum creatinine and international normalized ratio.
- The institution of donation after cardiac death organs has increased the number of deceased donor organs available for transplantation.
- The application of living donor liver transplantation has decreased by more than half in the past several years.
- The definition of the expanded criteria donor has helped to identify specific donor and transplant characteristics associated with poor outcome.

Controversy is synonymous with liver transplantation where the stakes are high and the resources, in terms of donors, are limited. Through the years, medical advances in the field of transplantation have vastly improved the outcomes for recipients and the availability of donors. In such a dynamic field, disputes over the most effective application of this procedure are commonplace. Therefore, this chapter will focus on some of the most important current controversies in liver transplantation including liver allocation and distribution, variations in model for end-stage liver disease (MELD) score, donation after cardiac death (DCD), living donor liver transplantation (LDLT), expanded criteria donor (ECD), and MELD exception scores.

Liver allocation and distribution

The equitable allocation and distribution of donor livers has been a controversial issue since liver transplantation became widely available more than a quarter of a century ago. The terms "allocation" and "distribution" reflect different processes and for the purposes of this discussion will be defined as follows. *Allocation* is the process by which liver candidates are prioritized for transplantation. The allocation scheme is dictated and overseen nationally by the United Network for Organ Sharing (UNOS) and is currently based almost entirely on the MELD score [1,2]. In addition, some patients may also receive a MELD score based on exception diagnoses as described below. Prioritizing patients for transplant has been one of the most controversial areas in the field and is continuously evolving to meet the changing requirements of liver transplant candidates. *Distribution* is essentially the delivery process; that is, the system by which donor livers are procured, matched, and delivered (transplanted) into prioritized patients within a geographic region. Perhaps more complex than liver allocation, distribution involves the supply (number of donor organs) and demand (number of transplant candidates) within a geographic area, as well as acceptance of specific organs for transplant based on their quality (or lack thereof) and policies regarding organ retention or sharing within the area.

Much of the ongoing controversy related to prioritizing patients and distributing donor organs for transplantation is the result of the increasing demand for the procedure. Since the inception of liver transplantation, the demand for organs has outpaced the supply. Consequently, as the liver transplant list grew over time, the disparity widened between the number of transplant

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

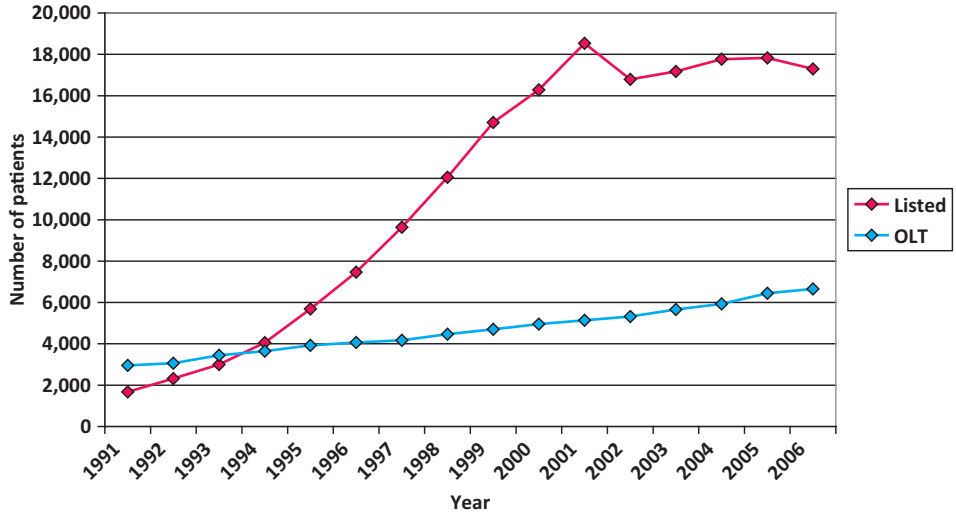

Figure 49.1 Number of listed and transplanted patients versus year. OLT, orthotopic liver transplant.

candidates and the limited donor pool. As a result, the competition for organs became increasingly intense and the prioritization of liver candidates and distribution of donor organs, in turn, more complicated. Through the years, three fundamental principles have formed the basis for liver allocation and distribution: (i) triage – the sickest liver candidates receive a higher priority for transplant compared with less sick patients; (ii) "first come, first served" – patients listed earlier receive a higher priority than patients listed later; and (iii) local organ utilization – donor organs are transplanted preferentially in the area of procurement. Most of the disputes about liver allocation and the distribution system over time are reflected in the relative importance given to each of these three principles. To understand the current controversies one must understand how the current system evolved [3].

Liver allocation is in a constant state of evolution. In the early 1990s when fewer patients were listed and competition for donor organ was less intense, liver allocation was less complicated. Candidates were prioritized based on only two criteria: waiting time and severity of illness as determined by the Child–Turcotte–Pugh (CTP) score; the higher the score, the higher the priority for transplant. There were only four gradations of illness (or statuses): status 3 for stable chronic patients (CTP score <10), status 2B for decompensated patients (CTP score ≥ 10), status 2A for critically ill patients (expected to die in less than 7 days), and status 1 for acute liver failure. Within each status, patients with the longest waiting time had the highest priority. Consequently, waiting time was an important determinant in prioritization for transplant. This system functioned relatively well during the time when the waiting list was small. In fact, in the early 1990s, the number of liver transplants exceeded the number of listed patients. However, during that decade, the size of the transplant list increased nearly ten-fold from 1,676 in 1991 to 16,292 in 2000 (Fig. 49.1). With the growing number of patients listed for transplant, three specific allocation problems became manifest. First, there were too few grades (statuses) of illness to adequately differentiate and prioritize thousands of patients. Therefore, physicians recognized the need for a more precise and complex prioritization scheme, especially for patients with decompensated disease whose need for transplant was greatest. Second, the inclusion of subjective variables in the CTP score (i.e., degree of ascites and encephalopathy) led to widespread "gaming" of the system. That is, physicians could describe the severity of ascites and encephalopathy in the worst possible terms, thereby increasing a patient's priority for transplantation. Third, waiting time was given too much emphasis. This was especially true for the lower priority statuses, status 2B and 3 (which accounted for two thirds of liver transplant recipients), where patients with longer waiting times were frequently transplanted ahead of sicker patients. In addition, because of the importance of waiting time, patients sought early listing to increase their priority for transplant. Consequently, the transplant list swelled with candidates whose need for transplant was quite low.

These problems in allocation were further compounded by flaws that developed in liver distribution. Until 15 years ago, liver transplantation was primarily performed in a relatively few, selected, large centers. Consequently, liver recipients traveled great distances and, in turn, since many regions did not have a transplant center, all locally procured donor organs were distributed out of the local area to these larger transplant centers. However, as more and more physicians became trained in transplantation during the 1980s and 1990s, they set up new transplant centers across the United States. While

increasing access to transplantation, these centers created novel challenges in liver distribution. Start-up centers began to compete with the larger, more established centers for the limited donor pool. The allocation and distribution of these donor livers is directed nationally by UNOS, although the functional unit is the local organ procurement organization (OPO) of which there are 50 across the United States. With few exceptions, preference is given to distributing donor livers to recipients listed within the local OPO. In fact, 70% of donor livers are transplanted into local recipients.

With the proliferation of liver transplant centers, a fundamental debate emerged regarding two competing interests in liver distribution: (i) retaining organs within the OPO of procurement based on considerations of efficiency and local organ ownership, versus (ii) sharing organs over a wider geographic region to expand the potential recipient pool, allowing sicker patients greater access to donor livers. In the debate over liver distribution, the new, smaller centers argued that they could provide excellent local transplant care obviating the need for patients relocating to larger centers. Local distribution of donor livers also has the advantage of faster and more efficient transplantation, which may improve recipient outcomes. In addition, it may permit greater use of ECD livers. Since these organs are particularly sensitive to prolonged cold ischemic time (the time between organ procurement and transplantation), they are less well adapted to regional sharing, which requires time to transport organs over great distances. On the other hand, the larger centers contended that distributing livers to their sicker patients would make better use of a precious resource, especially if the transplant was performed by their experienced team. Local ownership of donor organs was another factor that became a critical component in the debate. The establishment of a new transplant center within a state became an issue of local pride and retention of donor organs a requirement to maintain the center's viability. As a result, some states attempted to pass laws restricting the transport of organs outside their boundaries. Finally, the debate was further fueled by differences that emerged in the types of patients listed at small and large centers. Compared to the large centers, smaller programs had shorter lists with fewer sick patients. The established larger centers had built long lists with critically ill patients through years of national and international referrals. These differences in patient populations along with the local retention of donor organs led to wide disparities in transplant access across the United States. Less sick patients at small centers were transplanted much faster than sicker patients waiting in larger hospitals.

These systemic problems became increasingly acute as the national waiting list grew and more patients required access to donor organs. The inherent flaws in the liver allocation and distribution scheme led to a national perception amongst professionals and even the lay public that the system did not work properly. By the late 1990s, the discourse grew so intense that the federal government stepped in to perform an independent review of the entire process through the Institute of Medicine [4]. Their conclusions were expressed in regulatory terms through the "final rule" that stipulated three major revisions in allocation (points 1 and 2) and distribution (point 3):

1. Since it was determined to be irrelevant to a patient's need for transplant, waiting time should be eliminated as a determinant for prioritization.
2. The prioritization of liver candidates for transplantation should be based on an objective and more precise scoring system.
3. In order to provide equitable access to liver transplantation across the country, uniform and larger organ distribution areas, each serving a population base of at least 9 million people, should be established. Organs should be allocated and distributed based on patients' medical needs with less emphasis placed on keeping organs in the local area where they are procured.

Two of these three recommendations were fully implemented. Most notable, the MELD score was established as the means for prioritizing candidates for transplantation. The MELD score is based on a mathematical model predictive of 90-day mortality and defined by the following equation, which includes only three objective variables (serum creatinine, bilirubin, and international normalized ratio (INR)):

$$0.957 \times \ln(\text{creatinine mg/dL}) + 0.378 \times \ln(\text{bilirubin mg/dL}) + 1.120 \times \ln(\text{INR}) + 0.6431.$$

The higher each determinant value, the higher the MELD score and 90-day mortality, and the higher the priority for transplant. Each patient is awarded a MELD score, expressed in whole numbers; the minimum score is 6 and the maximum value is capped at 40. Thus, there are 35 possible MELD scores, compared to four under the prior system. While remaining as a determinant, waiting time serves as a "tie breaker" for candidates with the same MELD score. Since the number of gradations of status increased from four to 35, waiting time was greatly devalued under the MELD system compared with the earlier allocation scheme. In addition, the MELD score offered the possibility of achieving national parity in prioritizing patients for transplantation. Since it was determined solely by objective variables, the MELD score should be the same across the country with little of the subjective variability that plagued earlier allocation schemes.

Following implementation of MELD-based liver allocation in 2002 in the United States, several important

changes occurred. First, the triage of transplant candidates improved and sicker patients were more effectively prioritized and transplanted than under the prior allocation system [5,6]. As a result, sicker patients were transplanted faster and correspondingly the number of patients dying on the waiting list dropped by 16% between 2001 and 2006. As expected, patients were sicker at the time of transplant, and the average MELD score of liver transplant recipients increased from 14 before MELD-based allocation to 22 afterwards. Second, the emphasis on waiting time was greatly reduced. As a result, fewer patients sought early listing and some of those with compensated liver disease were removed from the list. Therefore, the number of listed patients dropped by 13%, from 11,126 in 2001 to 9,646 the following year [7]. Third, unrelated to the implementation of MELD-based allocation, the donor supply improved. The total number of donors increased 30% from 2001 to 2006 due to activity on several fronts (as discussed below) including a nationwide initiative aimed at increasing donor awareness and more aggressive utilization of previously untapped sources of donors. Finally, the allocation system was further amended in 2005 to reduce the transplant priority for less sick patients. The basis for this amendment was the observation that many low MELD score patients (MELD score <15) were still able to receive a liver transplant, particularly in regions of the country with an ample donor supply.

In fact, between September 2001 and June 2003, 24% of all US liver recipients had a MELD score <15. Since many of these recipients had compensated liver disease, two concerns were raised. For a patient with compensated liver disease, the benefit of receiving a transplant is not as evident compared to sicker patients. The risk of transplantation in these low MELD recipients could be higher compared with the relatively low mortality risk of remaining on the transplant list. In an analysis from the Scientific Registry of Transplant Recipients (SRTR), the benefit of transplant was analyzed by comparing the 1-year waiting list and post-transplant mortality rates for liver transplant candidates and recipients based on MELD score [8]. This study showed that for low MELD patients (MELD score <15), the 1-year recipient mortality risk was much higher for recipients (who received transplantation) compared with candidates (who remained on the list) (hazard ratio (HR) = 3.64 at MELD 6–11, HR = 2.35 at MELD 12–14; both $P < 0.001$). In response to these data, UNOS amended the allocation scheme to reduce the priority of patients with a MELD score <15. While status 1 patients remain at highest priority, organs are subsequently offered locally within the procuring OPO and then within the UNOS region to patients with MELD scores ≥15. Listed patients with MELD scores <15 are only eligible for deceased donor (DD) livers after these status 1 and MELD ≥15 candidates have been exhausted. After this change, the proportion of low MELD liver recipients dropped by about one fifth [9]. In summary, these improvements in the prioritization of liver candidates along with the increase in donor supply helped to alleviate disparities in access to transplantation and, to a certain extent, quelled the national debate about liver transplantation.

However, despite the advancements, some problems have persisted. Of the three recommendations by the US Institute of Medicine, only the two regarding liver allocation (the creation of an objective scoring system and the de-emphasis of waiting time) were implemented. There has been no change in liver distribution relative to increasing the organ allocation area, simply because the liver transplant community could not reach a consensus on this topic. Consequently, some disparities in access to transplantation have persisted. A recent analysis demonstrated a wide geographic variation in the severity of illness of liver recipients [10]. This analysis found that OPOs serving a small population transplant significantly less sick patients. Twelve of the nation's 50 OPOs have fewer than 100 patients listed, representing the bottom quartile in OPO size. In fact, the mean number of patients listed in these small OPOs (43) is less than one tenth that of the remaining larger OPOs (462). However, the distribution of MELD scores within all of these OPOs is the same, with only 2% of listed patients with a MELD score >24. Therefore, in small OPOs in which a mean of 43 patients are listed for transplantation, none or only one patient is likely to have a MELD score >24 at any given time. However, in large OPOs, where more than 400 patients on average are listed, the number of patients with a MELD score >24 is likely to be eight or more. The national distribution policy dictates that, in general, livers should be allocated to the patient with the highest MELD score within the OPO where the organs are procured. Therefore, when an organ becomes available, large OPOs are more likely to have a patient with a higher MELD score (>24) compared with a small OPO. Consequently, the proportion of patients who received a transplant with a MELD score >24 is more than 2.5 times higher in large OPOs than in small OPOs (49% versus 19%; $P < 0.001$). In addition, patients are transplanted faster within the small OPOs. The rate of transplantation (per years listed) was 2.5-fold higher for patients listed in small OPOs versus large OPOs (1.03 versus 0.41; $P < 0.001$). Despite transplanting less sick patients faster, the 1-year patient and graft survival rates for small OPOs and large OPOs are not statistically different and waiting list mortality rates are similar in both. The consequences of this disparity have important implications for individual patients as well as for the liver distribution system as a whole. For the individual patient,

selection of a transplant center within a small OPO will result in a faster transplant at a lower MELD score, but no better outcome in terms of pretransplant waiting list mortality rate or post-transplant survival. For the liver distribution and allocation system, transplantation of less sick patients within these selected OPOs represents a failure to fulfill the Institute of Medicine mandate, which states that organs should be distributed based on patients' medical needs with less emphasis placed on keeping organs in the local area where they were procured.

In response to this problem, UNOS is in active discussion with the liver community about widening the area of organ distribution; that is, regional sharing. While most transplant professionals support the concept of regional sharing, there is no consensus on its implementation.

Another problem in implementing regional sharing is that in general, smaller programs in remote regions are less supportive of increasing the organ distribution area because their local organs would preferentially be shared over a larger base of patients. On the other hand, big transplant programs in large metropolitan cities are more favorably inclined towards regional sharing since they could access more organs from a larger catchment area. Lack of consensus is the result of each center supporting the regional sharing system that would provide its center with the greatest number of transplants. Another problem in implementing regional sharing is the disparity in the distribution of patients and transplant centers across the United States. The large metropolitan population centers (mainly on the east and west coasts) have more transplant candidates and transplant centers compared to smaller cities, mostly located within the middle of the country. In addition, the largest cities have more transplant candidates per population because of better access to medical care and the relocation of sick patients to large, inner-city transplant centers. Were the Insitute of Medicine mandate followed, creating uniform organ distribution areas of 9 million people would encompass an area as small as metropolitan New York City (with five liver programs and 1,500 listed patients) and a region as large as 1 million square miles in the Rocky Mountain West (with one program and 120 listed patients). Establishing uniform allocation areas with such stark differences in geographic characteristics and population density is obviously difficult and probably impossible. In addition, there are significant logistic problems in sharing organs across wide expanses of sparsely populated regions. The time, and attendant cost, required to transport organs over vast areas are of particular concern since cold ischemic time is an important determinant of graft function. Therefore, at the time of this writing, the likelihood of adopting a national system for regional sharing of all donor livers in the near future seems remote. However, in the near future, there will likely be implementation of an incremental shift towards a limited regional sharing plan, e.g., for the relatively few liver candidates with extremely high priority for transplant (i.e., MELD score >34). Ultimately, most transplant professionals believe that some form of regional sharing will likely be implemented throughout the country. Because of the inability of the liver community to reach a consensus on this important issue, development of a regional sharing plan may require a governmental mandate following an independent review, similar to what was required prior to the implementation of the MELD system.

Another potential improvement under consideration by UNOS is liver allocation based on the survival benefit of transplant [11]. Transition to such a system would represent a fundamental change in organ allocation, but has many attractive features. There are essentially three means by which liver candidates may be prioritized for transplantation, each with distinct advantages and disadvantages. The current allocation system is devised to prioritize patients based on their need or urgency for transplant independent of transplant outcome. The advantage of this system is that the patients with the greatest risk of death receive the highest priority for transplant. However, the disadvantage is that some patients with a high pretransplant priority have a high post-transplant mortality risk. Allocating livers to such patients would not represent the most utilitarian use of organs. A second means of prioritization is based on a utilitarian approach. That is, patients with the greatest chance of post-transplant survival would receive the highest transplant priority. The benefit of this allocation scheme is that only the best transplant candidates would receive organs thereby maximizing the lifespan of each patient and organ. However, many of the ideal candidates for transplant have a low urgency for transplant. Therefore, adoption of this system would likely increase the pretransplant waiting list mortality.

The third organ allocation scheme, and the one under current consideration, would be a combination of the two systems and is termed "transplant benefit" or "survival benefit." Under this proposed system, for each donor liver that becomes available, the transplant survival benefit score would be computed for each candidate on the waiting list based on their specific characteristics as well as those of the particular donor. This benefit is calculated based on the difference in 5-year mean survival with the transplant compared to the survival rate of remaining on the list. Proponents of this system contend that survival-based allocation makes the best use of each donor organ. In addition, they point to modeling projections that 2,000 life-years would be saved were such a scheme implemented. However, there are problems with this system, the greatest of which is that the current means of predicting post-transplant survival is inaccurate. The r^2

statistic for survival benefit liver allocation is only 0.6 (where 1 is the perfect prediction of the modeling for post-transplant survival). Many experts believe that this is too low to permit its implementation for liver allocation. (By comparison, the r^2 statistic for the predictive capacity of MELD is approximately 0.82.) In addition, opponents contend that the projected number of lives saved by survival benefit liver allocation each year (102) is minimal compared to the nearly 17,000 patients listed for transplant. Finally, changing the entire allocation scheme would likely create new unforeseen problems that could be worse. While survival-based organ allocation has been implemented for lung transplantation, its application in liver transplantation remains under intense review and consideration. As the financial resources in all fields of medicine are becoming increasingly restricted, expensive medical procedures such as liver transplantation will be required to demonstrate sufficient benefit to warrant continued funding from payors. Allocating and distributing livers under a "survival benefit" system could potentially provide for a more effective application of liver transplantation in such a financially constrained environment.

Variation in MELD score

Since it was developed more than 10 years ago, the MELD score has received intense scrutiny on virtually every aspect of its effect on liver allocation. One area of interest is the variation in two of its determinants (INR and serum creatinine) and the potential impact on liver allocation. The INR was devised primarily to standardize the anticoagulation effects of warfarin and not to provide a reproducibly precise assessment of severity of illness in patients with end-stage liver disease. Standardization of therapeutic anticoagulation became necessary when clinicians noted that the various thromboplastin reagents used to determine prothrombin time differed markedly in their responsiveness to the anticoagulant effects of warfarin. To rectify this problem, the World Health Organization (WHO) proposed the INR, which is a correction formula that adjusts for the variable sensitivities of different thromboplastin reagents. The INR can be defined by the following equation:

$$\text{INR} = (\text{patient's prothrombin time} / \text{mean normal prothrombin time})^{x},$$

where x is the international sensitivity index. The INR allows for the standardization of the prothrombin time ratio (determined by any thromboplastin reagent) to a reference WHO thromboplastin standard. With this standardization, the INR allows safe and effective dosing of warfarin, independent of the sensitivity of the thromboplastin reagent.

In liver patients, however, there has never been a formal demonstration of reproducibly precise INR values. In fact, wide INR variations in liver patients have been recognized for years based on the selection of the thromboplastin reagent [12]. (Whether this interlaboratory INR variation was recognized when MELD was developed is unclear.) The reason(s) for the wide variation in INR in liver patients compared with patients receiving oral anticoagulants is not known. One explanation may be the different mechanisms of prothrombin time elevation caused by warfarin and liver disease. Warfarin causes prolonged prothrombin time through inhibition of the vitamin K-dependent γ-carboxylation of coagulation factors II, VII, IX, and X. In liver disease, the elevated prothrombin time is due in large part to a decreased production of coagulation factors. A recent study evaluated the effect of INR variation on MELD score in liver transplant candidates. These investigators found that based on the selection of clinical laboratory, the same blood sample can yield up to a 2.1-fold difference in INR, which corresponds to a change in MELD score of up to 9 points (Fig. 49.2) [13]. The importance of these findings is underscored by the observation that the greatest variations in INR (and corresponding MELD score) occurred in the patients with the highest INR and highest MELD score. That is, the patients with the highest priority for transplant have the greatest variation in MELD score. Similar findings have been replicated in other studies [14–16]. The fundamental problem with this interlaboratory variation in INR and MELD score is its impact of parity, especially since the greatest differences are noted in patients with the highest MELD scores. Patients with an urgent need for transplant could be advantaged or penalized by changes in their MELD score based on the selection of the clinical laboratory where the INR is measured. Similarly, if one center were using an INR assay yielding lower INR values than another center, all of its patients would be correspondingly disadvantaged. Several possible responses regarding this issue have been proposed [17]:

1. The problem could be ignored, with the recognition that clinically relevant variations in the MELD score are acceptable. This seems to be the most likely response.
2. Uniform reagents and measuring devices could be utilized by all laboratories across the country measuring the INR for the MELD score. Given the virtually infinite variety in the combination of regents and devices, such a response seems impractical.
3. A central laboratory for measuring INR could be developed within the local allocation area to minimize the INR variation. While possible, this solution would be logistically difficult especially when MELD scores are urgently required for ill patients.
4. A correction factor could be devised to normalize the MELD score between different clinical laboratories.

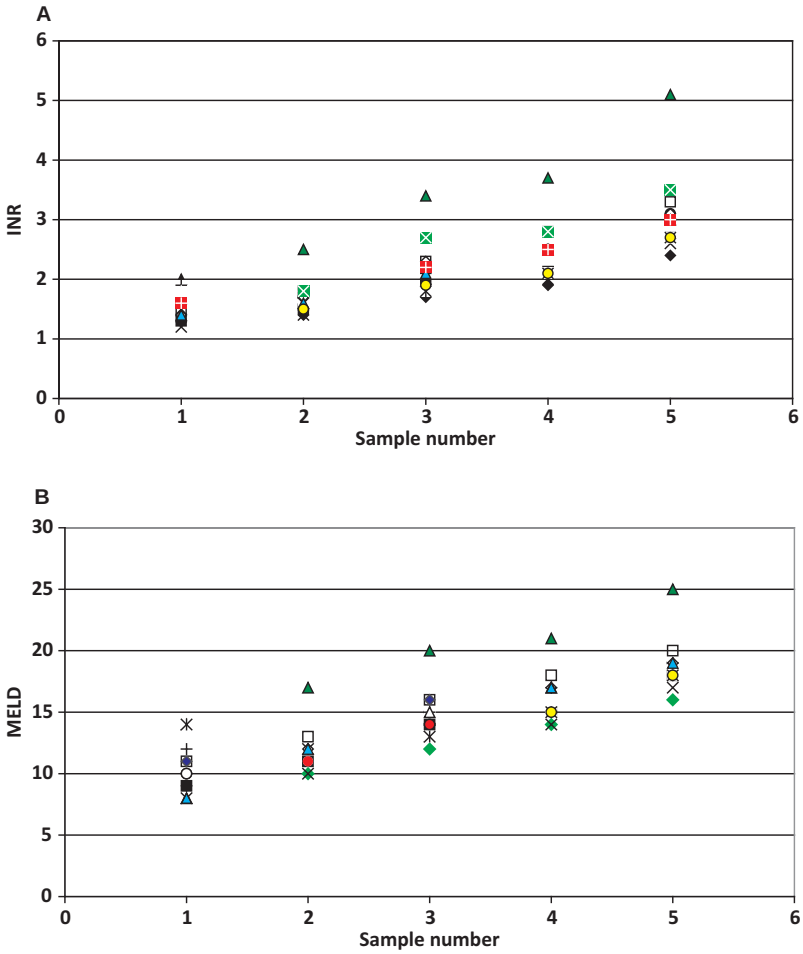

Figure 49.2 (A) International normalized ratio (INR) versus standardized blood sample number. (B) Model for end-stage liver disease (MELD) score versus standardized blood sample number.

Again, similar to point 2 above, this is likely impractical.

5 The INR could be removed from the MELD score. An analysis has demonstrated that removal of the INR from the MELD score would only minimally impact its predictive capacity; the *c*-statistic of the MELD-XI (without the INR) was comparable (0.829) to the MELD (0.842) [18].

6 The maximum INR value in the calculation of the MELD score could be capped, similar to the serum creatinine (Cr), which is capped at 4.0. Capping the INR would minimize the contribution of high values to the MELD score and would help to reduce interlaboratory variation [19]. This solution is currently under consideration and would likely be an important and easily implemented remediation of the INR problem.

The serum Cr is also subject to variation relative to the methodology selected for its measurement as well as patient gender. In particular, investigators have shown that elevated bilirubin levels may interfere with colorimetric assays for Cr [20]. They evaluated four different Cr assays in liver patients to assess changes in MELD score. Agreement was found to be poor among all Cr assays and the variation in MELD score was greatest for the patients with the highest bilirubin. For those whose bilirubin was <5.8 mg/dL, only 3% had a difference of ≥2 MELD points. However, in patients with higher values (bilirubin ≥23. 4 mg/dL), 78% had a difference of ≥3 MELD points. This variability among different assays, especially in patients with high bilirubin levels (and therefore high MELD scores and transplant priority) could have a relevant impact on prioritization for liver transplantation. The same investigators also reported the importance of the differences in Cr relative to the glomerular filtration rate (GFR) between the genders [21]. Compared to men, women have long been recognized to have lower serum Cr for the same GFR. Therefore, for the same degree of renal impairment, females would have a lower Cr, a lower corresponding MELD score, and lower priority for transplantation. These investigators used a correction formula to compensate for this difference and reported that correcting the Cr increases MELD score by 2 or 3 points in 65% of female liver candidates. Whether this variation in Cr relative to MELD score is sufficiently important

to address through changes in the allocation system is unclear. However, the variation in MELD score relative to serum Cr and INR point out potential flaws in this carefully constructed allocation system.

Donation after cardiac death

Despite an overall shortage of donor organs, the number of donor livers has increased dramatically over the past decade due to changes in medical as well as administrative practice. Between 2000 and 2006 the number of donor livers increased by 33% from 4,997 to 6,651 in the United States [7]. Perhaps the most important reason for this increase was a change in administrative practices promulgated by the Organ Donation Breakthrough Collaborative in 2003, which facilitated the creation of systems within acute care hospitals and OPOs to ensure accurate and timely referral, screening, consent, organ recovery, and successful placement of organs [22].

In addition to these administrative changes, there have been three important medical innovations that have tapped into previously unavailable or underutilized sources of donors: DCD, ECD, and LDLT. The conventional deceased donor, donation after brain death (DBD), is a patient on a ventilator with a devastating brain injury whose death is declared based on the fulfillment of the strict criteria for brain death. On the other hand, DCD donors, while on a mechanical ventilator with irrecoverable brain injury (usually from trauma or hemorrhage), do not meet the strict criteria for brain death [23]. Prior to the development of DCD, such patients had not been eligible for donation. The protocol for DCD was therefore developed as a very controlled and regulated process through which these patients could be legally utilized for donation. Such patients are extubated and subsequently die (usually within 30 minutes) with the declaration of death occurring after the cessation of cardiac activity.

While utilization of such donors increases the overall donor pool, the means of acquiring DCD donors fundamentally compromises the quality and function of the donor organ. Between the time of extubation and cessation of heart function (donor warm ischemic time), there is a period of hypotension and hypoperfusion of the donor organ that negatively impacts its viability and function. While quite variable, the donor warm ischemic time is the single most important determinant of donor organ quality. In some cases, the warm time is so prolonged that the quality of the donor organs is compromised to the extent that the donor organ is discarded. In general, the outcomes with DCD liver recipients are inferior to those in DBD liver recipients. Specifically, two analyses from the SRTR (one between 1993 and 2001 and another from 1996 to 2003) reported virtually identical results with a mean 50% higher 1-year graft loss rate with DCD compared with DBD (29.4% versus 19.8 %; $P < 0.01$) [24,25]. Perhaps the greatest progress towards improving outcomes is the identification of risk factors associated with graft loss with DCD. These include donor age >35 years (HR = 1.17), donor warm ischemia time >30 minutes (HR = 2.34), and donor cold ischemia time >10 hours (HR = 1.18); as well as recipient factors of age >60 years (HR = 1.17), life support (HR = 1.54), prior transplant (HR = 1.84), hemodialysis (HR = 1.26), and Cr >2.0 mg/dL (HR = 1.23) ($P < 0.001$). As these risk factors became recognized, the protocols for DCD procurement improved along with better selection of recipients for these marginal organs.

With these changes, some investigators found that patient outcomes with DCD are similar to DBD. For example, in a study where low-risk recipients were paired with low-risk DCD donors (warm ischemic time <30 minutes and cold ischemic time <10 hours), 1-year graft survival rates (81%) were not significantly different from those in DBD recipients (80%). However, despite these favorable results, the overall performance of DCD grafts is clearly inferior to DBD. The most important clinical complication associated with DCD is biliary strictures. Because the cause of biliary disease in DCD recipients is different to that in DBD recipients, so is the characteristic distribution of strictures within the liver. The biliary tree receives its critical perfusion through the arterial system and is therefore quite sensitive to hypoperfusion that may occur during DCD organ procurement. Consequently, DCD recipients are more likely to develop diffuse biliary stricturing throughout the liver, whereas most strictures in DBD recipients are at the biliary anastomosis. In fact, biliary disease is twice as common in DCD compared to DBD recipients and may frequently lead to significant graft dysfunction or failure [26,27]. The diffuse nature of the strictures in many DCD recipients makes them less amenable to interventional drainage and patients may be rendered as "biliary cripples," with serious chronic intractable biliary disease .

Implementation of DCD has expanded the total number of donor livers available for transplantation. The number of DCD donors in the United States increased more than ten-fold from just 23 in 1999 (<1% of liver transplants) to 307 in 2007 (4.9% of liver transplants) (Fig. 49.3). However, there was a slight decrease in the number of cases in 2008 to 276 cases (4.5% of all liver transplants) [28]. The reason(s) for the slight decline is not known, but is likely due to increased awareness of the associated risks and perhaps more careful selection of donors and recipients. Due to the higher risk of graft failure associated with DCD as well as the inherent complexities in organ procurement, some centers have not fully embraced the concept of DCD as a source of additional

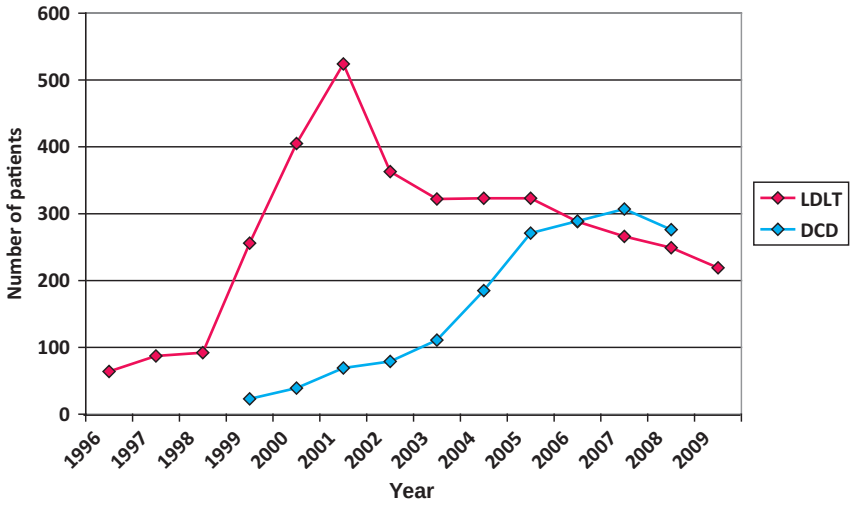

Figure 49.3 Numbers of living donor liver transplantation (LDLT) and donation after cardiac death (DCD) transplants versus year.

donor livers. Consequently, the application of DCD is quite variable amongst transplant centers across the country. In some regions of the United States, DCD accounts for nearly 10% of all adult deceased donor liver transplantation (DDLT) and in other areas fewer than 1%. DCD will likely remain as an important, but limited, means of expanding the donor pool, especially in areas where the donor supply is most limited. The effective application of DCD for liver transplantation requires cooperation between the OPO and the local transplant center(s) to ensure maximal utilization of these higher risk organs as well as careful application of the donor procurement protocols.

Living donor liver transplantation

The use of living donors has been another important development to partially alleviate the shortage of donor organs [29]. The first successful case was reported in 1989 and over the subsequent decade the procedure was largely limited to Asia where cultural mores prohibit the widespread application of deceased donation. At that time, the procedure utilized the left hepatic lobe or one of its segments. In the United States, relatively few cases were performed until 1999, largely in pediatric recipients where the parental donors readily accepted the procedural risk of donation and the small size of the left hepatic lobe provided a sufficient hepatic reserve. After 1999, LDLT was more widely applied and its rapid growth was due primarily to two factors. First, the growing shortage of deceased donors intensified in the late 1990s, forcing transplant centers to seek innovative strategies to increase the donor pool. Second, selected centers reported successful LDLT with the right hepatic lobe, which is larger than the left lobe and provided adequate hepatic volume to support full-size adults. The subsequent growth in LDLT was rapid; in 1998, fewer than 100 cases were performed while the number increased to 524 in 2001, remarkably accounting for 11% of adult liver transplants in the United States (Fig. 49.3) [7]. There were initial projections that LDLT would constitute up to 50% of all liver transplants, although this has never been realized.

The choice to pursue LDLT for a specific patient is a complex consideration of the advantages and disadvantages of the procedure. The primary advantage associated with LDLT is speed and timing. Patients with an urgent need for transplant and no immediate prospects for DDLT are the best candidates for LDLT – such as patients with low MELD scores with hepatocellular carcinoma or primary sclerosing cholangitis with recurrent sepsis. While awaiting a deceased donor, such patients are at risk for dying or suffering decompensation, thereby jeopardizing the success of the DDLT. The primary risk for the LDLT recipient is associated with the immediate perioperative risk of complications, which are higher compared with DDLT, including death. In short, the patient who chooses to pursue LDLT incurs a potentially higher short-term risk related to an expedited transplant with the potential benefit of improved long-term survival by avoiding the risk of death while on the waiting list or decompensation which could ultimately jeopardize the success of DDLT. In fact, a recent study by the Adult-to-Adult Living Donor Liver Transplant Study Group (A2ALL) compared outcomes of LDLT versus DDLT [30]. The starting point for this study (from the time of donor evaluation) was carefully selected to encompass the clinical scenario (described above) related to the risks and benefit associated with the procedure. Of the 807 potential living donor recipients, 389 underwent LDLT, 249 underwent DDLT, 99 died without transplantation, and 70 were awaiting transplantation at last follow-up. Compared to

waiting for DDLT, the receipt of an LDLT organ was associated with a significant survival benefit with an adjusted mortality HR of 0.56 (P <0.001). The benefits were even greater at centers performing more than 20 LDLTs, with a mortality HR of 0.35 (P <0.001). Therefore, this study demonstrated for the first time that the choice to pursue LDLT is associated with at least a 44% reduction in mortality risk compared to waiting for DDLT.

Despite these data supporting its use, LDLT has been negatively impacted by several recent developments. Consequently, the initial enthusiasm surrounding the procedure has waned, the number of cases in the United States has dropped significantly, and its role in the field of liver transplantation is being reconsidered. After the implementation of MELD-based liver allocation in 2002, there was less need for LDLT. As discussed above, better access to DDLT, due to improvements in liver allocation along with better donor supply, obviated the need for a living donor. In fact, a recent study found that 11% of LDLT donor candidates could not even finish their evaluation, because the recipient underwent DDLT prior to its completion [31]. Another reason for the decline in LDLT is the emergence of data showing inferior outcomes compared to DDLT. The rate of allograft failure in a risk-adjusted analysis was shown to be increased with LDLT (HR = 1.66; P <0.05) compared with DDLT [32]. In addition, the complication rate was significantly higher with LDLT. Data from the A2ALL study found that the following complications occurred at a higher rate after LDLT versus DDLT: biliary leak (31.8% versus 10.2%), reexploration (26.2% versus 17.1%), hepatic artery thrombosis (6.5% versus 2.3%), and portal vein thrombosis (2.9% versus 0.0%) (P <0.05) [33]. The reduction in LDLT cases over time was also due in part to a front-loaded effect. That is, at the inception of LDLT at each center, the most ideal donor–recipient pairs were identified and transplanted. However, after these cases were expended, it became apparent that many potential LDLT recipients were unable to identify a suitable donor and therefore were ultimately rejected for the procedure. This is reflected in the A2ALL study where the overall rate of donor acceptance was significantly higher during the early experience (47% in 1998–2000) compared with a later era (35% in 2001–2003; P <0.0002) [31]. Finally, the full extent of donor risk did not become apparent until several years after the widespread application of the procedure. Initial reports of donor complications were relatively low (less than 20%) [34]. However, a more comprehensive report of donor complications reported a complication rate of 38% that was nearly twice as high. While 27% of complications were minor, the remaining 11% were more serious, including 2% that were considered life threatening and 0.8% that led to death [35]. Reports began to surface of donor deaths and aborted donations (patients who underwent anesthesia in the operating room, but had the donor operation aborted prior to successful donation). Twelve (3%) aborted donors were reported from the A2ALL series and an additional 12 (4.7%) from Toronto [35,36]. While the risk of donor death is not known due to the absence of a comprehensive database, there are at least 13 worldwide donor deaths "definitely" related to the donor operation, making an estimated risk of 0.15% [37]. Because of all of these concerns, the number of LDLTs performed in the United States decreased by one half from its peak year of 2001 when 524 cases were performed, to only 219 adult recipients in 2009, representing just 3.5% of all liver transplants.

What does the future hold for LDLT? It will likely remain a viable procedure where the supply of DD organs is limited. In Asia, where LDLT remains the predominant means of providing liver transplantation, its application remains robust. In fact, the Asan Medical Center in Seoul, Korea – a country with less than one quarter the population of the United States – performs over 300 cases annually, which is more than the entire volume of LDLTs in the United States. In the latter, LDLT may remain a viable means to provide access to liver transplantation in selected patients, particularly in regions where the donor shortage is especially acute such as Boston, New York, Chicago, and California. However, in most other parts of the United States, the application of LDLT will likely remain quite limited. In addition, unless a program performs approximately ten or more cases each year, it seems unlikely that they would be able to maintain adequate performance standards for this technically complex procedure. In 2009, only seven hospitals in the United States had performed such a volume.

Expanded criteria donors

The use of ECDs, defined as donors who are not ideal or standard, is another strategy to increase the donor pool. While marginal liver grafts have been transplanted for decades, the concept of ECD is to objectively define the characteristics and associated risk of using these organs. By doing so, clinicians may learn how to mitigate these factors and select the best recipients for these marginal grafts, thereby maximizing organ utility. Perhaps the most detailed description of the ECD procedure was by Feng et al., who identified seven donor and graft factors associated with graft failure: donor age >40 years, DCD, split/partial grafts, African-American race, less height, cerebrovascular accident, and "other" causes of brain death [38]. Using these specific features, they devised the donor risk index (DRI), which is the relative risk of graft loss for an organ with a specific set of donor

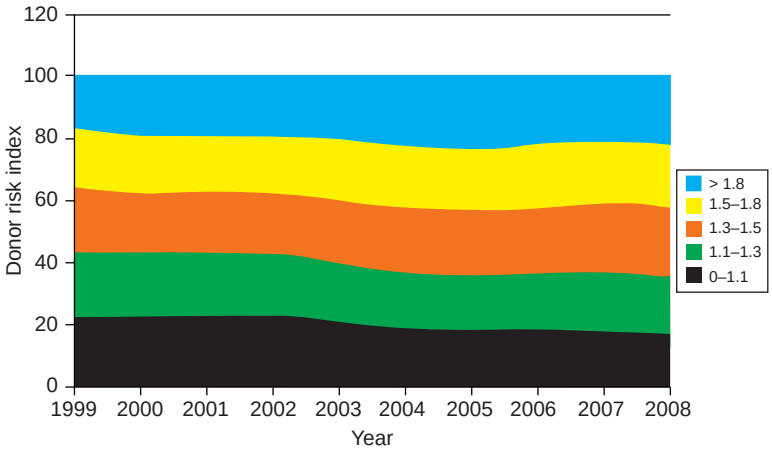

Figure 49.4 Donor risk index in primary liver recipients. (Reproduced from Thuluvath et al. [28] with permission from Wiley-Blackwell. Data as of May 2009.)

and transplant characteristics compared with a reference case, where DRI = 1.0. The higher the DRI, the higher is the 1-year graft loss rate. For example, the 1-year graft loss rate for a high DRI liver (DRI >2.0) is 28.6%, which is more than twice that of an ideal donor (DRI <1.0) at 12.4%.

Over the past decade, transplant centers have utilized an increasingly high proportion of marginal or high DRI livers. Between 1999 and 2008, there was a 36% increase in donors with a DRI of >1.8, with a corresponding 17% decrease in donors with a DRI of <1.3 (Fig. 49.4) [28]. When selecting recipients to receive a high DRI liver, transplant centers have developed a utilitarian approach towards graft disposition. Surgeons have learned through experience that transplanting high DRI livers into high MELD score patients is associated with higher rates of graft loss. Specifically, when using a liver with DRI ≥1.7, the 1-year graft loss rate is 37% higher in recipients with a MELD score ≥27 compared with a better liver (DRI <1.7) [39]. Therefore, high DRI organs are frequently rejected for use in high MELD recipients and are utilized in low MELD recipients where graft loss rates are lower. One-year graft loss rates in these low-risk patients (MELD score <15) are 21% lower than in high-risk recipients (MELD score ≥27) (20.9% and 26.6%, respectively). A recent SRTR analysis confirmed the widespread use of this strategy where investigators demonstrated an inverse relationship between DRI and recipient MELD score [40]. The liver DRI decreased as MELD score increased and the highest median DRI (1.50) was in patients transplanted in the lowest MELD categories (score <12). Conversely, the lowest median DRI (1.22) occurred in patients transplanted with a MELD score of 40. While this strategy may provide the most utilitarian use of a wide spectrum of donor livers, the benefit to specific recipients is less clear. Low MELD recipients (MELD score <12) receiving a high DRI liver suffer a significantly higher mortality with transplant, compared to remaining on the waiting list. In fact, the highest relative risk of mortality occurred in recipients with the lowest MELD scores (score 6–8) who received high DRI organs (HR = 3.70; P <0.0005). So, which patients benefit the most from receiving high DRI livers? All recipients with a MELD score ≥20 had a significant survival benefit from transplantation, regardless of DRI. However, the patients who had the greatest relative benefit from high DRI organs were those with the highest MELD scores, due to their significant risk of death without transplantation. Even with the highest quartile risk DRI, recipients with the highest MELD score (score = 40) had a significantly lower mortality rate with transplant compared to remaining on the list. However, the impact of implementing such a practice would probably not have its intended result. In Schaubel et al.'s analysis, only 1% of all recipients had a MELD score of 40 and received a high DRI graft [40]. Therefore, these donor–recipient matches were likely selected for favorable outcome. Without selection mechanisms in place, the outcomes of high MELD/high DRI transplants might be very poor.

Currently, the liver transplant list is filled with a wide range of liver candidates, from those with minimal or no decompensation, to patients whose 90-day mortality is virtually 100%. The spectrum of quality in donor organs is equally wide. One of the greatest unmet challenges is devising a system that effectively matches specific organs and recipients to maximize the utilization of marginal grafts without impacting recipient outcomes.

MELD exception scores

Another area of considerable controversy is that of MELD exception scores. MELD exception scores are awarded to patients whose mortality risk is not adequately reflected by their laboratory MELD score. Assignment of MELD

exception scores occurs through the regional review board for one of two broad indications: hepatocellular carcinoma (HCC) and non-HCC diagnoses. For HCC, candidates within the Milan criteria (or, in some regions, other similar specified criteria) receive a standard MELD exception score (22 points) to limit the risk of removal from the waiting list due to cancer progression. The number of transplant recipients with HCC increased from 999 in 2002 to 1,656 in 2008 or 27% of all liver transplants. Patients beyond the Milan criteria are also awarded MELD exception scores if approved by their regional review board. Some of these candidates meet prespecified tumor specifications – International Registry of Hepatic Tumors in UNOS region 4 [41] or University of California, San Francisco (UCSF) criteria [42] – both of which are slightly over the Milan criteria. Other patients with nonstandardized criteria for HCC are evaluated on a case-by-case basis by the regional review boards. The proportion of HCC patients on the waiting list (at the year's end) with a nonstandard HCC MELD exception score increased from 1.0% in 2002 to 20.6% in 2008 [28]. Many such patients may have been successfully downstaged with loco-regional therapies.

MELD exception scores are also awarded by the regional review board for indications other than HCC. Such patients have a risk of death, as subjectively judged by their transplant team, that is not reflected by their laboratory MELD score. These may be recognized diagnoses that include specific disorders (e.g., familial amyloidosis, hepatopulmonary syndrome, portpulmonary hypertension) or complications of liver disease (e.g., ascites, encephalopathy, biliary complications). The number and percentage of liver candidates with non-HCC MELD exception scores has increased every year since the institution of MELD-based allocation, from 382 in 2002 to 890 in 2008 [28]. However, the number of candidates with MELD exceptions on the waiting list (at the year's end, 2008) varies widely between UNOS regions, with only 16 in region 10 compared to 48 in region 5. Special concern relates to patients receiving non-HCC MELD exception points, particularly in regions where organs are in the highest demand, namely region 5 (California) and region 9 (New York), because these patients receive a very high priority for transplantation. For example, in New York, which runs a single list for the entire state (and region), there are 33 such patients, whose mean score is 27.2 points. In region 5, 48 patients have a mean score of 24.3. The high MELD scores awarded to these patients enhance the likelihood of them receiving a transplant. In fact, the rate of transplant is nearly three-fold higher than for patients with standard laboratory MELD scores [43]. There is concern that these non-HCC MELD exclusion scores may reflect another version of subjective upgrading that plagued previous allocation scheme (as described above).

To address this concern, UNOS organized a conference (MELD Exception Study Group and Conference (MESSAGE)) where standard criteria were developed and published for 17 exceptional medical conditions frequently encountered by the US regional review boards. The recommendations were researched, discussed utilizing an evidenced-based format, and ultimately published in 2006 to provide guidelines for regional review boards [44]. While these recommendations are not binding, they have been implemented in varying degrees within each region. The national impact of the MESSAGE guidelines on non-HCC MELD exception points is difficult to assess, but an analysis shows some improvement after their publication in 2006. There was a slight increase in the percentage of patients receiving a DDLT with a MELD exception other than HCC, from 7.6% in 2003 to 8.6% in 2007 [45]. The fraction of each region's total DDLTs with non-HCC exceptions has become more uniform. In 2003, the percentage of regional DDLTs with non-HCC exceptions ranged from 2% to 21%. By 2007, this range had narrowed to between 5% and 10% for all regions. There have been discussions about creating a national review board to ensure national uniformity in the diagnosis and scoring of these patients as well as normalizing the points awarded to each patient, but none has been formed as yet. One of the problems related to implementing a national review board is the wide disparity in MELD scores for liver recipients between regions. In regions that transplant at lower MELD scores, the number of MELD points requested for non-HCC MELD exception points would be lower than in regions where MELD scores are higher. This is reflected in the wide range of MELD scores given for non-HCC MELD exceptions, which range from a mean of 19.1 in UNOS region 3 to 28.5 in region 2.

Annotated references

Berg CL, Gillespie BW, Merion RM, et al. Improvement in survival associated with adult-to-adult living donor liver transplantation. *Gastroenterology* 2007;133:1806–13.

This is the first study that demonstrated the potential benefit for LDLT recipients compared with the option of remaining on the transplant list for a DD transplantation.

Feng S, Goodrich NP, Bragg-Gresham JL, et al. Characteristics associated with liver graft failure: the concept of a donor risk index. *Am J Transplant* 2006;6:783–90.

The authors describe specific risk factors associated with graft loss in liver transplant recipients and in doing so define the donor risk index (DRI, which serves as a yardstick to objectively assess the quality of a donor graft in liver transplantation.

Mateo R, Cho Y, Singh G, et al. Risk factors for graft survival after liver transplantation from donation after cardiac death donors: an analysis of OPTN/UNOS data. *Am J Transplant* 2006;6:791–6.

This paper describes the significant risk factors for graft loss associated with liver transplant recipients of DCD organs. The authors describe a means to match the recipients and DCD donors to maximize patient outcomes.

Merion RM, Schaubel DE, Dykstra DM, Freeman RB, Port FK, Wolfe RA. The survival benefit of liver transplantation. *Am J Transpl* 2005;5:307–13.

This study demonstrates the lower limit for the survival benefit for liver transplantation at a MELD score of 15. The findings in this study changed the liver allocation policy known as the "share 15" rule.

Schaubel DE, Guidinger MK, Biggins SW, et al. Survival benefit-based deceased-donor liver allocation. *Am J Transplant* 2009;9:970–81.
The development of a liver allocation system based on the survival benefit is described. While such a system has been adopted for lung transplantation, the liver allocation scheme remains under review.

Multiple choice questions

49.1 Which of the three following determinants in the model for end-stage liver disease (MELD) score has the highest multiplicative factor?

- **a** Bilirubin.
- **b** International normalized ratio (INR).
- **c** Serum creatinine.
- **d** Both b and c

49.2 Which of the following have helped to increase the number of deceased donor organs for liver transplantation?

- **a** Expanded criteria donors (ECDs).
- **b** Donation after cardiac death (DCD).
- **c** Living donors.
- **d** a, b, and c.
- **e** a and b.

49.3 Which of the following factors is associated with the decline in the number of living donor liver transplantations (LDLTs) performed in the United States?

- **a** The availability of deceased donor livers.
- **b** Donor complication rates.
- **c** Recipient complication rates.
- **d** All of the above.

49.4 As a means to increase access to transplantation for sick patients, the United Network for Organ Sharing has implemented a widely accepted regional sharing plan for deceased donor livers across the United States.

- **a** True.
- **b** False.

49.5 The donor risk index (DRI) is which of the following?

- **a** The ratio of observed versus expected graft loss.
- **b** The relative risk of graft loss for an organ with a specific set of donor characteristics compared with reference case.
- **c** Is only applicable to kidney transplantation.
- **d** The relative risk of graft loss for an organ with a specific set of donor and graft characteristics compared with a reference case.

49.6 What is the basis for the liver allocation currently under active consideration?

- **a** Pretransplant survival.
- **b** Utilitarian.
- **c** Survival benefit of the transplant.
- **d** The donor risk index.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

APPENDIX
Multiple Choice Answers

Chapter 1 History Taking and Physical Examination for the Patient with Liver Disease

1.1 The correct answer is **e**, 200 mg.

1.2 The correct answer is **b**, Wilson disease.

Chapter 6 Bilirubin Metabolism and Jaundice

6.1 The correct answer is **c**, Urine dipstick for bilirubin: negative.

Comment: The negative urine dipstick despite obvious jaundice indicates that the patient has a purely unconjugated hyperbilirubinemia.

6.2 The correct answer is **c**, A decrease in total bilirubin from 4.0 to 0.4 mg/dL.

Comment: Unconjugated hyperbilirubinemia, reticulocytosis, and anemia often occur together in the presence of hemolysis. The unconjugated hyperbilirubinemia is a direct consequence of the breakdown of hemoglobin in hemolyzed red blood cells, and will diminish very quickly with a decrease in the rate of red blood cell destruction. The reticulocytosis is the bone marrow's response to the anemia induced by hemolysis, and will persist until the anemia has been repaired. This may require several weeks after cessation of the hemolytic process.

Reference

- Berk PD, Martin JF, Blaschke TF, Scharschmidt BF, Plotz PH. Unconjugated hyperbilirubinemia. Physiologic evaluation and experimental approaches to therapy. *Ann Intern Med* 1975;82:552–70.

6.3 The correct answer is **d**, Dubin–Johnson syndrome.

Comment: The progressive familial and benign recurrent intrahepatic cholestasis syndromes are both characterized by defects in bile secretion, with cholestasis and accumulation of bile acids in the serum. Conjugated hyperbilirubinemia is a secondary consequence of disordered bile secretion and consequent structural damage to the biliary tract. In contrast, conjugated hyperbilirubinemia in Dubin–Johnson syndrome is the consequence of a specific defect in secretion of bilirubin glucuronides into the bile. Bile secretion, including that of bile acids is normal, and there is no cholestasis.

Reference

- Thompson R, Jansen PLM. Genetic defects in hepatocanalicular transport. *Semin Liver Dis* 2000;20(3):365–72. DOI: 10.1055/s-2000-9384.

Chapter 8 Mechanisms of Liver Injury

8.1 The correct answer is **c**, FasL and Fas.

Comment: FasL was given intravenously in this experiment and resulted in massive hepatocyte apoptosis and fulminant hepatic failure. FasL binds and activates its cognate cell surface receptor Fas with subsequent activation of caspase 8, cleavage of Bid, activation of Bak and Bax, mitochondrial permeabilization, and apoptosis.

8.2 The correct answer is **c**, The innate immune system is a critical component of pathways that perpetuate liver injury and inflammation.

Comment: The innate immune system is a critical component of pathways that perpetuate liver injury and inflammation. Kupffer cells, natural killer cells, and natural killer T cells are vital components of the innate immune system in the liver. They secrete inflammatory cytokines such as TNF-α and interleukin-6, as well as death ligands such as Fas and TRAIL. Hepatocyte cell death can occur via apoptosis or necrosis, however the role of necroptosis, if any, is unknown. Caspase inhibition was associated with a decrease in aminotransferase levels in patients with chronic hepatitis C. Hepatocyte apoptosis is dependent on mitochondria, but can be initiated from the cell surface via death receptors, or from intracellular perturbations.

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.
© 2012 John Wiley & Sons, Ltd. Published 2012 by John Wiley & Sons, Ltd.

Chapter 9 Hepatic Manifestations of Systemic Disorders

9.1 The correct answer is **e**, All of the above.

Comment: The initial manifestations of hepatobiliary tuberculosis include a remarkable variety of presentations. Although traditionally considered in the presence of fever and raised serum alkaline phosphatase levels, clinicians should consider the possibility of tuberculosis in other settings, including all of the options noted above.

Reference

- Alvarez SZ. Hepatobiliary tuberculosis. *J Gastroenterol Hepatol* 1998;13:833–9.

9.2 The correct answer is **b**, Current guidelines advise antibiotic prophylaxis for exposed individuals in endemic regions.

Comment: Leptospirosis may present with acute abdominal pain, and doxycycline is the treatment of choice, but is not recommended as a prophylactic measure.

Reference

- Brett-Major DM, Lipnick RJ. Antibiotic prophylaxis for leptospirosis. *Cochrane Database Syst Rev* 2009:1; CD007342.

9.3 The correct answer is **c**, Increased levels of protoporphyrin in erythroid cells and feces helps establish the diagnosis.

Comment: Hepatic involvement is relatively uncommon in cases of erythropoietic protophoryria, and because the primary enzyme defect is in the erythroid cell line, liver transplantation is not curative. Phlebotomy is the treatment for porphyria cutanea tarda; alcoholic beverages may exacerbate acute intermittent porphyria.

Reference

- Kauppinen R. Porphyrias. *Lancet* 2005;365:241–52.

9.4 The correct answer is **c**, A gluten-free diet may improve the disease course of primary biliary cirrhosis when underlying celiac disease is present.

Comment: Although celiac disease is frequently associated with a wide variety of liver disorders, the elimination of gluten from the diet has no effect on the natural course of these other conditions.

Reference

- Rubio-Tapia A, Murray JA. The liver in celiac disease. *Hepatology* 2007;46:1650–8.

Chapter 10 Hepatobiliary Complications of Hematopoietic Cell Transplantation

10.1 The correct answer is **d**, Matched donor/recipient HCT.

Comment: HLA mismatched donor/recipient pairs are a higher risk clinical scenario for the development of GVHD compared to autologous or greater HLA matching. The presence of HBV and HCV in the donor or recipient or the presence of recipient iron overload increases the risk of acute and chronic liver disease following HCT.

Reference

- Strasser SI, Sullivan KM, Myerson D, et al. Cirrhosis of the liver in long-term marrow transplant survivors. *Blood* 1999;93:3259–66.

10.2 The correct answer is **b**, Terminal hepatic venule occlusion on biopsy.

Comment: Sinusoidal obstruction syndrome occurs early after transplant and presents classically with hepatomegaly, ascites, weight gain, and hyperbilirubinemia. Because of the sinusoidal portal hypertension, the hepatic venous pressure gradient is characteristically elevated and often >10 mmHg. Terminal hepatic venule occlusion is a late feature of SOS and is not necessary for the diagnosis. Thus the term venoocclusive disease (VOD) has been replaced with SOS.

References

- Shulman HM, McDonald GB, Matthews D, et al. An analysis of hepatic venocclusive disease and centrilobular hepatic degeneration following bone marrow transplantation. *Gastroenterology* 1980;79:1178–91.

Chapter 11 The Liver in Pregnancy

11.1 The correct answer is **d**.

Comment: Answer d is not associated with ICP and is therefore the correct answer. ICP occurs during the second or third trimester and is characterized by pruritus and an elevation of serum aminotransferases and bile acid concentrations. The main complications are prematurity and sudden intrauterine fetal death (1–2 % of cases currently). ICP is never associated with liver failure or encephalopathy. Ursodesoxycholic acid improves liver tests and pruritus. ICP recurs in 60–70% of cases during subsequent pregnancies.

Reference

- Pusl T, Beuers U. Intrahepatic cholestasis of pregnancy. *Orphanet J Rare Dis* 2007;2:26.

11.2 The correct answer is **a**.

Comment: Answer a is not associated with AFLP is therefore the correct answer. AFLP is a rare disease unique to pregnancy that occurs typically during the third trimester. If the diagnosis is delayed, AFLP may lead to acute liver failure with hepatic encephalopathy. The primary therapy of AFLP is early delivery, which has dramatically improved both maternal and fetal prognosis. An association has been found between AFLP and a defect of long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD) in the fetus. Women in whom AFLP develops and their offspring should undergo DNA testing for the main associated genetic mutation (G1528C) in the gene coding for LCHAD. AFLP may recur during subsequent pregnancies, although recurrence is not the rule.

Reference

Chapter 13 Preoperative Evaluation of the Patient with Liver Disease

13.1 The correct answer is **e**, Cancel the surgery.

Comment: The liver biochemical abnormalities in this patient are most consistent with alcoholic liver disease. The patient may have alcoholic hepatitis, which is associated with a high surgical mortality rate. Until the diagnosis is clear and, if necessary, the patient is abstinent from alcohol for 12 weeks, elective surgery should be deferred.

References

- O'Leary JG, Yachimski PS, Friedman LS. Surgery in the patient with liver disease. *Clin Liver Dis* 2009;13:211–31.

13.2 The correct answer is **c**, A serum bilirubin level >50 μmol/L plus a prothrombin time index <50%.

Comment: Post-resectional liver failure is defined as a prothrombin time index (control prothrombin time divided by the patient's prothrombin time) of less than 50% (corresponding to an INR of >1.7) and a serum bilirubin level >50 μmol/L (2.9 mg/dL). When these criteria are met, the postoperative mortality rate has been reported to be 59%, compared with 1.2% when they are not met.

Reference

- van den Broek MA, Olde Damink SW, Dejong CH, et al. Liver failure after partial hepatic resection: definition, pathophysiology, risk factors and treatment. *Liver Int* 2008;28:767–80.

Chapter 14 Portal Hypertension: Nonsurgical and Surgical Management

14.1 The correct answer is **c,** Nonselective β-blocker.

Comment: Bleeding esophageal varices should be treated by pharmacologic and endoscopic treatments. The former should be intravenous administration of terlipressin or somatostatin, and the latter should be endoscopic sclerotherapy or band ligation. Oral administration of nonselective β-blockers is applied for primary or secondary prophylaxis of variceal bleeding.

Reference

- Sanyal AJ, Bosch J, Blei A, Arroyo V. Portal hypertension and its complications. *Gastroenterology* 2008;134:1715–28.

14.2 The correct answer is **a**, Small esophageal varices in Child–Pugh class A patients.

Comment: Varices with a high risk factor of bleeding are those found in Child–Pugh class C patients, and varices with a large size and/or red signs.

Reference

- Krawitt EL. *Medical Management of Liver Disease*. New York: Marcel Dekker, 1999.

Chapter 15 Renal Complications of Liver Disease and the Hepatorenal Syndrome

15.1 The correct answer is **a**, Renal failure where there is no structural damage in the kidneys.

Comment: Functional renal failure is a type of renal failure where there is no structural damage in the kidneys. It can be acute or chronic. Hepatorenal syndrome is only one type of functional renal failure. The cutoff value for the diagnosis of functional renal failure is 1.5 mg/dL.

Reference

- Montoliu S, Ballesté B, Planas R, et al. Incidence and prognosis of different types of functional renal failure in cirrhotic patients with ascites. *Clin Gastroenterol Hepatol* 2010;8:616–22.

15.2 The correct answer is **b**, It can include conditions such as glomerulonephritis in cirrhosis.

Comment: Acute kidney failure differs from functional renal failure in that the term denotes acute renal failure from whatever cause, whether there is structural damage in the kidneys or not, whereas the term functional renal failure requires that there is no structural damage in the kidneys. Therefore the causes of acute kidney injury are not specific to cirrhosis. It is a term that is well versed within the nephrology communities, but it has only just started to be used amongst hepatologists. The first stage of acute kidney injury requires a rise of 0.3 mg/dL for diagnosis even when the serum creatinine is still within the normal range.

Reference

- Mehta RL, Kellum JA, Shah SV, et al. Acute Kidney Injury Network: report of an initiative to improve outcomes in acute kidney injury. *Crit Care* 2007;11:R31.

15.3 The correct answer is **b**, The patient usually has signs to suggest a hyperdynamic circulation.

Comment: Type 1 hepatorenal syndrome is a form of functional renal failure. It occurs acutely, but is a condition that evolves over 2 weeks rather than 2 days. Hepatorenal syndrome is a consequence of the hemodynamic changes that occur in advanced cirrhosis, so the patient usually manifests signs of hemodynamic changes such as those associated with a hyperdynamic circulation. Although patients with acute hepatorenal syndrome usually have severe renal sodium retention, it is not a sine qua non diagnostic criterion, as patients with hepatorenal syndrome have been known to have high renal sodium excretion.

References

- Dudley FJ, Kanel GC, Wood LJ, et al. Hepatorenal syndrome without avid sodium retention. *Hepatology* 1986;6:248–51.
- Salerno F, Gerbes A, Gines P, et al. Diagnosis, prevention and treatment of hepatorenal syndrome in cirrhosis. *Gut* 2007;56:1310–8.

15.4 The correct answer is **a**, It should start as soon as all other cause of acute renal failure have been excluded.

Comment: The treatment for acute or type 1 hepatorenal syndrome should start as soon as all other causes of acute renal failure have been excluded. The usual first-line treatment is vasoconstrictor therapy. There have not been any randomized controlled trials to support the recommendation of the insertion of a transjugular intrahepatic portosystemic stent shunt as a first-line treatment. Vasoconstrictor therapy should continue for as long as the patient shows a response in terms of a reduction in serum creatinine levels. For terlipressin and norepinephrine, this should be less than 15 days; for a combination of midodrine and octreotide, this can be several weeks long. Although empirical antibiotic use is recommended in patients who present with acute renal failure, once bacterial infection is excluded, antibiotics should be stopped.

Reference

- Garcia-Tsao G, Parikh CR, Viola A. Acute kidney injury in cirrhosis. *Hepatology* 2008;48:2064–77.

15.5 The correct answer is **d**, Correcting the renal failure pre transplant can significantly improve patient survival post transplant.

Comment: Since the graft and patient survival are lower for patients with hepatorenal syndrome who receive a combined liver–kidney transplant when compared with those who receive a liver transplant alone, it is recommended that a liver transplant alone should be done first, unless the patient has been on renal replacement therapy for over 3 months, when the reverse is true. The presence of hepatorenal syndrome pre transplant increases post-transplant morbidity and reduces post-transplant graft and patient survival, hence it is recommended that the renal failure is corrected before the patient receives a liver transplant.

References

Chapter 16 Pulmonary Manifestations of Liver Disease

16.1 The correct answer is **b**, Contrast Doppler echocardiography.

Comment: This patient has worsening dyspnea on exertion without evidence of significant intrinsic lung disease or fluid overload in addition to a low diffusing capacity for carbon monoxide. This clinical picture is suggestive of hepatopulmonary syndrome. The most appropriate next test is contrast echocardiography to assess intrapulmonary shunting.

16.2 The correct answer is **c**, Right heart catheterization.

Comment: This patient has decompensated cirrhosis with a high MELD score. He has marked lower extremity edema out of proportion to ascites, and

echocardiographic findings suggestive of portopulmonary hypertension. Right heart catheterization is needed to define whether portopulmonary hypertension is present and to assess its severity. This would guide further management including medical therapy and candidacy for transplantation.

Chapter 17 Ascites and Spontaneous Bacterial Peritonitis

17.1 The correct answer is **d**, Oral spironolactone and furosemide.

Comment: In general oral spironolactone and furosemide constitute first-line treatment of patients with cirrhosis and ascites. Normokalemia is maintained and natriuresis is optimized. Intravenous furosemide causes azotemia and hypokalemia. Oral furosemide without spironolactone causes hypokalemia. Large-volume paracentesis is reserved for tense ascites and diuretic-resistant ascites.

Reference

- Runyon BA. Management of adult patients with ascites due to cirrhosis: an update. *Hepatology* 2009;49:2087–107.

17.2 The correct answer is **c**, Cefotaxime 2 g intravenously every 8 hours for 5 days.

Comment: Patients with cirrhosis do not tolerate the nephrotoxicity of gentamicin. Ceftriaxone 1 g intravenously daily prevents bacterial infections in patients with cirrhosis and gut hemorrhage, but does not treat SBP well at this dose due to its high protein binding and the low protein nature of ascitic fluid that develops SBP. At least 2 g of ceftriaxone must be used to treat SBP. Anaerobes seldom cause SBP; therefore anaerobic coverage is not needed.

Reference

- Runyon BA. Management of adult patients with ascites due to cirrhosis: an update. *Hepatology* 2009;49:2087–107.

Chapter 18 Hepatic Encephalopathy

18.1 The correct answer is **a**, True: a significant proportion of portal vein ammonia is generated by intestinal ammonia.

18.2 The correct answer is **b**, False: HE does not primarily arise because of large portosystemic shunts.

18.3 The correct answer is **a**, True: the correction of precipitating factors for HE is effective therapy.

18.4 The correct answer is **b**, False: prophylaxis with lactulose after TIPS has not been shown to reduce episodes of HE.

18.5 The correct answer is **a**, True: decreased brain myoinositol levels on NMR spectroscopy support the presence of cerebral edema in HE.

18.6 The correct answer is **a**, True: the presence of minimal HE predicts the development of overt HE.

18.7 The correct answer is **b**, False: blood ammonia levels are not useful for the diagnosis of HE.

18.8 The correct answer is **a**, True: neomycin inhibits intestinal glutaminase activity.

18.9 The correct answer is **a**, True: the treatment of minimal HE is associated with improved driving ability.

18.10 The correct answer is **b**, False: asterixis is not highly specific for the diagnosis of HE.

Chapter 19 Acute Liver Failure

19.1 The correct answer is **b**, True: the use of *N*-acetylcysteine in the setting of ALF not due to acetaminophen has been shown to improve transplant-free survival if given prior to the development of stage 1–2 hepatic encephalopathy.

Comment: A recent prospective, randomized, double-blind, placebo-controlled trial in the setting of ALF not due to acetaminophen showed a significant improvement in transplant-free survival in patients with early-stage encephalopathy (stages 1 and 2) who received NAC. There was no difference in overall survival in the entire group (all stages of encephalopathy). Thus NAC use early in the course of ALF may prevent progression to deeper encephalopathy with its associated complications.

Reference

- Lee WM, Hynan LS, Rossaro L, et al. Intravenous *N*-acetylcysteine improves transplant-free survival in early stage non-acetaminophen acute liver failure. *Gastroenterology* 2009;137:856–64.

19.2 The correct answer is **b**, The most common cause of death in the setting of acute liver failure is cerebral edema and brainstem herniation.

Comment: Cerebral edema and brainstem herniation remain the major cause of death in the setting of acute liver failure (nearly 50%). This is closely followed by infection/sepsis and multiorgan system failure.

Reference

- Ritt DJ, Whelan G, Werner DJ, Eigenbrodt EH, Schenker S, Combes B. Acute hepatic necrosis with stupor or coma. An analysis of thirty-one patients. *Medicine (Baltimore)* 1969;48:151–72.

19.3 The correct answer is **b**, Viral hepatitis is the most common cause of ALF worldwide.

Comment: Worldwide, the hepatitis viruses, particularly hepatitis B virus, make up the majority of cases of ALF. In western countries, drug-induced liver injury is more often seen. Acetaminophen is the most common drug implicated and is associated with overdosage.

Chapter 20 Primary Sclerosing Cholangitis

20.1 The correct answer is **d**, Generally, IBD is diagnosed prior to liver disease.

20.2 The correct answer is **c**, Liver transplantation has been consistently shown to improve outcomes in patients with PSC.

Chapter 21 Primary Biliary Cirrhosis

21.1 The correct answer is **c**, Serum antimitochondrial antibody.

21.2 The correct answer is **c**, Ursodeoxycholic acid.

Chapter 23 Hepatitis A and E

23.1 The correct answer is **c**, Detectable IgM anti-HAV.

23.2 The correct answer is **c**, Be told that immunologic memory exists despite absence of anti-HAV.

Chapter 26 Alcoholic Liver Disease

26.1 The correct answer is **b**, Corticosteroids.

26.2 The correct answer is **a,** The graft and patient survival are similar to that in nonalcoholic cirrhosis.

Chapter 27 Drug-induced Liver Disease

27.1 The correct answer is **b**, Concomitant use of statins does not increase the risk of acetaminophen hepatotoxicity

Comment: Co-prescription of medications can influence the risk of acetaminophen hepatotoxicity. In both sexes, the risk of liver injury is decreased with statin use and increased with ethanol. NAC remains the cornerstone of treatment in all patients with significant acetaminophen hepatotoxicity. More recently, when used in patients with grades I and II hepatic encephalopathy, it was shown to confer a survival benefit even in cases of acute liver failure resulting from drugs other than acetaminophen.

References

- Lee WM, Hynan LS, Rossaro L, et al. Intravenous *N*-acetylcysteine improves transplant-free survival in early stage non-acetaminophen acute liver failure. *Gastroenterology* 2009;137:856–64.
- Suzuki A, Yuen N, Walsh J, et al. Co-medications that modulate liver injury and repair influence clinical outcome of acetaminophen-associated liver injury. *Clin Gastroenterol Hepatol* 2009;7:882–8.

27.2 The correct answer is **d**, Atorvastatin.

Comment: Genetic factors have been linked to drug hepatotoxicity. While the risk of hepatic injury with nevirapine, abacavir, and flucloxacillin have been linked to specific HLA alleles, polymorphisms of the mitochondrial DNA polymerase-γ 1 (POLG1) gene confer a predisposition to sodium valproate hepatotoxicity in children.

References

- Daly AK. Drug-induced liver injury: past, present and future. *Pharmacogenomics* 2010;11:607–11.
- McFarland R, Hudson G, Taylor RW, et al. Reversible valproate hepatotoxicity due to mutations in mitochondrial DNA polymerase gamma (POLG1). *Arch Dis Child* 2008;93:151–3.

Chapter 29 Wilson Disease

29.1 The correct answer is **f**, All of the above.

29.2 The correct answer is **f**, Living donor transplant using a parent as a donor is never possible for these patients.

29.3 The correct answer is **d**, Desferrioxamine is not useful as a treatment for Wilson disease.

Chapter 30 Hemochromatosis and Iron Storage Disorders

30.1 The correct answer is **b**, Hepcidin.

Comment: The iron transporter, ferroportin, is located on the basolateral surface of duodenal enterocytes, and is responsible for egress of iron from enterocytes into the blood. Hepcidin is the major iron regulatory hormone and it acts to downregulate iron absorption by binding to ferroportin, resulting in its internalization and degradation.

Reference

- Nemeth E, Ganz T. The role of hepcidin in iron metabolism. Acta Haematol 2009;122:78–86.

30.2 The correct answer is **d**.

Comment: In cases of *HFE*-related hereditary hemochromatosis, liver biopsy is usually not indicated if the patient has normal liver enzyme levels and a serum ferritin level below 1,000 ng/mL (e.g., patients a and b). Such patients would be treated by phlebotomy to deplete their excess iron stores. Patient d is homozygous for the C282Y mutation and has a serum ferritin level above 1,000 ng/mL and elevated ALT activity – liver biopsy is indicated based on either of these findings.

Reference

- Olynyk JK, Trinder D, Ramm GA, Britton RS, Bacon BR. Hereditary hemochromatosis in the post-HFE era. *Hepatology* 2008;48:991–1001.

Chapter 31 Alpha-1 Antitrypsin Deficiency

31.1 The correct answer is **c**, PAS-positive, diastase-resistant globules in hepatocytes.

31.2 The correct answer is **a**, Liver transplantation.

Chapter 32 Nonalcoholic Fatty Liver Disease

32.1 The correct answer is **e**, All of the above.

32.2 The correct answer is **c**, Exercise (with or without weight loss) can reduce liver fat.

Chapter 33 Vascular Diseases of the Liver

33.1 The correct answer is **a**, Polycythemia vera.

Comment: Polycythemia vera is the most common prothrombotic disorder leading to Budd–Chiari syndrome, seen in up to 45% of patients. It must be considered in the diagnostic evaluation for hypercoagulable disorders in patients presenting with Budd–Chiari syndrome.

33.2 The correct answer is **e**, Cystic lesions in the liver.

Comment: Budd–Chiari syndrome may present on imaging with hepatomegaly and ascites; caudate lobe hypertrophy is seen with chronic disease and may obstruct the intrahepatic portion of the inferior vena cava. Regenerative nodules may also be seen due to compensatory increase in arterial blood flow; however, cystic lesions are not observed in Budd–Chiari syndrome.

Chapter 34 The Liver in Circulatory Failure

34.1 The correct answer is **d**, Acute hepatic ischemic injury.

Comment: The typical time course of serum aminotransferases in acute hepatic ischemic injury consists of a rapid raise and early peak followed by prompt decline after resolution of the hypotensive event. The time course of acute viral hepatitis is slower, and the remainder entities generally do not exhibit marked elevation of the serum aminotransferases.

34.2 The correct answer is **d**, Sorafenib chemotherapy.

Comment: With the exception of the oral agent sorafenib, all other modalities either directly embolize branches of the hepatic artery or carry a risk of hepatic artery injury and the potential for hepatic infarction.

Chapter 35 Benign Tumors, Nodules, and Cystic Diseases of the Liver

35.1 The correct answer is **d**, Hepatocyte nuclear factor 1 α (HNF-1α) inactivation.

Comment: Transformation from hepatocellular adenoma to hepatocellular carcinoma is strongly associated with β-catenin, male gender, size of nodules particularly if greater than 5 cm, and enlarging nodules. Hepatocellular adenomas with HNF-1α inhibition do not appear to develop hepatocellular carcinoma.

35.2 The correction answer is **d**, Massively enlarged cysts throughout all segments of the liver.

Comment: Treatment of polycystic liver disease is only offered to patients with significant symptoms or complications from cyst compression including severe pain, direct compression of the bile ducts or hepatic veins causing jaundice or ascites, or cyst infection because of the potential for significant morbidity and mortality with intervention.

Chapter 36 Hepatocellular Carcinoma

36.1 The correct answer is **c**, Surgical resection.

Comment: Surgical resection is the best option for those patients with normal liver or with compensated cirrhosis with normal bilirubin and an absence of clinically relevant portal hypertension.

Reference

- Bruix J, Sherman M. Management of hepatocellular carcinoma. *Hepatology* 2005;42:1208–36.

36.2 The correct answer is **d**, Sorafenib increases survival in advanced HCC because it leads to tumor shrinkage as demonstrated by dynamic imaging techniques.

Comment: Sorafenib is currently the only approved treatment for advanced HCC. It has shown survival benefit in two randomized controlled trials and it acts in delaying the tumor progression. However, in a few cases (less than 5%), sorafenib induces tumor response. AFP has a very low diagnostic accuracy and its use is not recommended for HCC surveillance. Once a liver nodule is detected

by ultrasonography in a cirrhotic liver, conclusive HCC diagnosis can be done without histologic confirmation if the nodule displays a specific vascular pattern (contrast uptake during the arterial phase followed by washout in the venous phases). The main cause of HCC worldwide is, by far, chronic HBV infection. Finally, vascular invasion, extrahepatic spread, and the presence of symptoms are parameters associated with poor prognosis and define advanced disease.

References

Chapter 38 Amoebic and Pyogenic Liver Abscesses

38.1 The correct answer is **d**, Differences in the membrane's lipid arrangement on electron microscopy.

38.2 The correct answer is **c**, Gal/GalNAc inhibits assembly of C5b-9 preventing the formation of the membrane attack complex.

38.3 The correct answer is **e**, All of the above are potential causes of pyogenic liver abscess.

Chapter 39 Parasitic Diseases

39.1 The correct answer is **d**, 1, 2, 3 and 4.

39.2 The correct answer is **c**, Visceral leishmaniasis.

Chapter 40 Granulomas of the Liver

40.1 The correct answers are: a – 5; b – 1; c – 2; d – 4; e – 3.

40.2 The correct answer is **e**, Giant cell inclusions (asteroid bodies) are pathognomonic of sarcoidosis.

Comment: Giant cell inclusions such as asteroid or Schaumann bodies are often present but are not specific to sarcoidosis.

Reference

- Devaney K, Goodman ZD, Epstein MS, et al. Hepatic sarcoidosis: clinicopathologic features of 100 patients. *Am J Surg Pathol* 1993;17:1272–80.

Chapter 41 Hepatobiliary Manifestations of Human Immunodeficiency Virus

41.1 The correct answer is **e**, Didanosine.

Comment: NCPH has been recently described in the HIV-monoinfected population and may represent the most striking manifestation of long-term consequences of HIV and its treatment on the liver. Didanosine use has been consistently reported to be associated with it. The characteristic liver histologic lesions are either nodular regenerative hyperplasia or hepatoportal sclerosis. Both manifest clinically as NCPH, and esophageal variceal bleeding is the most frequent complication.

Reference

- Vispo E, Moreno A, Maida I, et al. Noncirrhotic portal hypertension in HIV-infected patients: unique clinical and pathological findings. *AIDS* 2010;24:1171–6.

41.2 The correct answer is **d**, HCV coinfection.

Comment: Early referral to transplant, MELD score at the time of transplantation, and inability to control HIV (reach CD4+ T-cell count above 100 and undetectable plasma HIV-1 RNA viral load) are the most important variables associated with death in HIV-infected patients undergoing a liver transplant. HCV coinfection has been reported to be associated with worse outcome in some studies of HIV-infected patients undergoing liver transplantation.

References

- Murillas J, Rimola A, Laguno M, et al. The model for end-stage liver disease score is the best prognostic factor in human immunodeficiency virus 1-infected patients with end-stage liver disease: a prospective cohort study. *Liver Transpl* 2009;15:1133–41.

- Ragni MV, Belle SH, Im K, et al. Survival of human immunodeficiency virus-infected liver transplant recipients. *J Infect Dis* 2003;188:1412–20.

Chapter 44 The First Six Months Following Liver Transplantation

44.1 The correct answer is **c**, The histopathologic diagnosis of acute cellular rejection does not includes the presence of lobular microabscesses.

Comment: Acute cellular rejection of the hepatic allograft frequently manifests during the first 3 months following liver transplantation. Laboratory findings include nonselective elevation of total bilirubin, transaminases, and alkaline phosphatase. Diagnosis is confirmed by examination of a core needle biopsy.

Reference

- Demetris AJ, Batts KP, Dhillon AP, et al. Banff schema for grading liver allograft rejection: an international consensus document. *Hepatology* 1997;25:658–63.

44.2 The correct answer is **d**, Cytomegalovirus (CMV) infection.

Comment: Common causes of graft loss following the first few weeks after liver transplantation are HAT, PNF, and ACR. CMV infection can be associated with poor graft and patient outcomes, however, in the era of antiviral prophylaxis, it is typically encountered after the first month.

Reference

- Limaye AP, Bakthavatsalam R, Kim HW, et al. Impact of cytomegalovirus in organ transplant recipients in the era of antiviral prophylaxis. *Transplantation* 2006;81:1645–52.

44.3 The correct answer is **d**, Parkinson disease.

Comment: Immunosuppressive medications prescribed to prevent graft rejection result in short- and long-term morbidity and mortality. Therefore, special attention should be paid to the prevention and treatment of these complications.

Reference

- McGuire BM, Rosenthal P, Brown CC, et al. Long-term management of the liver transplant patient: recommendations for the primary care doctor. *Am J Transplant* 2009;9:1988–2003.

Chapter 47 Recurrent Disease Following Liver Transplantation

47.1 The correct answer is **d**, An individual patient undergoing liver transplantation for HCV-related end-stage liver disease has a risk of 20–30% of developing cirrhosis by 5 years after transplant.

Comment: Histologic HCV recurrence is nearly universal after liver transplantation. Fibrosis is progressive in many and approximately 20–30% of patients will develop cirrhosis within 5 years of transplant. Once cirrhosis develops, 30% will decompensate within 1 year and half of those will die within a year of decompensation.

47.2 The correct answer is **d**, HBIg and tenofovir combination therapy.

Comment: Prophylaxis for HBV recurrence after liver transplant is recommended for all patients with HBV, whether HBV DNA positive or not at the time of transplant. A patient with a detectable viral load is at higher risk for recurrence than those with undetectable levels at the time of transplant. Patients with high viral levels at the time of transplant are at the highest risk. Optimal prophylaxis consists of HBIg in combination with a nucleos(t)ide analog. Lamivudine therapy has a higher risk of viral resistance and thus is not the recommended first-line agent. Short-term HBIg therapy would not be recommended for patients with HBV DNA-positive status at the time of transplant. More data are required to know if short-term HBIg therapy is acceptable for HBV DNA-negative patients.

Chapter 49 Controversies in Liver Transplantation

49.1 The correct answer is **b**, The international normalized ratio (INR).

Comment: The MELD score is described by the following equation: $[0.957 \times \ln(\text{creatinine mg/dL}) + 0.378 \times \ln(\text{bilirubin mg/dL}) + 1.120 \times \ln(\text{INR}) + 0.6431] \times 10$. The INR has the highest associated multiplicative factor (1.12) and as such has the greatest weight of the three determinants.

References

- Kamath PS, Wiesner RH, Malinchoc M, et al. A model to predict survival in patients with end-stage liver disease. *Hepatology* 2001;33:464–70.
- Wiesner RH, McDiarmid SV, Kamath PS, et al. MELD and PELD: application of survival models to liver allocation. *Liver Transpl* 2001;7:567–80.

49.2 The correct answer is **e**, Expanded criteria donors (ECDs) and donation after cardiac death (DCD).

Comment: Only ECD and DCD organs are from deceased donors. However, the combined utilization of ECDs, DCD, and living donor liver transplantation has increased the total donor pool for liver transplantation.

References

- Mateo R, Cho Y, Singh G, et al. Risk factors for graft survival after liver transplantation from donation after cardiac death donors: an analysis of OPTN/UNOS data. *Am J Transplant* 2006;6:791–6.
- Trotter JF, Wachs M, Everson GT, Kam I. Adult-to-adult transplantation of the right hepatic lobe from a living donor. *N Engl J Med* 2002;346:1074–82.

49.3 The correct answer is **d**, The availability of deceased donor livers, the donor complication rate, and the recipient complication rate are all relevant.

Comment: Each of the above factors has been associated with the decline in the number of LDLTs performed in the United States. Although the number of cases has dropped, LDLT will likely remain a viable means to

provide transplantation especially in areas where the supply of deceased donor livers is critically limited.

Reference

- Trotter JF. Living donor liver transplantation: is the hype over? *J Hepatol* 2005;42:20–5.

49.4 The correct answer is **b**, The statement is false.

Comment: Regional sharing of deceased donor livers is one of the most controversial issues in liver transplantation. While many transplant professionals favor its development, regional sharing has not been widely accepted by the liver transplant community. Consequently, there is currently no regional sharing plan except in a very limited fashion.

49.5 The correct answer is **d**, The donor risk index (DRI) is the relative risk of graft loss for an organ with a specific set of donor and graft characteristics compared with a reference case.

Comment: The DRI was developed to identify objective donor and transplant characteristics associated with graft loss. Identification of these specific factors may help to understand the risk of using transplant organs. By doing so, clinicians may learn how to mitigate these factors and select the best recipients for marginal grafts, thereby maximizing organ utility.

Reference

- Feng S, Goodrich NP, Bragg-Gresham JL, et al. Characteristics associated with liver graft failure: the concept of a donor risk index. *Am J Transplant* 2006;6:783–90.

49.6 The correct answer is **c**, The basis for liver allocation currently under active consideration is the survival benefit of the transplant.

Comment: Liver allocation based on the survival benefit of the transplant is under active consideration by the liver transplant community. Under this proposed system, for each donor liver that becomes available, the transplant survival benefit score would be computed for each candidate on the waiting list based on their specific characteristics as well as those of the particular donor. Such a national allocation system has already been adopted for lung transplantation.

hepatotoxicity 508, **716**, 754–5
ALF 717
clinical features 754
LFTs 754
management and prevention 754
mechanism 754–5
risk factors **708**, 754
steatosis 718
metabolism **788**
valsartan, hepatotoxicity 364, 733
van den Bergh reaction 33, **34**, 39
vancomycin, in hepatic encephalopathy 436, 438
vanishing bile duct syndrome 180
drug-induced **716**, 718–19
Vaqta 530, 531, **531**
variceal blood pressure 340
variceal embolization 352
variceal hemorrhage
in HHT **919**
primary prophylaxis 343–7, **344**
β-blockers 344–5, 389
endoscopic band ligation 336, *337*, 346–7
endoscopic sclerotherapy 336–8, **337**, 346
nitrosovasodilators 345–6
recommendations 347, **347**
surgical 347
TIPS *341*, 347, 351–2
rebleeding 334–5
secondary prophylaxis 353–5, **354**
β-blockers 353–4
endoscopy 354
liver transplantation 355
surgery 355
TIPS 355
treatment 347–53
active hemorrhage 349–50, 352–3, *353*
combined therapy 350–1, **351**, **352**
complications 348–9
endoscopic 350
hemodynamic resuscitation 348
salvage therapy 351–2
varicella-zoster virus 1072
and ALF 448
post-HCT 262–3
variegate porphyria **242**
vasa aberrantia 101
vascular disorders 198–202, 911–23
Budd-Chiari syndrome *see* Budd-Chiari syndrome
drug-induced **716**, 720–1, **721**
patterns of injury 198–9, *199*, *200*
post-transplant recurrence 1166
sinusoidal lesions 200–2, *201*
venous outflow obstruction 199–200, *200*, *201*
see also individual disorders
vascular endothelial cell growth factor *see* VEGF
vascular imaging 66–7, *67*
vasoactive peptide 99
vasoconstrictors 330
hepatorenal syndrome 373–4
vasodilators 331–2
carbon monoxide 122, 128, 303, 332
nitric oxide *see* nitric oxide
nitrovasodilators 345–6
renal vasodilators 369
splanchnic 332–3
vasopressin, in variceal hemorrhage 349
vasopressor therapy 456
VCAM-1 495
vecuronium 317
VEGF 333, 382, 495
venae comitantes of vagus nerve 327–8
venlafaxine **755**
veno-venous bypass *1142*
venoocclusive disease *see* sinusoidal obstruction syndrome
venous outflow obstruction 199–200, *200*, *201*
verapamil
drug interactions 1118
hepatotoxicity 732–3
steatohepatitis 718
Veress needle 53
Versant assay 601
Versant HCV LiPA assay 602

Companion website

Purchasing this book entitles you to access to the companion website:

www.schiffsdiseasesoftheliver.com

The website includes:

- Eighty multiple choice questions of the standard used in ABIM board exams in gastroenterology, to allow the user to self-assess their clinical knowledge
- All 450+ figures from the book in a high-quality, fully transportable and downloadable electronic format
- High-quality video clips of a variety of surgical procedures
- 35 case studies featuring real-life clinical scenarios.

How to access the website:

1. Carefully scratch away the top coating on the label below to reveal PIN code.
2. Go to www.schiffsdiseasesoftheliver.com to register your PIN and access the site.
